than the pinch-off voltage V_p . For the example under consideration with $V_p = -4$ V, this means that $V_{GD} = V_{GS} - V_{DS}$ be more negative than -4 V. Therefore, $V_{DS} - V_{GS} \geq +4$ V. Thus, for $V_{GS} = 0$, the active region will begin at $V_{DS} = +4$ V. When $V_{GS} = -1$ V, the active region will begin at $V_{DS} = +3$ V, for now $V_{GD} = -4$ V. When $V_{GS} = -2$ V, the active region begins at $V_{DS} = +2$ V, and when $V_{GS} = -3$ V, the active region begins at $V_{DS} = +1$ V. The dotted line in Figure 117.14 marks the boundary between the nonsaturated and active regions.

The upper boundary of the active region is marked by the onset of the avalanche breakdown of the gate-to-channel PN junction. When $V_{GS} = 0$, this breakdown occurs at $V_{DS} = BV_{DS} = BV_{DG}$. Since $V_{DG} = V_{DS} - V_{GS}$ and breakdown occurs when $V_{DG} = BV_{DG}$, as V_{GS} increases the breakdown voltages decrease as given by $BV_{DG} = BV_{DS} - V_{GS}$. Thus, $BV_{DS} = BV_{DG} + V_{GS}$. For example, if the gate-to-channel breakdown voltage is 50 V, the V_{DS} breakdown voltage will start off at 50 V when $V_{GS} = 0$ but decreases to 46 V when $V_{GS} = -4$ V.

In the nonsaturated region I_{DS} is a function of both V_{GS} and V_{DS} , and in the lower portion of the nonsaturated region where V_{DS} is small compared to V_p , I_{DS} becomes an approximately linear function of V_{DS} . This linear portion of the nonsaturated is called the *voltage-variable resistance* (VVR) region, for in this region the JFET acts like a linear resistance element between source and drain. The resistance is variable in that it is controlled by the gate voltage.

JFET as an Amplifier — Small-Signal AC Voltage Gain

Let us consider the common-source amplifier of Figure 117.16. The input AC signal is applied between gate and source, and the output AC voltage between is taken between drain and source. Thus, the source electrode of this triode device is common to input the output, hence the designation of this JFET configuration as a common-source (CS) amplifier.

A good choice of the DC operating point or quiescent point (“Q-point”) for an amplifier is in the middle of the active region at $I_{DS} = I_{DSS}/2$. This allows for the maximum symmetrical drain current swing, from the quiescent level of $I_{DSQ} = I_{DSS}/2$, down to a minimum of $I_{DS} \cong 0$, and up to maximum of $I_{DS} = I_{DSS}$. This choice for the Q-point is also a good one from the standpoint of allowing for an adequate safety margin for the location of the actual Q-point due to the inevitable variations in device and component characteristics and values. This safety margin should keep the Q-point well away from the extreme limits of the active region, and thus ensure operation of the JFET in the active region under most conditions. If $I_{DSS} = +10$ mA, then a good choice for the Q-point would thus be around +5 mA. The AC component of the drain current, i_{ds} , is related to the AC component of the gate voltage, v_{gs} , by $i_{ds} = g_m \cdot v_{gs}$, where g_m is the dynamic transfer conductance and is given by $g_m = 2 \sqrt{I_{DS} \cdot I_{DSS}} / (-V_p)$. If $V_p = -4$ V, then $g_m = \sqrt{5 \text{ mA} \cdot 10 \text{ mA}} / 4 \text{ V} = 3.54 \text{ mA/V} = 3.54 \text{ mS}$. If a small AC signal voltage, v_{gs} , is superimposed on the quiescent DS gate bias voltage $V_{GSQ} = V_{GS}$, only a small segment of the transfer characteristic adjacent to the Q-point will be traversed, as shown in Figure 117.17. This small segment will be close to a straight line, and as a result the AC drain current, i_{ds} , will have a waveform close to that of the AC voltage applied to the gate. The ratio of i_{ds} to v_{gs} will be the slope of the transfer curve as given by $i_{ds}/v_{gs} \cong dI_{DS}/dV_{GS} = g_m$. Thus, $i_{ds} \cong g_m \cdot v_{gs}$. If the net load driven by the drain of the JFET is the drain

FIGURE 117.15 JFET transfer characteristics.

FIGURE 117.16 Common source amplifier.

FIGURE 117.17 JFET transfer characteristic.

load resistor, R_D , as shown in [Figure 117.16](#), then the AC drain current i_{ds} will produce an AC drain voltage of $v_{ds} = -i_{ds} \cdot R_D$. Since $i_{ds} = g_m \cdot v_{gs}$, this becomes $v_{ds} = -g_m \cdot v_{GS} \cdot R_D$. The AC small-signal voltage gain from gate to drain thus becomes $A_V = v_O/v_{IN} = v_{ds}/v_{gs} = -g_m \cdot R_D$. The negative sign indicates signal inversion, as is the case for a common-source amplifier.

If the DC drain supply voltage is $V_{DD} = +20\text{V}$, a quiescent drain-to-source voltage of $V_{DSQ} = V_{DD}/2 = +10\text{V}$ will result in the JFET being biased in the middle of the active region. Since $I_{DSQ} = 5\text{ mA}$ in the example under consideration, the voltage drop across the drain load resistor, R_D , is 10 V. Thus, $R_D = 10\text{ V}/5\text{ mA} = 2\text{ k}\Omega$. The AC small-signal voltage gain, A_V , thus becomes $A_V = -g_m \cdot R_D = -3.54\text{ mS} \cdot 2\text{ k}\Omega = -7.07$. Note that the voltage gain is relatively modest compared to the much larger voltage gains that can be obtained in a bipolar-junction transistor (BJT) common-emitter amplifier. This is due to the lower transfer conductance of both JFETs and MOSFETs compared to BJTs. For a BJT the transfer conductance is given by $g_m = I_C/V_T$, where I_C is the quiescent collector current and $V_T = kT/q \cong 25\text{ mV}$ is the “thermal voltage.” At $I_C = 5\text{ mA}$, $g_m = 5\text{ mA}/25\text{ mV} = 200\text{ mS}$ for the BJT, as compared to only 3.5 mS for the JFET in this example. With a net load of 2 k Ω , the BJT voltage gain will be -400 as compared to the JFET voltage gain of only 7.1.

Thus, FETs have the disadvantage of a much lower transfer conductance and therefore lower voltage gain than BJTs operating under similar quiescent current levels, but they do have the major advantage of a much higher input impedance and a much lower input current. In the case of a JFET the input signal is applied to the reverse-biased gate-to-channel PN junction and thus sees very high impedance. In the case of a common-emitter BJT amplifier the input signal is applied to the forward-biased base-emitter junction and the input impedance is given approximately by $r_{IN} = r_{BE} \cong 1.5 \cdot \beta \cdot V_T/I_C$. If $I_C = 5\text{ mA}$ and $\beta = 200$, for example, then $r_{IN} \cong 1500\ \Omega$. This moderate input resistance value of 1.5 k Ω is certainly no problem if the signal source resistance is less than around 100 Ω . However, if the source resistance is above 1 k Ω , then there will be a substantial signal loss in the coupling of the signal from the signal source to the base of the transistor. If the source resistance is in the range of above 100 k Ω , and certainly if it is above 1 M Ω , there will be severe signal attenuation due to the BJT input impedance, and a FET amplifier will probably offer a greater overall voltage gain. Indeed, when high impedance signal sources are encountered, a multistage amplifier with a FET input stage, followed by cascaded BJT stages is often used.

117.4 Metal-Oxide Silicon Field-Effect Transistors

A metal-oxide silicon field-effect transistor (MOSFET) is similar to a JFET, in that it is a type of transistor in which the current flow through the device between the drain and source electrodes is controlled by the voltage applied to the gate electrode. A simple physical model of the MOSFET is shown in [Figure 117.18](#). The gate electrode is electrically insulated from the rest of the device by a thin layer of silicon dioxide (SiO_2). In the absence of any gate voltage there is no conducting channel between source and drain, so the device is off and $I_{DS} \cong 0$. If now a positive voltage is applied to the gate, electrons will be drawn into the silicon surface region immediately underneath the gate oxide. If the gate voltage is above the threshold voltage, V_p , there will be enough electrons drawn into this silicon surface region to make the electron population greater than the hole population. This surface region under the oxide will thus become N-type; this region will be called an *N-type surface inversion layer*. This N-type surface inversion layer will now constitute an N-type conducting channel between source and drain, as shown in [Figure 117.19](#), so that now current can flow and $I_{DS} > 0$. Further increases in the gate voltage, V_{GS} , above the threshold voltage, V_p , will cause more electrons to be drawn into the channel. The increase in the electron population in the channel will result in an increase in the conductance of the channel and thus an increase in I_{DS} .

At small values of the drain-to-source voltage, V_{DS} , the drain current, I_{DS} , will increase linearly with V_{DS} , but as V_{DS} increases the channel will become constricted at the drain end and the curve of I_{DS} versus V_{DS} will start to bend over. Finally, if V_{DS} is large enough such that $V_{GS} - V_{DS} < V_p$ the channel becomes pinched off at the drain end and the curve of I_{DS} versus V_{DS} will become almost horizontal, as shown in

FIGURE 117.18 MOSFET physical model.

FIGURE 117.19 $V_{GS} > V_T$

FIGURE 117.20 I_{DS} versus V_{DS} curve.

FIGURE 117.21 Transfer characteristic.

Figure 117.20. This region where I_{DS} becomes relatively independent of V_{DS} is called the *active region*. When the MOSFET is used as an amplifier it should be operated in the active region.

In the active region I_{DS} is relatively independent of V_{DS} but is a strong function V_{GS} . The transfer relationship between I_{DS} and V_{GS} in the active region is given approximately by the square law equation $I_{DS} = K(V_{GS} - V_T)^2$, where K is a constant. In Figure 117.21, a graph of the I_{DS} versus V_{GS} transfer characteristics of an N-channel MOSFET is shown.

In the active region, under small-signal conditions, the AC component of the drain current is related to the AC component of the gate voltage by $i_{ds} = g_m \cdot v_{gs}$, where g_m is the *dynamic transfer conductance*. We have that $g_m = dI_{DS}/dV_{GS} = 2K(V_{GS} - V_T)$. Since $K = I_{DS}/(V_{GS} - V_T)^2$, this can be expressed as $g_m = 2I_{DS}/(V_{GS} - V_T)$. Since $(V_{GS} - V_T) = \sqrt{I_{DS}/K}$, this can also be rewritten as $g_m = 2\sqrt{K \cdot I_{DS}}$.

MOSFET as an Amplifier — Small-Signal AC Voltage Gain

In Figure 117.22 some MOSFET symbols are shown for both N-channel and P-channel devices. Let us consider the MOSFET common-source amplifier circuit of Figure 117.23. The input AC signal is applied between the gate and the source as v_{gs} , and the output AC voltage is taken between the drain and the source as v_{ds} . Thus, the source electrode of this triode device is common to input and output — hence the designation of this MOSFET configuration as common-source (CS) amplifier.

Let us assume a quiescent current level of $I_{DSQ} = 10$ mA and $V_{GS} - V_T = 1$ V. The AC component of the drain current, i_{ds} , is related to the AC component of the gate voltage, v_{gs} , by $i_{ds} = g_m \cdot v_{gs}$, where g_m is the *dynamic transfer conductance*, and is given by $g_m = 2K(V_{GS} - V_T) = 2I_{DS}/(V_{GS} - V_T) = 2 \cdot 10$ mA/1 V = 20 mS. If a small AC signal voltage, v_{gs} , is superimposed on the DC gate bias voltage V_{GS} , only a small segment of the transfer characteristic adjacent to the Q-point will be traversed, as shown in Figure 117.24. This small segment will be close to a straight line, and as a result the AC drain current, i_{ds} , will have a waveform close to that of the AC voltage applied to the gate. The ratio of i_{ds} to v_{gs} will be the slope of the transfer curve, is given by $i_{ds}/v_{gs} \cong dI_{DS}/dV_{GS} = g_m$. Thus, $i_{ds} \cong g_m \cdot v_{gs}$. If the net load driven by the drain of the MOSFET is the drain load resistor, R_D , as shown in Figure 117.23, then the AC drain current

FIGURE 117.22 MOSFET symbols.

FIGURE 117.23 Common-source amplifier.

FIGURE 117.24 Transfer characteristic.

FIGURE 117.25 CMOS circuit.

i_{ds} will produce an AC drain voltage of $v_{ds} = -i_{ds} \cdot R_D$. Since $i_{ds} = g_m \cdot v_{gs}$, this becomes $v_{ds} = -g_m v_{gs} \cdot R_D$. The AC small-signal voltage gain from gate to drain thus becomes $A_V = v_o/v_{in} = v_{ds}/v_{gs} = -g_m \cdot R_D$. The negative sign indicates signal inversion, as is the case for a common-source amplifier.

If the DC drain supply voltage is $V_{DD} = +20$ V, a quiescent drain-to-source voltage of $V_{DSQ} = V_{DD}/2 = +10$ V will result in the MOSFET being biased in the middle of the active region. Since $I_{DSQ} = 10$ mA in the example under consideration and the voltage drop across the drain load resistor (R_D) is 10 V, we obtain $R_D = 10$ V/10 mA = 1 k Ω . The AC small-signal voltage gain, A_V , thus becomes $A_V = -g_m \cdot R_D = -20$ mS \cdot 1 k Ω = -20. Note that the voltage gain is relatively modest, as compared to the much larger voltage gains that can be obtained in a bipolar-junction transistor (BJT) common-emitter amplifier. This is due to the lower transfer conductance of both JFETs and MOSFETs compared to BJTs. For a BJT the transfer conductance is given by $g_m = I_C/V_T$, where I_C is the quiescent collector current and $V_T = kT/q \cong 25$ mV is the thermal voltage. At $I_C = 10$ mA, $g_m = 10$ mA/25 mV = 400 mS, compared to only 20 mS for the MOSFET in this example. With a net load of 1 k Ω , the BJT voltage gain will be -400, compared to the MOSFET voltage gain of only -20.

Thus, FETs do have the disadvantage of a much lower transfer conductance and therefore lower voltage gain than BJTs operating under similar quiescent current levels, but they do have the major advantage of a much higher input impedance and a much lower input current. In the case of a MOSFET the input signal is applied to the gate, which is insulated from the rest of the device by the thin SiO₂ layer, and thus sees very high impedance. In the case of a common-emitter BJT amplifier, the input signal is applied to the forward-biased base-emitter junction and the input impedance is given approximately by $r_{IN} = r_{BE} \cong 1.5 \cdot \beta \cdot V_T/I_C$ where V_T is the thermal voltage of about 25 mV. If $I_C = 5$ mA and $\beta = 200$, for example, then $r_{IN} \cong 1500$ Ω . This moderate input resistance value of 1.5 k Ω is certainly no problem if the signal source resistance is less than around 100 Ω . However, if the source resistance is above 1 k Ω , there will be a substantial signal loss in the coupling of the signal from the signal source to the base of the transistor. If the source resistance is in the range of above 100 k Ω , and certainly if it is above 1 M Ω , there will be severe signal attenuation due to the BJT input impedance, and an FET amplifier will probably offer a greater overall voltage gain. Indeed, when high-impedance signal sources are encountered, a multistage amplifier with an FET input stage followed by cascaded BJT stages is often used.

MOSFETs for Digital Circuits

MOSFETs are used very extensively for digital applications. For high-density integrated circuits, MOSFETs offer great advantages over BJTs and JFETs from the standpoint of a much smaller size and lower power consumption.

A very important MOSFET configuration is the *complementary symmetry MOSFET*, or CMOS circuit. In Figure 117.25, a CMOS inverter circuit is shown, comprising an N-channel MOSFET (NMOS) and a P-channel MOSFET (PMOS). In Figure 117.25(b), the situation is shown with the input signal in the high or “1” state. The NMOS is now on and exhibits a moderately low resistance, typically on the order of 100 Ω . The PMOS is off and acts as a very high resistance. This situation results in the output voltage, V_o going low, close to ground potential (0 V).

In Figure 117.25 (c), the situation is shown with the input signal in the low, or “0” state. The NMOS is off and acts as a very high resistance, and the PMOS is on and exhibits a moderately low resistance,

typically on the order of $100\ \Omega$. This situation results in the output voltage, V_o , being pulled up high (the “1” state), close to the V_{DD} supply.

We note that under both input conditions one of the transistors will be off, and as a result the current flow through the two transistors will be extremely small. Thus, the power dissipation will also be very small, and, indeed, the only significant amount of power dissipation in the CMOS pair occurs during the short switching interval when both transistors are simultaneously on.

117.5 New Trends

The need for high-speed transistors for various communications applications has led to various developments. These include decreases in device dimensions for reduced capacitance, and for MOSFETs reduced channel lengths down to the range of less than 100 nm. Also, there is the use of III-V compound semiconductors, notably gallium arsenide, in which the substantially higher electron mobility as compared to silicon offers the possibility of a substantially higher speed. The addition of a small amount of germanium to silicon also produces substantially higher electron mobility. Heterostructure transistors using SiGe as the base material can also result in substantially higher speed devices. The GaAs and SiGe transistors do, however, have the disadvantage of higher processing costs as compared to silicon transistors.

Defining Terms

Active region — The region of transistor operation in which the output current is relatively independent of the output voltage. For the BJT, this corresponds to the condition that the emitter base junction is on, and the collector base junction is off. For the FETs, this corresponds to the condition that the channel is on or open at the source end and pinched off at the drain end.

Acceptors — Impurity atoms that, when added to a semiconductor, contribute holes. In the case of silicon, acceptors are atoms from the third column of the periodic table, such as boron.

Anode — The P-type side of a diode.

Cathode — The N-type side of a diode.

CMOS — The complementary-symmetry MOSFET configuration composed of an N-channel MOSFET and a P-channel MOSFET, operated such that when one transistor is on, the other is off.

Contact potential — The internal voltage that exists across a PN junction under thermal equilibrium conditions, when no external bias voltage is applied.

Donors — Impurity atoms that, when added to a semiconductor, contribute free electrons. In the case of silicon, donors are atoms from the fifth column of the periodic table, such as phosphorus, arsenic, and antimony.

Dopants — Impurity atoms that are added to a semiconductor to modify electrical conduction characteristics.

Doped semiconductor — A semiconductor that has had impurity atoms added to modify the electrical conduction characteristics.

Extrinsic semiconductor — A semiconductor that has been doped with impurities to modify the electrical conduction characteristics.

Forward bias — A bias voltage applied to the PN junction of a diode or transistor that makes the P-type side positive with respect to the N-type side.

Forward current — The large current flow in a diode that results from the application of a forward-bias voltage.

Hole — An electron vacancy in a covalent bond between two atoms in a semiconductor. Holes are mobile charge carriers with an effective charge that is opposite to the charge on an electron.

Intrinsic semiconductor — A semiconductor with a degree of purity such that the electrical characteristics are not significantly affected.

Majority carriers — In a semiconductor, the type of charge carrier with the larger population. For example, in an N-type semiconductor, electrons are the majority carriers.

- Minority carriers** — In a semiconductor, the type of charge carrier with the smaller population. For example, in an N-type semiconductor, holes are the minority carriers.
- N-type semiconductor** — A semiconductor that has been doped with donor impurities to produce the condition that the population of free electrons is greater than the population of holes.
- Ohmic, nonsaturated, or triode region** — These three terms all refer to the region of FET operation in which a conducting channel exists all of the way between source and drain. In this region the drain current varies with both the gate voltage and the drain voltage.
- Output characteristics** — The family of curves of output current versus output voltage. For the BJT, output characteristics are curves of collector current versus collector voltage for various constant values of base current or voltage and are also called the *collector characteristics*. For FETs, these will be curves of drain current versus drain voltage for various constant values of gate voltage and are also called the *drain characteristics*.
- P-type semiconductor** — A semiconductor that has been doped with acceptor impurities to produce the condition that the population of holes is greater than the population of free electrons.
- Pinch-off voltage, V_p** — The voltage that, when applied across the gate-to-channel PN junction, will cause the conducting channel between drain and source to become pinched off. This is also represented as $V_{GS}(\text{off})$.
- Reverse bias** — A bias voltage applied to the PN junction of a diode or transistor that makes the P-type side negative with respect to the N-type side.
- Reverse current** — The small current flow in a diode that results from the application of a reverse bias voltage.
- Thermal voltage** — The quantity kT/q where k is Boltzmann's constant, T is absolute temperature, and q is electron charge. The thermal voltage has units of volts and is a function only of temperature, being approximately 25 mV at room temperature.
- Threshold voltage** — The voltage required to produce a conducting channel between source and drain in a MOSFET.
- Transfer conductance** — The AC or dynamic parameter of a device that is the ratio of the AC output current to the AC input voltage. The transfer conductance is also called the *mutual transconductance* and is usually designated by the symbol g_m .
- Transfer equation** — The equation that relates the output current (collector or drain current) to the input voltage (base-to-emitter or gate-to-source voltage).
- Triode** — The three-terminal electron device, such as a bipolar junction transistor or a field-effect transistor.

An integrated circuit is an electronic device in which there is more than one circuit component in the same package. Most integrated circuits contain many transistors, together with diodes, resistors, and capacitors. Integrated circuits may contain tens, hundreds, or even many thousands of transistors. Indeed, some integrated circuits for computer and image-sensing applications may have millions of transistors or diodes on a single silicon chip.

A monolithic integrated circuit is one in which all of the components are contained on a single-crystal chip of silicon. This silicon chip typically measures from $1 \times 1 \times 0.25$ mm thick for the smallest integrated circuits to $10 \times 10 \times 0.5$ mm for the larger integrated circuits.

A hybrid integrated circuit has more than one chip in the package. The chips may be monolithic integrated circuits and separate or “discrete” devices such as transistor or diode chips. There can also be discrete passive components such as capacitor and resistor chips. The chips are usually mounted on an insulating ceramic substrate, usually alumina (Al_2O_3), and are interconnected by a thin-film or thick-film conductor pattern that has been deposited on the ceramic substrate. Thin-film patterns are deposited by vacuum evaporation techniques and are usually about 1 micrometer in thickness, whereas thick-film patterns are pastes that are printed on the substrate through a screen and usually range in thickness from 10 to 30 micrometers.

Integrated circuits can be classified according to function, the two principal categories being *digital* and *analog* (also called *linear*) integrated circuits. A digital integrated circuit is one in which all of the transistors operate in the switching mode, being either off (in the cut-off mode of operation) or on (in

the saturation mode) to represent the high and low (1 and 0) digital logic levels. The transistors during the switching transient pass very rapidly through the active region. Virtually all digital integrated circuits are of the monolithic type and are composed almost entirely of transistors, usually of the MOSFET type. Some digital integrated circuits contain more than one million transistors on a single silicon chip.

Analog or linear integrated circuits operate on signal voltages and currents that are in analog or continuous form. The transistors operate mostly in the active (or linear) mode of operation. There are many different types of analog integrated circuits, such as operational amplifiers, voltage comparators, audio power amplifiers, voltage regulators, voltage references, video (wide-bandwidth) amplifiers, radio-frequency amplifiers, modulators and demodulators for AM and FM, logarithmic converters, function generators, voltage-controlled oscillators, phase-locked loops, digital-to-analog and analog-to-digital converters, and other devices. The majority of analog integrated circuits are of the monolithic type, although there are many hybrid integrated circuits of importance.

In addition to the two basic functional categories of analog and digital integrated circuits, there are many integrated circuits that have both analog and digital circuitry in the same integrated circuit package, or even on the same chip. Some of the analog integrated circuits mentioned previously, such as the digital-to-analog and analog-to-digital converters, contain both types of circuitry.

Almost all integrated circuits are fabricated from silicon. The principal exceptions are some very high-speed digital integrated circuits that use gallium arsenide (GaAs) to take advantage of the very high electron mobility in that material. Integrated circuits are fabricated using the same basic processes as for other semiconductor devices. In integrated circuits the vast majority of devices are transistors and diodes, with relatively few passive components such as resistors and capacitors. In many cases no capacitors at all are used, and in some cases there are no resistors either. The active devices contained in an integrated circuit are transistors, including bipolar junction transistors (BJTs), junction field-effect transistors (JFETs), and metal-oxide silicon field-effect transistors (MOSFETs). Digital integrated circuits are made up predominantly of MOSFETs, with generally very few other types of components. Some analog integrated circuits use mostly, or even exclusively, BJTs, although many integrated circuits use a mixture of BJTs and field-effect transistors (either JFETs or MOSFETs), and some are even exclusively FETs, with no BJTs at all.

The sections that follow give very brief descriptions of some of the analog integrated circuits.

118.1 Operational Amplifiers

An operational amplifier is an integrated circuit that produces an output voltage, V_O , that is an amplified replica of the difference between two input voltages, as given by the equation $V_O = A_{OL}(V_1 - V_2)$, where A_{OL} is called the *open-loop gain*. The basic symbol for the operational amplifier is shown in Figure 118.1. Most operational amplifiers are of the monolithic type, and there are hundreds of different types of operational amplifiers available from dozens of different manufacturers.

The operational amplifier was one of the first types of analog integrated circuits developed. The term *operational amplifier* comes from one of the earliest uses of this type of circuit — in analog computers dating back to the early and middle 1960s. Operational amplifiers were used in conjunction with other circuit components, principally resistors and capacitors, to perform various mathematical operations,

FIGURE 118.1 Operational amplifier symbols: (a) basic operational amplifier symbol; (b) symbol with input polarities indicated explicitly; (c) symbol with input polarities indicated explicitly. FIGURE 118.2 Closed-loop (negative feedback) operational amplifier system. (Source: Soclof, S. 1991. *Design and Applications of Analog Integrated Circuits*. Prentice Hall, Englewood Cliffs, NJ.)

such as addition, subtraction, multiplication, integration, and differentiation — hence the name “operational amplifier.” The range of applications of operational amplifiers has vastly expanded since these early beginnings; operational amplifiers are now used to perform a multitude of tasks through the entire field of electronics.

Operational amplifiers are usually used in a feedback, or closed-loop, configuration, as shown in Figure 118.2. Under the assumption of a large open-loop gain, A_{OL} , the output voltage is given by

$$V_O = V_1[1 + (Z_2/Z_2)] - V_2(Z_2/Z_1).$$

The following is a list of some important applications of operational amplifiers:

Difference amplifier. This produces an output voltage proportional to the difference of two input voltages.

Summing amplifier. This produces an output voltage that is a weighted summation of a number of input voltages.

Current-to-voltage converter. This produces an output voltage that is proportional to an input current.

Voltage-to-current converter. This produces an output current that is proportional to an input voltage but is independent of the load being driven.

Active filters. This is a very broad category of operational amplifier circuit that can be configured as low-pass, high-pass, band-pass, or band-stop filters.

Precision rectifiers and clipping circuits. This is a broad category of wave-shaping circuits that can be used to clip off or remove various portions of a waveform.

Peak detectors. This produces an output voltage proportional to the positive or negative peak value of an input voltage.

Logarithmic converters. This produces an output voltage proportional to the logarithm of an input voltage.

Exponential or antilogarithmic converters. This produces an output voltage that is an exponential function of an input voltage.

Current integrator or charge amplifier. This produces an output voltage proportional to net flow of charge in a circuit.

Voltage regulators. This produces an output voltage that is regulated to remain relatively constant with respect to changes in the input or supply voltage and with respect to changes in the output or load current.

Constant current sources. This produces an output current that is regulated to remain relatively constant with respect to changes in the input or supply voltage and with respect to changes in the output or load impedance or voltage.

Amplifiers with electronic gain control. These are amplifiers in which the gain can be controlled over a wide range by the application of an external voltage.

Function generators. These are circuits that can be used to generate various types of waveforms, including square waves and triangular waves.

FIGURE 118.3 Voltage comparator. (Source: Soclof, S. 1991. *Design and Applications of Analog Integrated Circuits*. Prentice Hall, Englewood Cliffs, NJ.)

Clamping circuits. These circuits produce an output voltage that has the same AC waveform as the input signal, but the DC level is shifted by an amount controlled by a fixed reference voltage.

Analog signal multiplexer. This circuit combines several input signals for transmission over a signal communications link by means of *time-domain multiplexing*.

Sample-and-hold circuit. The input signal is sampled over a short period of time, and the sampled value is then held at that value until the next sample is taken.

Analog multiplier. This produces an output voltage proportional to the product of two input voltages.

118.2 Voltage Comparators

A voltage comparator is an integrated circuit as shown in Figure 118.3 that is used to compare two input voltages and produce an output voltage that is in the high (or “1”) state if $V_1 > V_2$ and in the low (or “0”) state if $V_1 < V_2$. It is essentially a one-bit analog-to-digital converter.

In many respects, voltage comparators are similar to operational amplifiers, and, indeed, operational amplifiers can be used as voltage comparators. A voltage comparator is, however, designed specifically to be operated under open-loop conditions, basically as a switching device. An operational amplifier, on the other hand, is almost always used in a closed-loop configuration and is usually operated as a linear amplifier.

Being designed to be used in a closed-loop configuration, the frequency response characteristics of an operational amplifier are generally designed to ensure an adequate measure of stability against an oscillatory type of response. This results in a sacrifice being made in the bandwidth, rise time, and slewing rate of the device. In contrast, since a voltage comparator operates as an open-loop device, no sacrifices have to be made in the frequency response characteristics, so a very fast response time can be obtained.

An operational amplifier is designed to produce a zero output voltage when the difference between the two input signals is zero. A voltage comparator, in contrast, operates between two fixed output voltage levels, so the output voltage is either in the high or low states.

The output voltage of an operational amplifier will saturate at levels that are generally about 1 or 2 V away from the positive and negative power supply voltage levels. The voltage comparator output is often designed to provide some degree of flexibility in fixing the high- and low-state output voltage levels and for ease in interfacing with digital logic circuits.

There are many applications of voltage comparators. These include pulse generators, square-wave and triangular-wave generators, pulse-width modulators, level and zero-crossing detectors, pulse regenerators, line receivers, limit comparators, voltage-controlled oscillators, analog-to-digital converters, and time-delay generators.

118.3 Voltage Regulators

A voltage regulator is an electronic device that supplies a constant voltage to a circuit or load. The output voltage of the voltage regulator is regulated by the internal circuitry of the device to be relatively independent of the current drawn by the load, the supply or line voltage, and the ambient temperature. A voltage regulator may be part of some larger electronic circuit but is often a separate unit or module, usually in the form of an integrated circuit. A voltage regulator, as shown in Figure 118.4, is composed of three basic parts:

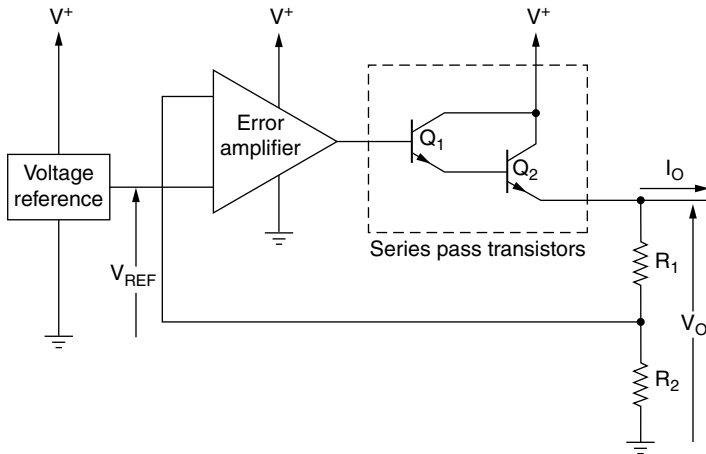

FIGURE 118.4 Voltage regulator: basic block diagram. (Source: Soclof, S. 1991. *Design and Applications of Analog Integrated Circuits*. Prentice Hall, Englewood Cliffs, NJ.)

A voltage reference circuit that produces a reference voltage that is independent of the temperature and supply voltage

An amplifier to compare the reference voltage with the fraction of the output that is fed back from the voltage regulator output to the inverting input terminal of the amplifier

A series-pass transistor or combination of transistors to provide an adequate level of output current to the load being driven

Voltage regulators usually include protection circuitry such as current limiting and thermal limiting to protect the integrated circuit against overheating and possible damage.

An important type of voltage regulator is the *switching-mode regulator*, in which the series-pass transistors are not on continuously but, rather, are rapidly switched from being completely on to completely off. The output voltage level is controlled by the fraction of time that the series-pass transistors are on (i.e., the duty cycle). Switching-mode regulators are characterized by having very high efficiencies, often above 90%.

118.4 Power Amplifiers

Although most integrated circuit amplifiers can deliver only small amounts of power to a load, generally well under 1 watt, there are integrated circuits that are capable of supplying much larger amounts of power, up in the range of several watts, or even several tens of watts. There are a variety of integrated circuit audio power amplifiers available that are used in the range of frequencies up to about 10 or 20 kHz for amplification of audio signal for delivery to loudspeakers. These integrated circuit audio power amplifiers also are used for other applications, such as relay drivers and motor controllers.

There are also available a variety of power operational amplifiers. The maximum current available from most operational amplifiers is generally in the range of about 20 to 25 mA. The maximum supply voltage rating is usually around 36 V with a single supply or +18 V and -18 V when a split supply is used. For an operational amplifier with a 36 V total supply voltage, the maximum peak-to-peak output voltage swing available will be around 30 V. With a maximum output current rating of 20 mA, the maximum AC power that can be delivered to a load is $P_L = 30 \text{ V} \times 20 \text{ mA}/4 = 150 \text{ mW}$. Although this level of output power is satisfactory for many applications, a considerably larger power output is required for some applications.

Larger AC power outputs from operational amplifiers can be obtained by adding external *current boost* power transistors that are driven by the operational amplifier to the circuit. There are also available *power*

operational amplifiers that are capable of operation with supply voltages as high as 200 V, and with peak output current swings as large as 20 A. With the proper heat sinking for efficient transfer of heat from the integrated circuit to the ambient, the power operational amplifiers can deliver output power up in the range of tens of watts to a load.

118.5 Wide-Bandwidth (Video) Amplifiers

Video, or wide-bandwidth, amplifiers are designed to give a relatively flat gain versus frequency response characteristic over the frequency range that is generally required to transmit video information. This frequency range is from low frequencies, generally around 30 Hz, up to several megahertz. For standard television reception, the bandwidth required is around 4 MHz, but for other video display applications the bandwidth requirement may be as high as 20 MHz, and for some applications up in the range of 50 MHz.

In contrast, the bandwidths required for audio applications extend only over the frequency range corresponding to the range of the human ear — around 50 Hz to 15 kHz.

The principal technique that is used to obtain the large bandwidths that are required for video amplifiers is the trading off of reduced gain in each amplifier stage for increased bandwidth. This tradeoff is accomplished by the use of reduced load resistance for the various gain stages of the amplifier and by the use of negative feedback. In many video amplifiers both techniques are employed. Adding additional gain stages can compensate for the reduction in the gain of the individual stages.

Included in the category of video amplifiers are the very-wide-bandwidth operational amplifiers. Most operational amplifiers are limited to a bandwidth of around 1 to 10 MHz, but there are wide-bandwidth operational amplifiers available that can be used up in the range of 100 to 200 MHz.

118.6 Modulators, Demodulators, and Phase Detectors

This is a category of integrated circuit that can be used to produce amplitude-modulated (AM) and frequency-modulated (FM) signals. These same integrated circuits can also be used for the demodulation, or detection, of AM and FM signals. In the AM case these integrated circuits can be used to generate and to demodulate *double-sideband/suppressed carrier* (DSB/SC) and *single-sideband/suppressed carrier* (SSB/SC) signals. Another application of this type of integrated circuit is as a *phase detector*, in which an output voltage proportional to the phase difference of two input signals is produced.

118.7 Voltage-Controlled Oscillators

A voltage-controlled oscillator (VCO) is an oscillator circuit in which the frequency of oscillation can be controlled by an externally applied voltage. VCOs are generally designed to operate over a wide frequency range, often with a frequency ratio of 100:1. One important feature that is often required for VCOs is a linear relationship between the oscillation frequency and the control voltage. Many VCOs have a maximum frequency of operation of around 1 MHz, but there are some emitter-coupled VCOs that can operate up to 50 MHz.

118.8 Waveform Generators

A waveform generator is an integrated circuit that generates the following three types of voltage waveforms: square waves, triangular waves, and sinusoidal waves. The square and triangular waves can be generated by the same type of circuits as used for VCOs.

For the generation of a sinusoidal waveform a feedback amplifier using an LC tuned circuit or an RC phase shift network in the feedback loop can be used. These feedback oscillators can produce a very low-distortion sine wave, but it is difficult to modulate the oscillation frequency over a very wide range by means of a control voltage. The VCO, on the other hand, is capable of a frequency sweep ratio as large

FIGURE 118.5 Phase-locked loop. (Source: Soclof, S. 1991. *Design and Applications of Analog Integrated Circuits*. Prentice Hall, Englewood Cliffs, NJ.)

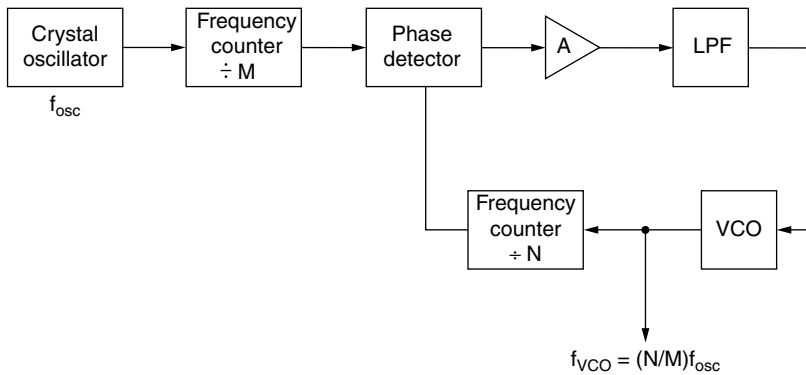

FIGURE 118.6 PLL frequency synthesizer. (Source: Soclof, S. 1991. *Design and Applications of Analog Integrated Circuits*. Prentice Hall, Englewood Cliffs, NJ.)

as 100:1, with very good linearity between the frequency and the control voltage. A sinusoidal waveform can be obtained from a VCO by using a wave-shaping network to convert the triangular wave output to a sine wave.

118.9 Phase-Locked Loops

A phase-locked loop (PLL) is a feedback loop comprising a phase detector, low-pass filter, and a voltage-controlled oscillator (VCO) as shown in Figure 118.5. When the PLL has locked in on a signal, the frequency of the VCO will exactly follow the signal frequency.

The PLL can be used as an FM demodulator or detector. In this case the VCO control voltage is proportional to the frequency deviation of the FM signal and represents the demodulated output voltage. Another closely related application is the demodulation of frequency-shift keying (FSK) signals, a process that is similar to FM except that the signal frequency is shifted between just two values.

On important application of PLLs is in frequency synthesis, in which a precise series of frequencies is produced, all derived from a stable crystal-controlled oscillator. In Figure 118.6, a PLL frequency synthesizer circuit is shown.

118.10 Digital-to-Analog and Analog-to-Digital Converters

A digital-to-analog converter (D/A or DAC) is an integrated circuit that converts a digital input signal to an analog output voltage (or current) that is proportional to the digital signal. DACs vary in resolution from 4 to 16 bits.

An analog-to-digital converter (A/D or ADC) is an integrated circuit that converts an analog input signal to a digital output. ADCs vary in resolution from a simple voltage comparator used as a 1-bit ADC to 16-bit ADCs.

For some applications, such as storing entire frames of video information in one-thirtieth of a second, very high conversion rates are required. For these applications parallel comparator (or “flash”) ADCs are used with conversion rates as high as 500 MHz for an 8-bit ADC.

118.11 Radio-Frequency Amplifiers

There are radio-frequency (R-F) integrated circuits that use tuned circuits and operate as band-pass amplifiers. These are used in communications circuits, such as AM and FM radio, and in television for signal amplification and mixing.

118.12 Integrated Circuit Transducers

This is a broad category of integrated circuits that are used for the conversion of various physical inputs to an electrical signal. These circuits include the magnetic field sensor, based on the Hall effect, which produces an output voltage proportional to the magnetic field strength. There are also temperature sensor integrated circuits that can produce a voltage or current output that is proportional to the temperature. There are electromechanical integrated circuit transducers such as pressure sensors that produce an output voltage proportional to pressure. Miniature solid-state accelerometers based on integrated circuit sensors are also available.

118.13 Optoelectronic Devices

A very important category of integrated circuit transducers is that of the optoelectronic devices. These devices range from photodiode or phototransistor-amplifier modules to image sensors containing in the range of one million individual photodiode image-sensing elements. These image-sensing integrated circuit chips also include additional circuitry to properly transfer out (line by line, in a serial output) the information from the two-dimensional array of the image sensor.

There are also integrated circuits used with light emitting diodes (LEDs) and laser diodes for the generation of light pulses for optoelectronic communications systems, including fiber optic systems.

In the case of a fiber optic communications system, a small diameter glass fiber is used as a conduit or wave guide to guide a beam of a light from transmitter to receiver. Optoelectronic integrated circuits are used at the transmitting end with LEDs or laser diodes for the generation and emission of the optical signal. Optoelectronic integrated circuits are used at the receiving end with photodiodes or phototransistors for the detection, amplification, and processing of the received signal.

118.14 Recent Trends

The first integrated circuits were based on bipolar junction transistors. Present day digital integrated circuits are almost entirely composed of MOSFET devices, especially in the form of the CMOS configuration. There has also been the trend in analog integrated circuits to the use of more MOSFET devices, especially in the CMOS configuration. Analog integrated circuits can incorporate both bipolar and MOSFET devices on the same chip and are often referred to as BiCMOS circuits.

Advances in the processing technology of analog integrated circuits have led to circuits offering higher speeds, greater power outputs, and greater precision. Also mixed-signal integrated circuits with a combination of analog devices and digital devices have become more important, offering the possibility of having an entire electronic system on a chip.

Defining Terms

Hybrid integrated circuit — An electronic circuit package that contains more than one chip. These chips can be a mixture of monolithic ICs, diodes, transistors, capacitors, and resistors.

Integrated circuit — An electronic circuit package that contains more than one circuit element.

Monolithic integrated circuit — A single-crystal chip of a semiconductor, generally silicon, that contains a complete electronic circuit.

The subject of optoelectronics deals with the interaction of light and electronic devices. There are three basic categories of optoelectronic devices: (1) light sensing devices, such as photocells, photodiodes, and phototransistors, in which the incoming light produces an electrical output, (2) light emitting devices, such as light-emitting diodes and laser diodes in which an electrical input produce a light output, (3) power conversion devices, such as a solar cell, in which a light input, usually sunlight, is converted to electrical power.

119.1 Photoconductive Cells

The simplest type of optoelectronic device is the photoconductive cell that is based on the phenomenon of photoconductivity. [Figure 119.1](#) presents a piece of semiconductor. Contacts are made to the two ends and a battery or DC power supply is connected. In response to the applied voltage V , a current I will flow. According to Ohm's Law, $I = V/R = V \cdot G$, where G is the conductance of the semiconductor material. The conductance G is related to the *conductivity*, σ , by $G = \sigma A/L$, where L = length and A = area. Now there will be light incident of this material. If the photons entering the semiconductor have energy, E_{PHOTON} , greater than the energy gap, E_G , then they will be absorbed. The photon energy will be transferred

FIGURE 119.1 Photoconductive cell.

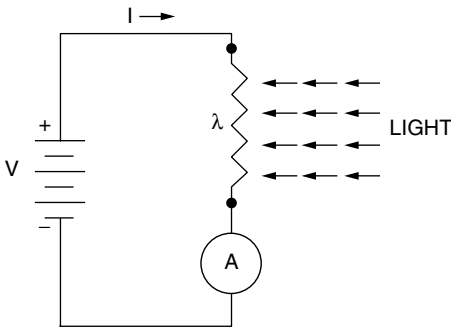

FIGURE 119.2 Simple light meter circuit.

FIGURE 119.3 Light-sensing circuit using an operational amplifier.

to electrons in covalent bonds, allowing them to break loose, becoming free electrons, and leaving holes behind. This is the photogeneration process.

As a result of the increase in the free electron and hole population the conductivity will increase to become $\sigma = \sigma_0 + \Delta\sigma$, where σ_0 is the conductivity under dark conditions, and $\Delta\sigma$ is the increase in σ due to the photogeneration process. As a result of the $\Delta\sigma$, there will be an increase in the conductance, ΔG , and correspondingly an increase in the current flow, ΔI . This change in the conductivity due to the photogeneration process is the basis of the photoconductive cell. The photoconductive cell is also known as a photocell or photoresistor.

Figure 119.2 shows a very simple circuit using a *photocell*. The light shining on the photocell reduces its resistance, and the resulting current flow can be measured by a current meter or DMM. A resistor can be used to convert the current to a voltage, which can then be amplified by the amplifier. Another circuit shown in Figure 119.3 uses this *current-to-voltage* operational amplifier circuit. Current I will flow through the operational amplifier feedback resistor, R_F . If we assume that the operational amplifier has $I_{BIAS} \ll I$ and $A_{OL} \gg 1$, then $V_O = -I \cdot R_F$, where $I = V \cdot G_{PHOTOCELL}$.

The most commonly used semiconductors for photoconductive cells are II–VI compound semiconductors such as cadmium sulfide (CdS), cadmium selenide (CdSe), and zinc sulfide (ZnS). The maximum spectral response of these materials is in the visible region of the spectrum, and they are often used for light meters for photographic purposes. They are also used for such applications as automatically turning on lights. A major disadvantage of these photoconductive cells is their very slow response times of milliseconds up to seconds. Consequently, they are not viable for high-speed applications such as optical communications. For long-wavelength detectors in the infrared region III–V, semiconductors with very small energy gaps such as InAs and InSb are used. For detection out into the far infrared region, detectors operating at cryogenic temperatures are used, such as germanium operating at liquid nitrogen (77°K) or liquid helium (4.2°K) temperatures.

FIGURE 119.4 Circuit representation of a photodiode.

119.2 Photodiodes

In this section, we discuss what happens when light is incident on a PN junction diode. Photons penetrate into the semiconductor. If the photon energy, E_{PHOTON} , is greater than the energy gap, E_G , then there will be photon absorption and the photogeneration of electron–hole pairs. As the photons penetrate into the semiconductor, the photon flux will diminish due to the absorption of photons and the resulting photogeneration process. These are the *photogenerated minority carriers*. The minority carrier population on both sides is normally very small, but can be drastically increased as a result of the photogeneration process.

The photogenerated minority carrier electrons on the P-type side will diffuse to the junction, roll down the hill and be collected by the N-type side. Every electron collected by the N-type side will result in an electron being expelled from the N-type side into the metal wire and then flowing around the circuit.

The photogenerated minority carrier holes on the N-type side will diffuse to the junction, roll down the hill, and be collected by the P-type side. Every hole collected by the P-type side will result in an electron being drawn into the P-type side from the metal wire. This results in an electron flowing around the circuit. Note that the flow of the PMCs on both sides of the junction results in an external current flow in the same direction as the dark reverse current. The illumination of a photodiode can indeed result in a very large increase in the reverse current, I_R , by many orders of magnitude.

A photodiode is basically the same as an ordinary PN junction diode, except that it is placed in a package with a transparent window so that light can get in. It is often of much larger surface area than an ordinary diode to increase the collection of photons. A photodiode can be represented as a constant current source, I_{PHOTO} , in parallel with an ordinary PN junction diode as shown in Figure 119.4. The current I_L represents the photocurrent resulting from the photogeneration process. Under dark conditions, $I_{\text{PHOTO}} = 0$, and we have just the characteristics of an ordinary diode. However, under illuminated conditions, $I_{\text{PHOTO}} > 0$, the total reverse current, I_R , is now the dark reverse current plus I_{PHOTO} . The photocurrent, I_{PHOTO} , is directly proportional to the photon flux. That is the basic operation of the photodiode. Under forward bias conditions, a very large forward current will flow due to the majority carriers climbing the potential hill at the junction. Under dark reverse bias conditions, the current flow will be very small due to the very small density of minority carriers. However, upon illumination, the reverse current flow can be increased by many orders of magnitude. Next we will look at the equation for current as a function of voltage for the photodiode, and then look at curves of current versus voltage.

The diode equation is now modified by inclusion of I_L , giving $I = I_0[\exp(V/nV_T) - 1] - I_L$. Under short-circuit conditions, as shown in Figure 119.5, $V = 0$, so $I = I_{\text{SC}} = -I_L$; thus in these conditions, the photodiode will produce a current flow as a result of the photogeneration process. This current will be directly proportional to the incident photo flux, ϕ , or light intensity, so $I_{\text{SC}} = -I_L \propto \phi$.

Now consider open-circuit conditions with $I = 0$, so that $V = V_{\text{OC}} = \textit{open-circuit voltage}$ as shown in Figure 119.6. Since $I = 0$, the photocurrent I_L must produce a forward current flow through the PN junction equal to I_L , and the diode equation can be written as $I_0[\exp(V/nV_T) - 1] - I_L = 0$. Solving for

FIGURE 119.5 Photodiode under short-circuit conditions.

FIGURE 119.6 Photodiode under open-circuit conditions.

the exponential term gives $\exp(V/nV_T) = 1 + I_L/I_0$, so that solving for the *open-circuit voltage* gives $V_{OC} = nV_T \cdot \ln[1 + (I_L/I_0)]$.

Since I_0 is generally extremely small, often down in the femtoampere ($10E-15$ A) range, we usually will have $I_L \gg I_0$. Thus, $V_{OC} \cong n \cdot \text{Ln} (I_L/I_0)$, that is, a logarithmic function of the illumination level. We see that the short-circuit current, I_{SC} , is a linear function of the light level, whereas the open-circuit voltage, V_{OC} , is a logarithmic function of the light level.

Current Responsivity

In this section, we look at current responsivity. Consider the case of an ideal photodetector such as an “ideal photodiode” as illustrated in [Figure 119.7](#). Photon flux density, ϕ photons/sec-cm², is incident on the photodetector. The photons enter the semiconductor and are absorbed, producing photogenerated free electrons and holes. This results in a photocurrent, I_{PHOTO} flowing around the circuit. For an ideal photodetector every incident photon results in the flow of one electron around the circuit.

Let the active area of the device be A cm². A photon flux of ϕ photons/sec-cm² will result in an electron flow of $\phi \cdot A$ electrons/sec around the circuit. This electron flow will correspond to a current flow of $I = q \cdot (\text{electron flow})$ so $I = q \cdot \phi \cdot A$. The current responsivity is the ratio of the photocurrent, I , to the optical power, P , incident on the device active area. Thus current responsivity = I/P , where $P = \text{photon flux times the energy per photon}$. The energy per photon is $E_{PHOTON} = hc/\lambda$, so the incident optical power is $P = \phi \cdot A \cdot (hc/\lambda)$. We get this for the current responsivity. The ϕ and A terms in the numerator and denominator can be canceled out, resulting in this expression. The wavelength λ can be moved up to the numerator giving this equation. Since $hc/q = 1.239 \text{ V}\cdot\mu\text{m}$, the expression for the current responsivity can be written like this. We see that for the “ideal photodetector,” the current responsivity is directly proportional to the wavelength.

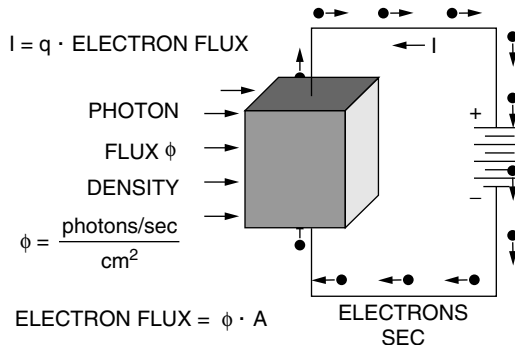

FIGURE 119.7 Current responsivity.

FIGURE 119.8 Current responsivity versus wavelength for ideal photodiode.

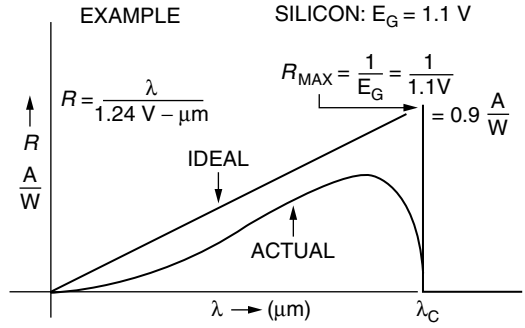

FIGURE 119.9 Current responsivity versus wavelength for real photodiode.

We will now look at a graph of current responsivity versus wavelength, λ , as shown in Figure 119.8. We note that if λ is expressed in units of μm , the current responsivity will have units of reciprocal volts ($1/\text{V}$). Since watts = volts \cdot amperes, the units of $1/\text{volts}$ = amperes/watts = A/W . For the “ideal photodetector,” a straight line like this is obtained.

For any real semiconductor photodetector, there will be no photon absorption when $E_{\text{PHOTON}} < E_G$. This corresponds to $\lambda > \lambda_c$, the *critical wavelength*. Beyond $\lambda = \lambda_c$, there will be no photon absorption and no photogeneration will be possible, and thus the current responsivity will be zero. For the ideal photodetector, the maximum current responsivity will be right at $\lambda = \lambda_c$.

At $\lambda = \lambda_c$, $E_{\text{PHOTON}} = E_G = 1.24 \text{ V}\cdot\mu\text{m}/\lambda_c$, so that $\lambda_c = 1.24 \text{ V}\cdot\mu\text{m}/E_G$. Thus, $\lambda_c/1.24 \text{ V}\cdot\mu\text{m} = 1/E_G$, so the maximum current responsivity = $1/E_G$. For the case of silicon, the energy gap is $E_G = 1.1 \text{ V}$. Thus the maximum current responsivity = $1/E_G = 1/(1.1 \text{ V})$, which gives a value of $0.9/\text{V} = 0.9 \text{ A}/\text{W}$ for the maximum current responsivity.

The typical *spectral response* curve for an actual silicon photodiode is shown in Figure 119.9. Due to various loss factors, the current responsivity of an actual photodiode will be substantially less than that of the ideal device. The maximum current responsivity for a silicon photodiode is typically around $0.5 \text{ A}/\text{W}$. The loss factors include the reflection of some of the incident photons at the photodiode surface, incomplete absorption of photons, especially at the longer wavelengths, and the recombination of the photogenerated minority carriers.

Photodiode Current versus Voltage Curves

The focus of this section is the current versus voltage characteristics of photodiodes. Figure 119.10 presents the current and voltage axes and reference directions of voltage and current. The current versus

FIGURE 119.10 Photodiode current versus voltage curves.

FIGURE 119.11 Photodiode current versus voltage curves with load line.

FIGURE 119.12 Photovoltaic mode peak power point and power output.

voltage curve under dark conditions is the same as for an ordinary diode. Under illuminated conditions the curve shifts down by an amount equal to the photocurrent, I_L . Under short-circuit conditions, $V = 0$. The current when $V = 0$ is $I(V = 0) = I_{SC} = -I_L$. Under open-circuit conditions, $I = 0$ and $V(I = 0) = V_{OC} = n \cdot V_T \cdot \ln[(I_L/I_0) + 1]$. In Figure 119.11, a load resistor, R , is connected across the photodiode. The *load line* is given by $I = -V/R$, and thus has a *slope* $= -1/R$. The photodiode is now operating in the photovoltaic mode, because it is generating a voltage that drives the current around the loop. The intersection of the *load line* with the current versus voltage curve is the *operating point*. The power delivered to the load is $P = -V \cdot I$. Since $V > 0$ and $I < 0$, $P > 0$, so in the *photovoltaic mode* with the current versus voltage curve in the fourth quadrant, the photodiode converts light energy to electrical energy. This is photovoltaic energy conversion, and is the basis of the solar cell, which is a large area photodiode designed for the conversion of sunlight to electricity.

The area of this rectangle is equal to the power delivered to the load. If a smaller value for R is used, the load line slope will be larger and since the current is approximately equal to the short-circuit current, I_{SC} , but if the voltage is smaller, the power output will be smaller. If a larger value for R is used, the load line slope will be smaller and since voltage is approximately equal to the open-circuit voltage, V_{OC} , but if the current is smaller, the power output will be smaller.

The optimum load resistance, R_{OPT} , is one that results in the maximum output power. The load line for R_{OPT} intersects the current versus voltage curve at the peak power point. The value of R_{OPT} will change as the illumination level changes.

The “ideal” current versus voltage curve for a solar cell would have a rectangular shape as shown in Figure 119.12. The output power would then be $P = V_{OC} \cdot I_{SC}$. The actual output power when $R = R_{OPT}$ will be $P = V \cdot I$. The *curve factor* $= (V \cdot I)/(V_{OC} \cdot I_{SC})$, and is typically around 0.6. The photodiode or solar cell is now operating in the fourth quadrant in the *photovoltaic mode*.

The photodiode can be biased for operation in the third quadrant by a battery or DC power supply as shown in Figure 119.13. The *load line* is given by the equation $V = V_B - I \cdot R$. Thus, $V = V_B$ when $I = 0$, and the slope is given by $dI/dV = -1/R$. With the DC operating point or quiescent point (Q-point) in the third quadrant, the photodiode is now in the *photoconductive mode*.

The current through the load resistor is the photocurrent, I_L . Under dark conditions, $I_L = 0$ and $V = V_B$. As the light intensity increases, I_L increases and voltage increases. The Q-point moves along the *load line*, and as the light intensity continues to increase, voltage continues to increase. Since I_L is a linear function of the light intensity, the voltage will be a linear function of the light intensity. When V_B is removed, the photodiode is now operating in the photovoltaic mode.

If the diode is not biased by a battery or DC power, it will be operating in the fourth quadrant in the photovoltaic mode as shown in Figure 119.14. In this case, the voltage is not a linear function of the light intensity. When the photodiode is used as a solar cell for energy conversion, it is operated in the photovoltaic mode. However, when the photodiode is used for light sensing and optical communications, it is usually best to operate it in the photoconductive mode. This is because of the linear voltage versus

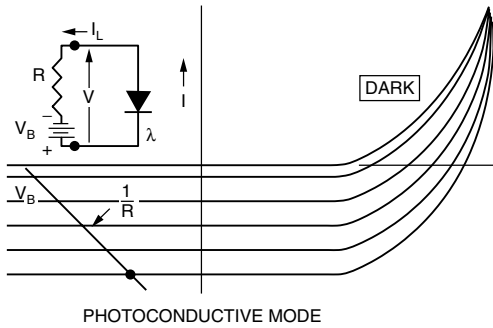

FIGURE 119.13 Photodiode current versus voltage curves — photoconductive mode.

FIGURE 119.14 Photodiode current versus voltage curves — photovoltaic mode.

light intensity transfer relationship. Also, the reverse bias voltage across the PN junction reduces the junction capacitance, so that a faster response time and a wider bandwidth is available.

119.3 Phototransistors

Now we will look at a *phototransistor*, which is an integrated combination of a photodiode and a transistor as shown in Figure 119.15. This combination of the photodiode and transistor constitutes a phototransistor. The photodiode generates a photocurrent, I_L . If $V_{CE} > +0.2$ V, the transistor will be in the active region, and $I_C = \beta \cdot I_B$. Since $I_B = I_L$, $I_C = \beta \cdot I_B = \beta \cdot I_L$, as shown in Figure 119.16.

The current flowing through the phototransistor is $I = I_C + I_L = \beta \cdot I_L + I_L$.

This can be written as $I = (\beta + 1) I_L$. Since $\beta \gg 1$, this can be expressed as $I \cong \beta \cdot I_L$, as shown in Figure 119.17. The current produced by a phototransistor is thus greater than that produced by a photodiode by a factor of the transistor current gain, β , and since $\beta \sim 100 - 300$ for phototransistors, this can represent a very large gain indeed. Whereas a photodiode may have responsivity of about 0.5 mA/mW at 0.9 μm , a phototransistor may have responsivity up in the 50 to 150 mA/mW range.

Now let us consider a *photodarlington*, which is an integrated combination of a photodiode and a Darlington transistor, as shown in Figure 119.18. The photocurrent I_L is multiplied by the net current gain of the Darlington pair, which is approximately $\beta_1 \cdot \beta_2$. Since $\beta \sim 100$, this current gain will be of the order of 10,000. Thus, current responsivity values of the order of 5 mA/mW are possible.

Regarding phototransistor structure, starting with an N-type substrate, there is a P-type (boron) diffusion into the substrate. Then there is an N^+ diffusion producing the result shown in Figure 119.19.

FIGURE 119.15 Phototransistor.

FIGURE 119.16 Phototransistor — internal current gain.

FIGURE 119.17 Phototransistor — current gain.

FIGURE 119.18 Photodarlington.

FIGURE 119.19 Phototransistor structure.

This is an integrated combination of a photodiode and a transistor. The photocurrent produced by the photodiode portion of this device becomes the base current of the transistor. The two contacts made to this device are to the emitter region and to the N-type substrate (collector) region on the bottom of the chip. The phototransistor offers the advantage of a much higher current responsivity than a photodiode. However, it has two major disadvantages.

First, since the current gain, β , is not a constant, but does vary with collector current level, the resulting current will not be a linear function of light intensity, as it is in the case of a photodiode. Second, the frequency and time-domain response is worse than that of a photodiode by approximately a factor of the current gain, β .

Consider the structure of a photodarlington transistor. Figure 119.20 shows the photodarlington with NPN transistors Q_1 and Q_2 . The emitter of transistor Q_1 , which is designated as E_1 , is connected to the base of Q_2 , which is designated as B_2 . The common N-type substrate serves as the cathode of the photodiode, the collector of Q_1 , and the collector of Q_2 . The external connections of this device are to the emitter of Q_2 , which is E_2 , and to the bottom side of the common N-type substrate.

The two transistors of the Darlington pair occupy only a small portion of the total chip area. The photodarlington transistor offers the advantage of a much higher current responsivity than that of a photodiode. However, as in the case of the phototransistor, it has two major disadvantages. First, since both β_1 and β_2 are not constants, but do vary with collector current level, the resulting current will not

FIGURE 119.20 Photodarlington structure.

be a linear function of light intensity, as it is in the case of a photodiode. Second, the frequency and time-domain response is much worse than that of a photodiode by approximately a factor of the net current gain, $\beta_1 \cdot \beta_2$.

119.4 PIN Photodiode

First, we will look at the structure of an “ordinary” photodiode. Openings are etched in the oxide layer as shown in Figure 119.21. A donor dopant such as phosphorus is deposited into the silicon surface. The donors are then diffused into the silicon at a high temperature (~ 1000 to 1200°C). The openings in the oxide layer are reoxidized during this process producing the result shown in Figure 119.22. Openings are etched in the oxide again. A metal film is deposited on the wafer surface and then etched to form this contact area.

The PIN photodiode is designed for very high-speed operations. In this case, a heavily doped P+ substrate is used, upon which a lightly doped P-type layer is deposited, as shown in Figure 119.23. This lightly doped P-type layer is called an “epitaxial layer” since it is a crystallographic continuation of the substrate. The thickness of the epitaxial layer is designated as t_{EPI} , as shown in Figure 119.24, and is generally in the range of $10\ \mu\text{m}$ to $50\ \mu\text{m}$.

A reverse bias voltage, V_R , is applied across the PN junction causing an increase in the width of the depletion region. With a large enough reverse bias voltage, the depletion region can extend all of the way across the lightly doped epitaxial layer as is Figure 119.25. Now the mobile charge carriers are rapidly swept out of this region due to the strong electric field. This region thus acts as an “insulating region,” hence the “I” in the name of the PIN diode. The width of this “fully depleted” region is $W = t_{\text{EPI}} - x_j$. The device capacitance under these “fully depleted” conditions is at a minimum given by $C_{\text{MIN}} = \epsilon \cdot A_j/W$, as shown in Figure 119.26. With a thick epitaxial layer, this capacitance can be made very small, and the small capacitance leads to a faster response time and a wider bandwidth.

Now let us consider what happens with photons incident on the PIN photodiode. The photons penetrate into the semiconductor and are absorbed. This results in the photogeneration of minority carriers as shown in Figure 119.27. The photogenerated minority carriers (electrons) in the epitaxial layer will flow toward the PN junction under the influence of the strong electric field in this region as in Figure 119.28. These photogenerated minority carriers will travel at a relatively high speed toward the PN junction due to this electric field, so not many will be lost due to recombination. As a result, the collection efficiency will be high. In addition, the transit time will be very small, which is another reason for this being a very fast device. Thus, the PIN photodiode will have a very fast response time due to the small junction capacitance and the short transit time of the photogenerated minority carriers. It will also have an improved response at longer wavelengths due to the improved collection efficiency.

FIGURE 119.28 PIN photodiode — collection of photo-generated minority carriers.

FIGURE 119.29 Schottky-barrier photodiode.

119.5 Schottky Photodiode

The Schottky photodiode is shown in Figure 119.29. A very thin film of metal, about 150 angstroms in thickness, is thin enough to allow most of the light to pass through and enter the silicon. This thin transparent metal film forms the metal side of a metal-silicon Schottky barrier. The Schottky photodiode often uses an N/N⁺ epitaxial structure as shown in Figure 119.30. Photons incident on this device will pass through the thin metal film and enter the silicon. An antireflective coating is often deposited on top of the metal film to reduce the amount of reflection.

The absorption of photons results in the photogeneration of free electrons and holes. The photogenerated holes then diffuse toward the metal-semiconductor Schottky barrier. As the photogenerated holes enter the metal, they immediately recombine with electrons. Other electrons flow into the metal layer to replace those lost to recombination with the holes, and this constitutes the photocurrent. Another process that can occur is the *photoemission* of electrons from the metal into the semiconductor. For this to happen the electrons must be given enough energy to surmount the potential barrier of height ϕ_b at the metal-silicon interface.

Since ϕ_b is smaller than the silicon energy gap E_G , the response of the Schottky photodiode can extend to wavelengths substantially longer than that of a silicon PN junction photodiode. For example, if $\phi_b = 0.65$ eV, the long wavelength limit for the photoemission process is $\lambda = 1.24 \text{ eV}\cdot\mu\text{m}/\phi_b = 1.24 \text{ eV}\cdot\mu\text{m}/0.65 \text{ eV} = 1.91 \mu\text{m}$. For the photogeneration process in silicon, the long wavelength limit is $\lambda_c = 1.24 \text{ eV}\cdot\mu\text{m}/E_G = 1.24 \text{ eV}\cdot\mu\text{m}/1.1\text{eV} = 1.13 \mu\text{m}$. Thus, for wavelengths between 1.13 μm and 1.91 μm , the response will be due just to the photoemission of electrons from the metal to the semiconductor.

FIGURE 119.30 Schottky-barrier photodiode with epitaxial layer.

FIGURE 119.31 Avalanche photodiode.

119.6 Avalanche Photodiodes

Now we examine an *avalanche photodiode* or APD. We start off with a P-type epitaxial layer on a heavily doped P+ substrate; this deep N+ guard ring is then diffused, followed by the diffusion of the much shallower N+ region. The finished device with the cathode contact metallization is shown in Figure 119.31.

The APD is usually operated under a relatively large reverse bias voltage in the 30 to 50 V range, such that the epitaxial layer is fully depleted, as shown in Figure 119.32. There is a strong electric field in this depletion region. Upon illumination with photons of energy greater than the energy gap E_G , there will be the photogeneration of free electrons and holes in the depletion region. These photogenerated charge carriers will then be accelerated by the strong electric field in this region. If the electric field is large enough, the photogenerated charge carriers will produce additional free electrons and holes by the impact ionization process.

In the absence of the N+ guard ring there would be a strong intensification of the electric field around the periphery of the PN junction where there is a high degree of curvature. This is shown in Figure 119.33. As a result, most of the avalanche multiplication would occur in this small region rather than over the much larger flat area of the junction. The purpose of the more deeply diffused N+ guard ring is to reduce the electric field intensification in this region, and thus prevent the avalanche multiplication occurring here. Now the avalanche multiplication occurs over the larger flat area of the PN junction.

The junction area of the APD is generally kept small to reduce the probability of crystallographic defects that could result in the premature breakdown of the junction at a reduced voltage. This would cause the breakdown voltage to be below the value required for a uniform avalanche multiplication over the entire flat area of the junction. The junction diameter is typically in the 10 to 100 μm range, and this also helps to reduce the junction capacitance for high-speed performance. The avalanche photodiode is thus a

FIGURE 119.32 Avalanche photodiode — carrier multiplication.

FIGURE 119.33 Avalanche photodiode — electric field intensification.

photodiode with a built-in gain, which is the avalanche multiplication factor, M , which can be in excess of 100. The principal advantages of the avalanche photodiode are high gain and speed, with gain-bandwidth products in excess of 100 GHz, and it is especially useful for fiber optic communication systems.

The principal disadvantage of the avalanche photodiode is the high noise generated as a result of the random nature of the avalanche multiplication process.

For a high gain, the avalanche photodiode must be biased at a voltage that is close to the junction breakdown voltage. As a result, a very stable, temperature-compensated biasing source is required, generally up in the 30 to 50V range.

119.7 Solar Cells

Solar cells are photodiodes made specifically to convert solar energy to electrical energy. The process is called *photovoltaic energy conversion*. Conversion efficiencies for silicon solar cells are typically in the 15% to 20% range, and GaAs cells can offer efficiencies close to 25%.

The construction of typical silicon solar cell is shown in [Figure 119.34](#). Phosphorus diffusion is used to produce a thin N^+ diffused layer on a P-type substrate. The N^+ diffused layer is very thin, only about 1 μm in thickness. Then metal grid lines and a contact strip to collect the current are deposited as shown in [Figure 119.35](#).

The top surface metallization occupies only about 5% of the top surface area, so that most of the silicon is exposed to the light. The bottom surface is completely covered by metal. There will be a substantial amount of incident light reflected from the silicon surface. To minimize this light reflection, a thin antireflective coating is deposited on the solar cell. The solar cell has an area in the range of 1 cm^2 up to 10 cm^2 .

119.8 Heterostructure Photodiode

A heterostructure photodiode uses more than one semiconductor material. An example of a heterostructure photodiode is shown in [Figure 119.36](#). We start off with a heavily doped N-type indium phosphide (N^+ InP) substrate. Indium phosphide is a III-V compound semiconductor. A more lightly doped N-type indium phosphide (N InP) epitaxial layer is then deposited on the N^+ InP substrate. The next epitaxial layer that is deposited is a ternary III-V compound semiconductor, N-type indium gallium arsenide, $\text{In}_{0.53}\text{Ga}_{0.47}\text{As}$. Then there is the diffusion of acceptors through a diffusion mask to produce a P+ region of InGaAs. Metallization and patterning form the anode contact of this photodiode. The InP layer has an energy gap of $E_G = 1.35$ eV. The ternary compound $\text{In}_{0.53}\text{Ga}_{0.47}\text{As}$ has a much smaller energy gap of $E_G = 0.75$ eV. The bottom contact metallization is deposited and patterned to have an opening or window for light to enter the device, as shown in [Figure 119.37](#). The dimensions of these diagrams are not to scale, and in actuality the N^+ InP substrate is much thicker than the InP and InGaAs epitaxial layers.

FIGURE 119.34 Solar cell.

FIGURE 119.35 Solar cell — grid lines.

FIGURE 119.36 Heterostructure photodiode.

FIGURE 119.37 Heterostructure photodiode — opening in contact to admit light.

FIGURE 119.38 Heterostructure photodiode — photons entering photodiode.

Photons enter the photodiode from the bottom as shown in Figure 119.38. Photons with energies less than the energy gap of the InP pass through the InP substrate and InP epitaxial layer to the InGaAs layer. Photons with energies greater than $E_G = 0.75$ eV are then absorbed in the InGaAs layer, and result in the photogeneration of free electrons and holes. The photogenerated holes can then diffuse to the P+ anode region and be collected, thus resulting in the production of a photocurrent. The $\text{In}_{.53}\text{Ga}_{.47}\text{As}$, arsenide energy gap of 0.75 eV corresponds to a photon wavelength of $\lambda_c = 1.65$ μm , and the InP energy gap of 1.35 eV corresponds to $\lambda_c = 0.918$ μm . Thus, photons with wavelengths between 0.918 μm and 1.65 μm will pass through the InP substrate and InP epitaxial layer, and be absorbed in the $\text{In}_{.53}\text{Ga}_{.47}\text{As}$ layer. The InP substrate and InP epitaxial layer thus act as a transparent window for this wavelength range.

A wavelength of $\lambda = 1.55$ μm is often used for long distance fiber optic systems, because the optical absorption of the glass fibers is a minimum in this wavelength range. Thus, this type of heterostructure photodiode, with its wavelength range of 0.92 μm to 1.65 μm , is often used for these fiber optic systems.

Another example of heterostructure photodiode that uses InP and InGaAs is shown in Figure 119.39. In this case also, the photons enter through a window in the metallization contact area. The photons then pass through the InP layers to the $\text{In}_{.53}\text{Ga}_{.47}\text{As}$ region where they are absorbed as shown in Figure 119.40. This again is the case for photons with energies between 0.75 eV and 1.35 eV, corresponding to wavelengths between 0.92 μm and 1.65 μm . The photogenerated holes in the $\text{In}_{.53}\text{Ga}_{.47}\text{As}$ absorption region will diffuse toward the InP PN junction.

With a reverse bias voltage across the PN junction there will be a depletion region adjacent to the junction, extending mostly on the more lightly doped N-type side of the junction as shown in Figure 119.41. With a large reverse bias voltage, there will be a strong electric field in the depletion region; thus, as the holes travel through this region they will be accelerated by the electric field.

FIGURE 119.39 Heterostructure photodiode using PIN and InGaAs.

FIGURE 119.40 Heterostructure photodiode — absorption region.

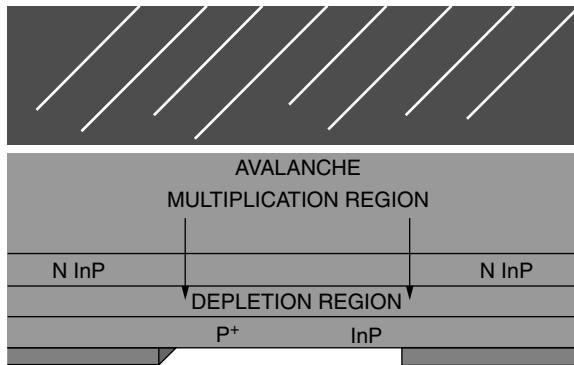

FIGURE 119.41 Heterostructure photodiode — avalanche multiplication.

With a large enough electric field, an avalanche multiplication process occurs, with additional holes and free electrons being produced by the impact ionization process. As a result of the avalanche multiplication process, the collection of electrons and holes will increase along with a corresponding increase in the photocurrent. This is, therefore, another example of an avalanche photodiode.

119.9 Light-Emitting Diodes

A light-emitting diode (LED) is to a great extent the opposite of a photodiode. A photodiode can be used to produce an electric current as a result of light shining on it, whereas an LED produces light as a result of current passing through it. The light emitted by an LED increases with increasing forward current, although the relationship between light intensity and current is not a linear one. LEDs and laser diodes are used in a wide variety of optoelectronic systems. In particular, laser diodes are widely used as the light source for high-speed fiber optic communication systems.

Figure 119.42 shows a PN junction. A forward bias voltage, V_F , makes the P-type side or anode positive with respect to the N-type side or cathode. The forward current, I_F , flows from the anode (P-type side) to the cathode (N-type side). Electrons are emitted from the cathode into the anode. As the electrons flow into the P-type side, they recombine with holes. As a result, the electron density decreases exponentially with distance as given by $n(x) = n(0) \cdot \exp(-x/L_N)$, where L_N = minority carrier (electron) diffusion length.

Holes are emitted from the anode into the cathode. As the holes flow into the N-type side, they recombine with electrons. The hole density decreases exponentially with distance as given by $p(x) = p(0) \cdot \exp(-x/L_P)$.

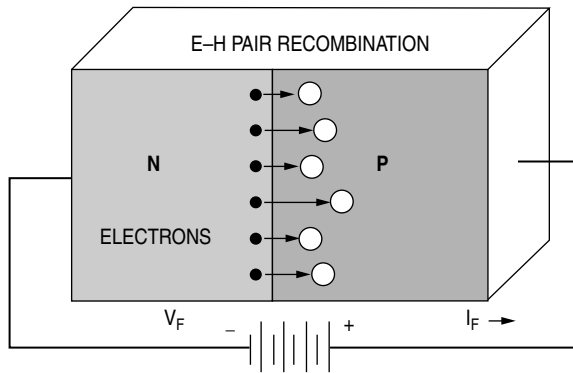

FIGURE 119.42 Light-emitting diode — electron–hole pair recombination.

L_p), where L_p = minority carrier (hole) diffusion length. Electrons and holes flow across the junction to the opposite sides, where they become *minority carriers* and recombine with the *majority carriers*.

Consider the case of a PN junction where the N-type side is very heavily doped (N^+) as compared to the P-type side. In this case, most of the diode current flow is due to the flow of electrons across the junction from N^+ to P. The electrons recombine with holes in the P-type side, mostly within a short distance from the junction. Electron–hole recombination occurs in this region.

In the case of silicon and germanium, almost all of the recombination events result in the generation of heat. In the III-V compound semiconductors, such as GaAs, most of the recombination events result in the generation of photons as illustrated in Figure 119.43. This is called *radiative recombination*. The photon energy is related to the photon wavelength by $E_{\text{PHOTON}} = hc/\lambda$ where h = Planck’s constant and c = velocity of light. Solving for the wavelength gives $\lambda = hc/E_{\text{PHOTON}}$. The energy evolved in an electron–hole pair recombination is usually close to the energy gap E_G , so $\lambda = hc/E_G$. If the energy gap E_G is expressed with units of electron-volts, E_G (in joules) = $q \cdot E_G$, where q is the magnitude of the electron–charge. We thus have $\lambda = hc/q \cdot E_G$, where E_G is given in units of electron volts; $hc/q = 1.239 \text{ eV}\cdot\mu\text{m}$, so $\lambda = 1.239 \text{ eV}\cdot\mu\text{m}/E_G$. For GaAs, $E_G = 1.43\text{V}$, so $\lambda = 0.9 \mu\text{m}$, which is in the near-infrared region. The photon emission occurs randomly through this region near the junction, and the photons travel out in all directions. A *laser diode* is a specially constructed LED in which the photons are all emitted in phase and travel in the same direction. The result is a very narrow collimated beam of light. The photons all have close to the same wavelength, so this is approximately a monochromatic light source. For this to happen in a laser diode, the forward current I_F must be greater than some threshold value, so $I_F > I_{\text{TH}}$. If $I_F < I_{\text{TH}}$, then the laser diode will act like an ordinary LED.

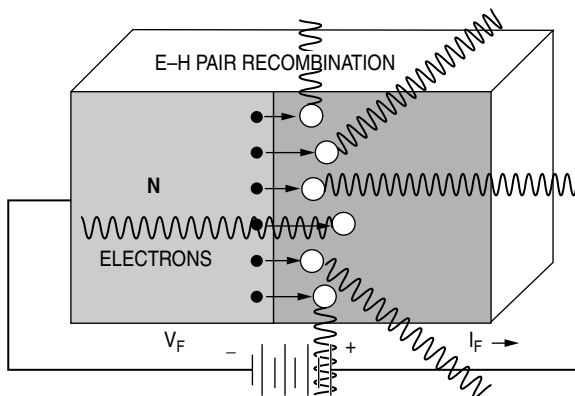

FIGURE 119.43 Light-emitting diode — photon emission.

FIGURE 119.44 Structure of light-emitting diode.

Structure of Light-Emitting Diodes

In this section, we focus on the structure and operation of light-emitting diodes. We will start off with a gallium arsenide (GaAs) substrate as shown in Figure 119.44. Next, a thin heavily-doped N^+ epitaxial layer of GaAs is deposited. Then there is the deposition of an SiO_2 layer and a photolithographic step to open windows in the SiO_2 layer. Metallization is then deposited and patterned for the cathode contact of the LED. The anode contact is made to the bottom of the P-type GaAs substrate. When the PN junction is forward biased, most of the current flow is due to the emission of electrons from the N^+ region into the P-type substrate. After traveling a short distance the minority carrier electrons in the P-type substrate recombine with the majority carrier holes. The average distance the electrons travel before recombination is very short, on the order of just $1\ \mu\text{m}$. Electron-hole pair recombination occurs close to the junction.

Reflection

In GaAs almost all of the recombination events are radiative, resulting in the emission of photons. The photons travel off in all directions, and only a few of the photons get out. Many photons are not traveling in the right direction to get out. Many photons are reflected at the GaAs surface. GaAs has a rather high index of refraction, $n_2 = 3.66$, so a substantial amount of the incident photon flux, ϕ_i , gets reflected. The reflection factor at the interface between two optical media for normal incidence is $R = \phi_r/\phi_i = (n_2 - n_1)^2 / (n_2 + n_1)^2$. For a GaAs ($n_2 = 3.66$)/air ($n_1 = 1.0$) interface, we have $R = (3.66 - 1)^2 / (3.66 + 1)^2$. This evaluates to $R = 0.33$, so one third of the incident photon flux is reflected at the GaAs/air interface. Thus, the transmission factor at the GaAs/air interface for normal incidence is $T = 1 - R = \phi_t/\phi_i = 0.67$.

As the angle of incidence, θ_i , increases, the reflection factor increases. For $\theta_i > \theta_c$, the reflection factor becomes unity, and we have *total internal reflection*. The angle θ_c is the critical angle for total internal reflection, and is given by the condition that $\sin \theta_c = n_1/n_2$. For the GaAs/air interface we have $\sin \theta_c = 1/3.66$, so $\theta_c = 15.9^\circ$. Thus, only those photons incident at the surface within a cone of half-angle $\theta_c = 15.9^\circ$ stand any chance of being emitted as shown in Figure 119.45. This represents only 2% of the total photon flux generated in the device, so we see that this is a severe problem. For the most favorable case of normal incidence the transmission factor is $T = 0.67$. We see that overall only about 1.3% of the internally-generated photons can get out.

Another problem is the reabsorption of photons within the GaAs itself, especially since most of the photon generation takes place on the P-type side of the P-N junction. The photon reabsorption problem can be decreased by using a P-type epitaxial layer on an N^+ substrate as shown in Figure 119.46. Now we have the emission of electrons upward from the N^+ GaAs substrate into the thin P-type GaAs epitaxial layer. There the injected minority carrier electrons can recombine with the holes. We have the subsequent emission of photons. One problem with this is that many of the electrons will travel all of the way across the thin P-type layer and be trapped by crystallographic defects at the surface called *surface states*. The

FIGURE 119.45 Light-emitting diode — effect of critical angle on light emission.

FIGURE 119.46 Light-emitting diode — photon emission.

trapped electrons will eventually recombine with holes, but with a nonradiative recombination process involving the evolution of heat rather than photons.

Now we will look at some heterojunction LEDs that help to solve some of these problems. Here in Figure 119.47 is a diagram of a heterostructure using GaAs and the ternary III-V compound semiconductor GaAlAs. There is a thin layer of GaAs sandwiched between two GaAlAs layers. The GaAs has an energy gap of $E_G = 1.5$ eV, and GaAlAs has $E_G = 3.0$ eV. Under forward bias conditions electrons from the N⁺ GaAlAs, and holes from the P-type GaAlAs flow into the GaAs layer. As a result of the differences of the energy gaps, the injected electrons become mostly confined to the GaAs layer as shown in Figure 119.48. Electron–hole pair recombination occurs in this GaAs carrier confinement region. There is the

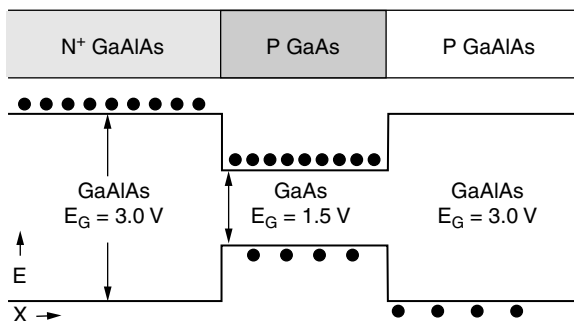

FIGURE 119.47 Heterostructure light-emitting diode — carrier confinement.

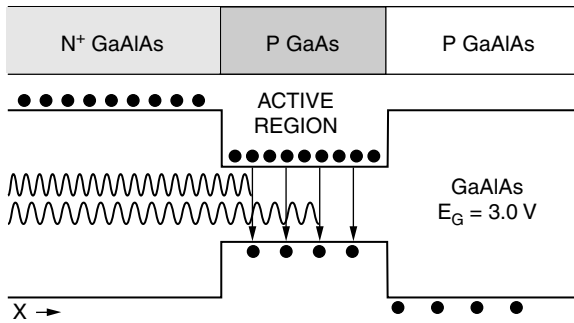

FIGURE 119.48 Heterostructure light-emitting diode — photon emission from active region.

subsequent emission of photons. Since the photon energy corresponds to the energy gap of the GaAs layer with $E_G = 1.5$ eV, there is no photon reabsorption occurring in the GaAlAs layers with $E_G = 3.0$ eV. Thus, the GaAlAs layers serve as transparent windows for the photon emission from the GaAs carrier confinement active layer.

Consider now the fabrication of a heterostructure LED, shown in [Figure 119.49](#). We start with a heavily doped P^+ GaAs substrate of about $200\ \mu\text{m}$ in thickness. A thin P-type GaAlAs epitaxial layer is then deposited. This is followed by the deposition of the thin P-type GaAs active layer. We then have the deposition of a heavily doped N^+ GaAlAs layer. The top metal contacts are then deposited and patterned, and a bottom contact to the substrate is also made. Under forward bias conditions there is the emission of electrons from the N^+ GaAlAs into the GaAs active layer as shown in [Figure 119.50](#). There is also the emission of holes from the P-type GaAlAs into the GaAs active layer. In the GaAs active layer there will be the recombination of electrons and holes, and the emission of the photons.

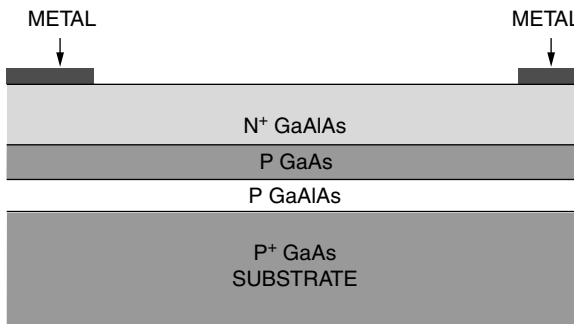

FIGURE 119.49 Structure of heterostructure light-emitting diode.

FIGURE 119.50 Heterostructure light-emitting diode — recombination in active layer.

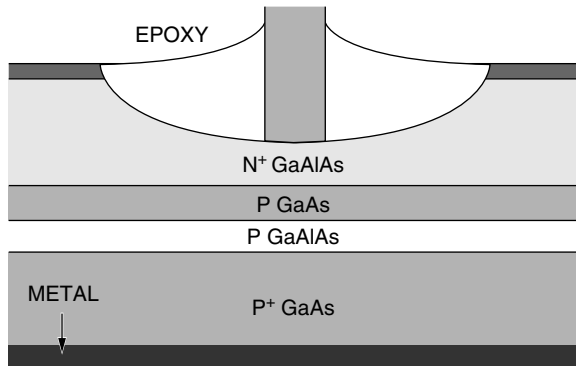

FIGURE 119.51 Coupling of light-emitting diode to optical fiber.

In many cases, the LED is used as the light source in a fiber optic system. For more efficient coupling of the light to a small diameter fiber, a cavity can be etched into the N^+ GaAlAs top layer as shown in Figure 119.51. The optical fiber is then butted up against the LED surface. The cavity is then refilled with an epoxy to hold the fiber into place. The bottom metal contact can also serve to reflect some of the photons back upward toward the fiber.

The close spacing of the end of the fiber to the active region and the higher refractive index of the fiber greatly improves the optical coupling. For example, with a fiber with an index of refraction of $n_1 = 1.5$ and GaAlAs with $n_1 \cong 3.0$, we now have a critical angle of $\theta_c \cong 30^\circ$, as compared to 16° for the GaAs/air interface. Now the fraction of photons incident on the surface within a cone of half-angle $\theta_c \cong 30^\circ$ is about 7%, as compared to 2% for the GaAs/air interface.

To further improve the efficiency of the surface-emitting LED, the bottom or anode contact can be limited to just a narrow strip. A layer of SiO_2 is deposited on the bottom surface, and a narrow opening is etched. Then the metal anode contact is deposited, and the LED mounted on a metal heat sink for more efficient transfer of heat from the device.

Edge-Emitting Double Heterostructure LED

We have been examining the surface-emitting LED. Now we turn to another basic type of heterostructure LED, the edge-emitting double heterostructure LED. A heterostructure LED with a thin GaAs active layer sandwiched between two GaAlAs layers is shown in Figure 119.52. The ternary compound semiconductor

FIGURE 119.52 Edge-emitting double heterostructure light-emitting diode.

FIGURE 119.53 Light emission from edge-emitting double-heterostructure light-emitting diode.

GaAlAs has an energy gap that is larger than that of GaAs, and an index of refraction that is substantially smaller than that of GaAs. Photons that are generated in the GaAs active layer that have an angle of incidence at the GaAs/GaAlAs interface greater than the critical angle, θ_c will undergo total internal reflection. These photons can then propagate through the thin active layer. The photons are then emitted out the edge, as shown in Figure 119.53, so this is called an edge-emitting LED.

To further improve the efficiency of this device, the top metal contact can be confined to a narrow strip about $50 \mu\text{m}$ wide. The current flow will then be confined to a small region as shown here, which will improve the efficiency of the LED. The confinement of the LED current to a small region will also be especially important for LASER diodes

The structure of an edge-emitting heterostructure LED is shown in Figure 119.54. Starting off with a GaAs substrate, about $200 \mu\text{m}$ thick, a heavily-doped N^+ GaAs layer with a doping of about $1 \cdot 10^{18}/\text{cm}^3$ is deposited. Next comes an N-type layer of $\text{Ga}_{0.3}\text{Al}_{0.7}\text{As}$ with a doping of about $1 \cdot 10^{18}/\text{cm}^3$ and a thickness of about $1 \mu\text{m}$. This is followed by the deposition of the P-type GaAs active layer with a doping in the $1 \cdot 10^{18}/\text{cm}^3$ range, and a thickness of about 0.1 to $0.2 \mu\text{m}$. On top of the GaAs active layer is a P-type $\text{Ga}_{0.3}\text{Al}_{0.7}\text{As}$ layer with a thickness of about $1 \mu\text{m}$ and a doping of about $1 \cdot 10^{18}/\text{cm}^3$. The topmost layer is a heavily-doped P^+ GaAs layer, with a doping up in the $1 \cdot 10^{19}/\text{cm}^3$ range, and a thickness of about $0.1 \mu\text{m}$. A layer of SiO_2 is then deposited. The SiO_2 layer is etched to produce an opening in the form of a narrow strip. The top metal anode contact is then deposited, and a bottom cathode metal contact is also deposited to complete the LED structure.

This edge-emitting LED emits at wavelengths near $\lambda = 1.24 \text{ eV}\cdot\mu\text{m}/E_G$, where $E_G = 1.43 \text{ eV}$ is the energy gap of the GaAs active layer. This gives an emission wavelength near $\lambda = 0.9 \mu\text{m}$. Good-quality glass optical fibers exhibit absorption minima at $1.3 \mu\text{m}$, with an attenuation of about 0.5 dB/km , and

FIGURE 119.54 Structure of edge-emitting double-heterostructure light-emitting diode.

at 1.55 μm with an attenuation of only 0.2 dB/km. Therefore, an edge-emitting LED with an emission wavelength of 1.55 μm is very desirable. This requires a material with an energy gap that is substantially smaller than that of GaAs.

Fabrication of Edge-Emitting Double-Heterostructure Light-Emitting Diodes

We will now look at an edge-emitting double-heterostructure LED with an emission wavelength near 1.55 μm . We start off with an N^+ indium phosphide (InP) substrate, about 200 μm in thickness. An N^+ indium phosphide layer is deposited, with a doping of about $3 \cdot 10^{18}/\text{cm}^3$ and a thickness of 0.2 μm . This is followed by the quaternary III-V compound semiconductor, indium gallium arsenide phosphide. The N^+ indium gallium arsenide phosphide layer has a doping of $1 \cdot 10^{18}/\text{cm}^3$ and a thickness of 1 μm . Next comes the active layer of the ternary compound, indium (0.47) gallium (0.53) arsenide with a doping in the $1 \cdot 10^{18}/\text{cm}^3$ range, and a thickness of 0.1 to 0.2 μm . On top of the active layer is a P^+ indium gallium arsenide phosphide layer with a doping of $10^{18}/\text{cm}^3$ and a thickness of 1 μm .

The top low-resistance contact layer is heavily doped P^+ indium phosphide, with a doping up in the $10^{19}/\text{cm}^3$ range, and a thickness of 0.1 μm . Next is the deposition of an SiO_2 insulating layer, and then the etching of this layer to produce an opening in the form of a narrow strip. Then comes the top surface anode contact metallization, followed by the bottom surface cathode contact metallization. The indium (0.47) gallium (0.53) arsenide active layer has an energy gap of $E_G = 0.8 \text{ eV}$. The corresponding emission wavelength is $\lambda = 1.55 \mu\text{m}$. This emission wavelength corresponds to the wavelength of minimum attenuation of the optical fiber.

Packaging of Light-Emitting Diodes

Now we focus on the packaging of a typical surface-emitting dome LED, as shown in [Figure 119.55](#). We start off with the metal leads for the diode anode and cathode contacts. The LED chip is bonded to a flat area on one of the metal contact leads. A small-diameter top contact wire is then connected between the LED chip and the other contact lead. Next is the injection molding of a transparent plastic encapsulation. This plastic encapsulation serves to protect the device, and at the same time allows the light to get out. The shape of the plastic encapsulation is such that there is a focusing action that narrows the beam width of the emitted light and thus increases the directivity of the LED.

FIGURE 119.55 Light-emitting diode packaging.

The index of refraction of the plastic of about 1.6 increases the critical angle for total internal reflection, θ_c , in the semiconductor from about 16° to about 26° . This increase in the critical angle from 16° to 26° will produce an increase in the emitted photon flux by a factor of about three.

119.10 Semiconductor Diode Lasers

In the recombination process in a semiconductor, electrons recombine with holes and give off energy E_G . Most of the recombination events in the III-V compound semiconductors are radiative recombinations, with photons being emitted. In an LED these recombination events occur spontaneously, and the emitted photons travel off in all directions.

In the *stimulated emission* process a photon produced by a recombination event stimulates the recombination of another free electron with a hole. This results in the emission of a second photon. The two photons are exactly at the same frequency and phase, and travel in the same direction. These photons then stimulate the recombination of another free electron and hole. This results in the emission of another photon. These photons will be at exactly the same frequency and phase, and travel in the same direction. This process of the stimulated emission of radiation can then continue through the active region of the device. Indeed, the word *laser* is an acronym for *light amplification by the stimulated emission of radiation*. The resulting emission is of photons that are at the same frequency, and hence this is monochromatic radiation. The photons are all in phase with each other, so this is coherent radiation. The photons are all traveling in the same direction resulting in a collimated beam of light. In actuality, both spontaneous and stimulated emission processes occur.

In an ordinary LED, the spontaneous emission process is by far the dominant process, so the emitted light is not monochromatic, but does have a spread of wavelengths. It is also not coherent and not collimated. In order to make the stimulated emission process the dominant one, the concentration of free electrons and holes in the active region must be sufficiently large. For this to happen, the forward current must be greater than some minimum threshold value, I_{TH} , for lasing action. In addition, the photons produced by this process must selectively be made to pass many times through the active volume of the device.

The stimulated emission process results in an increase in the photon flux, so this can be viewed as a light amplification process. There will also photon absorption taking place, and in order to have a net photon gain or amplification, the stimulated emission rate must exceed the photon absorption rate. For this to happen there must be a very high population density of free electrons and holes in the active region of the device. In order for this process to continue, there must be a feedback mechanism to feed photons back into the active volume. To accomplish this second objective, the laser diode is made in the form of an optical cavity with two parallel reflecting surfaces or mirrors. An electromagnetic wave that is traveling in a direction perpendicular to the end mirrors will be reflected upon reaching the end mirror. The reflected wave will now travel in the opposite direction. Upon reaching the other end there will be another reflection, and this process continues. The net electric and magnetic field distribution in this cavity will be the vector sum of all of the waves that are bouncing back and forth between the two mirrors. Let the spacing between the two reflecting surfaces be L . If L is an integer multiple of $\lambda/2$ such that $n \cdot (\lambda/2) = L$, then there will be a standing wave pattern in the cavity, and the waves will reinforce each other as shown in [Figure 119.56](#). Wavelengths that do not satisfy the condition that $n \cdot (\lambda/2) = L$ will suffer destructive interference and will rapidly decay to zero. At the wavelengths that satisfy the condition that $n \cdot (\lambda/2) = L$, this is a resonant cavity. In the microwave region this is called a cavity resonator, and is somewhat analogous to an L-C resonant circuit. In the optical part of the spectrum, it is called a Fabry-Perot resonator.

Photons that satisfy the wavelength condition and are traveling perpendicular to the reflecting surfaces will bounce back and forth between the two reflecting surfaces. These photons will stimulate the emission of other photons and there will be a build-up of this stimulated emission process. In order to allow the laser light to get out, one of the reflecting surfaces is actually only partially reflecting as shown in

FIGURE 119.56 Standing wave pattern in an optical cavity.

FIGURE 119.57 Light emission from laser diode.

Figure 119.57. As a result, the laser beam can escape from the partially reflecting-partially transmitting surface. Note that the laser light will actually not be truly monochromatic, but will consist of a number of discrete wavelength or modes that satisfy the condition that $n \cdot (\lambda/2) = L$, where n is an integer. However, since the photon energies must be close to the energy gap E_G , not all of the possible cavity modes will actually be produced. Only those modes that correspond to photon energies close to E_G will be produced.

The emission spectrum of an LED is shown in Figure 119.58. The peak wavelength is $\lambda_{\text{peak}} \cong hc/(qE_G) = 1.24 \text{ eV}\cdot\mu\text{m}/E_G$, and is in the 0.5- to 1.5- μm range for most LEDs. The radiation is in a narrow band of wavelengths, typically about 50 nm wide, centered about the peak wavelength, λ_{peak} . When lasing action occurs only those modes will appear that correspond to wavelengths within the LED emission spectrum will thus be present. As the forward current increases further above the threshold for lasing action, there will be a further narrowing of the emission spectrum. With further increases in the forward current the spectrum will be even narrower. Finally, with a large enough value of the forward current, all of the

FIGURE 119.58 Emission spectrum.

energy will be concentrated in just a few modes or spectral lines, and an approximately monochromatic output will be obtained.

Typical laser diodes are represented by GaAlAs with λ_{peak} in the 750 to 850 nm range and power outputs up to 5 watts. Quaternary compounds such as InGaAlP have $\lambda_{\text{peak}} = 670$ nm and power outputs up to 5 mW. Another example is InGaAsP with λ_{peak} in the 1300- to 1550-nm range and power outputs up to 100 mW.

InGaAsP lasers are especially useful for long-range fiber optic applications. This is a result of the emission wavelength of 1550 nm = 1.55 μm being in the range of minimum attenuation for the fiber. In addition, the power output of up to 100 mW for InGaAsP is another favorable factor for long-range fiber optic applications.

Some specially constructed laser diodes can be made to operate as just a single-mode laser, and this is especially useful for long-range wide-bandwidth fiber optic systems.

Edge-Emitting Double-Heterostructure Laser

Now we consider the fabrication of an edge-emitting double-heterostructure laser diode. A P-type GaAs active layer is sandwiched between two GaAlAs layers, as shown in Figure 119.59. The GaAs has a smaller energy gap than GaAlAs, and also has a larger index of refraction so $n_1 > n_2$. Light rays that are incident on the GaAs/GaAlAs interface with an angle of incidence θ_i greater than the critical angle for total internal reflection will undergo total reflection at the interface, as in Figure 119.60. The two opposite faces of the

FIGURE 119.59 Laser diode structure.

FIGURE 119.60 Laser diode light confinement.

FIGURE 119.61 Light emission from the active layer of a laser diode.

FIGURE 119.62 Double-heterostructure laser diode with an InGaAs active layer.

laser diode chip are cleaved mirror smooth surfaces, so there is a substantial amount of reflection at these faces. This forms a Fabry-Perot resonator. The other faces are roughened surfaces so that there will be no buildup of lasing modes in the perpendicular direction. The reflection coefficient at the GaAs/air interface for normal incidence is 0.33, so that a substantial amount of light will exit the cleaved faces.

A more detailed look at the structure of laser diodes is shown in Figure 119.61. The laser radiation is emitted from the P-type GaAs active layer that has an energy gap $E_G \cong 1.43$ eV. The corresponding wavelength is $\lambda = 1.24 \text{ eV}\cdot\mu\text{m}/1.43 \text{ eV} = 0.87 \mu\text{m} = 870 \text{ nm}$. For long-distance fiber optic applications, a wavelength of $1.55 \mu\text{m}$ is desirable because the attenuation of optical fibers is a minimum of about 0.2 dB/km at that wavelength. An emission wavelength of $1.55 \mu\text{m}$ can be obtained by using the ternary III-V compound semiconductor $\text{In}_{0.47}\text{Ga}_{0.53}\text{As}$. In Figure 119.62 shows a double-heterostructure laser diode with an $\text{In}_{0.47}\text{Ga}_{0.53}\text{As}$ active layer sandwiched between InGaAsP layers. The InGaAsP layer has a larger energy gap and a smaller index of refraction than the indium gallium arsenide active layer. Therefore, there are both carrier confinement and optical confinement in the active layer.

Laser Beamwidth

The beam width or angular spread of a laser beam is a function of the ratio of the wavelength to the dimensions of the active area from which the emission is taking place. For the case of $D \gg \lambda$, as in Figure 119.63, this is given approximately by $\sin \theta = \lambda/D_A$, where D_A is the diameter of the active area. With gas lasers the diameter of the active area is usually much larger than the wavelength, so the beam width will be very small. Because $\sin \theta \cong \lambda/D_A$, $\theta = \text{Arc sin} (\lambda/D_A)$. For $\lambda/D_A \ll 1$, $\theta \cong \lambda/D_A$. Consider the example of a helium-neon laser with $D_A = 3 \text{ mm}$. The wavelength is $\lambda = 633 \text{ nm} = 0.63 \mu\text{m}$, which

FIGURE 119.63 He-Ne laser beam width.

FIGURE 119.64 Laser diode beam width.

is in the red part of the visible spectrum. Assume that $\lambda/D_A = 633 \text{ nm}/3 \text{ mm}$, which gives $\lambda/D_A = 211 \cdot 10^{-6} = 2.11 \cdot 10^{-4}$. We thus obtain $\theta = 2.11 \cdot 10^{-4}$ radians. This corresponds to only 0.012° , so the beam divergence is very small indeed.

We now consider a laser diode, of which only the active layer is shown in Figure 119.64. The length of the active layer is typically in the 200- to 300- μm range. We typically have $H \cong 0.2 \mu\text{m}$ for the height or thickness of the active layer, and W in the range of 10 to 50 μm for the width. Since the thickness H of the active layer is actually smaller than the wavelength λ , the equation presented earlier for the beam divergence cannot be used. As a result of the small dimensions of the active layer in the laser diode, the angular spread of the beam will be much wider, especially in the direction perpendicular to the narrow dimension. The beam width in the direction perpendicular to the active layer is typically around 30° . The beam width in the direction parallel to the active layer is typically around 10° .

Although the laser diode does have a rather large beam width, the small dimensions of the active area and the coherent and nearly monochromatic nature of the light makes it possible to use lenses to produce well-collimated beams. It is also possible to focus the light in a very small spot size, as required for example in compact disc and laser disc applications. As a result of the small dimensions of the light emitting active area, the light output can be efficiently coupled to optical fibers as shown in Figure 119.65. The active area of a laser diode is usually comparable to or smaller than the area of an optical fiber, so a large fraction of the light output can be coupled into the fiber. Indeed, the coupling efficiency of light from a laser diode into a small diameter optical fiber can be of the order of 100 times greater than that of an LED.

FIGURE 119.65 Emission of light from laser diode into optical fiber.

Laser diodes can be turned on and off in times down in the 0.1 to 1 ns range, corresponding to bandwidths up to the range of 2 GHz, or data transmission rates in the 2-Gbps range. Laser diodes also have a much faster response time than LEDs. For LEDs the response time is in the 3- to 300-ns range, corresponding to bandwidths up to the range of 100 MHz, or data transmission rates in the 100-Mbps range.

Light Output versus Forward Current

A graph of the light output (photon flux) ϕ versus the forward current for a laser diode is shown in Figure 119.66. At lower levels of current, the characteristics are basically the same as an LED. At some threshold current value, I_{TH} , there is the onset of lasing action, and the light output starts to increase much more rapidly. The power output in the lasing region for the forward current greater than I_{TH} is much greater than it would be for a comparable LED. For drive currents below I_{TH} , the diode operates essentially like an ordinary LED, with spontaneous recombination events being dominant. For drive currents above I_{TH} , the diode operates in the lasing mode, with the stimulated recombination being dominant.

The light output from the laser diode can be modulated, just as in the case of an LED, by variation of the driving current the forward current. The case of pulse or digital modulation, in which the driving current is a rectangular pulse waveform is shown in Figure 119.67. To take advantage of the much faster response time and high power output of the diode when operating in the lasing mode, the device is usually biased at, or slightly above the threshold current I_{TH} . This keeps the device operating in the lasing mode all of the time. The output is in the form of a series of pulses of light. The most commonly used

FIGURE 119.66 Light output versus current for laser diode.

FIGURE 119.67 Light output modulation from laser diode.

type of pulse modulation is pulse code modulation or PCM in which the output is a series of off and on pulses representing a binary digital code of 1's and 0's. Another type of pulse modulation that can be used is pulse width modulation, or PWM. In this case the width of the pulses are proportional to the amplitude of an analog input signal.

Laser diodes offer several advantages over LEDs. The efficiency of a laser diode can be much greater than for an LED. The maximum frequency of modulation is much higher, the spectral width is much smaller, the emitting area is much smaller, and the output has phase coherence. The output of a laser diode can thus be easily turned into a well-collimated beam by a lens, and can also be focused down to a very small spot size. These factors make laser diodes especially useful for such applications as long-distance fiber optic systems and compact disc and laser disc systems. Laser diodes are, however, much more expensive than LEDs, and they require a more complex biasing circuit.

119.11 Conclusion

Some of the most important optoelectronic devices have been briefly described here. More detailed descriptions of their physics and properties are available in the works listed in the references.

Defining Terms

Avalanche photodiode — A photodiode in which the avalanche multiplication process increases the response of the device.

Critical wavelength — The long wavelength limit of photosensor devices, corresponding to photon energies that are just equal to the energy gap.

Current responsivity — The ratio of the current produced by illumination (*photocurrent*) to the incident optical power.

Heterojunction — Junction between two different semiconductor materials. Also known as a heterostructure.

Laser diode — A light-emitting diode that is especially constructed such that when operated above a threshold current level, will emit a coherent radiation of photons.

Light-emitting diode (LED) — A forward-biased diode that produces light as a result of the electron-hole pair recombination process. LEDs usually are made of III-V compound semiconductors such as gallium arsenide.

Photocell — Light-sensing device based on principle of photoconductivity. Also known as a *photoconductive cell* or *photoresistor*.

Photoconductive mode — Region of operation of a photodiode in which the PN junction is reverse biased. Photodiodes used for optical communications are usually operated in the photoconductive mode.

Photoconductivity — Change in conductivity of a semiconductor as a result of photons absorbed in the material.

Photodiode — A diode in which the reverse bias current is increased by the absorption of photons. A light-sensitive diode.

Phototransistor — An integrated combination of a photodiode and a transistor on one chip of silicon. The photocurrent of the photodiode is multiplied by the current gain of the transistor.

Photovoltaic mode — Region of operation of a photodiode in which the PN junction is forward biased. Solar cells operate in the *photovoltaic mode*.

PIN photodiode — A high-speed photodiode with a wide lightly-doped region that is fully depleted under operating conditions.

Radiative recombination — Recombination of electrons and holes in a semiconductor resulting in the emission of photons.

Schottky photodiode — A diode with enhanced short-wavelength response that uses a metal-semiconductor Schottky barrier instead of a PN junction.

Solar cell — A large-area photodiode especially constructed for the purpose of converting sunlight to electrical power.

Stimulated emission — Emission of light in which photons initiate the emission of other photons. The result is that the photons all have the same phase, frequency, and direction of propagation. This is called *coherent* emission of light.

120.1 Power Semiconductor Devices

Diodes • Thyristor and Triac • Gate-Turnoff Thyristor (GTO) • Power Transistors • Silicon Carbide and Gallium Nitride Devices • Hybrid Switching Devices • Future Switching Devices • Summary

120.2 Power Conversion

DC–DC Converters • AC–DC Converters • DC–AC Converters • Direct AC–AC Converters

Power electronics implies the use of electronics to convert electrical current and voltage into a more usable form for a given load. This typically involves the use of solid-state electronic switches of some sort, a converter circuit, and a control circuit. A variety of power electronic switches are available with a wide range of voltage and current ratings. Thus, power electronic circuits are used for low-power applications of only a few watts to very high-power applications using tens of megawatts. Power switches are discussed in the first section of this chapter.

Since the input and the output of the power electronic circuit can be AC or DC, there are four possible types of conversion:

AC–DC (rectification)

DC–AC (inversion)

AC–AC (change of voltage magnitude and/or frequency)

DC–DC (change of voltage magnitude)

Circuits that perform these functions are often referred to as converters, and within each class of converter there are a number of possible circuit topologies. Section two of this chapter discusses a number of converter circuits.

Applications for power electronics include power supplies for computers and other electronic devices, motor drives, uninterruptible power supplies, induction heaters, automotive ignition systems, battery chargers, flexible AC transmission system devices, electrically driven ships and vehicles, electrically controlled aircraft, and a host of other devices. Power electronics allows us to use electricity in the form (i.e., the voltage and frequency) that is most useful to the task at hand.

120.1 Power Semiconductor Devices

Power electronic devices require power switches to do their job. When we think of a switch, we normally think of a device that opens and closes. We also usually assume that the switch has infinite resistance when it is open and zero resistance when it is closed. [Figure 120.1\(a\)](#) shows an idealized characteristic (the shaded bars on the V and I axes) for a switch that conducts current in either direction with no

FIGURE 120.1 Ideal switch characteristics: (a) four-quadrant switch; (b) two-quadrant, voltage-blocking switch; (c) two-quadrant, reverse-conducting switch; and (d) one-quadrant switch.

voltage drop across the switch or holds off voltage of either polarity, without conducting current. A switch that can operate in this manner is a four-quadrant switch, since it can operate in any quadrant on the I-V axes. Most switches, however, are not capable of operating in all four quadrants; so one way of classifying switches is by the quadrants in which they operate. As shown in Figures 120.1(b), (c), and (d), switches may only operate in one or two quadrants. Figure 120.1(b) shows a two-quadrant switch that is capable of withstanding voltage in either direction, but can only conduct current in one direction, while Figure 120.1(c) shows a two-quadrant switch that conducts current in either direction but can only block voltage in the forward direction. Finally, Figure 120.1(d) shows a single-quadrant switch that can only block forward voltage or conduct positive current.

Of course, when one thinks about the operation of a switch, one assumes that it can be turned on or off, essentially at will. However, some power electronic switches are capable of closing but not opening when current is flowing through them. Thus, switches can also be categorized by how they operate. In particular, for an uncontrolled switch, such as a diode, the change between the on and off states is determined by the power circuit. Semi-controlled switches, such as the thyristor, are turned on by a control signal, but must be turned off by the operation of the power circuit. Finally, controlled switches can be turned on or off by application of an appropriate control signal, which may be a voltage or a current, depending on the switch. A number of popular semiconductor switches are described in this section.

Diodes

The diode consists of a P-N junction. [Figure 120.2\(a\)](#) shows a simple half-wave rectifier circuit containing a diode. The ideal diode blocks voltage when reversed biased and conducts when forward biased, with zero voltage drop across the diode. An ideal diode would not conduct any current when reverse biased and would provide any level of desired current with no voltage drop when forward biased, as shown in [Figure 120.2\(c\)](#). A real diode approximates that, as shown by the diode characteristic in [Figure 120.2\(d\)](#). When forward biased, there is a small voltage drop across the diode, typically about 0.7 to 1.0 volt for a silicon diode. This means the diode will dissipate power when current flows through it, and some type of cooling is necessary for high-power operation. When the diode is reverse biased, it allows a small leakage

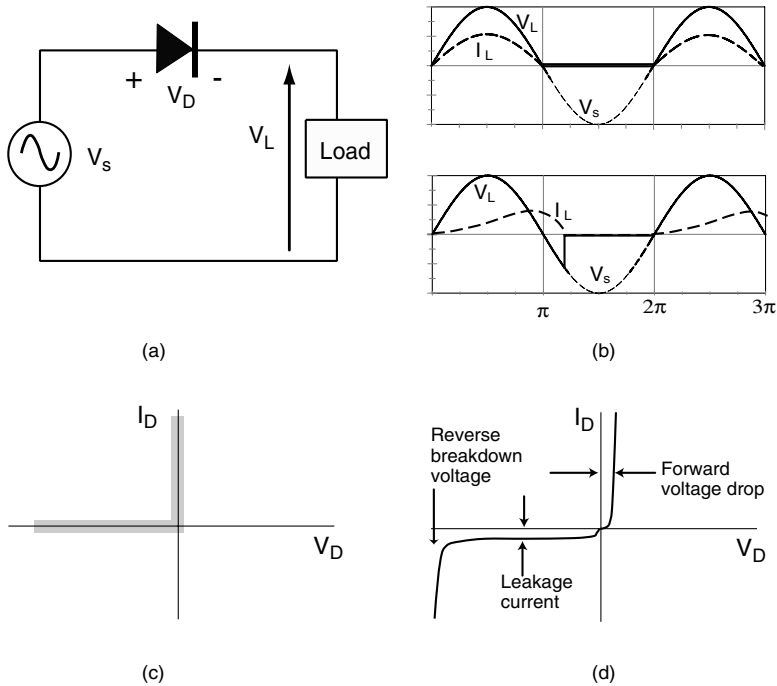

FIGURE 120.2 (a) Diode half-wave rectifier circuit. (b) Voltage and current waveforms for circuit of part (a) resistive load and R-L load. (c) Ideal diode volt-amp characteristic. (d) Actual diode volt-amp characteristic.

current until the reverse breakdown voltage is reached. When too much negative voltage is applied to the diode, it reaches a point where it begins conducting large amounts of current with little additional change in voltage. If the current is not limited by a series resistance, the diode would be rapidly destroyed due to the high-power dissipation. Clearly, a large reverse recovery voltage is desirable for high-power applications.

The principles of operation of the diode are demonstrated by the curves in Figure 120.2(b). The load is resistive for the top curves and resistive-inductive for the bottom curves. With a resistive load, the diode conducts during the positive half-cycle of the source voltage and blocks the negative half-cycle. Since the load is resistive, the current has the same wave shape as the voltage, except for the magnitude. For the lagging load, the diode cannot shut down while current is still flowing. Due to the inductance in the load, the current cannot change instantaneously. The current begins building up at the start of a positive half-cycle of voltage and is not back to zero when the source voltage goes negative. Thus, the diode continues conducting and the load voltage becomes negative as shown in Figure 120.2(b) until the current returns to zero. At that point the diode shuts off and the load voltage returns to zero until the next positive half-cycle.

It is important to realize, however, that a diode does not turn off instantaneously. Due to the charges within the diode, there is a small reverse recovery current that limits the speed of operation. For 60-Hz power applications the reverse recovery doesn't have a serious effect, but high-frequency applications may require fast-recovery diodes. Line frequency diodes, suitable for operation up to several hundred hertz, are available with ratings up to 6500 V and 8000 A. Fast recovery diodes have very low recovery times and are capable of operating up to several hundred kilohertz at 1 kV and 100 A. At 3 kHz, fast recovery diodes can operate up to 3300 V and 1400 A. Finally, Schottky diodes are used for low voltages (below 150 V) and very high-speed operation (up to 1 MHz). Figure 120.3 shows a picture of a stud-mounted rectifier rated for 150 A and 600 V. Manufacturers also provide integrated packages for standard configurations. Figure 120.4 shows a bridge rectifier module containing six diodes; the module is about 4" wide, with a peak reverse voltage of 1600 volts and a DC output current of 150 amps.

FIGURE 120.4 Integrated, diode bridge rectifier.

Thyristor and Triac

The term *thyristor* encompasses a family of devices with three terminals — anode, cathode, and gate. A popular member of the thyristor family is the silicon-controlled rectifier (SCR), which, like the diode, has two states, on or off. Unlike the diode, however, the SCR does not automatically conduct when forward biased. As the name implies, turn-on can be controlled. The SCR was invented and named by the General Electric Company in the late 1950s. The thyristor was invented as a solid-state replacement for the thyratron, which is a tube device that is filled with mercury vapor.

Figure 120.5(a) shows a half-wave rectifier circuit using an SCR. Note that the symbol for the SCR is similar to the diode, with the addition of a gate. Unlike the diode, the SCR has the ability to block voltage in either the forward or reverse direction. The ideal volt-ampere characteristic for an ideal SCR is shown in Figure 120.5(b). Without a gate signal, the SCR will not conduct when forward biased, unless the forward breakdown voltage is exceeded. If a voltage of proper magnitude and duration is applied to the gate of the SCR, then forward conduction can begin at voltages below the forward breakdown voltage. The forward voltage at which conduction begins is determined by the magnitude of the gate current. Higher gate current causes lower forward breakdown voltage. Once the SCR is in the conducting mode, the gate signal is no longer needed. The thyristor has a low forward voltage drop while in the conducting mode, typically about 2 volts. Exceeding the forward breakdown voltage, applying a voltage with an excessively high DV/DT , or too much thermal stress, can also trigger a thyristor; however, these methods are not recommended. To preclude excessive DV/DT or DI/DT , snubber circuits are required for the thyristor.

Like the diode, the SCR conducts until the current drops nearly to zero. The value at which the SCR turns off is called the holding current. For purposes of describing the operation of various circuits, however, the holding current is often assumed to be zero. Figure 120.5(c) shows the voltage and current waveforms for the half-wave rectifier, again for a resistive load and for an R-L load. In the upper curves of Figure 120.5(c), the turn-on of the SCR has been delayed by an angle α , which is determined by the control circuit that generates the gate signal. Since the load is resistive, the current looks exactly like the voltage, except for the magnitude. When the voltage and current reach zero, at π , the SCR shuts off, until the next positive half-cycle. Essentially, the SCR chops out a portion of the positive half-cycle and the entire negative half-cycle of voltage. When the load has an inductive component, as in the lower curves of Figure 120.5(c), the current can no longer change instantaneously, so when the SCR is triggered to apply voltage to the load, the current starts building up, lagging behind the voltage. Thus, when the voltage reaches zero, there is still current flowing in the circuit and the SCR does not shut down, resulting in a negative load voltage. The result is a lower (DC) load voltage than was obtained for the resistive case. The RMS load voltage is actually higher, however, since the SCR conducts for a longer period.

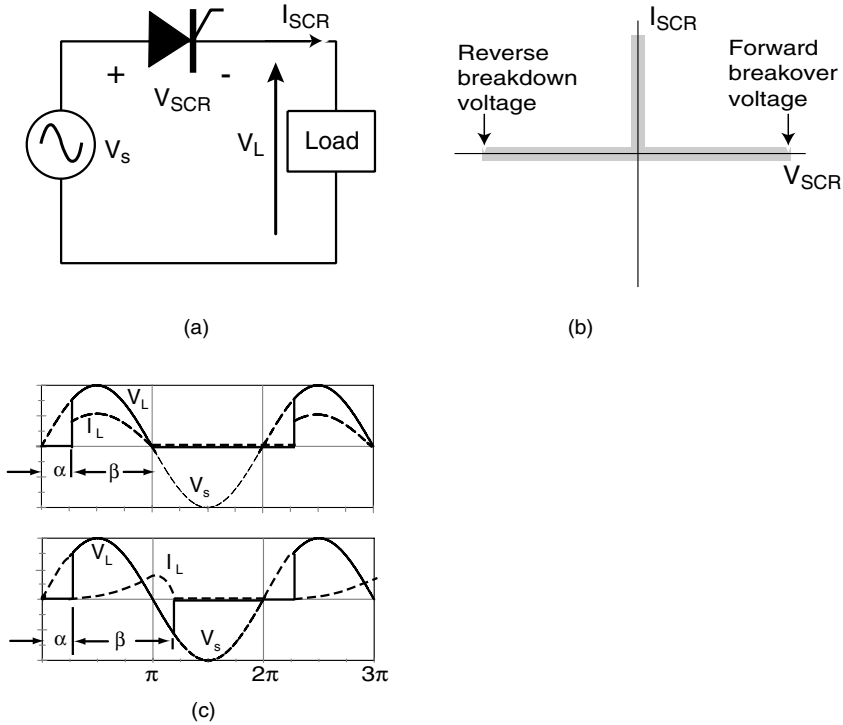

FIGURE 120.5 (a) Thyristor half-wave rectifier circuit. (b) Ideal thyristor volt-amp characteristic. (c) Voltage and current waveforms for circuit of part (a) resistive load and R-L load.

There are two types of thyristors. Phase-controlled, or converter, grade thyristors are used for rectifying line frequency voltage and current and offer very high voltage and current ratings with a low on-state voltage drop. Inverter grade thyristors are capable of faster operation and, as the name implies, are used in inverter circuits. However, since they cannot turn off, external commutation circuitry is required to artificially force the thyristor current to zero so it can shut off. Because of the need for commutating circuitry, other devices have largely replaced thyristors for inverter operation.

Some examples of high-end ratings for thyristors are 1500 A at 12 kV, 4000 A at 7 kV, and 7000 A at 6.5 kV. Figure 120.6 shows a photo of several thyristors of various sizes and styles. Thyristors can be connected in series for higher voltage ratings. Figure 120.7 shows a thyristor switch built from a press-pack stack of thyristors. The switch is rated at 50 kV and 1200 A and is about 30 in. high.

Diodes and SCRs allow rectification of AC voltage to DC; however, for some applications we want to control both half-cycles of the AC voltage. One example would be a dimmer switch for an incandescent light. An SCR-controlled, half-wave rectifier SCR would not allow the lamp to reach full brightness, because the negative half-cycle of voltage would always be blocked. Similarly, for some AC motors, we would want to control both the negative and positive half-cycles of the voltage, rather than rectify the voltage. Figure 120.8(a) shows a triac switch, which is essentially two SCRs placed back to back. The triac allows the control of AC voltage in both directions, and by delaying the firing of the triac in both directions we can reduce the RMS value of the voltage applied to the load. The triac tends to operate a bit slower than the SCR, so it is primarily useful for low-frequency applications.

Figure 120.8(b) shows the voltage and current waveforms for a simple triac AC voltage controller. In the upper curves, the load is purely resistive, and the voltage and current have the same wave shape. The triac effectively chops out a portion of each half-cycle of voltage. Intuitively, it makes sense that the larger the delay angle, α , the less will be the RMS voltage. The lower curves show an inductive load. In this

FIGURE 120.6 Several thyristors of varying sizes.

(a)

(b)

FIGURE 120.7 High-voltage switch built of stacked thyristors.

FIGURE 120.8 (a) Triac voltage-control circuit. (b) Voltage and current waveforms for circuit of part (a) resistive load and R-L load.

FIGURE 120.9 (a) GTO schematic element. (b) Ideal GTO volt-amp characteristic.

case, the current has not reached zero when the voltage does, and the voltage reverses polarity until the current reaches zero. If the inductance is large enough or the delay angle is small enough, the entire voltage waveform will be applied to the load.

The components discussed so far cannot interrupt a current; therefore, they continue delivering voltage to the load until the current reaches zero. In many applications, it is necessary to interrupt the current. Fortunately, several power electronic devices can turn off, as well as turn on.

Gate-Turnoff Thyristor (GTO)

As discussed above, the thyristor can be turned on with a positive gate current, but does not turn off until the current naturally goes to zero or is forced to zero by a commutating circuit. The gate-turnoff thyristor (GTO) was developed in the early 1980s and overcomes that limitation. A GTO operates much the same as a thyristor with respect to turn-on; however, a negative gate current can turn it off. The GTO has been used in motor drives and other applications, especially at high-power levels. With ratings of up to 6500 volts blocking and 4000 amps conducting, the GTO was largely responsible for the development of medium-voltage drives and megawatt inverters. Figure 120.9(a) shows the schematic symbol for the GTO and figure 120.9(b) shows its ideal volt-amp characteristic. In particular, GTOs generally have a low reverse breakdown voltage. For example, one manufacturer's GTO rated with a 4500-volt forward operating voltage has only a 19-volt reverse breakdown voltage. Some symmetrical GTOs are able to block voltages in both directions, however.

Compared to the SCR, the GTO has a similar turn-on time, but a faster turn-off time, making it suitable for higher-speed applications (typically a few kilohertz). The GTO has a higher forward voltage drop than the SCR when conducting (typically 3 volts), which means higher losses. The turn-on gate current for the GTO is somewhat higher than for the SCR, but the turn-off gate current is dependent on the current to be turned off and can be quite high, especially for GTOs with high blocking voltages. Thus, a GTO may require a large, expensive control circuit. Like standard thyristors, GTOs require snubber circuits, which limit the rate of rise of voltage across the switch or current through the switch. At high power levels, the snubbers can be very expensive.

Power Transistors

The transistor was invented in the 1940s, and began replacing the vacuum tube in amplifiers and other electronic applications. In those applications, the transistor operates in the active or linear region. For

power electronic applications, transistors are driven to saturation and used as switches to turn power on and off to a load. Bipolar junction transistors (BJT) and metal-oxide semiconductor field effect transistors (MOSFET) have been used for power electronic applications. BJTs are current controlled devices, while MOSFETs are voltage controlled, which results in simpler drive circuitry. However, the small- and intermediate-size motor drive market now uses pulse-width-modulated, insulated-gate bipolar transistors (IGBT) almost exclusively because they provide superior performance. BJTs, MOSFETs, and IGBTs are described in this section.

Bipolar Junction Transistors (BJT)

Figure 120.10(a) shows the circuit symbol for an NPN BJT, where NPN indicates the doping of the semiconductor layers in the transistor. NPN transistors have two N-doped layers sandwiched around a P-doped layer, while PNP transistors are just the opposite. The NPN BJT has higher current and voltage ratings than the PNP, so it is better suited for power applications. The current into the base of a transistor controls the delivery of current from the collector to the emitter. Applying a high base current drives a BJT into saturation, making it operate like a closed switch. Removing the base current causes a BJT to stop conducting, making it like an open switch. Figure 120.10(b) shows the idealized characteristic for the power BJT. In reality, there is a drop of about 2 volts from the collector to the emitter when the transistor is conducting. Unlike the diode or SCR, the BJT does not block reverse voltage; its reverse voltage rating may only be 5 to 10 volts. Thus, transistors are not used for AC applications unless they are protected by additional circuitry. They are available with ratings of 500 volts and up to 300 amps and have been used in devices up to several hundred kilowatts.

The main disadvantage of the power BJT is very low gain (I_C/I_B) — less than 10 for high voltage/power devices. A gain of 10 means that the base current must be 10% of the current that is to be switched, which, for high-power applications, would require a large power circuit to create the base current. A way to reduce the required base current is by using essentially a two-stage transistor, known as the Darlington connection, shown in Figure 120.10(c). The Darlington connection can be built from discrete components or as a single integrated circuit. In either case, the first transistor amplifies the base current into the second, and the overall gain is the product of the two individual gains. However, the Darlington connection has a higher forward voltage drop and longer turn-on time than the single BJT, which means higher losses and a lower frequency of operation. Darlington transistors are available with V_{CE} ratings

FIGURE 120.10 (a) BJT schematic element. (b) Ideal BJT volt-amp characteristic. (c) Darlington connection.

FIGURE 120.11 (a) MOSFET schematic element. (b) Ideal MOSFET volt-amp characteristic.

up to 1200 volts and current ratings up to 600 amps, although both ratings would not be available in a single device.

BJTs are difficult to operate in parallel and are limited to less than 10 kHz. As a result, BJTs have been largely replaced in new products by the MOSFET at low voltage and the IGBT at high voltage.

Metal-Oxide Semiconductor Field Effect Transistor (MOSFET)

Figure 120.11(a) shows the schematic symbol for a MOSFET, which is controlled by voltage rather than current. Figure 120.11(b) shows the ideal characteristic for the power MOSFET. Applying relatively small voltage (about 15 volts) between the gate and source turns on the MOSFET; applying zero volts turns the MOSFET off. Because of the low voltage and high gate input impedance, the gate current is very low. Thus, drive circuits for MOSFETs are relatively simple and can even be integrated with the MOSFET on a single power chip, greatly simplifying the system. MOSFETs can operate at much higher frequencies than BJTs, greater than 100 kHz, but are limited to low-power applications (a few kilowatts). Figure 120.12 shows a picture of some small MOSFETs. The largest one in the photo (at the left) is rated for 50 volts

FIGURE 120.12 Power MOSFETs.

and 20 amps of continuous current. The construction of the MOSFET inherently contains a reverse diode between the drain and source, which in some cases may allow reverse current.

The MOSFET can be modeled as a resistance in the on state. Low-voltage MOSFETs have an on-state resistance as low as 0.1 ohm, while high-voltage devices have an on-state resistance of several ohms. The voltage drop from drain to source is a product of the current times the on-state resistance, which can be significantly higher than that of a BJT. While its switching losses are much lower than the BJT, the higher forward voltage drop results in much higher conduction losses. Thus, the BJT becomes more economical at higher voltages (above 200 to 300 V). MOSFETs are available with ratings up to 600 volts at lower currents and about 200 amps at lower voltages. Like the BJT, the MOSFET does not block reverse voltage. The MOSFET can be easily paralleled for higher current capability.

Insulated Gate Bipolar Transistor (IGBT)

Since the BJT has low conduction losses, and the MOSFET has faster switching speed with simple control circuits, it obviously would be desirable to have a device that combined the good points of each. In the late 1980s, the insulated gate bipolar transistor (IGBT), which combines the best features of MOSFETs and BJTs, became commercially available. Schematic symbols for the insulated-gate bipolar transistor are shown in [Figure 120.13](#). Like the BJT, it has a collector and emitter; however, instead of a base terminal, it has a gate, like the MOSFET. The IGBT is essentially a monolithic Darlington pair in which a MOSFET is used to control a BJT. The MOSFET gate, with its high input impedance, results in a low-power voltage control for the device with relatively fast switching times, although slower than a MOSFET. The BJT portion, which conducts the main current, provides lower conduction losses than a MOSFET. During the 1990s, the IGBT became the device of choice for variable-speed AC motor drives up to several hundred horsepower. By the end of the 1990s, IGBTs were pushing the lower limits of applications for GTOs, as higher blocking voltage ratings became available. IGBTs are now available with ratings up to 1200 amps at 3300 volts or 900 amps at 4500 volts.

Standard IGBTs are not capable of operating at as high a frequency as MOSFETs, although some manufacturers offer IGBTs that are optimized for speed and can approach the switching speed of a MOSFET. There is a tradeoff because the on-state power loss of an IGBT increases as the frequency of operation increases. For example, one manufacturer quotes a forward voltage drop of 1.3 volts for a standard IGBT, 1.5 volts for a fast IGBT, and 1.9 volts for an ultra-fast IGBT. Thus, for the same current level, the ultra-fast device would dissipate about 50% more power than the standard device.

IGBTs can be purchased as discrete modules, but are often sold in packaged assemblies with built-in protective circuitry. [Figure 120.14](#) shows a discrete IGBT on the right and a cut-away of the same

FIGURE 120.13 Two alternative IGBT schematic elements.

FIGURE 120.14 IGBT cut-away and packaged.

FIGURE 120.15 IGBT power module.

type on the left. Figure 120.15 shows an IGBT module rated for 200 amps and Figure 120.16 shows a complete inverter package. The three devices at the top of the package are the IGBTs and the three devices at the bottom are freewheeling diodes. A significant advantage of the IGBT is that it does not require snubber circuits.

Silicon Carbide and Gallium Nitride Devices

Nonsilicon-based, large band-gap semiconductors, silicon carbide (SiC) and gallium nitride (GaN), are two promising materials for high-temperature power electronics applications. Silicon carbide technology is more mature than gallium nitride. SiC is currently the most practical high-temperature wide band gap material for advanced power conversion. The large band gap enables operation with junction temperatures higher than 600°C and a high breakdown electric field. Also, high thermal conductivity of SiC enables higher power density, thus leading to compact packaging. In addition, the high temperature capability of SiC greatly reduces cooling requirements, thus reduces the total size of the power electronics unit. Some important material properties of silicon, SiC, and gallium nitride materials are shown in [Table 120.1](#). Significant cost challenges have prevented these devices from being commercially successful. Crystal growth and material defect control are two of the primary issues that need to be resolved before cost can be competitive with silicon devices.

Presently, SiC Schottky diodes are commercially available from several suppliers. These devices can operate at high voltages and high temperatures. SiC and GaN diodes are best suited in high-temperature applications above 600 V.

TABLE 120.1 Material Properties of Si, SiC, and GaN

| Property | Si | 4H-SiC | GaN |
|--|------|--------|------|
| Band gap (Ev) | 1.1 | 3.26 | 3.49 |
| Electron mobility at 300 K (cm ² /Vs) | 1500 | 700 | 900 |
| Critical breakdown field (MV/cm) | 0.3 | 2.0 | 3.3 |
| Thermal conductivity (W/cm-K) | 1.5 | 4.5 | >1.7 |
| Relative dielectric constant (ϵ_r) | 11.8 | 10 | 9.0 |

Hybrid Switching Devices

MOS-Controlled Thyristor (MCT)

Thyristors have lower on-state losses than BJTs and IGBTs, but cannot easily be turned off. Thus, a thyristor device that is controlled by a MOSFET would be very desirable. The MOS-controlled thyristor (MCT) is a promising device that became available in lower ratings during the late 1990s. The MCT has lower on-state losses than the IGBT for a given turn-off switching time, but the maximum switching frequency for the MCT is lower than that of the IGBT. Research has demonstrated MCTs with blocking voltages of 3000 volts, with low on-state voltage drop; however, the manufacturing of the MCT is more complex than other power electronic devices. Thus, the initial devices that came to market were limited to 75 amps and 600 volts.

Gate Commutated Thyristor (GCT)/Integrated Gate Commutated Thyristor (IGCT)

The thyristor offers a low voltage drop while conducting resulting in low losses while in the on state. The GTO, as described above, made possible the development of multi-megawatt inverters; however, the turn-off of the GTO is relatively slow, which causes it to have relatively high turn-off losses. BJTs, on the other hand, offer faster, less loss in turn-off, but consume more power while conducting. Clearly, a device that could conduct as a thyristor and turn off as a transistor would be superior to a GTO. The gate commutated thyristor (GCT), which is such a device, was developed in the 1990s and introduced commercially in 1997. Since then it has begun to replace the GTO in high-power applications.

The GCT is based on the GTO, but is designed so that the cathode emitter shuts off instantly. As a result, the cathode current is transferred to the gate, causing the thyristor to become a transistor during shut-off, resulting in up to 40% less loss than in a GTO. Another advantage of the GCT is that it does not need DV/DT snubbers, which creates a significant decrease in parts count and thus cost for an inverter. Three types of GCTs are available: asymmetric, reverse blocking, and reverse conducting. [Figure 120.17](#) shows circuit symbols for the asymmetric and reverse blocking in 120.17(a) and for reverse conducting in 120.17(b). The reverse-conducting GCT requires a freewheeling diode, which may be built on the same silicon wafer as the GCT in some cases. GCTs have been built using wafers up to 6 in. in diameter, with ratings up to 6000 amps at 6 kV for asymmetrical devices. [Figure 120.18](#) shows a picture of a 4 in. GCT wafer. The radial lines that are connected by rings comprise the gate circuit, while the ring midway from the center to the edge of the wafer is the freewheeling diode.

Like a thyristor, the GCT has a low on-state voltage of about 2 volts at 4000 amps. To reduce the turn-off losses, the device current must be turned off in 1 microsecond. Since the voltage applied to the gate is only 20 volts or so, the circuit inductance must be extremely low. For example, to turn off a current of 3000 amps in 1 microsecond, with 20 volts, requires that the inductance in the circuit must be less than about 6 nH. Achieving such a low gate circuit inductance requires special design considerations. For this reason, many GCTs are sold integrated with a gate circuit. The integrated unit is thus called an integrated gate commutated thyristor (IGCT). [Figure 120.19](#) shows a picture of an IGCT package, which includes the GCT, freewheeling diode, and gate driver. The input circuit merely requires a 20-volt power supply and an infrared fiber optic link to deliver the turn-on and turn-off commands.

GCTs seem poised to take over virtually all applications that were previously done by GTOs. They currently offer a range of 0.3 MW to 300 MW at a cost per switched KW that is comparable to the IGBT. Due to its faster turn-off, the GCT can operate at higher frequencies than the GTO.

Handling and Testing MOS-gated devices

Although power electronic components are larger than their counterparts in electronic circuits, they remain susceptible to static electricity. Whether bread-boarding a circuit or troubleshooting a commercial system, proper care must be taken with respect to the MOS devices. MOS-gated devices should be kept in their antistatic shipping material until they are to be used or tested. When working with them, they should be handled by the package and not by the leads. Use of a grounding wrist strap, while not essential, is a good practice as well.

Future Switching Devices

All of the devices discussed above are built with silicon. Research is underway to build various components from silicon carbide. Preliminary results have shown that silicon carbide devices offer higher switching speeds, higher temperature operation, and lower conduction losses. While silicon carbide devices have been fabricated and tested, they are still several years from being commercially available.

Summary

Table 120.2 shows a summary of some of the characteristics of power electronic switches.

120.2 Power Conversion

Power converters are generally classified as follows:

1. DC–DC converters (choppers, buck and boost converters)
2. AC–DC converters (phase-controlled converters)
3. DC–AC converters (inverters)
4. Direct AC–AC converters (cycloconverters)

DC–DC Converters

DC–DC converters are used to convert unregulated DC voltage to regulated or variable DC voltage at the output. They are widely used in switch-mode DC power supplies and in DC motor drive applications. In DC motor control applications they are called *chopper-controlled drives*. The input voltage source is usually a battery or is derived from AC supply using a diode bridge rectifier. These converters are generally either hard-switched PWM types or soft-switched resonant-link types. There are several DC–DC converter topologies, the most common ones being buck converter, boost converter, and buck-boost converter.

Buck Converter

A buck converter is also called a *step-down converter*. Its principle of operation is illustrated in Figure 120.20(a). The IGBT acts as a high-frequency switch. The IGBT is repetitively closed for a time t_{on} and opened for a time t_{off} . During t_{on} the supply terminals are connected to the load and power flows from supply to the load. During t_{off} load current flows through the freewheeling diode D_1 , and the load voltage is ideally zero. The average output voltage is given by

$$V_{\text{out}} = D \cdot V_{\text{in}}$$

where D is the duty cycle of the switch and is given by $D = t_{\text{on}}/T$, where T is the time for one period. The term $1/T$ is the switching frequency of the power device IGBT.

Boost Converter

A boost converter is also called a *step-up converter*. Its principle of operation is illustrated by Figure 120.20(b). This converter is used to produce higher voltage at the load than the supply voltage. When

TABLE 120.2 Characteristics of Thyristor and Transistor Family Members for Power Electronics Applications

| Max switching frequency | NA | <1 KHz | 1 KHz | 5–10 KHz | up to 1 MHz | 50–100 KHz |
| Gate drive complexity | Simple turn on only | Expensive, high current for turn off | Simple, voltage control | Expensive, requires large base current when on | Simple voltage control | Simple voltage control |
| Forward voltage drop (volts) while conducting | 2 | 2–3 | 2–3 | 1–2 | Variable $I * Ron$ | 2–6 |
| Snubbers required | Sometimes | Yes | Turn on only | Yes | Less than BJT | Not usually |
| Status/prognosis | Useful for uncontrolled rectifiers and line commutated inverters | Mature technology, being replaced by IGCT and other variants | Good for high-power applications; technology still developing | Mature technology largely replaced by IGBTs in new products | Good for high-frequency low power (e.g., switched power supplies) | Technology still developing; widely used in low- and medium-power applications |

FIGURE 120.20 DC–DC converter configurations: (a) buck converter; (b) boost converter; (c) buck-boost converter. (Source: Rajashekara, K. S., Bhat, A. K. S., and Bose, B. K. 1997. Power electronics. In *The Electrical Engineering Handbook*, 2nd ed. R. C. Dorf, Ed., CRC Press, Boca Raton, FL, p. 709. With permission.)

the power switch is on, the inductor is connected to the DC source and the energy from the supply is stored in it. When the device is off, the inductor current is forced to flow through the diode and the load. The induced voltage across the inductor is negative. The inductor voltage adds to the source voltage of force the inductor current into the load. The output voltage is given by

$$V_{out} = V_{in} / (1 - D)$$

Thus, for variation of D in the range $0 < D < 1$, the load voltage V_o will vary in the range

$$V_{in} < V_{out} < \infty$$

Buck-Boost Converter

A buck-boost converter can be obtained by the cascade connection of the buck and the boost converter. The output voltage V_o is given by

$$V_o = V_{in} \cdot D / (1 - D)$$

The output voltage is higher or lower than the input voltage based on the duty cycle D . A typical buck-boost converter topology is shown in Figure 120.20(c). When the power devices are turned on, the input

provides energy to the inductor and the diode is reverse biased. When the devices are turned off, the energy stored in the inductor is transferred to the output. No energy is supplied by the input during this interval. In DC power supplies, the output capacitor is assumed to be very large, which results in a constant output voltage. The buck and boost converter topologies enable the four-quadrant operation of a DC motor. In DC drive systems, the chopper is operated in step-down mode during motoring and in step-up mode during regeneration operation.

Resonant-Link DC–DC Converters

The use of resonant converter topologies in power supplies would help to reduce the switching losses in DC–DC converters and enable the operation at switching frequencies in the megahertz range, which results in reduced size, weight, and cost of the power supplies. Other advantages of resonant converters are that the leakage inductances of the high-frequency transformers and the junction capacitances of semiconductors can be used to further increase the power density of the power supplies. An added advantage is the significant reduction of RFI/EMI. The major disadvantage of resonant converters is increased peak current or voltage stress.

Single-Ended Resonant Converters

These types of converters are referred to as *quasi-resonant converters*. Quasi-resonant converters (QRC) do exhibit a resonance in their power section, but, instead of the resonant elements being operated in a continuous fashion, they are operated for only one-half of a resonant sine wave at a time. The topologies within the quasi-resonant converters are simply resonant elements added to many of the basic PWM topologies as shown in [Figures 120.21](#) and [120.22](#). The QRCs can operate with zero-current switching or zero-voltage switching or both. The power switch in quasi-resonant converters connects the input voltage source to the tank circuit and is turned on and off in the same step fashion as in PWM switching power supplies. The conduction period of the devices is determined by the resonant frequency of the tank circuit. The power switch turns off after the completion of one-half of a resonant period. So, the current at turn-on and turn-off transitions is zero, thus eliminating the switching loss within the switch. In zero-voltage switching QRCs, at the turn-on and turnoff of the power devices, the voltage across the device is zero, thus again reducing the switching loss.

The major problems with the zero-current switching QRC are the high-peak currents through the switch and capacitive turn-on losses. The zero-voltage switching QRCs suffer from increased voltage stress on the power device. The full-wave mode-zero-voltage switching circuit suffers from capacitive turn-on losses.

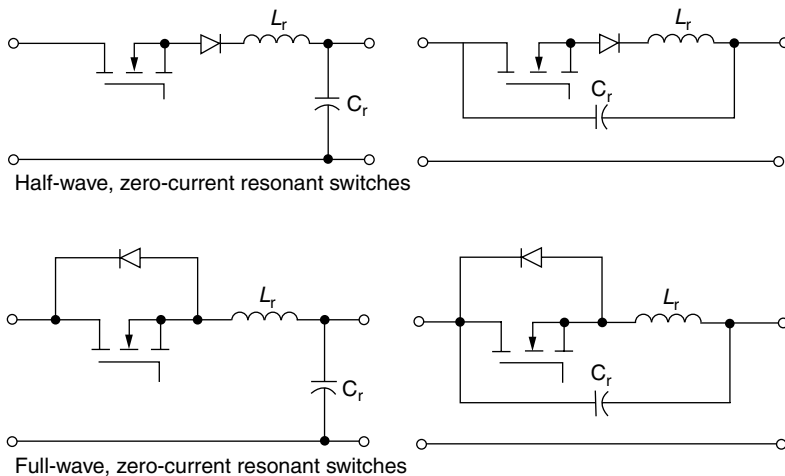

FIGURE 120.21 Zero-current resonant switches.

FIGURE 12.22 Zero-voltage quasiresonant switches.

Double-Ended Resonant Converters

These converters use full-wave rectifiers at the output, and they are generally referred to as resonant converters. A number of resonant converter configurations are realizable by using various resonant tank circuits; the three most popular configurations are the series resonant converter (SRC), the parallel resonant converter (PRC), and the series-parallel resonant converter (SPRC), as shown in Figure 12.23.

Series resonant converters have a high efficiency from full load to part load. Transformer saturation is avoided due to the series-blocking resonating capacitor. The major problems with the SRC are that it requires a very wide change in switching frequency to regulate the load voltage and that the output filter capacitor must carry high-ripple current.

Parallel resonant converters are suitable for low-output voltage, high-output current applications due to the use of filter inductance at the output with low-ripple current requirements for the filter capacitor. The major disadvantage of the PRC is that the device currents do not decrease with the load current, resulting in reduced efficiency at reduced load currents.

The SPRC has the desirable features of both the SRC and the PRC. Load voltage regulation in resonant converters for input supply variations and load changes is achieved by either varying the switching frequency or using fixed frequency pulse width modulation control.

AC-DC Converters

The basic function of the phase-controlled converter is to convert an alternating voltage of variable amplitude and frequency to a variable DC voltage. The power devices used for this application are generally SCRs. Varying the conduction time of the SCRs controls the average value of the output voltage. The turn-on of the SCR is achieved by providing a gate pulse when it is forward biased. The turnoff is achieved by the *commutation* of current from one device to another at the instant the incoming AC voltage has a higher instantaneous potential than that of the outgoing wave. Thus there is a natural tendency for current to be commutated from the outgoing to the incoming SCR without the aid of any external commutation circuitry. This commutation process is often referred to as *natural commutation*.

A three-phase full-wave converter consisting of six thyristor switches is shown in Figure 12.24(a). This is the most commonly used three-phase bridge configuration. Thyristors T1, T3, and T5 are turned on during the positive half-cycle of the voltages of the phases to which they are connected, and thyristors, T2, T4, and T6 are turned on during the negative cycle of the phase voltages. The reference for the angle

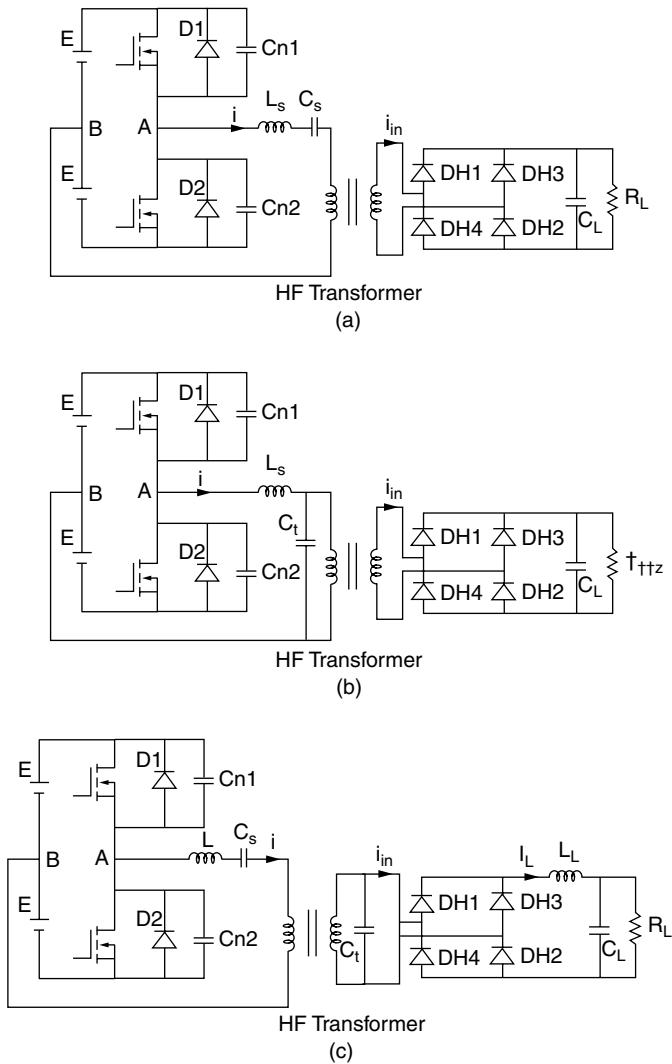

FIGURE 120.23 High-frequency resonant converter (half-bridge version) configurations suitable for operation above resonance. (a) Series resonant converter. Leakage inductances of the high-frequency (HF) transformer can be part of resonant inductance. (b) Parallel resonant converter. (c) Series-parallel resonant converter with capacitor C_t placed on the secondary side of the HF transformer. (Adapted from Rajashekara, K. S., Bhat, A. K. S., and Bose, B. K. 1997. Power electronics. In *The Electrical Engineering Handbook*, 2nd ed. R. C. Dorf, CRC Press, Boca Raton, FL, p. 788. With permission.)

in each cycle is at the crossing points of the phase voltages. The ideal output voltage, output current, and input current waveforms are shown in Figure 120.24(b). Controlling the firing angle α controls the output DC voltage. If the load is a DC motor, varying the firing angle α varies the speed of the motor.

The average output voltage of the converter at a firing angle α is given by

$$v_{d\alpha} = (3\sqrt{3} / \pi) E_m \cos \alpha$$

where E_m is the peak value of the phase voltage.

At $\alpha = 90^\circ$ the output voltage is zero. For $0^\circ < \alpha < 90^\circ$, $v_{d\alpha}$ is positive and power flows from the AC supply to the DC load. For $90^\circ < \alpha < 180^\circ$, $v_{d\alpha}$ is negative and the converter operates in the inversion

mode. Thus the power can be transferred from the motor to the AC supply, a process known as *regeneration*.

In Figure 120.24(a), the top or the bottom thyristors could be replaced by diodes. The resulting topology is called *thyristor semiconverter*. With this configuration, the input power factor is improved but the regeneration is not possible.

Power electronics. In *The Electrical Engineering Handbook, 2nd ed.*, R. C. Dorf, Ed., CRC Press, Boca Raton, FL, p. 774. With permission.)

DC-AC Converters

The DC-AC converters are generally called *inverters*. The AC supply is first converted to DC, which is then converted to a variable-voltage and variable-frequency power. The power conversion stage generally consists of a three-phase bridge converter connected to the AC power source, a DC link with a filter, and the three-phase inverter bridge connected to the load, as shown in Figure 120.25(a). In the case of battery-operated systems there is no intermediate DC link. An inverter can be classified as a voltage source inverter (VSI) or a current source inverter (CSI). A voltage source inverter is fed by a stiff DC voltage, whereas a current source inverter is fed by a stiff current source. A voltage source can be converted to a current source by connecting a series inductance and then varying the voltage to obtain the desired current. A VSI can also be operated in current-controlled mode and, similarly, a CSI can also be operated in the voltage control mode. These inverters are used in variable-frequency AC motor drives, uninterrupted power supplies, induction heating, static VAR compensators, and so on.

Voltage Source Inverter

The inverter configuration shown in Figure 120.25(a) is the voltage source inverter. The voltage source inverters are controlled either in square wave mode or in pulse width modulation (PWM) mode. In a square wave mode the frequency of the output is controlled within the inverter; the devices are being

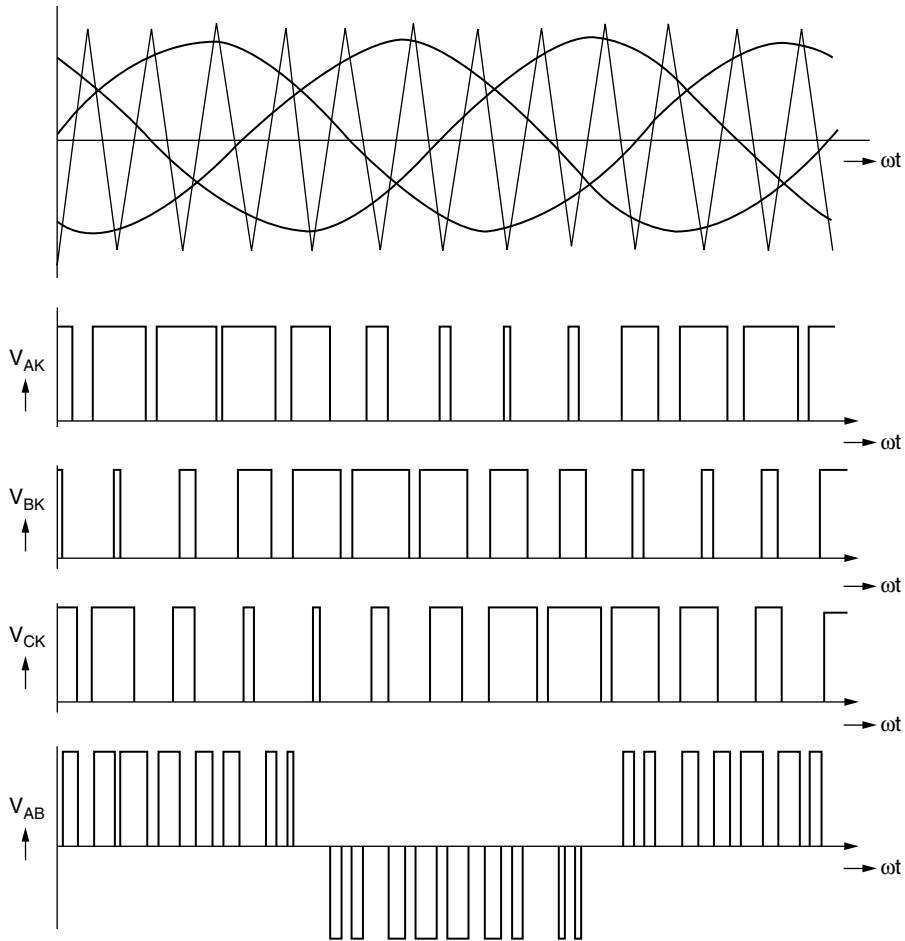

FIGURE 120.26 Three-phase sinusoidal PWM inverter waveforms. (Source: Rajashekara, K. S., Bhat, A. K. S., and Bose, B. K. 1997. Power electronics. In *The Electrical Engineering Handbook*, 2nd ed., R. C. Dorf, Ed., CRC Press, Boca Raton, FL, p. 775. With permission.)

used to switch the output circuit between the positive and negative bus. Each device conducts for 180° , and each of the outputs is displaced 120° to generate a six-step waveform as shown in Figure 120.25(b). The amplitude of the outputs voltage is controlled by varying DC link voltage. This step is accomplished by varying the firing angle of the thyristors of the three-phase bridge converter at the input. The six-step output is rich in harmonics and hence needs heavy filtering.

In PWM inverters the output voltage and frequency are controlled within the inverter by varying the width of the output pulses. Hence, at the front end, instead of a phase-controlled thyristor converter, a diode bridge rectifier can be used. A very popular method of controlling the output voltage and frequency is by sinusoidal pulse width modulation. In this method a high-frequency triangle carrier wave is compared with a three-phase sinusoidal waveform as shown in Figure 120.26. The power devices in each phase are switched on at the intersection of the sine and triangle waves. The amplitude and frequency of the output voltage are varied by varying the amplitude and frequency, respectively, of the reference sine waves. The ratio of the amplitude of the sine wave to the amplitude of the carrier wave is called the *modulation index*. The harmonic components in a PWM wave are easily filtered because they are shifted to a higher-frequency region. It is desirable to have a high ratio of carrier frequency to fundamental frequency to reduce the harmonics of lower-frequency components. There are several other PWM

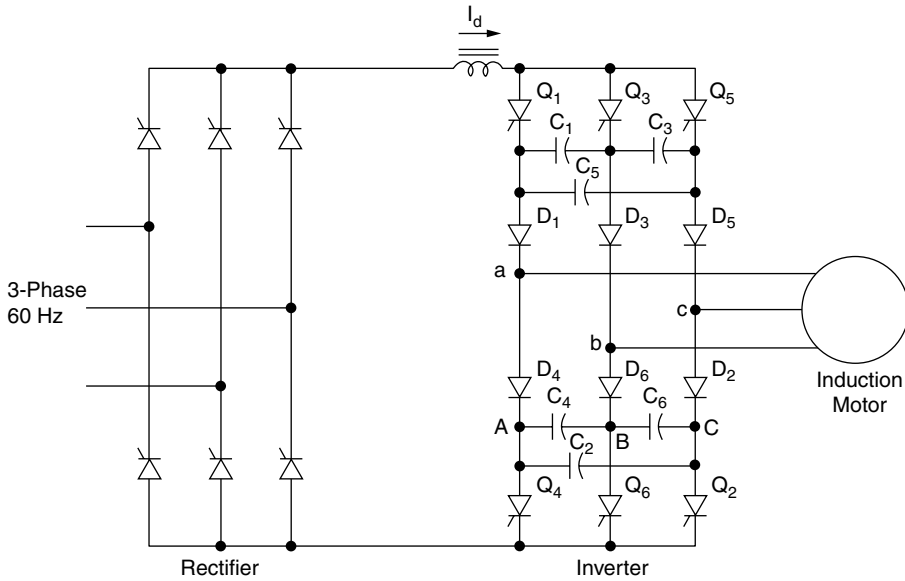

FIGURE 120.27 Force-commutated current-fed inverter control of an induction motor. (Source: Rajashekara, K. S., Bhat, A. K. S., and Bose, B. K. 1997. Power electronics. In *The Electrical Engineering Handbook, 2nd ed.*, ed. R. C. Dorf, CRC Press, Boca Raton, FL, p. 801. With permission.)

techniques mentioned in the literature. The most notable ones are selected harmonic elimination, hysteresis control, and the space vector PWM technique.

Current Source Inverter

Unlike the voltage source inverter — in which the voltage of the DC link is imposed on the motor windings — the current source inverter shown in Figure 120.27 imposes current into the motor. Here, the amplitude and phase angle of the motor voltage depend on the load conditions of the motor. The capacitors and series diodes help commutation of the thyristors. One advantage of this drive system is that regenerative braking is easily achieved because the rectifier and inverter can reverse their operation modes. Six-step machine current causes large harmonic heating and torque pulsation, which may be quite harmful at low-speed operation. Another disadvantage is that the converter system cannot be controlled in open loop like in a voltage source inverter.

Resonant-Link Inverter

The use of resonant switching techniques can be applied to inverter topologies to reduce the switching losses in the power devices. They also permit high switching frequency operation to reduce the size of the magnetic components in the inverter unit. In the resonant DC link inverter shown in Figure 120.28, a resonant circuit is added at the inverter input to convert a fixed DC to a pulsating DC voltage. This resonant circuit enables the devices to be turned on and off during the zero-voltage interval. Zero-voltage switching (ZVS) or zero-current switching (ZCS) is often called *soft switching*. Under soft switching, the switching loss in the power devices is almost eliminated. The EMI problem is less severe because resonant voltage pulses have lower DV/DT compared to those of hard-switched PWM inverters. Also, the machine insulation is less stretched because of lower DV/DT resonant voltage pulses. In Figure 120.28 all the inverter devices are turned on simultaneously to initiate a resonant cycle. The commutation from one device to another is initiated at the zero-DC link voltage. The inverter output voltage is formed by the integral numbers of quasi-sinusoidal pulses. The circuit consisting of devices Q, D, and the capacitor C acts as an active clamp to limit the DC link voltage to about 1.4 times the diode rectifier voltage V_s . It is possible to use passive clamp circuits instead of the active clamp.

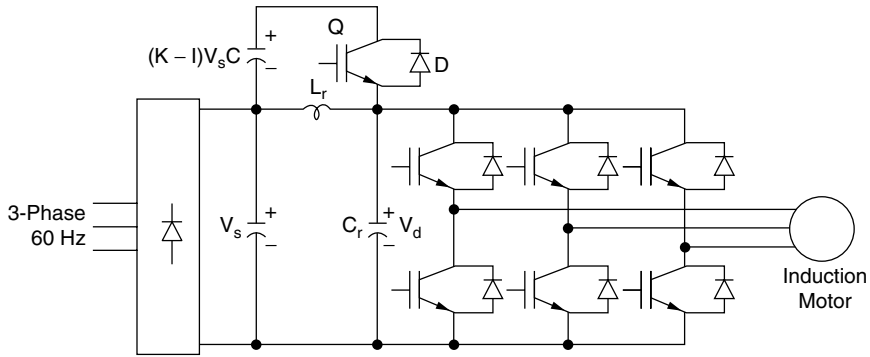

FIGURE 120.28 Resonant DC-link inverter system with active voltage clamping. (Source: Rajashekara, K. S., Bhat, A. K. S., and Bose, B. K. 1997. Power electronics. In *The Electrical Engineering Handbook*, 2nd ed., ed. R. C. Dorf, CRC Press, Boca Raton, FL, p. 776. With permission.)

Direct AC-AC Converters

The term *direct conversion* means that the energy does not appear in any form other than the AC input or AC output. The cycloconverters are direct AC-to-AC frequency changers. The three-phase full-wave cycloconverters configuration is shown in Figure 120.29. Two antiparallel, phase-controlled, six-pulse thyristor bridge converters supply each phase of the three-phase motor. The output frequency is lower than the input frequency and is generally an integral multiple of the input frequency. The cycloconverter permits energy to be fed back into the utility network without any additional measures. Also, the phase sequence of the output voltage can be easily reversed by the control system. Cycloconverters have found applications in aircraft systems and industrial drives for controlling synchronous and induction motors.

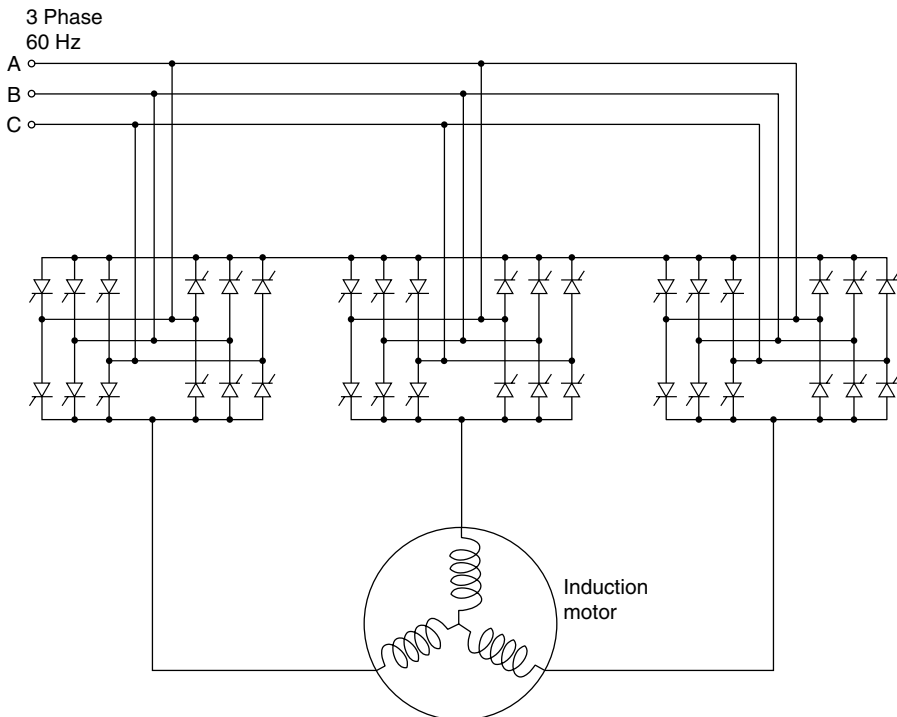

FIGURE 120.29 Cycloconverter control of an induction motor.

Defining Terms

Commutation — Process of transferring the current from one power device to another.

Duty cycle — Ratio between on time of a switch and the switching period.

Forward voltage — The voltage across the device when the anode is positive with respect to the cathode.

Full-wave control — Both the positive and negative half-cycle of the waveform is controlled.

Hysteresis control — A method of controlling current in which the instantaneous current can vary within a band.

Inverter — Circuit that converts DC to AC.

Isolated — A power electronic circuit or device having ohmic isolation between the input source and load circuit.

Rectifier — Circuit that converts AC to DC.

Snubber — An auxiliary circuit used to protect a power electronic switch from current or voltage transients. An R-L circuit in series can limit the rate of rise of current through the device; an R-C circuit in parallel with a switch limits the rate of rise of voltage across the device.

Switching frequency — The frequency at which the devices are turned on and turned off. Switching frequency = $1/(t_{\text{on}} + t_{\text{off}})$.

[The Fundamentals of A/D Converters](#)
[The Fundamentals of D/A Converters](#)

Analog-to-digital (A/D) and digital-to-analog (D/A) converters provide the fundamental interface between continuous-time signals and digital-processing circuitry. These devices find wide application in consumer electronics, digital audio, instrumentation, data acquisition, signal processing, communication, automatic control, and related areas. The A/D converter provides a discrete-time, discrete-valued **digital encoding** of a real-world signal, typically a voltage. The D/A converter reverses this process, producing a continuous-time, or analog, signal corresponding to a given digital encoding.

The block diagram for an example application including both A/D and D/A functions is given in [Figure 121.1](#). Here, the digital-processing block might be a dedicated digital signal processor (DSP) or a general purpose microprocessor or microcontroller that implements an application-specific signal-processing task. The input and output **signal conditioning** blocks provide functionality that might include input bandwidth limiting to prevent aliasing, output frequency shaping and bandwidth limiting to smooth the analog output, multiplexing of multiple input or output signals, or a **sample-and-hold** function. Component vendors provide some of the input and output signal conditioning functions within the A/D or D/A to simplify system integration.

Several conversion methods exist for A/D and D/A conversion. Competing methods co-exist primarily due to trade-offs in four major specifications; resolution (number of binary digits n in the conversion representation), **conversion rate** (the time required to complete a conversion), power consumption, and cost. [Table 121.1](#) and [Table 121.2](#) provide samples of representative converter integrated circuits (ICs) and their associated parameters. Refer to the manufacturer datasheets listed in the chapter references for further details and additional examples. More complete coverage of A/D and D/A principles and circuit design can be found in Razavi [1995] or Van De Plassche [1994].

The Fundamentals of A/D Converters

Many methods exist for implementing the A/D conversion function; **integrating**, **sigma-delta**, **successive approximation register** (SAR), **pipelined**, and **flash** compose the bulk of competing architectures. These methods offer different trade-offs between resolution, conversion rate, power consumption, and cost. Although these techniques differ in the manner in which they arrive at a digital encoding of the continuous-time signal, many aspects of A/D conversion process are architecture independent.

[Figure 121.2](#) shows a diagram of three important steps in the A/D quantization process, with the first two steps being signal conditioning. The first step is input bandwidth limiting, provided by the anti-alias

FIGURE 121.1 Example A/D and D/A application block diagram.

TABLE 121.1 Example A/D Integrated Circuits

| A/D Integrated Circuit | Resolution | Conversion Rate | Conversion Method |
|---------------------------|------------|-----------------|--------------------------|
| Analog Devices AD7791A | 24 bit | 60,200 μ s | Sigma-delta |
| Maxim MAX1186 | 10 bit | 25 ns | Pipelined |
| Maxim MAX105 | 6 bit | 1.25ns | Flash |
| National ADC12030 | 13 bit | 8.8 μ s | Successive approximation |
| Texas Instruments TLC7135 | 4.5 bit | 333,000 μ s | Dual-slope-integrating |

TABLE 121.2 Example D/A Integrated Circuits

| D/A Integrated Circuit | Resolution | Settling Time | Conversion Method |
|---------------------------|------------|------------------------|---------------------------|
| Analog Devices DAC08 | 8 bit | 85 ns | Multiplying |
| Analog Devices AD1871 | 24 bit | N/A, 96 Hz sample rate | Sigma-delta |
| Maxim MAX5207 | 16 bit | 25 μ s | Multiplying |
| Texas Instruments DAC2902 | 12 bit | 30 ns | Fixed precision reference |

filter. See graphs (a) and (b) of Figure 121.2. Basically, this attenuates high frequency signal and noise spectra so that the A/D output is not corrupted by high frequency spectra which modulate (i.e., alias) to low frequency by the sampling process. Filter requirements are set by the input signal spectra, the sample rate and the conversion method. For example, an integrating A/D usually has strict filter requirements, but a sigma-delta converter used in the same application may relax filter requirements to the point that inherent bandwidth limiting of the input signal is sufficient, and no explicit anti-alias filter is required.

The second step in the conversion process is the sample-and-hold operation. Graph (c) Figure 121.2 shows the detail of this operation. During the acquisition phase (which may be very short as shown here) the sample-and-hold output transitions to match the input signal. During the hold phase the output value is frozen at that value until the beginning of the next acquisition phase. The sample-and-hold acts to sample the input at exact increments of time, namely, the end of the acquisition phase. The sample-and-hold reduces errors in the A/D output by allowing the encoder to act upon a static input during each conversion process. Component vendors generally integrate the sample-and-hold along with

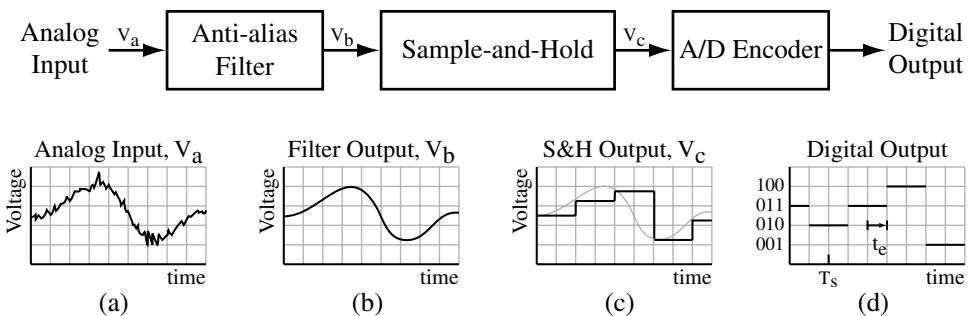

FIGURE 121.2 Steps in the A/D process.

FIGURE 121.3

the A/D converter. In topologies such as sigma-delta and SAR A/Ds the sample-and-hold function is inherent in the circuit architecture.

The third step in the conversion process is quantization, detailed in graph (d) of Figure 121.2. During each hold phase of the sample-and-hold the A/D encoder input will be encoded to one of 2^n (n is the number of bits of the A/D converter) discrete digital encoding levels and represented by this level for T_s sec. There is an aperture delay time, t_a , from the beginning of the sample-and-hold acquisition phase to when it is available at the encoder output. The aperture delay time depends largely upon the conversion method.

The signal conditioning blocks of Figure 121.2 suppress two main sources of noise and distortion, aliasing and signal variation during the encoding process. The encoder introduces additional noise that should be considered. Figure 121.3a shows the transfer function for an ideal 3-bit A/D. The finite quantization introduces an unavoidable quantization error. For example, if the analog input is at point A, there is no digital code exactly on the diagonal line, so it will be represented by 010 and there is a quantization error of $-(1 \text{ LSB})/4$ where an LSB is change in input voltage for a least significant bit. The quantization noise causes a fundamental limit to the signal-to-noise ratio of a converter. Increasing the converter resolution increases the signal-to-noise ratio. See Razavi [1995] or Oppenheim and Schaffer [1998] for more coverage of quantization principles.

The non-ideal transfer function of Figure 121.3b shows the final source of error to be discussed, inaccurate quantization levels. Ideally, the digital output will change each time the analog input changes by 1 LSB, called the code-width. The deviation in each code-width from the ideal 1 LSB is called the differential non-linearity (DNL). The largest deviation from any code center to the ideal diagonal line is referred to as the integral non-linearity (INL). Code-width errors will cause both noise and distortion in the digitally encoded waveform. There are many more error sources in actual circuit implementations. The Analog Devices application note is a good source for further exploration [AN-282].

To investigate how A/D quantization might be undertaken, consider the block diagram of a flash architecture given in Figure 121.4 for an n -bit converter. A resistive divider with 2^n resistors provides a set of reference voltages to an array of $2^n - 1$ comparators. The reference voltage of each comparator is 1 LSB greater than the reference voltage of the comparator immediately below it in the array. The bottom comparator has a reference voltage of $1/2$ LSB. Each comparator produces a "1" when the analog input is greater than its reference voltage and a "0" otherwise. Generally, clocked comparators are used so the output only changes at the rising edge of the clock and then remains static until the next rising edge. In

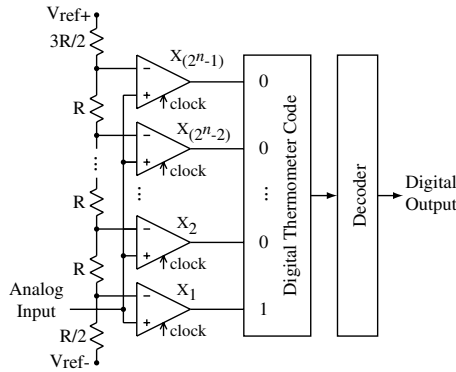

FIGURE 121.4 n -bit flash A/D architecture.

this case, the encoder architecture includes the sample-and-hold circuitry which is shown separately in Figure 121.2.

With this arrangement all comparators having a reference voltage less than the analog input will produce a “1” and all the remaining comparators will produce a “0.” This type of encoding is referred to as a thermometer code. The thermometer code is usually decoded to a binary output code.

The Fundamentals of D/A Converters

The purpose of a D/A converter is to produce a continuous-time analog voltage or current representing a digital input. Just as in the case of A/D conversion, many methods exist for implementing the D/A function; **multiplying, fixed precision reference**, hybrid, and **sigma-delta** compose the bulk of competing architectures. This discussion focuses on fundamental concepts that are largely independent of the conversion method rather than discuss details of each method.

Figure 121.5 shows a block diagram of the steps important to D/A conversion. Note that the last two blocks, the signal conditioning blocks, are the same as for A/D conversion (Figure 121.2) but they serve a much different purpose. The first step is the actual D/A converter, which converts a digital word into an analog signal, usually a voltage as shown in graphs (a) and (b) of Figure 121.5.

Figure 121.6 shows example circuitry to accomplish the D/A conversion task. The input register stores a new digital input at each rising edge of the sample clock. The output of this register controls an array of switches connecting an array of weighted current sources to a load resistor. Each current source is twice the size of the previous current source, just as each bit of the digital word represents a value that is twice the previous bit. If a bit is “1” it closes the switch. The current in that branch will then flow through the load resistor and create a voltage weighted by that bit of the data word. If a bit is “0” the

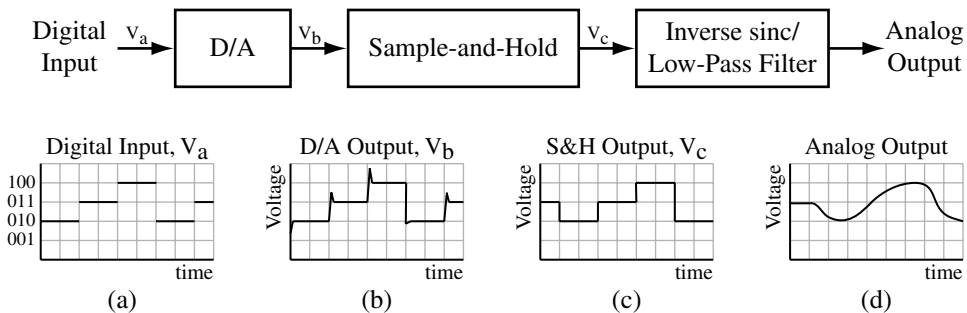

FIGURE 121.5 Steps in the D/A process.

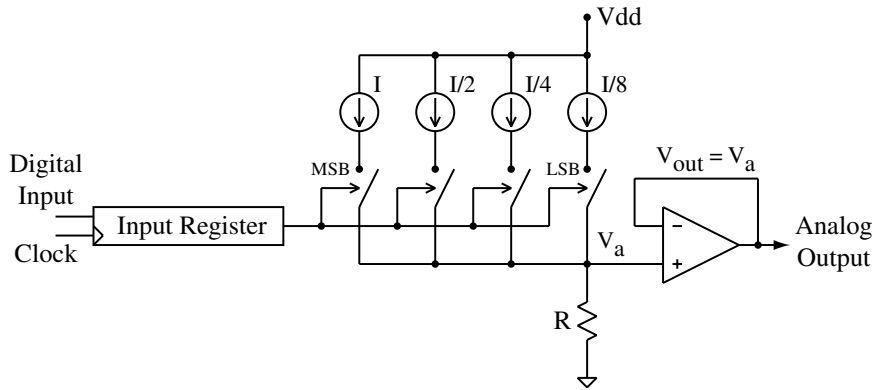

FIGURE 121.6 D/A architecture.

switch remains open. The current will then be prevented from flowing to the load resistance and it will not add to the output voltage. The currents from all bits which are “1” will sum in the load resistance and produce a voltage V_a corresponding to the value of the digital input word. The buffer amplifier drives the converter output to $V_{out} = V_a$ so that the output load will not affect the generated voltage.

As in the example just discussed, there is usually a sample clock which generates a new output upon each rising clock edge. This is called synchronization and allows precise control of when the output is generated. This is necessary because there may be significant skew between the bits of the input word arriving at the input of the D/A converter. But even with synchronization, there is often enough skew within the circuitry of the D/A converter that the output may momentarily go through a variety of output states before the final state is reached. This produces a “glitch” in the analog output each time a new output is generated, as shown in graph (b) of Figure 121.5. These glitches can add significant noise and distortion to the output waveform. The sample-and-hold block of Figure 121.5 eliminates glitches from the D/A converter by sampling the analog output after each glitch has settled. This result is shown in graph (c). The final block, the inverse sinc/analog low-pass filter, provides frequency shaping and bandwidth limiting to smooth the analog output as evident in graph (d). The inverse sinc filter is necessary to compensate for the sinc envelope present in the output spectra of the D/A.

Defining Terms

Conversion rate — The time elapsed between the start and completion of the conversion task. Typically applied in the context of A/D conversion. For D/A conversion, refer to settling time.

Digital-encoding — A variety of binary codes are utilized in conversion hardware. Examples include natural binary, binary-coded decimal (BCD), Gray code, sign-magnitude, offset binary, twos complement, and ones complement. Some converters allow for use of one or more of these coding schemes.

Fixed precision reference D/A — A converter architecture that utilizes either a fixed precision internal or external reference so the user cannot scale the output voltage by changing the reference.

Flash A/D — Technique for A/D conversion that utilizes $2^n - 1$ comparators, operating in parallel, to provide an n -bit digitization. This technique provides extremely fast conversion rates, while requiring a large component count in the IC realization.

Glitch — When a D/A converter receives a new output request, the asynchronous nature of the switching circuitry can result in momentary spikes or anomalous output values as the converter switches to the new state described by the digital encoding. These spurious changes in the output value are referred to as glitches, and the circuitry employed to remove or reduce their effects is said to deglitch the output.

- Integrating or ramp A/D** — Technique for A/D conversion wherein the input signal drives an electronic integrator. The height that the integration achieves over a reference time period is utilized to derive the converted value of the input signal. A very popular form of this technique utilized in many digital multimeters, is the dual-slope integrating A/D.
- Multiplying D/A** — A conventional architecture for D/A conversion that utilizes a fixed or variable-input reference voltage. The resulting output voltage is effectively a scaled product of the input reference voltage and the input digital encoding.
- Pipelined A/D** — A technique for A/D conversion which produces a relatively high sample rate high resolution output. It does this by utilizing a series of stages composed of a high sample rate low resolution flash A/D, a high resolution DAC, and a residue amplifier.
- Sample-and-hold** — Circuitry utilized to sample a continuous-time signal at a desired time, then hold the sample constant while an accompanying A/D completes a full conversion. A variant of this idea is the track-and-hold, which continuously follows the input signal until instructed to hold.
- Settling time** — With reference to the D/A task, the time elapsed between the change of the input digital encoding and the settling of the output analog signal to within a stated tolerance.
- Sigma-delta A/D** (also called delta-sigma A/D) — Technique for A/D conversion wherein the analog input signal level is compared to an approximate reconstruction of the input at each sampling instance. The repeated comparison results in a serial bit stream where the value of each bit denotes whether the input was greater than or less than the approximation at the given sample time. This technique typically involves a very high sampling rate that, when combined with a filtering of the low-resolution comparison results, yields a high precision moderate-rate conversion. This technique finds wide application in digital audio.
- Sigma-delta D/A** — Analogous to a sigma-delta A/D except that in this case the input is a multi-bit digital data stream and the output is an analog signal.
- Signal conditioning** — The general term for circuitry that preconditions the analog signal entering the A/D converter and similarly filters or smooths the output of the D/A.
- Successive approximation register A/D** — Technique for A/D conversion wherein a stepwise approximation of the input signal is constructed via a serial hardware comparator algorithm. The algorithm converges to an n -bit digitization of the input in n steps by successively assigning the most significant bits based upon a comparison of the input with the analog equivalent of the bits already assigned.

122.1 Introduction

The fundamental ideal behind all of a superconductor's unique properties is that **superconductivity** is a quantum mechanical phenomenon on a macroscopic scale created when the motions of individual electrons are correlated. According to the theory developed by John Bardeen, Leon Cooper, and Robert Schrieffer (BCS theory), this correlation takes place when two electrons couple to form a Cooper pair. For our purposes, we may therefore consider the electrical charge carriers in a superconductor to be Cooper pairs (or more colloquially, superelectrons) with a mass m^* and charge q^* twice those of normal electrons. The average distance between the two electrons in a Cooper pair is known as the coherence length, ξ . Both the coherence length and the binding energy of two electrons in a Cooper pair, 2Δ , depend upon the particular superconducting material. Typically, the coherence length is many times larger than the interatomic spacing of a solid, and so we should not think of Cooper pairs as tightly bound electron molecules. Instead, there are many other electrons between those of a specific Cooper pair allowing for the paired electrons to change partners on a time scale of $h/(2\Delta)$, where h is Planck's constant.

If we prevent the Cooper pairs from forming by ensuring that all the electrons are at an energy greater than the binding energy, we can destroy the superconducting phenomenon. This can be accomplished, for example, with thermal energy. In fact, according to the BCS theory, the critical temperature, T_c , associated with this energy is

$$\frac{2\Delta}{k_b T_c} \approx 3.5 \quad (122.1)$$

where k_b is Boltzmann's constant. For low critical temperature (conventional) superconductors, 2Δ is typically on the order of 1 meV, and we see that these materials must be kept below temperatures of about 10 K to exhibit their unique behavior. Superconductors with high critical temperature, in contrast, will superconduct up to temperatures of about 100 K, which is attractive from a practical view because the materials can be cooled cheaply using liquid nitrogen. A second way of increasing the energy of the electrons is electrically driving them. In other words, if the critical current density, J_c , of a superconductor

¹ This chapter is modified from Delin, K. A. and Orlando, T. P. 1993. Superconductivity. In *The Electrical Engineering Handbook*, ed. R. C. Dorf, pp. 1114–1123. CRC Press, Boca Raton, FL.

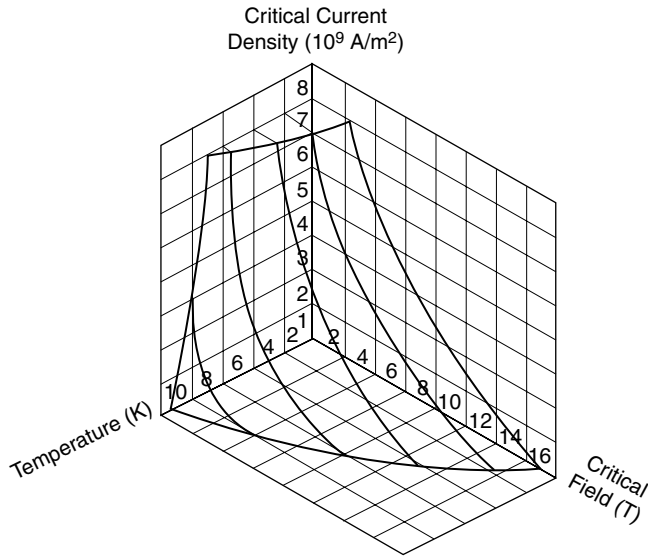

FIGURE 122.1 The phase space for the superconducting alloy niobium-titanium. The material is superconducting inside the volume of phase space indicated. [Source: Orlando, T. P. and Delin, K. A. 1991. *Foundations of Applied Superconductivity*. p. 10. Addison-Wesley, Reading, MA. With permission. (As adapted from Wilson, 1983.)]

is exceeded, the electrons have sufficient kinetic energy to prevent the formation of Cooper pairs. The necessary kinetic energy can also be generated through the induced currents created by an external magnetic field. As a result, if a superconductor is placed in a magnetic field larger than its critical field, H_c , it will return to its normal metallic state. To summarize, superconductors must be maintained under the appropriate temperature, electrical current density, and magnetic field conditions to exhibit its special properties. An example of this phase space is shown in Figure 122.1.

122.2 General Electromagnetic Properties

The hallmark electromagnetic properties of a superconductor are its ability to carry a static current without any resistance and its ability to exclude a static magnetic flux from its interior. It is this second property, known as the Meissner effect that distinguishes a superconductor from merely being a perfect conductor (which conserves the magnetic flux in its interior). Although superconductivity is a manifestly quantum mechanical phenomenon, a useful classical model can be constructed around these two properties. In this section we will outline the rationale for this classical model, which is useful in engineering applications such as waveguides and high-field magnets.

The zeros DC resistance criterion implies that the superelectrons move unimpeded. The electromagnetic energy density, w , stored in a superconductor is therefore

$$w = \frac{1}{2} \epsilon \mathbf{E}^2 + \frac{1}{2} \mu_0 \mathbf{H}^2 + \frac{n^*}{2} m^* \mathbf{v}_s^2 \quad (122.2)$$

where the first two terms are the familiar electric and magnetic energy densities, respectively. (Our electromagnetic notation is standard: ϵ is the permittivity, μ_0 is the permeability, \mathbf{E} is the electric field, and the magnetic flux density, \mathbf{B} , is related to the magnetic field, \mathbf{H} , via the constitutive law $\mathbf{B} = \mu_0 \mathbf{H}$.) The last term represents the kinetic energy associated with the undamped superelectrons' motion (n^* and \mathbf{v}_s are the superelectrons' density and velocity, respectively). Because the supercurrent density, \mathbf{J}_s , is related to the superelectron velocity by $\mathbf{J}_s = n^* q^* \mathbf{v}_s$, the kinetic energy term can be rewritten

$$n^* \left(\frac{1}{2} m^* \mathbf{v}_s^2 \right) = \frac{1}{2} \Lambda \mathbf{J}_s^2 \quad (122.3)$$

where Λ is defined as

$$\Lambda = \frac{m^*}{n^* (q^*)^2} \quad (122.4)$$

Assuming that all the charge carriers are superelectrons, there is no power dissipation inside the superconductor, and so Poynting's theorem over a volume V may be written

$$-\int_V \nabla \cdot (\mathbf{E} \times \mathbf{H}) \, dv = \int_V \frac{\partial w}{\partial t} \, dv \quad (122.5)$$

where the left side of the expression is the power flowing into the region. By taking the time derivative of the energy density and appealing to Faraday's and Ampère's laws to find the time derivatives of the field quantities, we find that the only way for Poynting's theorem to be satisfied is if

$$\mathbf{E} = \frac{\partial}{\partial t} (\Lambda \mathbf{J}_s) \quad (122.6)$$

This relation, known as the *first London equation* (after the London brothers, Heinz and Fritz), is thus necessary if the superelectrons have no resistance to their motion.

Equation (122.6) also reveals that the superelectrons' inertia creates a lag between their motion and that of the electric field. As a result, a superconductor can support a time-varying voltage drop across itself. The impedance associated with the supercurrent, therefore, is an inductor, and it will be useful to think of Λ as an inductance created by the correlated motion of the superelectrons.

If the first London equation is substituted into Faraday's law, $\nabla \times \mathbf{E} = -(\partial \mathbf{B} / \partial t)$, and integrated with respect to time, the *second London equation* results:

$$\nabla \times (\Lambda \mathbf{J}_s) = -\mathbf{B} \quad (122.7)$$

where the constant of integration has been defined to be zero. This choice is made so that the second London equation is consistent with the Meissner effect, as we now demonstrate. Taking the curl of the quasi-static form of Ampère's law, $\nabla \times \mathbf{H} = \mathbf{J}_s$, results in the expression $\nabla^2 \mathbf{B} = -\mu_o \nabla \times \mathbf{J}_s$, where a vector identity, $\nabla \times \nabla \times \mathbf{C} = \nabla (\nabla \cdot \mathbf{C}) - \nabla^2 \mathbf{C}$; the constitutive relation, $\mathbf{B} = \mu_o \mathbf{H}$; and Gauss's law, $\nabla \cdot \mathbf{B} = 0$, have been used. By now appealing to the second London equation, we obtain the vector Helmholtz equation

$$\nabla^2 \mathbf{B} - \frac{1}{\lambda^2} \mathbf{B} = 0 \quad (122.8)$$

where the penetration depth is defined as

$$\lambda \equiv \sqrt{\frac{\Lambda}{\mu_o}} = \sqrt{\frac{m^*}{n^* (q^*)^2 \mu_o}} \quad (122.9)$$

From Equation (122.8) we find that a flux density applied parallel to the surface of a semi-infinite superconductor will decay away exponentially from the surface on a spatial length scale of order λ . In other words, a bulk superconductor will exclude an applied flux as predicted by the Meissner effect.

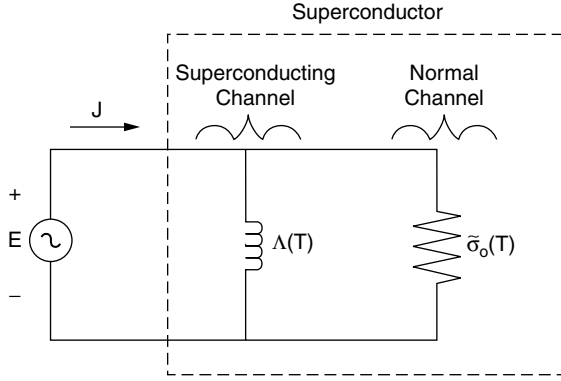

FIGURE 122.2 A lumped element model of a superconductor.

The London equations reveal that there is a characteristic length λ over which electromagnetic fields can change inside a superconductor. This penetration depth is different from the more familiar skin depth of electromagnetic theory, the latter being a frequency-dependent quantity. Indeed, the penetration depth at zero temperature is a distinct material property of a particular superconductor.

Notice that λ is sensitive to the number of correlated electrons (the superelectrons) in the material. As previously discussed, this number is a function of temperature, and so only at $T = 0$ do *all* the electrons that usually conduct ohmically participate in the Cooper pairing. For intermediate temperatures, $0 < T < T_c$, there are actually two sets of interpenetrating electron fluids: the uncorrelated electrons providing ohmic conduction and the correlated ones creating supercurrents. This two-fluid model is a useful way to build temperature effects into the London relations.

Under the two-fluid model, the electrical current density, \mathbf{J} , is carried by both the uncorrelated (normal) electrons and the superelectrons: $\mathbf{J} = \mathbf{J}_n + \mathbf{J}_s$, where \mathbf{J}_n is the normal current density. The two channels are modeled in a circuit, as shown in Figure 122.2, by a parallel combination of a resistor (representing the ohmic channel) and an inductor (representing the superconducting channel). To a good approximation, the respective temperature dependences of the conductor and inductor are

$$\tilde{\sigma}_o(T) = \sigma_o(T_c) \left(\frac{T}{T_c} \right)^4 \quad \text{for } T \leq T_c \quad (122.10)$$

$$\Lambda(T) = \Lambda(0) \left(\frac{1}{1 - (T/T_c)^4} \right) \quad \text{for } T \leq T_c \quad (122.11)$$

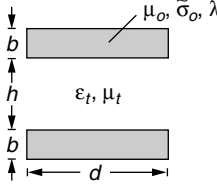

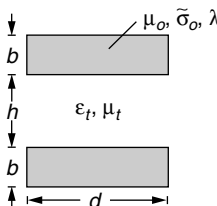

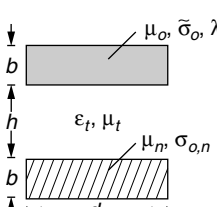

where σ_o is the DC conductance of the normal channel. (Strictly speaking, the normal channel should also contain an inductance representing the inertia of the normal electrons, but typically such an inductor contributes negligibly to the overall electrical response.) Since the temperature-dependent penetration depth is defined as $\lambda(T) = \sqrt{\Lambda(T)/\mu_o}$, the effective conductance of a superconductor in the sinusoidal steady state is

$$\sigma = \tilde{\sigma}_o + \frac{1}{j\omega \mu_o \lambda^2} \quad (122.12)$$

where the explicit temperature dependence notation has been suppressed.

Most of the important physics associated with the classical model is embedded in Equation (122.12). As is clear from the lumped element model, the relative importance of the normal and superconducting channels is a function not only of temperature but also of frequency. The familiar L/R time constant, here equal to $\Lambda\tilde{\sigma}_o$, delineates the frequency regimes where most of the total current is carried by \mathbf{J}_n (if

TABLE 122.1 Lumped Circuit Element Parameters Per Unit Length for Typical Transverse Electromagnetic Parallel Plate Waveguides*

|  <p>Two identical, thick $\lambda \ll b$ superconducting plates</p> | $\frac{\mu_t h}{d} + \frac{2\mu_0 \lambda}{d}$ | $\frac{\epsilon_t d}{h}$ | $\frac{4}{d\delta\tilde{\sigma}_o} \left(\frac{\lambda}{\delta}\right)^3$ |
|  <p>One thick $\lambda \ll b$ superconducting plate and one thick ($\delta_n \ll b$) ohmic plate</p> | $\frac{\mu_t h}{d} + \frac{\mu_0 \lambda}{d} + \frac{\mu_n \delta_n}{2d}$ | $\frac{\epsilon_t d}{h}$ | $\frac{1}{d\delta_n \sigma_{o,n}}$ |

* The subscript n refers to parameters associated with a normal (ohmic) plate. Using these expressions, line input impedance, attenuation, and wave velocity can be calculated.

Source: Orlando, T. P. and Delin, K. A. 1991. *Foundations of Applied Superconductivity*, p. 171. Addison-Wesley, Reading, MA. With permission.

$\omega\Lambda\tilde{\sigma}_o \gg 1$) or \mathbf{J}_s (if $\omega\Lambda\tilde{\sigma}_o \ll 1$). This same result can also be obtained by comparing the skin depth associated with the normal channel, $\delta = \sqrt{2/(\omega\mu_o\tilde{\sigma}_o)}$, to the penetration depth to see which channel provides more field screening. In addition, it is straightforward to use Equation (122.12) to rederive Poynting's theorem for systems that involve superconducting materials:

$$\begin{aligned}
 -\int_V \nabla \cdot (\mathbf{E} \times \mathbf{H}) dv = \frac{d}{dt} \int_V \left(\frac{1}{2} \epsilon \mathbf{E}^2 + \frac{1}{2} \mu_o \mathbf{H}^2 + \frac{1}{2} \Lambda(T) \mathbf{J}_s^2 \right) dv \\
 + \int_V \frac{1}{\tilde{\sigma}_o(T)} \mathbf{J}_n^2 dv
 \end{aligned}
 \tag{122.13}$$

Using this expression, it is possible to apply the usual electromagnetic analysis to find the inductance (L_0), capacitance (C_0), and resistance (R_0) per unit length along a parallel plate transmission line. The results of such analysis for typical cases are summarized in [Table 122.1](#).

122.3 Superconducting Electronics

The macroscopic quantum nature of superconductivity can be usefully exploited to create a new type of electronic device. Because all the superelectrons exhibit correlated motion, the usual wave-particle duality normally associated with a single quantum particle can now be applied to the entire ensemble of superelectrons. Thus, there is a spatiotemporal phase associated with the ensemble that characterizes the supercurrent flowing in the material.

Naturally, if the overall electron correlation is broken, this phase is lost and the material is no longer a superconductor. There is a broad class of structures, however, known as *weak links*, where the correlation is merely perturbed locally in space rather than outright destroyed. Colloquially, we say that the phase “slips” across the weak link to acknowledge the perturbation.

The unusual properties of this phase slippage were first investigated by Brian Josephson and constitute the central principles behind superconducting electronics. Josephson found that the phase slippage could be defined as the difference between the macroscopic phases on either side of the weak link. This phase difference, denoted as ϕ , determined the supercurrent, i_s , through and voltage, v , across the weak link according to the Josephson equations,

$$i_s = I_c \sin \phi \quad (122.14)$$

$$v = \frac{\Phi_o}{2\pi} \frac{\partial \phi}{\partial t} \quad (122.15)$$

where I_c is the critical (maximum) current of the junction and Φ_o is the quantum unit of flux. (The flux quantum has a precise definition in terms of Planck’s constant, h , and the electron charge, e : $\Phi_o \equiv h/(2e) \approx 2.068 \times 10^{-15}$ Wb). As in the previous section, the correlated motion of the electrons, here represented by the superelectron phase, manifests itself through an inductance. This is straightforwardly demonstrated by taking the time derivative of Equation (122.14) and combining this expression with Equation (122.15). Although the resulting inductance is nonlinear (it depends on $\cos \phi$), its relative scale is determined by

$$L_j = \frac{\Phi_o}{2\pi I_c} \quad (122.16)$$

a useful quantity for making engineering estimates.

A common weak link, known as the Josephson tunnel junction, is made by separating two superconducting films with a very thin (typically 20 Å) insulating layer. Such a structure is conveniently analyzed using the resistively and capacitively shunted junction (RCSJ) model shown in [Figure 122.3](#). Under the RCSJ model an ideal lumped junction [described by Equation (122.14) and Equation (122.15)] and a resistor R_j represent how the weak link structure influences the respective phases of the super and normal electrons, and a capacitor C_j represents the physical capacitance of the sandwich structure. If the ideal lumped junction portion of the circuit is treated as an inductor-like element, many Josephson tunnel junction properties can be calculated with the familiar circuit time constants associated with the model. For example, the quality factor Q of the RCSJ circuit can be expressed as

$$Q^2 = \frac{R_j C_j}{L_j / R_j} = \frac{2\pi I_c R_j^2 C_j}{\Phi_o} \equiv \beta \quad (122.17)$$

where β is known as the Stewart-McCumber parameter. Clearly, if $\beta \gg 1$, the ideal lumped junction element is underdamped in that the capacitor readily charges up, dominates the overall response of the

FIGURE 122.3 A real Josephson tunnel junction can be modeled using ideal lumped circuit elements.

circuit, and therefore creates a hysteretic i - v curve as shown in Figure 122.4(a). In the case when the bias current is raised from zero, no time-averaged voltage is created until the critical current is exceeded. At this point the junction switches to the voltage $2\Delta/e$ with a time constant $\sqrt{L_j C_j}$. Once the junction has latched into the voltage state, however, the bias current must be lowered to zero before it can again be steered through the superconducting path. Conversely, $\beta \ll 1$ implies that the L_j/R_j time constant dominates the circuit response, so that the capacitor does not charge up and the i - v curve is not hysteretic [Figure 122.4(b)].

Just as the correlated motion of the superelectrons creates the frequency-independent Meissner effect in a bulk superconductor through Faraday's law, so too the macroscopic quantum nature of superconductivity allows the possibility of a device whose output voltage is a function of a static magnetic field. If two weak links are connected in parallel, the lumped version of Faraday's law gives the voltage across the second weak link as $v_2 = v_1 + (d\Phi/dt)$, where Φ is the total flux threading the loop between the links. Substituting Equation (122.15) and integrating with respect to time yields

$$\phi_2 - \phi_1 = (2\pi \Phi) / \Phi_0 \tag{122.18}$$

showing that the spatial change in the phase of the macroscopic wavefunction is proportional to the local magnetic flux. The structure described is known as a *superconducting quantum interference device* (SQUID) and can be used as a highly sensitive magnetometer by biasing it with current and measuring the resulting voltage as a function of magnetic flux. Such SQUID structures have also been proposed for quantum bits in quantum computing. From this discussion, it is apparent that a duality exists in how

FIGURE 122.4 The i - v curves for a Josephson junction: (a) $\beta \gg 1$, (b) $\beta \ll 1$.

fields interact with the macroscopic phase: electric fields are coupled to its rate of change in time and magnetic fields are coupled to its rate of change in space.

122.4 Types of Superconductors

The macroscopic quantum nature of superconductivity also affects the general electromagnetic properties previously discussed. This is most clearly illustrated by the interplay of the characteristic lengths ξ , representing the scale of quantum correlations, and λ , representing the scale of electromagnetic screening. Consider the scenario where a magnetic field, H , is applied parallel to the surface of a semi-infinite superconductor. The correlations of the electrons in the superconductor must lower the overall energy of the system or else the material would not be superconducting in the first place. Because the critical magnetic field H_c destroys all the correlations, it is convenient to define the energy density gained by the system in the superconducting state as $(\frac{1}{2})\mu_o H_c^2$. The electrons in a Cooper pair are separated on a length scale of ξ , however, and so the correlations cannot be fully achieved until a distance roughly ξ from the boundary of the superconductor. There is thus an energy per unit area, $(\frac{1}{2})\mu_o H_c^2 \xi$, that is lost because of the presence of the boundary. Now consider the effects of the applied magnetic field on this system. It costs the superconductor energy to maintain the Meissner effect, $\mathbf{B} = 0$, in its bulk; in fact, the energy density required is $(\frac{1}{2})\mu_o H^2$. However, since the field can penetrate the superconductor a distance roughly λ , the system need not expend an energy per unit area of $(\frac{1}{2})\mu_o H^2 \lambda$ to screen over this volume. To summarize, more than a distance ξ from the boundary, the energy of the material is lowered (because it is superconducting), and more than a distance λ from the boundary the energy of the material is raised (to shield the applied field).

Now, if $\lambda < \xi$, the region of superconducting material greater than λ from the boundary, but less than ξ , will be higher in energy than that in the bulk of the material. Thus, the surface energy of the boundary is positive and so costs the total system some energy. This class of superconductors is known as type I. Most elemental superconductors, such as aluminum, tin, and lead, are type I. In addition to having $\lambda < \xi$, type I superconductors are generally characterized by low critical temperatures (~ 5 K) and critical fields (~ 0.05 T). Typical type I superconductors and their properties are listed in Table 122.2.

Conversely, if $\lambda > \xi$, the surface energy associated with the boundary is negative and lowers the total system energy. It is therefore thermodynamically favorable for a normal–superconducting interface to form inside these type II materials. Consequently, this class of superconductors does not exhibit the simple Meissner effect as do type I materials. Instead, there are now two critical fields: for applied fields below the lower critical field, H_{c1} , a type II superconductor is in the Meissner state, and for applied fields greater than the upper critical field, H_{c2} , superconductivity is destroyed. The three critical fields are related to each other by $H_c \approx \sqrt{H_{c1} H_{c2}}$.

In the range $H_{c1} < H < H_{c2}$, a type II superconductor is said to be in the vortex state because now the applied field can enter the bulk superconductor. Because flux exists in the material, however, the superconductivity is destroyed locally, creating normal regions. Recall that for type II materials the boundary between the normal and superconducting regions lowers the overall energy of the system. Therefore, the

TABLE 122.2 Material Parameters for Type I Superconductors*

| Material | T_c (K) | λ_o (nm) | ξ_o (nm) | Δ_o (meV) | $\mu_o H_{co}$ (mT) |

flux in the superconductor creates as many normal-superconducting interfaces as possible without violating quantum criteria. The net result is that flux enters a type II superconductor in quantized bundles of magnitude Φ_o known as *vortices* or *fluxons* (the former name derives from the fact that current flows around each quantized bundle in the same manner as a fluid vortex circulates around a drain). The central portion of a vortex, known as the core, is a normal region with an approximate radius of ξ . If a defect-free superconductor is placed in a magnetic field, the individual vortices, whose cores essentially follow the local average field lines, form an ordered triangular array, or flux lattice. As the applied field is raised beyond H_{c1} (where the first vortex enters the superconductor), the distance between adjacent vortex cores decreases to maintain the appropriate flux density in the material. Finally, the upper critical field is reached when the normal cores overlap and the material is no longer superconducting. Indeed, a precise calculation of H_{c2} using the phenomenological theory developed by Vitaly Ginzburg and Lev Landau yields

$$H_{c2} = \frac{\Phi_o}{2\pi\mu_o \xi^2} \tag{122.19}$$

which verifies out simple picture. The values of typical type II material parameters are listed in Table 122.3 and Table 122.4.

Type II superconductors are of great technical importance because typical H_{c2} values are at least an order of magnitude greater than the typical H_c values of type I materials. It is, therefore, possible to use type II materials to make high-field magnet wire. Unfortunately, when current is applied to the wire, there is a Lorentz-like force on the vortices, causing them to move. Because the moving vortices carry flux, their motion creates a static voltage drop along the superconducting wire by Faraday's law. As a result, the wire no longer has a zero DC resistance, even though the material is still superconducting. To fix this problem, type II superconductors are usually fabricated with intentional defects, such as impurities or grain boundaries, in their crystalline structure to pin the vortices and prevent vortex motion. The pinning as created because the defect locally

| Bi ₂ Sr ₂ CaCu ₂ O ₈ | 85 |
| Bi ₂ Sr ₂ Ca ₂ Cu ₃ O ₁₀ | 110 |
| TlBa ₂ Ca ₂ Cu ₃ O ₁₀ | 125 |
| HgBa ₂ Ca ₂ Cu ₃ O ₈ | 131 |

weakens the superconductivity in the material, and it is thus energetically favorable for the normal core of the vortex to overlap the nonsuperconducting region in the material. Critical current densities usually quoted for practical type II materials, therefore, really represent the depinning critical current density where the Lorentz-like force can overcome the pinning force. (The depinning critical current density should not be confused with the depairing critical current density, which represents the current when the Cooper pairs have enough kinetic energy to overcome their correlation. The depinning critical current density is typically an order of magnitude less than the depairing critical current density, the latter of which represents the theoretical maximum for J_c .)

By careful manufacturing, it is possible to make superconducting wire with tremendous amounts of current-carrying capacity. For example, standard copper wire used in homes will carry about 10^7 A/m², whereas a practical type II superconductor like niobium-titanium can carry current densities of 10^{10} A/m² or higher even in fields of several teslas. This property, more than a zero DC resistance, is what makes superconducting wire so desirable.

Defining Terms

Superconductivity — A state of matter whereby the correlation of conduction electrons allows a static current to pass without resistance and a static magnetic flux to be excluded from the bulk of the material.

Further Information

Every two years an Applied Superconductivity Conference is held devoted to practical technological issues. The proceedings of these conferences have been published every other year from 1977 to 1991 in the *IEEE Transactions on Magnetics*.

In 1991 the *IEEE Transactions on Applied Superconductivity* began publication. This quarterly journal focuses on both the science and the technology of superconductors and their applications, including materials issues, analog and digital circuits, and power systems. The proceedings of the Applied Superconductivity Conference now appear in this journal.

123.1 Introduction

Advances in VLSI technology now allow us to build systems-on-chips (SoCs), also known as systems-on-silicon (SoS). SoCs are complex at all levels of abstraction; they contain hundreds of millions of transistors; they also provide sophisticated functionality, unlike earlier generations of commodity memory parts. As a result, SoCs present a major productivity challenge.

One solution to the SoC productivity problem is to use embedded computers.¹ An embedded computer is a programmable processor that is a component in a larger system that is not a general-purpose computer. Embedded computers help tame design complexity by separating (at least to some degree) hardware and software design concerns. A processor can be used as a predesigned component — known as intellectual property (IP) — that operates at a known speed and power consumption. The software required to implement the desired functionality can be designed somewhat separately.

In exchange for separating hardware and software design, some elements traditionally found in hardware design must be transferred to software design. Software designers have traditionally concentrated on functionality while hardware designers have worried about critical delay paths, power consumption, and area. Embedded software designers must worry about real-time deadlines, power consumption, and program and data size. As a result, embedded SoC design disciplines require a blending of hardware and software skills.

This chapter considers the characteristics of SoCs built from embedded processors. The next section surveys the types of requirements that are generally demanded from embedded SoCs. Section 123.3 surveys the characteristics of components used to build embedded systems. Section 123.4 introduces the types of architectures used in embedded systems. Section 123.5 reviews design methodologies for embedded SoCs.

123.2 Requirements on Embedded SoCs

A digital system typically uses embedded processors to meet a combination of performance, complexity, and possibly design time goals. If the system's behavior is very regular and easy to specify as hardware, it may not be necessary to use embedded software. An embedded processor becomes more attractive when the behavior is too complex to be easily captured in hardwired logic.

Using embedded processors may reduce design time by allowing the design to be separated into distinct software and hardware units. In many cases, the CPU will be predesigned; even if the CPU and associated hardware is being designed for the project, many aspects of the hardware design can be performed separately from the software design. (Experience with embedded system designs does show, however, that the hardware and software designs are intertwined and that embedded software is prone to some of the same scheduling problems as mainframe software projects.)

But even if embedded processors seem attractive by reducing much of the design to “just programming,” it must be remembered that embedded software design is much more challenging than typical applications programming for workstations or PCs. Embedded software must be designed to meet not just functional requirements — the software's input and output behavior — but also stringent nonfunctional requirements. Those nonfunctional requirements include:

- *Performance* — Although all programmers are interested in speed of execution, performance is measured much more precisely in the typical embedded system. Many embedded systems must meet real-time deadlines. The deadline is measured between two points in the software: if the program completely executes from the starting point to the end point by the deadline, the system malfunctions.
- *Energy/power* — Traditional programmers don't worry about power or energy consumption. However, energy and power are important to most embedded systems. Energy consumption is of course important in battery-operated systems, but the heat generated as a result of power consumption is increasingly important to wall-powered systems.
- *Size* — The amount of memory required by the embedded software determines the amount of memory required by the embedded system. Memory is often one of the major cost components of an embedded system.

Embedded software design resembles hardware design in its emphasis on nonfunctional requirements such as performance and power. The challenge in embedded SoC design is to take advantage of the best aspects of both hardware and software components to quickly build a cost-effective system.

123.3 Embedded SoC Components

CPUs

As shown in Figure 123.1, a CPU is a programmable instruction set processor. Instructions are kept in a separate memory — a program counter (PC) that points to the current instruction. This definition does not consider reconfigurable logic to be a programmable computer, because it does not have a separate instruction memory and a PC. Reconfigurable logic can be used to implement sequential machines, and so a CPU could be built in reconfigurable logic. But the separation of CPU logic and memory is an important abstraction for program design.

FIGURE 123.1 A CPU and memory.

An embedded processor is judged by several characteristics:

- *Performance* — The overall speed of execution may be important in some systems, but in many cases we particularly care about the CPU's performance on critical sections of code.
- *Energy and power* — Processors provide different mechanisms to manage power consumption.
- *Area* — The area of the processor contributes to the total implementation cost of the SoC. The area of the memory required to store the program also contributes to implementation cost.

These characteristics are judged relative to the embedded software they are expected to run. A processor may exhibit very different performance or energy consumption on different applications.

RISC processors are commonly used in embedded computing. ARM² and MIPS³ processors are examples of RISC processors that are widely used in embedded systems. A RISC CPU uses a pipeline to increase CPU performance. Many RISC instructions take the same amount of time to execute, simplifying performance analysis. However, many RISC architectures do have exceptions to this rule. An example is the multiple-register feature of the ARM processor: an instruction can load or store a set of registers, for which the instruction takes one cycle per instruction.

Most CPUs used in PCs and workstations today are superscalar processors. A superscalar processor builds on RISC techniques by adding logic that examines the instruction stream and determines, based on what CPU resources are needed, when several instructions can be executed in parallel. Superscalar scheduling logic adds quite a bit of area to the CPU in order to check all the possible conflicts between combinations of instructions; the size of a superscalar scheduler grows as n^2 , where n is the number of instructions that are under consideration for scheduling. Many embedded systems, and in particular SoCs, do not use superscalar processors and instead stick with RISC processors. Embedded system designers tend to use other techniques, such as instruction-set optimization caches, to improve performance. Because SoC designers are concerned with overall system performance, not just CPU performance, and because they have a better idea of the types of software run on their hardware, they can tackle performance problems in a variety of ways that may use the available silicon area more cost-effectively.

Some embedded processors are known as digital signal processors (DSPs). The term DSP was originally used to mean one of two things: either a CPU with a Harvard architecture that provided separate memories for programs and data; or a CPU with a multiply-accumulate unit to efficiently implement digital filtering operations. Today, the meaning of the term has blurred somewhat. For instance, version 9 of the ARM architecture is a Harvard architecture to better support digital signal processing. Modern usage applies the term DSP to almost any processor that can be used to efficiently implement signal processing algorithms.

The application-specific integrated processor (ASIP)⁴ is one approach to improving the performance of RISC processors for embedded application. An ASIP's instruction set is designed to match the requirements of the application software it will run. On the one hand, special-purpose function units and instructions to control them may be added to speed up certain operations. On the other hand, function units, registers, and busses may be eliminated to reduce the CPU's cost if they do not provide enough benefit for the application at hand. The ASIP may be designed manually or automatically based on profiling information. One advantage of generating the ASIP automatically is that the same information can be used to generate the processor's programming environment: a compiler, assembler, and debugger are necessary to make the ASIP useful building blocks.

Another increasingly popular architecture for embedded computing is very long instruction word (VLIW). A VLIW machine can execute several instructions simultaneously but, unlike a superscalar processor, relies on the compiler to schedule parallel instructions at compilation time. A pure VLIW machine uses slots in the long, fixed-length instruction word to control the CPU's function units, with NOPs used to indicate slots that cannot be used for useful work by the compiler. Modern VLIW machines, such as the TI C6000⁵ and the Motorola/Agere StarCore,⁶ group single-operation instructions into execution packets; the packet's length can vary depending on the number of instructions that the compiler was able to schedule for simultaneous operation. VLIW machines provide instruction-level parallelism

with a much smaller CPU than is possible in a superscalar system; however, the compiler must be able to extract parallelism at compilation time to be able to use the CPU's resources. Signal processing applications often have parallel operations that can be exploited at compilation time. For example, a parallel set of filter banks runs the same code on different data; the operations for each channel can be scheduled together in the VLIW instruction group.

Interconnect

Embedded SoCs may connect several CPUs, on-chip memories, and devices on a single chip. High-performance interconnect systems are required to meet the system's performance demands. The interconnection systems must also comply with standards so that existing components may be connected to them.

Busses are still the dominant interconnection scheme for embedded SoCs. Although richer interconnection schemes could be used on-chip, where they are not limited by pinout as in board-level systems, many existing architectures are still memory-limited and not interconnect-limited. However, future generations of embedded SoCs may need more sophisticated interconnection schemes.

A bus provides a protocol for communication between components. It also defines a memory space and the uses of various addresses in that memory space, for example, the address range assigned to a device connected to the bus. Busses for SoCs may be designed for high-performance or low-cost operation. A high-performance bus uses a combination of techniques — advanced circuits, additional bus lines, efficient protocols — to maximize transaction performance. One common protocol used for efficient transfers is the block transfer, in which a range of locations is transferred based on a single address, eliminating the need to transfer all the addresses on the bus. Some recent busses allow split transactions — the data request and data transfer are performed on separate bus cycles, allowing other bus operations to be performed while the original request is serviced. A low-cost bus design provides modest performance that may not be acceptable for instruction fetching or other time-critical operations. A low-cost bus is designed to require little hardware in the bus itself and to impose a small hardware and software overhead on the devices connecting to the bus. A system may contain more than one bus; a bridge can be used to connect one bus to another.

The ARM AMBA bus specification⁷ is an example of a bus specification for SoCs. The AMBA spec actually includes two busses: the high-performance AMBA high-performance bus (AHB) and the low-cost AMBA peripherals bus (APB). The Virtual Sockets Interface committee has defined another standard for interconnecting components on SoCs.

Memory

One of the great advantages of SoC technology is that memory can be placed on the same chip as the system components that use the memory. On-chip memory both increases performance and reduces power consumption because on-chip connections present less reactive load than do pins and traces between chips; however, an SoC may still need to use separate chips for off-chip memory.

Although on-chip embedded memory has many advantages, it still is not as good as commodity memory. A commodity SRAM or DRAM's manufacturing process has been carefully tuned to the requirements of that component. In contrast, an on-chip memory's manufacturing needs must be balanced against the requirements of the logic circuits on the chip. The transistors, interconnections, and storage nodes of on-chip memories all have somewhat different needs than logic transistors.

Embedded DRAMs suffer the most because they need quite different manufacturing processes than do logic circuits. The processing steps required to build the storage capacitors for the DRAM cell are not good for small-geometry transistors. As a result, embedded DRAM technologies often compromise both the memory cells and the logic transistors, with neither being as good as they would be in separate, optimized processes. Although embedded DRAM has been the subject of research for many years, its limitations have kept it from becoming a widely used technology at the time of this writing.

SRAM circuits' characteristics are closer to those of logic circuits and so can be built on SoCs with less penalty. SRAM consumes more power and requires more chip area than does DRAM, but SRAM does not need refreshing, which noticeably simplifies the system architecture.

Software Components

Software elements are also components of embedded systems. Just as pre-designed hardware components are used to both reduce design time and to provide predictions of the characteristics of parts of the system, software components can also be used to speed up software implementation time and to provide useful data on the characteristics of systems.

CPU vendors often supply software libraries for their processors. These libraries generally supply code for two types of operations. First, they provide drivers for input and output operations. Second, they provide efficient implementations of commonly-used algorithms. For example, libraries for DSPs generally include code for digital filtering, fast Fourier transforms, and other common signal processing algorithms. Code libraries are important because compilers are still not as adept as expert human programmers at creating code that is both fast and small.

The real-time operating system (RTOS) is the second major category of software component. Many applications perform several different types of operations, often with their own performance requirements. As a result, the software is split into processes that run independently under the control of an RTOS. The RTOS schedules the processes to meet performance goals and efficiently utilize the CPU and other hardware resources. The RTOS may also provide utilities, such as interprocess communication, networking, or debugging. An RTOS's scheduling policy is necessarily very different from that used in workstations and mainframes, because the RTOS must meet real-time deadlines. A priority-driven scheduling algorithm such as rate-monotonic scheduling (RMS)⁹ is often used by the RTOS to schedule activity in the system.

123.4 Embedded System Architectures

The hardware architecture of an embedded SoC is generally tuned to the requirements of the application. Different domains, such as automotive, image processing, and networking all have very different characteristics. In order to make best use of the available silicon area, the system architecture is chosen to match the computational and communication requirements of the application. As a result, a much wider range of hardware architectures is found for embedded systems as compared with traditional computer systems.

Figure 123.2 shows one common configuration, a bus-based uniprocessor architecture for an embedded system. This architecture has one CPU, which greatly simplifies the software architecture. In addition to I/O devices, the architecture may include several devices known as accelerators designed to speed up computations. (Though some authors refer to these units as co-processors, we prefer to reserve that term for units that are dispatched by the CPU's execution unit.) For example, a video operation's inner loops may be implemented in an application-specific IC (ASIC) so that the operation can be performed more

FIGURE 123.2 A bus-based, single-CPU embedded system.

FIGURE 123.3 The TI OMAP architecture.¹⁰

quickly than would be possible on the CPU. An accelerator can achieve performance gains through several mechanisms: by implementing some functions in special hardware that takes fewer cycles than is required on the CPU, by reducing the time required for control operations that would require instructions on the CPU, and by using additional registers and custom data flow within the accelerator to more efficiently implement the available communication. The single-CPU/bus architecture is commonly used in applications that do not have extensive real-time characteristics and ones that need to run a wider variety of software. For example, many PDAs use this type of architecture. A single-CPU system simplifies software design and debugging since all the work is assumed to happen on one processing element. The single CPU system is also relatively inexpensive.

In general, however, a high-performance embedded system requires a heterogeneous multiprocessor — a multiprocessor that uses more than one type of processing element and/or a specialized communication topology. Scientific parallel processors generally use a regular architecture to simplify programming. Embedded systems use heterogeneous architectures for several reasons:

- *Cost* — A regular architecture may be much larger and more expensive than a heterogeneous architecture, which freed from the constraint of regularity, can remove resources from parts of the architecture where they are not needed and add them to parts where they are needed.
- *Real-time performance* — Scientific processors are designed for overall performance but not to meet deadlines. Embedded systems must often put processing power near the I/O that requires real-time responsiveness; this is particularly true if the processing must be performed at a high rate. Even if a high-rate, real-time operation requires relatively little computation on each iteration, the high interrupt rate may make it difficult to perform other processing tasks on the same processing element.

Many embedded systems use heterogeneous multiprocessors. One example comes from telephony. A telephone must perform both control- and data-intensive operations: both the network protocol and the user interface require control-oriented code; the signal-processing operations require data-oriented code. The Texas Instruments OMAP architecture, shown in [Figure 123.3](#), is designed for telephony: the RISC processor handles general-purpose and control-oriented code while the DSP handles signal processing. Shared memory allows processes on the two CPUs to communicate, as does a bridge. Each CPU has its own RTOS that coordinates processes on the CPU and also mediates communication with the other CPU.

The C-Port network processor,¹¹ whose hardware architecture is shown in [Figure 123.4](#), provides an example of a heterogeneous multiprocessor in a different domain. The multiprocessor is a high-speed bus. The RISC executive processor is C programmable and provides overall control, initialization, etc. Each of the 16 HDLC processors is also C programmable. Other interfaces for higher-speed networks are not general-purpose computers and can be programmed only with register settings.

Another category of heterogeneous parallel embedded systems is the networked embedded system. Automobiles are a prime example of this type of system: the typical high-end car includes over a hundred microprocessors ranging from 4-bit microcontrollers to high-performance 32-bit processors. Networks help to distribute high-rate processing to specialized processing elements, as in the HP DesignJet, but they are most useful when the processing elements must be physically distributed. When the processing elements are sufficiently far apart, busses designed for lumped microprocessor systems do not work well. The network is generally used for data transfer between the processing elements, with each processing element maintaining its own program memory as well as a local data memory. The processing elements

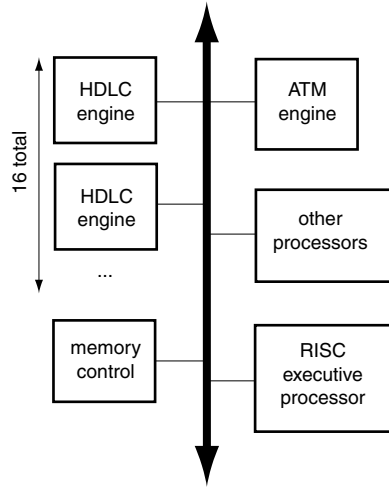

FIGURE 123.4 Block diagram of the C-Port network processor.¹¹

communicate data and control information as required by the application. I²C and CAN are two widely used networks for distributed systems.

123.5 Embedded SoC Design Methodologies

Specifications

As described in Section 123.2, embedded computers are typically used to build systems with complex functionality. Therefore, capturing a functional description of the system is an important part of the design process. A variety of specification languages have been developed. Many of these languages were developed for software systems, but several languages have been developed over the past decade with embedded systems in mind.

Specification languages are generally designed to capture particular styles of design. Many languages have been created to describe control-oriented systems. An early example was Statecharts,¹² which introduced hierarchical states that provided a structured description of state machines. The SDL language¹³ is widely used to specify protocols in telecommunications systems. The Esterel language¹⁴ describes a reactive system as a network of communicating state machines.

Data-oriented languages find their greatest use in signal processing systems. Dataflow process networks¹⁵ are one example of a specification language for signal processing. Object-oriented specification and design have become very popular in software design. Object-oriented techniques mix control and data orientation. Objects tend to reflect natural assemblages of data; the data values of an object define its state and the states of the objects define the state of the system. Messages providing communication and control. The real-time object-oriented Methodology (ROOM)¹⁶ is an example of an object-oriented methodology created for embedded system design.

In practice, many systems are specified in the C programming language. Many practical systems combine control and data operations, making it difficult to use one language that is specialized for any type of description. Algorithm designers generally want to prototype their algorithms and verify them through experimentation; as a result, an executable program generally exists as the golden standard with which the implementation must conform. This is especially true when the product's capabilities are defined by standards committees, which typically generate one or more reference implementations, usually in C. Once a working piece of code exists in C, there is little incentive to rewrite it in a different specification language; however, the C specification is generally a long way from an implementation. Algorithmic designs are usually written for uniprocessors and ignore many aspects of I/O, whereas embedded systems must perform real-time I/O and often distribute tasks among several processing elements. Algorithm designers often do not optimize their code for any particular platform, and their

FIGURE 123.5 The waterfall model of software development.

code is certainly not optimized for any particular embedded platform. As a result, a C language specification often requires substantial re-engineering before it can be used in an embedded system.

Design Flows

In order to better understand modern design methodologies for embedded SoCs, we can start with traditional software engineering methodologies. The waterfall model, one of the first models of software design, is shown in Figure 123.5. The waterfall model is a top-down model with only local feedback. Other software design models, such as the spiral model, try to capture more bottom-up feedback from implementation to system design; however, software design methodologies are designed primarily to implement functionality and to create a maintainable design. Embedded SoCs must, as mentioned in Section 123.2, satisfy performance and power goals as well. As a result, embedded system design methodologies must be more complex.

The design of the architecture of an embedded SoC is particularly important because the architecture defines the capabilities that will limit both the hardware and software implementations. The architecture must, of course, be cost effective, but it must also provide the features necessary to do the job. Because the architecture is custom designed for the application, it is quite possible to miss architectural features that are necessary to efficiently implement the system. Retrofitting those features back into the architecture may be difficult or even impossible if the hardware and software design efforts do not keep in sync.

Important decisions about the hardware architecture include:

- How many processing elements are needed?
- What processing elements should be programmable and which ones should be hardwired?
- How much communication bandwidth is needed in the system and where is it needed?
- How much memory is needed and where should it go in the system?
- What types of components will be used for processors, communication, and memory?

The design of the software architecture is just as important and goes hand-in-hand with the hardware architecture design. Important decisions about the software architecture include:

- How should the functionality be split into processes?
- How are input and output performed?
- How should processes be allocated to the various processing elements in the hardware architecture?
- When should processes be scheduled?

In practice, information required to make these decisions comes from several sources. One important source is previous designs. Though technology and requirements both change over time, similar designs can provide valuable lessons on how to (and not to) design the next system. Another important source is implementation. Some implementation information can come from pre-designed hardware or software components, which is one reason why intellectual-property-based design is so important. Implementation can also come from early design efforts.

A variety of CAD algorithms have been developed to explore the embedded system design space and to help automate system architectures. Vulcan²¹ and Cosyma²² were early hardware/software partitioning systems that implemented a design using a CPU and one or more custom ASICs. Other algorithms target more general architectures.^{23,24}

Once the system architecture has been defined, the hardware and software must be implemented. Hardware implementation challenges include:

- finding efficient protocols to connect together existing hardware blocks,
- memory design,
- clock rate optimization,
- power optimization.

Software implementation challenges include:

- meeting performance deadlines,
- minimizing power consumption,
- minimizing memory requirements.

The design must be verified throughout the design process. Once the design progresses to hardware and software implementation, simulation becomes challenging because the various components operate at very different levels of abstraction. Hardware units are modeled at the clock-cycle level. Software components must often be run at the instruction level or in some cases at even higher levels of abstraction. A hardware/software co-simulator¹⁹ is designed to coordinate simulations that run at different time scales. The co-simulator coordinates multiple simulators — hardware simulators, instruction-level simulators, behavioral software processes — and keeps track of the time in each simulation. The co-simulator ensures that communications between the simulators happen at the right time for each simulator.

Design verification must include performance, power, and size as well as functionality. Although these sorts of checks are common in hardware design, they are relatively new to software design. Performance and power verification of software may require cache simulation. Some recent work has developed higher-level power models for CPUs.

Platform-Based Design

One response to the conflicting demands of SoC design has been the development of platform-based design methodologies. On the one hand, SoCs are becoming very complex. On the other hand, they must be designed very quickly to meet the electronics industry's short product lifecycles.

Platform-based design tries to tackle this problem by dividing the design process into two phases. In the first phase, a platform is designed. The platform defines the hardware and software architectures for the system. The degree to which the architecture can be changed depends on the needs of the marketplace. In some cases, the system may be customizable only by reprogramming. In other cases, it may be possible to add or delete hardware components to provide specialized I/O, additional processing capabilities, etc. In the second phase, the platform is specialized into a product. Because much of the initial design work was done in the first phase, the product can be developed relatively quickly based on the platform.

Platform-based design is particularly well suited to products derived from standards. On the one hand, all products must meet the minimum requirements of the standard. On the other hand, standards committees generally leave room for different implementations to distinguish themselves: added features, lower power, etc. Designers will generally want to modify their design to add features that differentiate their product in the marketplace.

Platform-based design also allows designers to incorporate design experience into products. Each product derived from the platform will teach something: how to better design part of the system, unexpected needs of customers, etc. The platform can be updated as new products are developed from it so that successive designs will be easier.

Platforms are usually designed within a technology generation. A new VLSI technology generally changes enough design decisions that platforms must be rethought for each new generation of technology. Therefore, the platform itself must be designed quickly and each product based on the platform must be completed quickly in order to gain effective use of the platform design effort in the 18-month lifecycle of a manufacturing technology.

Software Performance Analysis and Optimization

Although methods for hardware performance analysis and optimization are well known, software techniques for optimizing performance have been developed only recently to meet the demands of embedded design methodologies.

The performance of an embedded system is influenced by several factors at different levels of abstraction. The first is the performance of the CPU pipeline itself. RISC design techniques tend to provide uniform execution times for instructions, but software performance is not always simple to predict. Register forwarding, which is used to enhance pipeline performance, also makes execution time less predictable. Branch prediction causes similar problems.

Superscalar processors, because they schedule instructions at execution time based upon execution data, provide much less predictable performance than do either RISC or VLIW processors. This is one reason why superscalar processors are not frequently used in real-time embedded systems.

The memory system is often an even greater source of uncertainty in embedded systems. CPUs use caches to improve average memory response time, but the effect of the cache on a particular piece of software requires complex analysis. In pathological cases, the cache can add uncertainty to execution times without actually improving the performance of critical software components. Cache simulation is often used to analyze the behavior of a program in a cache. Analysis must take into account both instructions and data. Unlike in workstation CPUs, in which the cache configuration is chosen by the CPU architect based on benchmarks, the designer of an embedded SoC can choose the configurations of caches to match the characteristics of the embedded software. Embedded system designers can choose between hardware and software optimizations to meet performance goals.

Analyzing the performance of a program requires determining both the execution path and the execution time of instructions along that path.¹⁸ Both are challenging problems.²⁰ The execution path of a program clearly depends on input data values. To ensure that the program meets a deadline, the worst-case execution path must be determined. The execution time of instructions along the path depend on several factors: data values, interactions between instructions, and cache state.

Energy/Power Analysis and Optimization

Many embedded systems must also meet energy and power goals as well as performance goals. The specification may impose several types of power requirements: peak power consumption, average power consumption, energy consumption for a given operation.

To a first-order, high-performance design is low-power design. Efficient implementations that run faster also tend to reduce power consumption, but trade-offs between performance and power in embedded system design. For example, the power consumption of a cache depends on both its size and the memory system activity.²⁵ If the cache is too small, too many references require expensive main memory accesses. If the cache is too large, it burns too much static power. Many applications exhibit a sweet spot at which the cache is large enough to provide most of the available performance benefit while not burning too much static power. Techniques have been developed to estimate hardware/software power consumption.²⁶

System-level approaches can also help reduce power consumption.²⁷ Components can be selectively turned off to save energy; however, because turning a component on again may consume both time and energy, the decision to turn it off must be made carefully. Statistical methods based on Markov models can be used to create effective system-level power management methodologies.

123.6 Summary

Embedded computers promise to solve a critical design bottleneck for SoCs. Because we can design CPUs relatively independently of the programs they run and reuse those CPUs design across many chips, embedded computers help to close the designer productivity gap. Embedded processors, on the other hand, require that many design techniques traditionally reserved for hardware — deadline-driven performance, power minimization, size — must now be applied to software as well. Design methodologies for embedded SoCs must carefully design system architectures that will allow hardware and software components to work together to meet performance, power, and cost goals while implementing complex functionality.

124.4 Interfacing SPICE to MATLAB

Best-Fit Linear Model of a Diode • Op Amp Circuit with Series-
Shunt Feedback Network

124.5 Conclusions

John Okyere Attia

Prairie View A&M University

SPICE is an of the industry standard software for circuit simulation [1]. It can perform DC, AC, transient, Fourier, and Monte Carlo analyses. There are several SPICE-derived simulations packages, including Orcad PSPICE, Meta-software HSPICE, and Intusoft IS-SPICE.

PSPICE contains more features than classical SPICE. Some of the most useful additional features are a post-processor program, PROBE, that can be used for interactive graphical display of simulation results; and an analog behavioral model facility that allows modeling of analog circuit functions by using mathematical equations, tables, and transfer functions [2,3].

MATLAB is primarily a tool for matrix computations [4,5]. MATLAB has a rich set of plotting capabilities. The graphics are integrated in MATLAB. Since MATLAB is also a programming environment, a user can extend the functional capabilities by writing new modules (*m-files*). This chapter shows how the strong features of PSPICE and the powerful functions of MATLAB can be used to perform extensive and complex data analysis of electronic circuits [3,6].

TABLE 124.1 Element Name and Corresponding Element

| First Letter of Element Name | Circuit Element, Sources, and Subcircuit |
|------------------------------|--|
| B | GaAs MES field-effect transistor |
| C | Capacitor |
| D | Diode |
| E | Voltage-controlled voltage source |
| F | Current-controlled current source |
| G | Voltage-controlled current source |
| H | Current-controlled voltage source |
| I | Independent current source |
| J | Junction field-effect transistor |
| K | Mutual inductors (transformers) |
| L | Inductor |
| M | MOS field-effect transistor |
| Q | Bipolar junction transfer |
| R | Resistor |
| S | Voltage-controlled switch |
| T | Transmission line |
| V | Independent voltage source |
| X | Subcircuit |

124.1 PSPICE Fundamentals

A general SPICE program consists of the following components: (a) title; (b) element statements; (c) control statements, and (d) end statement. The following two sections will discuss the element and control statements.

Element Statements

Element statements specify the elements in the circuit. An element statement contains the (a) element name; (b) the circuit nodes to which each element is connected; and (c) the values of the parameters that electrically characterize the element. The element name must begin with a letter of the alphabet that is unique to a circuit element, source, or subcircuit. Table 124.1 shows the beginning alphabet of an element name and the corresponding element.

Circuit nodes are positive integers. The nodes in the circuit need not be numbered sequentially. Node 0 is predefined for ground of a circuit. Element values can be integer, floating point number, and floating point followed by an exponent.

Resistors

The general format for describing resistors is

```
Rname N+ N- value*
```

where the name must start with the letter *R*. *N+* and *N-* are the positive and negative nodes of the resistor, respectively.

Value specifies the value of the resistor. The latter may be positive or negative, but not zero.

Inductors

The general format for describing linear inductors is

```
Lname N+ N- value [IC = initial_current]
```

where the inductor name must start with the letter L , $N+$ and $N-$ are positive and negative nodes of the inductor, respectively, $Value$ specifies the value of the inductance, and the initial condition for transient analysis is assigned using $IC = initial_current$, to specify the initial current.

Capacitors

The general format for describing linear capacitors is

```
Cname N+ N- value [IC = initial_voltage]
```

where the capacitor name must start with the letter C , $N+$ and $N-$ are the positive and negative nodes of the capacitor, respectively, $Value$ indicates the value of the capacitance, and the initial condition for transient analysis is assigned using $IC = initial_voltage$ on the capacitor.

Independent Voltage Source

The general format for describing independent voltage source is

```
Vname N+ N- [DC value] [AC magnitude phase]  
[PULSE V1 V2 td tr tf pw per]
```

or

```
[SIN V0 Va freq td df phase]
```

or

```
[EXP V1 V2 td1 t1 td2 t2]
```

or

```
[PWL t1 V1 t2 V2 . . . tn, Vn]
```

or

```
[SFFM V0 Va freq md fs]
```

where the voltage source must start with letter V , $N+$ and $N-$ are the positive and negative nodes of the source, respectively, and sources can be assigned values for DC analysis [$DC\ value$], AC analysis [$AC\ magnitude\ phase$], and transient analysis. Only one of the transient response source options ($PULSE$, SIN , EXP , PWL , $SFFM$) can be selected for each source. The AC phase angle is in degrees. Discussion on the transient signal generators ($PULSE$, SIN , EXP , PWL , $SFFM$) can be found in Al-Hashimi [2], Attia [3], or Roberts and Sedra [7].

Independent Current Source

The general format for describing independent current source is

```
Iname N+ N- [DC value] [AC magnitude phase]  
[PULSE V1 V2 td tr tf pw per]
```

or

```
[SIN V0 Va freq td df phase]
```

or

```
[EXP V1 V2 td1 t1 td2 t2]
```

or

```
[PWL t1 V1 t2 V2 . . . tn, Vn]
```

or

```
[SFFM V0 Va freq md fs]
```

where the current source must start with letter *I*, *N+* and *N-* are the positive and negative nodes of the source, respectively. Current flows from a positive node to the negative node, and independent current sources can be assigned values for DC analysis [*DC value*], AC analysis [*AC magnitude phase*], and transient analysis. Only one of the transient response source options (*PULSE*, *SIN*, *EXP*, *PWL*, *SFFM*) can be selected for each source. The AC phase angle is in degrees.

124.2 Control Statements

Circuit Title

The circuit title must be the first statement in the SPICE program or circuit netlist. If this is not done, the program will assume that the first statement is the circuit title.

DC Analysis (.DC)

The .DC control statement specifies the values that will be used for DC sweep or DC analysis. The general format for the .DC statement is

```
.DC SOURCE_NAME START-VALUE STOP_VALUE INCREMENT_VALUE
```

where SOURCE_NAME is the name of an independent voltage or current source and START_VALUE, STOP_VALUE and INCREMENT_VALUE represent the starting, ending, and increment values of the source, respectively.

Transient Analysis (.TRAN)

The .TRAN control statement is used to perform transient analysis on a circuit. The general format of the .TRAN statement is:

```
.TRAN TSTEP TSTOP <TSTART> <TMAX> <UIC>
```

where the terms inside the angle brackets are optional, *TSTEP* is the printing or plotting increment, *TSTOP* is the final time of the transient analysis, *TSTART* is the starting time for printing out the results of the analysis. If it is omitted, it is assumed to be zero. The transient analyses always start at time zero, *TMAX* is the maximum step size that PSPICE uses for the purposes of computation. If *TMAX* is omitted, the default is the smallest value of either *TSTEP* or $(TSTOP - TSTART)/50$, and *UIC* (Use Initial Conditions) is used to specify the initial conditions of capacitors and inductors.

There are five SPICE-supplied sources that can be used for transient analysis: (1) *PULSE* (for periodic pulse waveform); (2) *EXP* (for exponential waveform); (3) *PWL* (for piece-wise linear waveform); (4) *SIN* (for a sine wave); and (5) *SFFM* (for frequency-modulated waveform). The format for specifying the above sources for transient analysis can be obtained from Al-Hashimi [2], Attia [3], or Roberts and Sedra [7].

AC Analysis (.AC)

The .AC control statement is used to perform AC analysis on a circuit. The general format of the .AC statement is

```
.AC FREQ_VAR NP FSTART FSTOP
```

where *FREQ_VAR* is one of three keywords that indicates the frequency variation by decade (DEC), octave (OCT), or linearly (LIN), *NP* is the number of points; its interpretation depends on the keyword

TABLE 124.2 Name Types for AC Output Variable

| Output Variable | Meaning |
|-----------------|--|
| V or I | Magnitude of V or I |
| VR or IR | Real part of complex value V or I |
| VI or II | Imaginary part of complex number V or I |
| VM or IM | Magnitude of complex number V or I |
| VDB or IDB | Decibel value of magnitude, i.e., $20 \log 10 V $ or $20 \log 10 I $ |

(DEC, OCT, or LIN) in the FREQ. DEC - NP is the number of points per decade. OCT - NP is the number of points per octave. LIN - NP is the total number of points spaced evenly from frequency FSTART and ending at FSTOP, *FSTART* is the starting frequency; *FSTART* cannot be zero, and *FSTOP* is the final or ending frequency.

Printing Command (.PRINT)

The .PRINT control statement is used to print tabular outputs. The general format of the .PRINT statement is

```
.PRINT ANALYSIS_TYPE OUTPUT_VARIABLE
```

where *ANALYSIS_TYPE* can be *DC*, *AC*, *TRAN*. Only one analysis type must be specified for .PRINT statement and *OUTPUT_VARIABLE* can be voltages or currents. Up to eight output variables can accompany one .PRINT statement. If more than eight output variables are to be printed, additional .PRINT statements can be used.

The output variable may be node voltages and current through voltage sources. PSPICE allows one to obtain current flowing through passive elements. The voltage output variable has the general form

```
V(node 1, node 2) or V(node 1) if node 2 is node "0."
```

The current output variable has the general form

```
I (Vname)
```

where *Vname* is an independent-voltage source specified in the circuit netlist.

For PSPICE, the current output variable can also be specified as *I(Rname)*, where *Rname* is resistance defined in the input circuit. For AC analysis, output voltage and current variables may be specified as real or imaginary magnitude and phase. Table 124.2 shows the name types for AC output variables.

Initial Conditions (.IC, UIC)

The .IC statement is only used when the transient analysis statement, .TRAN, includes the "UIC" option. The initial voltage across a capacitor or the initial current flowing through an inductor can be specified as part of capacitor or inductor component statement. For example, for a capacitor we have

```
Cname N+ N- value IC = initial voltage
```

and for an inductor, we use the statement

```
Lname N+ N- value IC = initial current
```

It should be noted that the initial conditions on an inductor or capacitor are used provided that .TRAN statement includes the "UIC" option.

Several SPICE control commands are shown in [Table 124.3](#). Details of using the control statements can be found in Vladimirescu [1], Al-Hashimi [2], and Attia [3].

TABLE 124.3 Other PSPICE Control Statements

| Control Statement | Description |
|-------------------|---|
| * | * in the first column indicates a comment line. |
| .FOUR | Allows the user to perform Fourier analysis. Fourier components from DC to the <i>n</i> th harmonic are calculated. |
| .MC | Used to vary device parameter and to observe the overall system for variation in circuit parameters. |
| .NODESET | Used to set the operating point at specified nodes of a circuit during the initial run of a transient analysis. |
| .OP | Used to obtain the nodal voltages and the current flowing through independent voltage sources. |
| .SENS | Performs DC sensitivity of circuit element values and variation of model parameters. |
| .TEMP | Used to change the temperature at which a simulation is performed. |
| .TF | Used to obtain the small-signal gain, DC input resistance, and DC output resistance. |
| .WCASE | Causes sensitivity and worst-case analysis to be performed. |

PSPICE Probe Statement (.PROBE)

Probe is a PSPICE interactive graphics processor that allows the user to display SPICE simulation results in graphical format on a computer monitor. Probe has facilities that allow the user to access any point on a displayed graph and obtain its numerical values. In addition, Probe has many built-in functions that enable a user to compute and display mathematical expression that models aspects of circuit behavior. The general format for specifying the probe statement is

```
.PROBE OUTPUT_VARIABLES
```

where *OUTPUT_VARIABLES* can be node voltages and/or devices currents. If no *OUTPUT_VARIABLE* is specified, Probe will save all node voltages and device currents.

124.3 MATLAB Fundamentals

The Colon Symbol

The colon symbol (:) is one of the most important operators in MATLAB. It can be used (a) to create vectors and matrices; (b) to specify sub-matrices and vectors; and (c) to perform iterations.

Creation of Vectors and Matrices

The statement

```
j1 = 1:9
```

will generate a row vector containing the numbers from 1 to 9 with unit increment. Nonunity, positive, or negative increments may be specified.

Specifying Submatrices and Vectors

Individual elements in a matrix can be referenced with subscripts inside parentheses. For example, $j2(4)$ is the fourth element of vector $j2$. Also, for matrix $j3$, $j3(2, 3)$ denotes the entry in the second row and third column. Using the colon as one of the subscripts denotes all of the corresponding row or column. For example, $j3(:,4)$ is the fourth column of matrix $j3$. Also, the statement $j3(2,:)$ is the second row of matrix $j3$. If the colon exists as the only subscript, such as $j3(:)$, the latter denotes the elements of matrix $j3$ strung out in a long column vector.

Iterative Uses of Colon Command

The iterative uses of the colon command are discussed in the next section.

TABLE 124.4 Relational Operators

| Relational Operator | Meaning |
|---------------------|-----------------------|
| < | Less than |
| <= | Less than or equal |
| > | Greater than |
| >= | Greater than or equal |
| == | Equal |
| ~= | Not equal |

FOR Loops

FOR loops allow a statement or group of statements to be repeated a fixed number of times. The general form of a FOR loop is

```
for index = expression
statement group C
end
```

The expression is a matrix and the statement group *C* is repeated as many times as the number of elements in the columns of the expression matrix. The index takes on the elemental values in the matrix expression. Usually, the expression is something like

```
m:n or m:i:n
```

where *m* is the beginning value, *n* the ending value, and *i* the increment.

IF Statements

The general form of the *simple IF statement* is

```
if logical expression 1
statement group G1
end
```

In the case of a simple IF statement, if the logical expression *1* is true, the statement group *G1* is executed. However, if the logical expression is false, the statement group *G1* is bypassed and the program control jumps to the statement that follows the end statement. Several variations of the IF statement are described in Etter [5] and Attia [6].

IF statements use relational or logical operations to determine what steps to perform in the solution of a problem. The relational operators in MATLAB for comparing two matrices of equal size are shown in Table 124.4.

When any one of the above relational operators is used, a comparison is done between the pairs of corresponding elements.

Graph Functions

MATLAB has built-in functions that allow you to generate x-y and 3-D plots. MATLAB also allows you to give titles to graphs, label the x- and y- axes, and add grids to graphs.

X-Y Plots and Annotations

If *x* and *y* are vectors of the same length, then the command

```
plot(x, y)
```

plots the element of *x* (x-axis) versus the elements of *y* (y-axis).

To plot multiple curves on a single graph, one can use the *plot* command with multiple arguments, such as

```
plot(x1, y1, x2, y2, x3, y3, ..., xn, yn)
```

The variables x_1, y_1, x_2, y_2 , and so on are pairs of vector. Each x - y pair is graphed, generating multiple lines on the plot. The above *plot* command allows vectors of different lengths to be displayed on the same graph. MATLAB automatically scales the plots.

When a graph is drawn, one can add a grid, title, label, and x - and y - axes to the graph. The commands for grid, title, x -axis label, and y -axis label are *grid* (grid lines), *title* (graph title), *xlabel* (x -axis label), and *ylabel* (y -axis label), respectively.

Logarithmic and Plot3 Functions

Logarithmic and semilogarithmic plots can be generated using the commands *loglog*, *semilogx*, and *semilogy*. Descriptions of these commands follow:

loglog(x,y) – Generates a plot of $\log_{10}(x)$ versus $\log_{10}(y)$

semilogx(x, y) – Generates a plot of $\log_{10}(x)$ versus linear axis of y

semilogy(x, y) – Generates a plot of linear axis of x versus $\log_{10}(y)$

The *plot3* function can be used to do three-dimensional line plots. The function is similar to the two-dimensional plot function. The *plot3* function supports the same line size, line style, and color options that are supported by the *plot* function. The simplest form of the *plot3* function is

```
plot(x, y, z)
```

where x, y , and z are equal-sized arrays containing the locations of the data points to be plotted.

Subplot Function

The graph window can be partitioned into multiple windows. The *subplot* command allows the user to split the graph into two subdivisions or four subdivisions. The general form of the *subplot* command is

```
subplot(i j k)
```

The digits i and j specify that the graph window is to be split into an i -by- j grid of smaller windows, arranged in i rows and j columns. The digit k specifies the k th window for the current plot. The subwindows are numbered from left to right, top to bottom.

Fprintf

The *fprintf* command can be used to print both text and matrix values. The format for printing the matrix can be specified, and line feed can also be specified. The general form of this command is

```
fprintf('text with format specification', matrices)
```

The format specifier, such as *%7.3e*, is used to show where the matrix value should be printed in the text. *7.3e* indicates that the value should be printed with an exponential notation of 7 digits, 3 of which should be decimal digits.

Other format specifiers are *%c* (single character); *%d* (signed decimal notation); *%e* (exponential notation); *%f* (fixed-point notation); and *%g* (signed decimal number in either *%e* or *%f* format, whichever is shorter). The text with format specification should end with *\n* to indicate the end of line.

M-files

MATLAB is capable of processing a sequence of commands that are stored in files with extension *m*. MATLAB files with extension *m* are called *m-files*. The latter are ASCII text files and are created with a

text editor or word processor. M-files can either be scripts or functions. Script and function files contain a sequence of commands. However, function files take arguments and return values.

Script Files

Script files are especially useful for analysis and design problems that require long sequences of MATLAB commands. With a script file written using a text editor or word processor, the file can be invoked by entering the name of the m-file without the extension. Statements in a script file operate globally on the workspace data.

Function Files

Function files are m-files that are used to create new MATLAB functions. Variables defined and manipulated inside a function file are local to the function, and they do not operate globally on the workspace. However, arguments may be passed into and out of a function file.

The general form of a function file is

```
function variable(s) = function_name (arguments)
% help text in the usage of the function
.
.
end
```

Data Analysis Functions

In MATLAB, data analyses are performed on column-oriented matrices. Variables are stored in the individual column cells, and each row represents different observation of each variable. Functions act on the elements in the column. Table 124.5 gives a brief description of various MATLAB functions for performing data analysis.

TABLE 124.5 Data Analysis Functions

| Function | Description |
|---------------|--|
| corrcoef(x) | Determines correlation coefficients. |
| diff(x) | Computes the differences between elements of an array x. It approximates derivatives. |
| max(x) | Obtains the largest value of x. If x is a matrix, max(x) returns a row vector containing the maximum elements of each column. |
| [y, k]=max(x) | Obtains the maximum value of x and corresponding locations (indices) of the first maximum value for each column of x. |
| mean(x) | Determines the mean or the average value of the elements in the vector. If x is a matrix, mean(x) returns a row vector that contains the mean value of each column. |
| median(x) | Finds the median value of elements in vector x. If x is a matrix, this function returns a row vector containing the median value of each column. |
| min(x) | Finds the smallest value of x. If x is a matrix, min(x) returns a row vector containing the minimum values from each column. |
| [y, k]=min(x) | Obtains the smallest value of x and the corresponding locations(indices) the first minimum value from each column of x. |
| sort(x) | Sort the rows of matrix x in ascending order. |
| std(x) | Calculates and returns the standard deviation of x if it is a one-dimensional array. If x is a matrix, a row vector containing the standard deviation of each column is computed and returned. |
| sum(x) | Calculates and returns the sum of the elements in x. If x is a matrix, this function calculates and returns a row vector that contains the sum of each column. |
| trapz(x,y) | Trapezoidal integration of the function $y = f(x)$. |

TABLE 124.6 Save Command Options

| Option | Description |
|---------------------|--|
| -mat | Save data in MAT file format (default) |
| -ascii | Save data using 8-digit ASCII format |
| -ascii -double | Save data using 16-digit ASCII format |
| -ascii -double -tab | Saves data using 16-digit ASCII format with tabs |

Curve Fitting (Polyfit, Polyval)

The MATLAB *polyfit* function is used to compute the best fit of a set of data points to a polynomial with a specified degree. The general form of the function is

```
poly_xy = polyfit(x, y, n)
```

where x and y are the data points, n is the n -th degree polynomial that will fit the vectors x and y , and $poly_xy$ is a polynomial that fits the data in vector y to x in the least-squares sense. $poly_xy$ returns $(n + 1)$ coefficients in descending powers of x .

Thus, the polynomial fit to vectors x and y is given as

$$poly_xy(x) = a_1x^n + a_2x^{n-1} + \dots + a_m$$

The degree of the polynomial is n and the number of coefficients $m = n + 1$. The coefficients (a_1, a_2, \dots, a_m) are returned by the MATLAB *polyfit* function

Save, Load, and Textread Functions

Save and Load Commands

The *save* command saves data in the MATLAB workspace to disk. The *save* command can store data either in memory-efficient binary format, called a *MAT-file*, or *ASCII file*. The general form of the *save* command is

```
save filename [List of variables] [options]
```

where *save* (without filename, list of variables, and options) saves all the data in the current workspace to a file named *matlab.mat* in the current directory. If a filename is included in the command line, the data will be saved in file "*filename.mat*." If a list of variables is included, only those variables will be saved.

Options for the *save* command are shown in Table 124.6.

MAT-files are preferable for data that are generated to be used by MATLAB. *MAT-files* are platform independent. The files can be written and read by any computer that supports MATLAB. The *ASCII files* are preferable if the data are to be exported or imported to programs other than MATLAB.

The *load* command will load data from *MAT-file* or *ASCII file* into the current workspace. The general format of the *load* command is

```
load filename [options]
```

where *load* (by itself without filename and options) will load all the data in file *matlab.mat* into the current workspace and *load filename* will load data from the specified filename.

Options for the *load* command are shown in Table 124.7.

TABLE 124.7 Load Command Option

| Option | Description |
|--------|--|
| -mat | Load data from MAT file (default in file extension is mat) |
| -ascii | Load data from space-separated file |

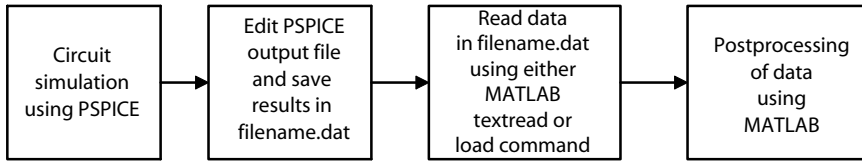

FIGURE 124.1 Flowchart of circuit simulation using PSPICE and post-processing of PSPICE.

TABLE 124.8 Voltage versus Current of a Diode

| Forward-Biased Voltage, V | Forward Current, A |
|---------------------------|--------------------|
| 0.1 | 1.33e-13 |
| 0.2 | 1.79e-12 |
| 0.3 | 24.02e-12 |
| 0.4 | 0.321e-9 |
| 0.5 | 4.31e-9 |
| 0.6 | 57.69e-9 |
| 0.7 | 7.72e-7 |

The Textread Function

The *textread* command can be used to read ASCII files that are formatted into columns of data, where values in each column might be a different type. The general form of the *textread* command is

```
[a, b, c,...] = textread(filename, format, n)
```

where *filename* is the name of file to open. The filename should be in quotes, as in 'filename', *format* is a string containing a description of the type of data in each column. The format list should be in quotes. Supported functions include *%d* (read a signed integer value); *%u* (read an integer value); *%f* (read a floating point value); and *%s* (read a whitespace separated string), *n* is the number of lines to read. If *n* is missing, the command reads to the end of the file, and *a,b,c...* are the output arguments. The number of output arguments must match the number of columns that are being read.

124.4 Interfacing SPICE to MATLAB

To exploit the best features of PSPICE and MATLAB, circuit simulation is performed by using PSPICE. The PSPICE results, which are written into a file, *filename.out*, are edited using a text editor or a word processor and the data will be saved as *filename.dat*. The data are read using either MATLAB *textread* or *load* commands. Further processing of the data is performed using MATLAB. The methodology is shown in Figure 124.1.

In the following examples, the methodology described in this section will be used to analyze data obtained from electronic circuits.

Best-Fit Linear Model of a Diode

A forward biased diode has the corresponding voltage and current shown in Table 124.8. (a) Draw the equation of best fit for the diode data. (b) For the voltage of 0.64 V, what is the diode current?

The MATLAB script for analyzing the diode data follows:

```
% Example of Best-fit linear model
vt = 25.67e-3;
vd = [0.1 0.2 0.3 0.4 0.5 0.6 0.7];
id = [1.33e-13 1.79e-12 24.02e-12...
0.321e-9 4.31e-9 57.69e-9 7.72e-7];%
lnid = log(id);% Natural log of current
```

FIGURE 124.2 Best fit linear model of a diode.

```
% Determine coefficients
pfit = polyfit (vd, lnid, 1);% Curve fitting
% Linear equation is y = mx + b
b = pfit(2);
m = pfit(1);
ifit = m*vd + b;
% Calculate current when diode voltage is 0.64 V
Ix = m*0.64 + b;
I_64v = exp(Ix);
% Plot v versus ln(i) and best-fit linear model
plot(vd, ifit, 'b', vd, lnid, 'ob')
xlabel ('Voltage, V')
ylabel ('ln(i),A')
title ('Best-Fit Linear Model')
fprintf('Diode current for voltage of 0.64V is %9.3e\n', I_64v)
```

The plot is shown in Figure 124.2. Based on MATLAB, the diode current for voltage of 0.64V is 1.629e-007 A.

Op Amp Circuit with Series-Shunt Feedback Network

Figure 124.3 shows an op amp circuit with series-shunt feedback network. $R_S = 1\text{ K}\Omega$, $R_L = 10\text{ K}\Omega$, and $R_1 = 5\text{ K}\Omega$. Find the gain, V_o/V_s if R_F varies from $10\text{ K}\Omega$ to $100\text{ K}\Omega$. Plot voltage gain with respect to R_F . Assume that the op amp is UA741 and the input voltage V_S is sinusoidal waveform with a frequency of 5 KHz and a peak voltage of 1 mV.

PSPICE program for determining the gain follows:

```
* Example - OP AMP CIRCUIT WITH SERIES-SHUNT FEEDBACK
VS 1 0 AC 1E-3 0
RS 1 2 1K
```

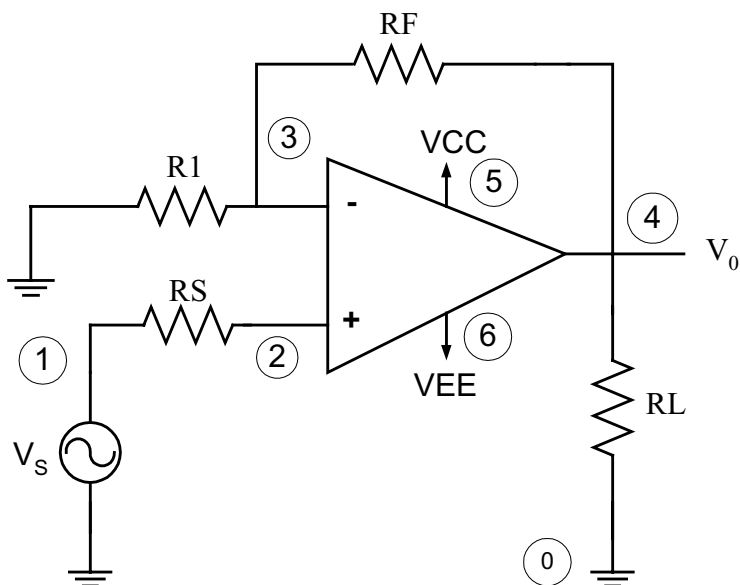

FIGURE 124.3 Op amp circuit with series-shunt feedback network.

The gain versus feedback resistance is shown in Figure 124.4.

124.5 Conclusions

SPICE is an industry-standard software for circuit simulation. MATLAB is primarily a tool for matrix computations. It has numerous functions for data processing and analysis. PSPICE can be used to perform DC, AC, transient, Fourier, temperature and Monte Carlo analysis of electronic circuits with device models and subsystem subcircuits. MATLAB can then be used to perform calculation of device parameters, curve fitting, statistical analysis, and two-dimensional and three-dimensional plots. The strong features of PSPICE and powerful functions of MATLAB, when used in conjunction, allow extensive and complex data analysis of electronic circuits.

Glenn Blackwell
Purdue University

Much like Moore's Law (3) is still true for semiconductor fabrications, the drive for more complexity in less space also continues in packaged assemblies. Smaller passive and integrated circuit (IC) packages and higher I/O counts, along with thinner printed circuit boards (PCBs) and the use of high-density interconnect (HDI) technologies continue to be driven by the desire for smaller, lighter, and higher-performing electronic products. This chapter is intended to provide an overview of currently used electronic packaging technologies, both of IC packages and of circuit board/circuit "packaging" or assemblies. Due to its brevity, the chapter is not intended to provide a comprehensive solution to any particular packaging problem, but rather to only introduce the reader to the breadth of solutions that are available, and to references that will allow the reader to delve further into the issues presented here. It also assumes that the reader is somewhat familiar with basic IC and PCB/PCA terminology, as well as with the three basic surface mount technology (SMT) assembly steps of solder paste deposition, parts placement, and reflow soldering.

IC packages may be developed by a packaging company, or by an IC manufacturer to use for their product. As an example of the proliferation of packages, consider the variety of packages that one manufacturer, Amkor Technology, makes available in several areas of current packaging (1):

- Ball grid array (BGA)
 - Plastic ball grid array (PBGA), the standard BGA package, 119 to 1156 ball count available
 - High-performance BGA (HPBGA), with enhanced thermal performance 276 to 1036 ball count
 - Multichip module BGA (MCM-PBGA), designed to use multiple die in one package, 119 to 1156 ball count
 - SuperBGA (SBGA), with high thermal performance
- Exposed pad technology ICs, with bottom solderable pads (die paddle) that are soldered directly to a corresponding pad on the PCB, for enhanced thermal performance
 - ExposedPad small-outline IC (SOIC), an SOIC with pad, 8 to 28 lead counts available

- ExposedPad TQFP, a thin quad flat pack with pad, 32 to 256 lead counts available
- ExposedPad TSSOP, thin small shrink outline package with pad, 8 to 80 pads available
- Tape packages from Amkor show four variations
- Chip scale packages from Amkor show nine variations

Many other package styles are available from Amkor and from other manufacturers. Examples are shown at websites and data books from Intel (2), Maxim (4), National Semiconductor (5), and others. Because of the proliferation of packages, it is imperative that the user always consult the latest manufacturer data.

Hundreds of published documents and standards exist that are related to many aspects of electronic packaging. Some of the publishers of these documents and standards follow:

- The **JEDEC** (Joint Electron Device Engineering Council) Solid State Technology Association (www.jedec.org) is the semiconductor engineering standardization body of the Electronic Industries Alliance (EIA). JEDEC/EIA publishes over 220 documents related to semiconductor packages and packaging. JEDEC also publishes a number of documents related to the testing of semiconductors.
- The Association Connecting Electronics Industries/IPC (www.ipc.org) publishes over 120 documents related to bare PCB design and manufacturing, and PCA assembly, test, and cleaning. Example IPC standards include:
 - IPC-2220, Design Standard Series
 - IPC7095, Design and Assembly Process Implementation for BGAs
 - J-STD-012,- Implementation of Flip Chip and Chip Scale Technology

Other groups that work in the area of packaging include:

- International Microelectronics and Packaging Society (formerly International Society for Hybrid Microelectronics, ISHM) (www.imaps.org)
- Surface Mount Technology Assn. (www.smta.org)

IC packaging technologies can be divided into the following types:

- Through-hole technology (THT) packaging
- Surface mount technology (SMT) packaging, which includes the following subtypes:
 - Leaded SMT devices
 - Leadless SMT devices
 - Chip scale packages: packaged ICs for which the package size does not exceed the die dimensions by more than 20%
 - Flip chip packages: die that have been passivated and bumped (described later), and are suitable for direct attach without a required protective covering
 - Tape packages, using a flexible tape to connect the die to the package
- Bare die that are suitable for chip-on-board (COB) assembly using ball and/or wedge wire bonding techniques. Protective covering/coating of some type is typically required when bare die are placed on PCAs.

Discussions of the various types of IC packages include the pitch of package terminations. Pitch is defined as the center-to-center dimension of adjacent leads or, for leadless devices, the center-to-center dimension of adjacent terminations.

125.1 IC Packaging

THT packages can be used with the standard SMT solder paste and reflow soldering processes. This “pin in paste” or “intrusive reflow” process is described in several articles (11,12,24,26,31). As THT ICs made up less than 15% of worldwide IC production in 2002, no further specific discussion of these packages is provided in this chapter. The reader is referred to the Intel and National websites, as well as to *The Electronic Packaging Handbook* (14).

FIGURE 125.1 SMT package examples (lead pitch varies).

SMT IC packages undergo the standard manufacturing steps of die mount, wire bonding, and encapsulation. The final lead/termination configuration may be of several styles. These include the j-lead, gull-wing lead, unformed flat pack lead, and leadless terminations. The SMT IC may be in a SOIC, a plastic leaded chip carrier (PLCC), a BGA, a leadless ceramic chip carrier (LLCC), or one of several other SMT package styles. Unfortunately for the engineer and PCB layout designer, there is a lack of standardization in SMT packaging. Packages that are virtually identical in appearance may have a “controlling dimension” in inches or in millimeters. This is also true of passive SMT parts, where a “1206” package capacitor measures $0.120" \times 0.060"$, but a “3216” capacitor measures $3.2 \text{ mm} \times 1.6 \text{ mm}$, making it almost, but not quite, equivalent to a 1206. The 3216 metric capacitor would actually be $0.126" \times 0.063"$. An excellent discussion of passive part types and dimensions can be found in Prasad (27). As of this writing, passive parts are available as small as 0201s ($0.020" \times 0.010"$) (15). Examples of SMT IC packages are shown in Figure 125.1.

In the 1980s and 1990s, a number of IC assembly technologies developed to utilize either bare die or very small packages that approximated the size of bare die. Flip chips use the same bare die as COB, but the bond pads are placed toward the board or “face” down. Also placed face down are chip scale packages (CSPs), which are die enclosed in a package that is no more than 120% of the bare die X-Y dimensions. All of these die-size components are responses to the increasing demands for higher-density, higher-speed performance, and increased functionality.

125.2 PCB Design

The process steps from the design of a schematic to the successful design of a printed circuit board suitable for assembly are many, such as the following:

- Power and ground planes
- Issues relating to RF or fast risetime circuits
- Issues relating to analog and digital circuits on the same board
- Issues relating to testability, that is, design for test (DFT)
- Issues relating to manufacturability, that is, design for manufacturability (DFM)
- Issues relating to overall product packaging

While all of these are very important issues, they are not covered in this chapter and are mentioned only as issues that relate to the choice of both IC and PCB packaging techniques.

FIGURE 125.2 Leaded SMT transistor and diode packages: SOT-23, SOT-223, and TO-252 (DPAK).

125.3 Surface Mount Packages

SMT package types include the following:

- Leadless resistor and capacitor chips
- Leaded transistor and diode packages
- Leaded chip carriers, which have formable leads external to the body of the device
- Leadless chip carriers, which have terminations that adhere to the body of the device
- Area array packages, which have terminations in the form of solder spheres under the body of the device
- Power packages that may be leaded or leadless but which have a metal slug exposed on either the top or bottom of the device, used for attachment to either a separate heat sink or a copper pad on the surface of the PCB

Passive packages are not be discussed further in this chapter.

125.4 Transistor Packages

Leaded SMT packages are used for transistors, diodes, and integrated circuits. Transistors are commonly in a variety of SOT packages, including SOT-23 (also used for diodes), SOT-89, SOT-223, and TO-252 (Motorola D-PAK) packages. Packages such as the SOT-89, SOT-223, and TO-252 are used for high-power devices since they include relatively large solder tabs to improve heat transfer to the board. The SOT-23 package has been modified by several manufacturers to increase the lead count to a total of five or six, and to use them for IC packaging, such as op amps. Overall body size remains the same (Figure 125.2).

125.5 Leaded IC Packages

Selected leaded SMT IC packages are described below. This list should not be considered all inclusive, as new packages and package modifications are released by IC manufacturers on a regular basis.

- The modified SOT-23 package noted above with 25- and 50-mil pitch gull-wing leads.
- PLCCs with 50-mil pitch j-leads. This is the only SMT IC that is easily socketable (Figure 125.3).
- Small outline ICs, with 50-mil (1.27-mm) pitch gull-wing leads. Variations on the SOIC include the thin small outline package (TSOP), and the thin shrink small outline packages (TSSOP) with a 25-mil or 0.65-mm lead pitch (Figure 125.4).
- Quad flat packs (QFPs), with 25-mil (0.65-mm pitch) gull-wing leads (Figure 125.5).
- Flat packs with leads straight out from the four sides of the body. Typically these leads will be formed at the time of part placement.

125.6 Leadless IC Packages

Many packages are available with terminations that wrap around the bottom edge of the IC body, and do not have a formable lead external to the body. These include the leadless ceramic chip carrier (LLCCC) and the “no-lead” quad pack, with the common designation of a QFN package. The QFN, used by Maxim and TI, among others (10), is also available as an exposed pad power package (PQFN), with a solderable

FIGURE 125.3 PLCC-20 with J-leads.

FIGURE 125.4 Small outline IC: SOW-20 with gull-wing leads.

FIGURE 125.5 QFP-132 with gull-wing leads.

die pad under the device to be soldered to a corresponding pad on the PCB to allow for heat transfer to the board.

125.7 Area Arrays

The generic surface mount area array is known as a pad grid array or land grid array. The two most common types of area arrays are the BGA and the column grid array (CGA). Area arrays have a series of pads, with or without attachment interconnections, distributed across the bottom of the package. The pad array may be continuous across the entire surface, it may not be present directly under the die, or there may be a series of thermal pads directly under the die that are not used for I/O but rather for creating thermal connections to the PCB.

The BGA package is a style for which there is an overwhelming amount of information. A search of the Compendex Engineering Index for “ball grid array” results in 1145 articles being returned. Therefore, information about all aspects of BGAs can be found in virtually any technical journal related to the field.

BGAs are SMPs using an array of solder balls on the pads as the interconnect medium (Figure 125.6 and Figure 125.7). A corresponding array of solder lands is present on the board where the BGA will be mounted. The balls will be fused to the package pads by the IC supplier. The balls may be eutectic or near-eutectic solder and are commonly 0.75 mm (0.030”) in diameter. Coplanarity of the balls is very important for acceptable soldering, with a requirement of at least 4 mils for standard 1.27-mm/50-mil pitch parts. BGAs and the smaller micro-BGA packages may have ball pitches of 1.27mm/50 mils, 1 mm/40 mils, down to 0.5 mm/20 mils for some micro BGA (μ BGA) packages.

The BGA may be placed on a substrate with only flux present on the substrate pads or with additional solder paste on the pads. During reflow the balls will collapse to about 80% of their pre-reflow diameter, and during liquidus they will provide some self-centering on the pads. Since the balls collapse during the process, BGA assembly with additional solder paste is robust with regard to reasonable coplanarity issues on the board and of the balls themselves.

Most BGAs are in overmolded plastic packages. As such they are considered a class 3 component, susceptible to moisture absorption, and as such must be placed and reflowed within 24 hours of their

FIGURE 125.6 Ball grid array. BGA-256 with center ball depletion.

removal from dry pack, unless stored in a low-humidity environment. This cannot be emphasized enough, since the molding compound used for most BGAs absorbs moisture at a higher rate than the compound used for other IC packages.

BGAs are considered a viable alternative to QFPs when lead counts exceed 200, or when placement issues of 0.65-mm (0.025") and smaller-pitch QFPs override inspection issues of BGAs. With their higher pitch, BGAs can typically be placed with standard SMT placement systems, requiring less X-Y accuracy than QFPs with their 0.65-mm (0.025") and 0.5-mm (0.020") pitches. Their biggest disadvantage is that only the outer ring of balls/pads can be inspected without x-ray, and there is no reliable way to “touch up” a solder joint. Most manufacturers recommend that any rework be accomplished by removal and replacement of the BGA package.

CGAs have high-temperature columns of solder attached to pads on the bottom of the package. Eutectic solder paste is placed on the pad array of the substrate. When the system is reflowed, only the eutectic solder reflows, leaving the package with a controlled standoff from the substrate. Due to the height of the columns, the package accommodates well to thermal cycling, but uses a less robust placement/assembly procedure than BGAs.

125.8 Chip on Board

COB refers to the placement of bare IC die onto the substrate, with bond pads up. Since most IC die are available in bare die configuration, this assembly technique is usable by any manufacturer willing to make the investment in wire bonding and test equipment (Figure 125.8). In both COB and flip chips, discussed in the next section, multiple die/chips may be combined in a single package resulting in a system in a package (SIP).

In COBs, the die is placed into epoxy on the substrate, and the bond pads are then connected to the substrate using standard IC wire-bonding techniques. Once the bare die are wire bonded, the die and its associated wires are covered with epoxy for both mechanical and environmental protection. Die bond-pad pitch is commonly 0.25 mm (0.010"), with a corresponding requirement for very accurate placement. COB is attractive when space is extremely limited, such as in PCMCIA cards, and when maximum interconnect density is required. This technique is also attractive for low-cost high-volume consumer products, and is used extensively in digital watches and calculators. The die used for COBs are commonly known as “back-bonded” semiconductor chips, since the back of the chip is bonded to the substrate. This results in very good heat transfer to the substrate.

Any operation that uses bare IC die is faced with the issue of known good die (KGD) (9,25). IC manufacturers test bare die for certain performance parameters, but do not do full tests until the die is

FIGURE 125.7 BGA-225 with full ball coverage.

FIGURE 125.8 Example of chip on board.

packaged in its final form. Assemblers considering any of the assembly options discussed in this chapter will need to determine the “goodness” of the bare die they are using. While some IC manufacturers have put KGD testing into place, not all have done so.

One approach to the use of bare die in an assembly is for the user to put into place all the necessary new equipment for not only die mounting and wire bonding, but also for full test and burn in of the bare die. For these purposes, die probe and test carriers are available, and burn-in carrier and socket assemblies have been developed. These allow temporary connection with the die without damaging the die pad area for any subsequent assembly operations.

The EIA through JEDEC has put forth a procurement standard, EIA/JEDEC Standard #49, “Procurement Standard for Known Good Die (KGD).” The intent of this standard is to make suppliers of die aware of “the high levels of as-delivered performance, quality and long term reliability expected of this product type.” The die procured may be used in multichip modules (MCMs) or hybrid assemblies (14,22), or in board-level assemblies such as COB or flip chip components. The standard applies to both military and commercial uses of KGD. It notes that KGD users must recognize that the levels of quality and reliability users have come to expect from packaged devices cannot be assured with bare die, although it also notes that KGD are “intended” to have equivalent or better performance than equivalent packaged parts. It also notes that close cooperation between supplier and user of KGD is a necessity. The standard notes that the user accepts the responsibility for final hermetic sealing and/or plastic encapsulation.

125.9 Flip Chip

Flip chips are passivated IC die placed on the substrate with bond pads down. The lands on the substrate must match the bond pad geometry on the chip. As in COBs, die bond-pad pitch is commonly 0.25 mm (0.010”), with a corresponding requirement for very accurate placement. The die used for flip chip assembly are face-bonded chips. Rather than the “bare” bond pads used on back-bonded chips, face-bonded chips must have prepared bond pads suitable for direct placement and soldering to the substrate lands. Typical pad preparations include

- Solder-coated copper ball
- Bond pad with bump (“bumped” chip)
- Substrate land with bump (Figure 125.9)

Pad bumping is done with solder at each bond pad while the die are still in wafer form, requiring special processing by the die manufacturer. A variety of bumping techniques can be used, and should be

FIGURE 125.9 Example of flip-chip solder bump.

FIGURE 125.10 Flip chip with underfill.

understood by the user (27). After individual die are sliced from the wafer, the chip will be placed on the substrate lands and reflowed in a conventional reflow oven.

Unprotected flip chips are prone to thermally induced cracking, so standard assembly practice is to fill the area under the chip with adhesive in order to equalize the stresses across the chip (Figure 125.10) (13,14).

Bare die, whether wire bonded or flipped, can be placed in a common IC package to create a multichip module (MCM) (14). If the functions of the die combine to form a complete operating unit, this may also be known as a SIP (23,30).

125.10 Chip Scale Packages

CSPs have been defined by the IPC in PAS-62084, “Implementation of Flip Chip and Chip Scale Technology” as IC die that have been enclosed in a package that is no larger than 1.2 times the dimensions of the bare die itself. The packages have pitch dimensions as small as 0.25 mm/10 mil, making them valuable in space-limited applications such as memory products, PC cards, and MCMs.

Substrate, leadframe, and wafer-scale CSPs (some manufacturers also use the term μ BGA) pack more functions into less space than many previous packages (21,26,29). CSPs are available in pin counts from 4 to 48 leads and more, are thin, and have very low parasitics. Most CSPs can be handled by standard placement machines. Current solder deposition and reflow systems are capable of soldering CSPs, most of which have a 0.5-mm lead pitch. Reliability can be an issue, although manufacturers subject these packages to the same reliability criteria applied to other semiconductor packaging styles.

125.11 High-Density Interconnects

In PCB terminology, a through hole is a conductive hole in the board that is used both for interlayer connectivity as well as accommodating a part (THT) lead (Figure 125.11). A via is a conductive hole for interlayer connectivity that may extend through the board or may connect only certain layers. For both through holes and vias, a defining measurement is the “aspect ratio” that relates the diameter of the hole

FIGURE 125.11 Example of PCB and microvia construction.

to the length of the hole. A microvia is defined as a conductive hole that has an aspect ratio of 1:1, which means that a microvia only connects two adjacent conductive layers of the PCB, and the diameter of the hole is equal to the thickness of the one board layer (6,16–19).

While HDI and microvias are in limited use today, the continuing push for smaller circuitry, higher clock speeds, and faster rise times will guarantee that their use will rapidly increase (7,8,18,23).

The fields of RF and microwave engineering involve the exploitation of the electromagnetic spectrum in the hundreds of megahertz to hundreds of gigahertz region. A precise and standard definition of RF signals and microwave signals is not agreed upon, but microwave engineering is identified by certain physical characteristics of circuits, systems, and measurement procedures that are uniquely important at frequencies above several hundred megahertz but below light waves.

Figure 126.1 illustrates schematically the electromagnetic spectrum from audio frequencies through cosmic rays. As seen in the illustration, the RF spectrum is defined loosely as the electromagnetic waves from approximately 300 MHz to 1 GHz, while the microwave spectrum includes frequencies in the 1-GHz to 100-GHz range. Alternatively, the RF and microwave spectrum can be defined in terms of the wavelength, λ_0 , according the expression

$$\lambda_0 = c/f \quad (126.1)$$

where c = velocity of light and f = frequency.

The RF and microwave spectra are further divided into frequency bands as illustrated in Figure 126.2. Although frequency band designation standards using letters to define frequency ranges are presented in the technical literature, competing standard definitions exist and the use of lettered band designations can be misleading. Diagonal hashing at the ends of the frequency bands in Figure 126.2 indicates variations in the definitions by different sources in the literature. The double-ended arrows appearing above some of the bands indicate the definitions by the Institute of Electrical and Electronics Engineers (IEEE) for these bands. Both the IEEE and U.S. military have established letter designations for RF and microwave bands, but the designations are highly dissimilar. Bands identified as D, E, G, and L, for example, exist in both designations but do not identify the same spectra.

126.1 Unique Characteristics

Wavelength Comparable to Component Dimensions

At lower frequencies where the wavelength of the electromagnetic energy is several orders of magnitude larger than the dimensions of the circuit or system being examined, performance analysis using node voltages or loop currents is accurate. Consideration of propagation effects is not required. There is effectively no delay between the cause and effect of current and voltage changes in the system. As the frequency increases, however, the wavelength shrinks until the components (e.g., lumped inductors,

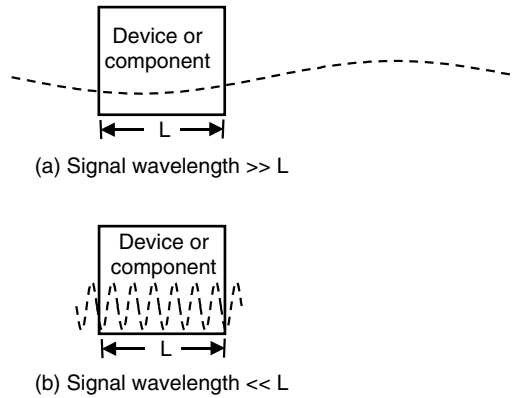

FIGURE 126.3 Illustration of the relationship between device or component dimensions, L , and signal wavelength, λ .

capacitors, or transistors) are of comparable size to the wavelength. Figure 126.3 illustrates this phenomenon. As these frequencies are approached, signal propagation effects become critical to the performance analysis of the circuit or system. Guided waves, signal transmission, signal reflection, and standing waves are key concepts involved in RF and microwave engineering.

Guided Waves

At higher frequencies it is often necessary to consider an electronic signal as an electromagnetic wave and the structure that guides this wave as a transmission line. Thus, wires become transmission lines for the RF and microwave engineer. The properties of transmission lines can be exploited to the advantage of the RF/microwave designer to realize circuit functions with very low loss. The physical realization of high frequency transmission lines come in several forms. Figure 126.4 illustrates some of the most important realizations of transmission lines in RF and microwave systems.

Transmission Lines

Figure 126.4(a) illustrates a two-wire transmission line. This sort of line is common at lower frequencies (television antenna cables often utilize this type of transmission line), but tends to become very lossy and ill behaved electrically at RF and microwave frequencies. The diameter of the wire and separation between the wires are critical parameters in determining the propagation properties of this type of line.

A coaxial cable is illustrated in Figure 126.4(b). This type of cable is very common in RF and microwave systems of all types. In the coaxial cable, a center conductor runs through a dielectric cylinder surrounded by a metallic outer shield. Both the inner and outer conductor diameters as well as the dielectric material properties determine the propagation characteristics of this type of cable. The outer conductor shields the electronic signal from interference and prevents losses due to unwanted signal radiation.

A section of rectangular waveguide is illustrated in Figure 126.4(c). Waveguide structures are used in many legacy microwave systems, but are also important for many high power and millimeter wave systems today. Waveguides consist of a closed conducting structure with a fixed cross section. Waveguides are often air filled but can also be filled with dielectric material. The dimensions of the guide and the dielectric properties determine the propagation characteristics of waveguides. One characteristic that distinguishes the metal waveguide from the other structures of Figure 126.4 is that it consists of a single conductor. This characteristic results in a number of different possible propagation modes for the waveguide. Each propagation mode has distinct velocity and attenuation characteristics. For most applications, single-mode propagation is desired to avoid signal distortion and attenuation. By appropriate selection of the cross-sectional dimensions of the waveguide, a dominant mode can be established over a specific frequency band. At lower frequencies, the wave will not propagate through the guide and at higher frequencies the wave will propagate in undesirable and multiple modes.

FIGURE 126.4 Physical representations of several important guided wave structures.

Figures 126.4(d) and (e) illustrate two realizations of planar-guided wave structures. These types of structures are extremely important in the development of RF and microwave integrated circuits. Since integrated circuits are fabricated as part of the semiconductor wafer production process, the transmission lines that are part of those circuits must be compatible with those planar processes. The microstrip and coplanar waveguide lines are easily fabricated on a semiconductor wafer using normal metal deposition and patterning processes. Both of the planar transmission lines of Figures 126.4(d) and (e) have properties similar to coaxial cable. In the case of microstrip lines, the upper conductor is analogous to the center conductor in the coax while the lower conductor is analogous to the outer conductor. The dielectric thickness and upper conductor line width along with the dielectric properties are the critical parameters that determine the propagation characteristics of microstrip line. In the case of coplanar waveguide, the center conductor is analogous to the center conductor of the coax while the two outer conductors are equivalent to the outer conductor of the coax. Critical parameters that determine propagation characteristics of coplanar waveguide include the width of the center conductor, the spacing between the center and outer conductors and the dielectric properties of the substrate.

All of the transmission line types illustrated in Figure 126.4 can be analyzed and modeled using the equivalent circuit illustrated in Figure 126.5. A differential length of transmission line Δz is associated with the following four characteristic parameters:

- R, resistance per unit length of the conductors (Ω/m),
- L, inductance per unit length of the conductors (H/m),
- G, conductance per unit length (S/m),
- C, capacitance per unit length (F/m).

Analysis of the equivalent circuit results in the definition of important transmission line characteristics. The *characteristic impedance* of a transmission line given in terms of the equivalent circuit is

$$Z_0 = \sqrt{\frac{R + j\omega L}{G + j\omega C}} \quad (126.2)$$

FIGURE 126.5 Distributed equivalent circuit model for a transmission line. (Source: Golio, M., Ed., *RF and Microwave Handbook*, CRC Press, Boca Raton, FL, 2000.)

The characteristic impedance of a transmission line is the impedance that when placed at the termination of the line results in no reflected energy. Such a transmission line is called “matched.”

The *propagation constant* for the transmission line can be written as

$$\gamma = \alpha + j\beta = \sqrt{(R + j\omega L)(G + j\omega C)} \quad (126.3)$$

The *phase velocity* or *propagation velocity* of the electromagnetic energy is expressed as

$$v = \frac{\omega}{\beta} \quad (126.4)$$

Phase velocity is the speed at which energy or information moves along the transmission line.

S-Parameters

To analyze microwave transmission and circuit design problems, generalized parameters are desirable. For low frequency circuits these parameters are often defined in terms of node voltages and currents. Y-parameters, z-parameters and h-parameters are all examples of generalized network parameters that are defined in terms of voltages and currents. At RF and microwave frequencies, however, these parameters are very difficult to measure. The y-, z-, and h-parameters all involve parameter definitions that require that short circuits or open circuits be applied to the network. But at high frequencies, short circuits and open circuits are extremely difficult to realize. Conventional short and open circuits will exhibit stray capacitance and radiation characteristics at high frequencies that will dominate the performance of the structure. In addition, an attempt to provide a short or open circuit to an active device can result in oscillations at unwanted frequencies.

For RF and microwave circuits and systems, it is more convenient to develop parameters based on energy flow through multiport networks. Figure 126.6(a) illustrates a two-port network. A flow graph can be drawn to analyze the energy flow of a two-port network as shown in Figure 126.6(b). The flow graph has two nodes for each port — an incident wave node and a reflected wave node. The incident wave is the *a* node while the reflected wave is the *b* node. The numeral suffix on the *a* and *b* values denotes the port number.

Signal flow through the two-port can be described as follows. A wave incident on port 1 is represented as *a*₁. Part of that wave will be reflected through the *S*₁₁ path and appear as *b*₁. The remainder of that wave goes through the *S*₂₁ path and appears at the output as *b*₂. Similarly, a wave incident at port 2 appears as *a*₂ and is partially reflected through the *S*₂₂ path and partially transmitted through the *S*₁₂ path.

For a two-port device, the four s-parameters can therefore be written as

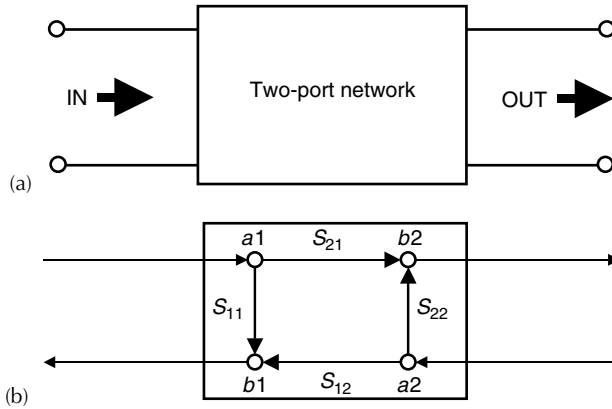

FIGURE 126.6 (a) Simple representation of a two-port network. (b) Flow graph of a two-port network.

$$S_{11} = \left. \frac{b1}{a1} \right|_{Z_0 \text{ load on port 2}} \quad (126.5)$$

$$S_{12} = \left. \frac{b1}{a2} \right|_{Z_0 \text{ load on port 1}} \quad (126.6)$$

$$S_{21} = \left. \frac{b2}{a1} \right|_{Z_0 \text{ load on port 2}} \quad (126.7)$$

$$S_{22} = \left. \frac{b2}{a2} \right|_{Z_0 \text{ load on port 1}} \quad (126.8)$$

These expressions also suggest the means of measuring the s-parameters. S_{11} can be measured when port 2 is terminated with its characteristic impedance by measuring the ratio of the reflected and incident wave. S_{21} is measured with the characteristic impedance termination on port 2 by measuring the ratio of the transmitted to incident wave. S_{22} and S_{12} are similarly measured with port 1 terminated in its characteristic impedance.

The s-parameters defined by Equation (126.5) through Equation (126.8) are complex quantities normally expressed as magnitude and phase. Several scalar quantities that can be defined in terms of s-parameters are also commonly utilized by microwave engineers. Note that S_{11} and S_{22} can be thought of as complex reflection ratios since they represent the magnitude and phase of waves reflected from ports 1 and 2, respectively. It is common to evaluate the quality of the match between components using the *reflection coefficient* defined as

$$\Gamma = |S_{11}| \quad (126.9)$$

for the input reflection coefficient of a two-port network, or

$$\Gamma = |S_{22}| \quad (126.10)$$

for the output reflection coefficient.

Reflection coefficient is often expressed in dB and referred to as *return loss* expressed as

$$L_{return} = -20\log(\Gamma) \quad (126.11)$$

Analogous to the reflection coefficient, both a forward and reverse transmission coefficient can be defined. The forward transmission coefficient is given as

$$T = |S_{21}| \quad (126.12)$$

while the reverse transmission coefficient is expressed as

$$T = |S_{12}| \quad (126.13)$$

As in the case of reflection coefficient, transmission coefficients are often expressed in dB and referred to as *gain* given by

$$G = 20\log(T) \quad (126.14)$$

Another commonly measured and calculated parameter is the *standing wave ratio* or the *voltage standing wave ratio* (VSWR). This quantity is the ratio of maximum to minimum voltage at a given port. It is commonly expressed in terms of a reflection coefficient as

$$(VSWR) = \frac{1 + \Gamma}{1 - \Gamma} \quad (126.15)$$

Propagation and Attenuation in the Atmosphere

Electromagnetic signals are attenuated by the atmosphere as they propagate from source to target. In general, atmospheric attenuation increases with increasing frequency. As shown in Figure 126.7, however, there is significant structure in the atmospheric attenuation versus frequency plot. If only attenuation is considered, it is clear that low frequencies would be preferred for long-range communications systems in order to take advantage of the low attenuation of the atmosphere. If high data rates or large information content is required, however, higher frequencies are needed. In addition to the atmospheric attenuation, the wavelengths of microwave systems are small enough to become affected by water vapor and rain. Above 10 GHz these effects become important. Above 25 GHz, the effect of individual gas molecules

FIGURE 126.7 Attenuation of electromagnetic signals in the atmosphere as a function of frequency.

becomes important. Water and oxygen are the most important gases. These have resonant absorption lines at ~23, ~69, and ~120 GHz. In addition to absorption lines, the atmosphere also exhibits “windows” that may be used for communication, notably at ~38 GHz and ~98 GHz.

RF and microwave signal propagation is also affected by objects such as trees, buildings, towers, and vehicles in the path of the wave. Indoor systems are affected by walls, doors, furniture, and people. The interaction events of electromagnetic signals with objects can be categorized as reflection, refraction, diffraction, and scattering. Reflection occurs when a wave meets a planar object. The wave is reflected back with minimal distortion. Refraction occurs when a wave encounters a medium with a different wave speed (change in dielectric constant). The direction and speed of the wave is altered by refraction events. Diffraction occurs when a wave encounters a corner and is bent around the corner. Diffraction effects are diminished at higher frequencies but can be very important at lower frequencies. Finally, the term *scattering* refers to events that redirect the wave but are too complex to consider only as reflection, refraction, or diffraction.

As a result of the interaction of electromagnetic signals with objects, the propagation channel for wireless communication systems consists of multiple paths between the transmitter and receiver. Each path will experience different attenuation and delay. Some transmitted signals may experience a deep fade (large attenuation) due to destructive multipath cancellation. Similarly, constructive multipath addition can produce signals of large amplitude. Shadowing can occur when buildings or other objects obstruct the line-of-site path between transmitter and receiver.

The design of wireless systems must consider the interaction of specific frequencies of RF and microwave signals with the atmosphere and with objects in the signal channel that can cause multipath effects.

Material Properties

Electrical properties of metals, ceramics, and ferromagnetic materials are different at higher frequencies than they are at DC or low frequencies. The unique high-frequency properties of materials can result in both limitations and opportunities for exploitation to the microwave engineer.

Metals

The conductivity of metal objects is affected dramatically by the penetration of high-frequency electromagnetic fields into a conductor. The field amplitude decays exponentially from its surface value according to

$$A = e^{-x/\delta_s} \quad (126.16)$$

where x is the normal distance into the conductor measured from the surface, and δ_s is the skin depth. The skin depth or depth of penetration into a metal is defined as the distance the wave must travel in order to decay by an amount equal to $e^{-1} = 0.368$ or 8.686 dB. The skin depth δ_s is given by

$$\delta_s = \frac{1}{\sqrt{\pi f \mu \sigma}} \quad (126.17)$$

where f is the frequency, σ is the metal conductivity, and μ is the permeability of the metal is given as

$$\mu = \mu_0 \mu_r \quad (126.18)$$

with μ_0 equal to the permeability of free space and μ_r the relative permeability of the metal. For most metals used as conductors for microwave and RF applications, the relative permeability, μ_r , is equal to 1. The relative permeability of ferroelectric materials such as iron and steel is typically on the order of several hundred.

Skin depth is closely related to the shielding effectiveness of a metal since the attenuation of electric field strength into a metal can be expressed as in Equation (126.16). For static or low-frequency fields,

the only method of shielding a space is by surrounding it with a high-permeability material. For RF and microwave frequencies, however, a thin sheet or screen of metal serves as an effective shield from electric fields.

Skin depth can be an important consideration in the development of guided wave and reflecting structures for high-frequency work. For the best conductors, skin depth is on the order of microns for 1-GHz fields. Since electric fields cannot penetrate very deeply into a conductor, all current is concentrated near the surface. As conductivity or frequency approach infinity, skin depth approaches zero and the current is contained in a narrower and narrower region near the surface of the conductor. For this reason, only the properties of the surface metal affect RF or microwave resistance. A poor conductor with a thin layer of high-conductivity metal will exhibit the same RF conduction properties as a solid high-conductivity structure.

Dielectrics

The dielectric permittivity of ceramics and other commonly used materials varies from DC into the microwave and optical range. Over this range a number of different loss mechanisms must be considered. Dielectric permittivity of a material can be expressed as

$$\epsilon = \epsilon' - j\epsilon'' \tag{126.19}$$

where ϵ' is the real part of the dielectric permittivity. The existence of losses is explicitly included by the imaginary quantity, ϵ'' . Both the real and imaginary parts of Equation (126.19) are a function of frequency.

The general trend of the dielectric permittivity as a function of frequency is shown in Figure 126.8. There are several regimes in which the dielectric permittivity is changing. Each transition in the permittivity represents a distinct interaction mechanism between the field and the material.

In Figure 126.8, the high value of permittivity at low frequency is attributable to interface effects. As the frequency increases, the field polarity begins to move more quickly than the charge in the interface states can respond, and the dielectric permittivity settles to a bulk material value — the value that the material would exhibit if absent of interface charges.

FIGURE 126.8 The real part of permittivity, ϵ' , as a function of frequency. (Source: Golio, M., Ed., *RF and Microwave Handbook*, CRC Press, Boca Raton, FL, 2000.)

As the frequency is further increased, the next polarizability is associated with the material. Perovskites have oxygen vacancies that will exhibit a dipolar polarization. This effect can exhibit resonant frequencies as low as 100 MHz. It can therefore play a role in chip capacitors, which are typically made from mixed or doped perovskites. If appropriate attention is not paid to control the number of vacancies during the manufacturing process, frequency-dependent effects can appear in these devices at relatively low frequencies.

In the frequency range above 1 GHz, there will be contributions to the permittivity due to the ionic separation of the components of a material. Changes in the electromagnetic field at frequencies in this range will result in a decrease in the dielectric permittivity to a new plateau.

A final polarization at extremely high frequencies is the electronic contribution, that is, the distortion induced in the electronic cloud of the material by the external field.

The dielectric behavior presented in [Figure 126.8](#) is somewhat idealized. Typically there are multiple mechanisms and resonances resulting in a distribution of relaxation times. This in turn causes the transitions of [Figure 126.8](#) to be less distinct.

Ferrites

A class of magnetic materials known as ferromagnetic or ferrites has important properties at microwave frequencies, which allows them to be used to advantage for certain circuit functions. Internal magnetic moments in these materials spontaneously align parallel to each other to form domains, resulting in permeabilities considerably higher than unity. RF energy propagating through a ferromagnetic material will interact with the electrons of the material. The interaction results in a resonance behavior in the permeability of the material. The resonance (and therefore the permeability) can be affected by the application of a DC magnetic field. The use of this effect is exploited in the realization of a passive isolator device. Such a device allows a signal to flow nearly unattenuated and undistorted from port 1 to port 2, while a signal flowing from port 2 to port 1 is attenuated significantly. Microwave circulators are also realized using ferromagnetic materials.

Semiconductors

Although semiconductor materials are exploited in virtually all electronics applications today, the unique characteristics of RF and microwave signals require that special attention be paid to specific properties of semiconductors that are often neglected or of second-order importance for other applications. Two critical issues to RF applications are the speed of electrons in the semiconductor material, and the breakdown field of the semiconductor material.

The first issue, speed of electrons, is clearly important because the semiconductor device must respond to high-frequency changes in polarity of the signal. Improvements in efficiency and reductions in parasitic losses are realized when semiconductor materials are used which exhibit high electron mobility and velocity. [Figure 126.9](#) presents the electron velocity of several important semiconductor materials as a function of applied electric field. The carrier mobility is given by

$$\mu_c = \frac{v}{E} \quad \text{for small } E \quad (126.20)$$

where v is the carrier velocity in the material and E is the electric field.

Although silicon is the dominant semiconductor material for electronics applications today, [Figure 126.9](#) illustrates that III-V semiconductor materials such as GaAs, GaInAs, and InP exhibit superior electron velocity and mobility characteristics relative to silicon. Bulk mobility values for several important semiconductors are also listed in [Table 126.1](#). As a result of the superior transport properties, transistors fabricated using III-V semiconductor materials such as GaAs, InP, and GaInAs exhibit higher efficiency and lower parasitic resistance at microwave frequencies.

From a purely technical performance perspective, the above discussion argues primarily for the use of III-V semiconductor devices in RF and microwave applications. These arguments are not complete, however. Most commercial wireless products also have requirements for high-yield, high-volume, low-cost, and rapid product development cycles. These requirements can overwhelm the material selection

FIGURE 126.9 The electron velocity as a function of applied electric field for several semiconductor materials that are important for RF and microwave applications.

TABLE 126.1 Mobility and Breakdown Electric Field Values for Several Semiconductors Important for RF and Microwave Transmitter Applications

| Property | Si | SiC | InP | GaAs | GaN |
|---|-----------------|--------------------------------------|-----------------|-----------------|-------------------|
| Electron mobility (cm^2/Vs) | 1900 | 40 to 1000 | 4600 | 8800 | 1000 |
| Breakdown field (V/cm) | 3×10^5 | 20×10^4 to 30×10^5 | 5×10^5 | 6×10^5 | $>10 \times 10^5$ |

Source: Golio, M., Ed., *RF and Microwave Handbook*, CRC Press, Boca Raton, FL, 2000.

process and they favor mature processes and high-volume experience. The silicon high-volume manufacturing experience base is far greater than that of any III-V semiconductor facility.

The frequency of the application becomes a critical performance characteristic in the selection of device technology. Figure 126.10 illustrates the relationship between frequency of the application and device technology choice. Because of the fundamental material characteristics illustrated in Figure 126.9, silicon technologies will always have lower theoretical maximum operation frequencies than III-V technologies. The higher the frequency of the application, the more likely the optimum device choice will be a III-V transistor over a silicon transistor. Above some frequency (labeled $f_{\text{III-V}}$ in Figure 126.10), III-

FIGURE 126.10 An illustration of the relationship between frequency of application and device technology of choice.

V devices dominate with silicon playing no significant role in the microwave portion of the product. In contrast, below some frequency (labeled f_{Si} in Figure 126.10), the cost and maturity advantages of silicon provide little opportunity for III-V devices to compete. In the transition spectrum between f_{Si} and f_{III-V} , the device technology is not an either/or choice, since silicon and III-V devices coexist. Although silicon devices are capable of operating above frequency f_{Si} , this operation is often gained at the expense of DC current drain. As frequency is increased above f_{Si} in the transition spectrum, efficiency advantages of gallium arsenide and other III-V devices provide competitive opportunities for these parts. The critical frequencies, f_{Si} and f_{III-V} , are not static frequency values. Rather, they are continually being moved upward by the advances of silicon technologies — primarily by decreasing critical device dimensions.

The speed of carriers in a semiconductor transistor can also be affected by deep levels (traps) located physically either at the surface or in the bulk material. Deep levels can trap charge for times that are long compared to the signal period and thereby reduce the total RF power-carrying capability of the transistor. Trapping effects result in frequency dispersion of important transistor characteristics such as transconductance and output resistance. Pulsed measurements as described in Section 126.3 (especially when taken over temperature extremes) can be a valuable tool to characterize deep-level effects in semiconductor devices. Trapping effects are more important in compound semiconductor devices than in silicon technologies.

The second critical semiconductor issue mentioned above is breakdown voltage. The constraints placed on the RF portion of radio electronics are fundamentally different from the constraints placed on digital circuits in the same radio. For digital applications, the presence or absence of a single electron can theoretically define a bit. Although noise floor and leakage issues make the practical limit for bit signals larger than this, the minimum amount of charge required to define a bit is very small. The bit charge minimum is also independent of the radio system architecture, the radio transmission path or the external environment. If the amount of charge utilized to define a bit within the digital chip can be reduced, then operating voltage, operating current or both can also be reduced with no adverse consequences for the radio.

In contrast, the required propagation distance and signal environment are the primary determinants for RF signal strength. If 1 watt of transmission power is required for the remote receiver to receive the signal, then reductions in RF transmitter power below this level will cause the radio to fail. Modern radio requirements often require tens, hundreds, or even thousands of watts of transmitted power in order for the wireless system to function properly. Unlike the digital situation where any discernable bit is as good as any other bit, the minimum RF transmission power must be maintained. A watt of RF power is the product of signal current, signal voltage, and efficiency, so requirements for high power result in requirements for high voltage, high current, and high efficiency.

The maximum electric field before the onset of avalanche breakdown, *breakdown field*, is the fundamental semiconductor property that limits power operation in a transistor. Table 126.1 presents breakdown voltages for several semiconductors that are commonly used in transmitter applications. In addition to silicon, GaAs and InP, two emerging wideband gap semiconductors, and SiC and GaN are included in the table. Interest from microwave engineers in these less mature semiconductors is driven almost exclusively by their attractive breakdown field capabilities. Figure 126.11 summarizes the semiconductor material application situation in terms of the power-frequency space for RF and microwave systems.

126.2 Systems Applications

There are four important classes of applications for microwave and RF systems: communications, navigation, sensors, and heating. Each of these classes of applications benefits from some of the unique properties of high-frequency electromagnetic fields.

Communications

Wireless communications applications have exploded in popularity over the past decade. Pagers, cellular phones, radio navigation, and wireless data networks are among the RF products that consumers are

FIGURE 126.11 Semiconductor choices for RF applications are a strong function of the power and frequency required for the wireless application.

likely to be familiar with. Prior to the growth of commercial wireless communications, RF and microwave radios were in common usage for communications satellites, commercial avionics communications, and many government and military radios. All of these systems benefit from the high frequencies that offer greater bandwidth than low-frequency systems, while still propagating with relatively low atmospheric losses compared to higher-frequency systems.

Cellular phones are among the most common consumer radios in use today. Analog cellular (first generation or 1G cellular) operates at 900-MHz bands and was first introduced in 1983. Second-generation (2G) cellular technology using TDMA, GSM TDMA, and CDMA digital modulation schemes came into use more than 10 years later. The 2G systems were designed to get greater use of the 1.9-GHz frequency bands than their analog predecessors. Emergence of 2.5-G and 3-G systems operating in broader bands as high as 2.1 GHz is happening slowly. These systems make use of digital modulation schemes adapted from 2G GSM and CDMA systems. With each advance in cellular phones, requirements on the microwave circuitry have increased. Requirements for broader bandwidths, higher efficiency, and greater linearity have been coupled with demands for lower cost, lighter, smaller products, and increasing functionality. The microwave receivers and transmitters designed for portable cellular phones represent one of the highest volume manufacturing requirements of any microwave radio. Fabrication of popular cell phones has placed an emphasis on manufacturability and yield for microwave radios that was unheard of prior to the growth in popularity of these products.

Another microwave-based consumer product that is growing dramatically in popularity is the wireless local area network (WLAN) or Wi-Fi. These short-range systems offer data rates more than five times higher than cellular-based products using bandwidth at 2.4 GHz and 5 GHz. Although the volume demands for Wi-Fi components are not as high as for cellular phones, the emphasis on cost and manufacturability is still critical to these products.

Commercial communications satellite systems represent a microwave communications product that is less conspicuous to the consumer, but continues to experience increasing demand. Although the percentage of voice traffic carried via satellite systems is rapidly declining with the advent of undersea fiber-optic cables, new video and data services are being added over existing voice services. Today satellites provide worldwide TV channels, global messaging services, positioning information, communications

TABLE 126.2 Frequency Allocations for Communications Satellites

| Frequency Band (GHz) | Band Designation | Service |
|----------------------|------------------|---|
| 2.500–2.655 | S | Fixed regional systems, space to earth |
| 2.655–2.690 | | Fixed regional systems, earth to space |
| 3.625–4.200 | C | Fixed, space to earth |
| 5.925–6.245 | | Fixed, earth to space |
| 11.700–12.500 | Ku | Fixed, space to earth |
| 14.000–14.500 | | Fixed, earth to space |
| 17.8–18.6 | Ka | GSO FSS, space to earth |
| 19.7–20.2 | Ka | GSO FSS, space to earth |
| 18.8–19.3 | Ka | NGSO FSS, space to earth |
| 19.3–19.7 | Ka | NGSO MSS feeder links, space to earth |
| 27.5–28.35 | Ka | GSO FSS, earth to space (coordination required with LMDS) |
| 28.35–28.6 | Ka | GSO FSS, earth to space |
| 29.5–30.0 | Ka | GSO FSS, earth to space |
| 28.6–29.1 | Ka | NGSO FSS, earth to space |
| 29.1–29.5 | Ka | NGSO MSS feeder links, earth to space |
| 38.5–40.5 | V | GSO, space to earth |
| 37.5–38.5 | V | GSO and NGSO, space to earth |
| 47.2–48.2 | V | GSO, earth to space |
| 49.2–50.2 | V | GSO, earth to space |
| 48.2–49.2 | V | GSO and NGSO, earth to space |

from ships and aircraft, communications to remote areas, and high-speed data services including Internet access. Table 126.2 presents the frequency allocations for satellite communications systems in operation today. These allocations cover extremely broad bandwidths compared to many other communications systems and have spectrums from as low as 2.5 GHz to almost 50 GHz. Future allocations will include even higher frequency bands. In addition to the bandwidth and frequency challenges, microwave components for satellite communications are faced with reliability requirements that are far more severe than any earth-based systems.

Avionics applications include subsystems that perform communications, navigation, and sensor applications. Avionics products typically require functional integrity and reliability that are orders of magnitude more stringent than most commercial wireless applications. The rigor of these requirements is matched or exceeded only by the requirements for space and/or certain military applications. Avionics must function in environments that are more severe than most other wireless applications as well. Quantities for this market are typically very low when compared to commercial wireless applications; for example, the number of cell phones manufactured every single working day far exceeds the number of aircraft that are manufactured in the world in a year. Wireless systems for avionics applications cover an extremely wide range of frequencies, function, modulation type, bandwidth, and power. Due to the number of systems aboard a typical aircraft, *electromagnetic interference (EMI)* and *electromagnetic compatibility (EMC)* between systems are major concerns, and EMI/EMC design and testing are a major factor in the flight certification testing of these systems. RF and microwave communications systems for avionics applications include several distinct bands between 2 and 400 MHz and output power requirements as high as 100 watts.

In addition to commercial communications systems, military communications comprise an extremely important application of microwave technology. Technical specifications for military radios are often extremely demanding. Much of the technology developed and exploited by existing commercial communications systems today was first demonstrated for military applications. The requirements for military radio applications are varied, but will cover broader bandwidths, higher power, more linearity, and greater levels of integration than most of their commercial counterparts. In addition, reliability requirements for these systems are stringent. Volume manufacturing levels, of course, tend to be much lower than commercial systems.

Navigation

Electronic navigation systems represent a unique application of microwave systems. In this application, data transfer takes place between a satellite and a portable radio on earth. The consumer portable product consists of only a receiver portion of a radio. No data or voice signals are transmitted by the portable navigation unit. In this respect, electronic navigation systems resemble a portable paging system more closely than they resemble a cellular phone system. The most widespread electronic navigation system is geographic positioning system (GPS). The nominal GPS constellation is composed of 24 satellites in six orbital planes (four satellites in each plane). The satellites operate in circular 20,200-km-altitude (26,570 km radius) orbits at an inclination angle of 55° . Each satellite transmits a navigation message containing its orbital elements, clock behavior, system time, and status messages. The data transmitted by the satellite is sent in two frequency bands at 1.2 GHz and 1.6 GHz. The portable terrestrial units receive these messages from multiple satellites and calculate the exact location of the unit on the earth. In addition to GPS, other navigation systems in common usage include NAVSTAR, GLONASS, and LORAN.

Sensors (Radar)

Microwave sensor applications are addressed primarily with various forms of radar. Radar is used by police forces to establish the speed of passing automobiles, by automobiles to establish vehicle speed and danger of collision, by air traffic control systems to establish the locations of approaching aircraft, by aircraft to establish ground speed, altitude, other aircraft, and turbulent weather, and by the military to establish a multitude of different types of targets.

The receiving portion of a radar unit is similar to other radios. It is designed to receive a specific signal and analyze it to obtain desired information. The radar unit differs from other radios, however, in that the received signal is typically transmitted by the same unit. By understanding the form of the transmitted signal, the propagation characteristics of the propagation medium and the form of the received (reflected) signal, various characteristics of the radar target can be determined, including size, speed, and distance from the radar unit. As in the case of communications systems, radar applications benefit from the propagation characteristics of RF and microwave frequencies in the atmosphere. The best frequency to use for a radar unit depends upon its application. Like most other radio design decisions, the choice of frequency usually involves tradeoffs among several factors including physical size, transmitted power, and atmospheric attenuation.

The dimensions of radio components used to generate RF power and the size of the antenna required to direct the transmitted signal are, in general, proportional to wavelength. At lower frequencies where wavelengths are longer, the antennae and radio components tend to be large and heavy. At the higher frequencies where the wavelengths are shorter, radar units can be smaller and lighter.

Frequency selection can indirectly influence the radar power level because of its impact on radio size. Design of high-power transmitters requires that significant attention be paid to the management of electric field levels and thermal dissipation. Such management tasks are made more complex when space is limited. Since radio component size tends to be inversely proportional to frequency, manageable power levels are reduced as frequency is increased.

As in the case of all wireless systems, atmospheric attenuation can reduce the total range of the system. Radar systems designed to work above about 10 GHz must consider atmospheric loss at the specific frequency being used in the design.

Automotive radar represents a large class of radars that are used within an automobile. Applications include speed measurement, adaptive cruise control, obstacle detection, and collision avoidance. Various radar systems have been developed for forward-looking, rear-looking and side-looking applications.

V-band frequencies are exploited for forward-looking radars. Within V-band, different frequencies have been used in the past decade, including 77 GHz for U.S. and European systems, and 60 GHz in some Japanese systems. The choice of V-band for this application is dictated by the resolution requirement, antenna size requirement, and the desire for atmospheric attenuation to ensure that the radar is short range. The frequency requirement of this application has contributed to a slow emergence of this

product into mainstream use, but the potential of this product to have a significant impact on highway safety continues to keep automotive radar efforts active.

As in the case of communications systems, avionics and military users also have significant radar applications. Radar is used to detect aircraft both from the earth and from other aircraft. It is also used to determine ground speed, establish altitude, and detect weather turbulence.

Heating

The most common heating application for microwave signals is the microwave oven. These consumer products operate at a frequency that corresponds to a resonant frequency of water. When exposed to electromagnetic energy at this frequency, all water molecules begin to spin or oscillate at that frequency. Since all foods contain high percentages of water, electromagnetic energy at this resonant frequency interacts with all foods. The energy absorbed by these rotating molecules is transferred to the food in the form of heat.

RF heating can also be important for medical applications. Certain kinds of tumors can be detected by the lack of electromagnetic activity associated with them, and some kinds of tumors can be treated by heating them using electromagnetic stimulation.

The use of RF/microwaves in medicine has increased dramatically in recent years. RF and microwave therapies for cancer in humans are presently used in many cancer centers. RF treatments for heartbeat irregularities are currently employed by major hospitals. RF/microwaves are also used in human subjects for the treatment of certain types of benign prostate conditions. Several centers in the United States have been utilizing RF to treat upper airway obstruction and alleviate sleep apnea. New treatments such as microwave-aided liposuction, tissue joining in conjunction with microwave irradiation in future endoscopic surgery, enhancement of drug absorption, and microwave septic wound treatment are continually being researched.

126.3 Measurements

The RF/microwave engineer faces unique measurement challenges. At high frequencies, voltages and currents vary too rapidly for conventional electronic measurement equipment to gauge. Conventional curve tracers and oscilloscopes are of limited value when microwave component measurements are needed. In addition, calibration of conventional characterization equipment typically requires the use of open- and short-circuit standards that are not useful to the microwave engineer. For these reasons, most commonly exploited microwave measurements focus on the measurement of power and phase in the frequency domain as opposed to voltages and currents in the time domain.

Small Signal

Characterization of the linear performance of microwave devices, components, and boards is critical to the development of models used in the design of the next higher level of microwave subsystem. At lower frequencies, direct measurement of y -parameters, z -parameters, or h -parameters is useful to accomplish linear characterization. As discussed previously, however, RF and microwave design utilizes s -parameters for this application. Other small signal characteristics of interest in microwave design include impedance, VSWR, gain, and attenuation. Each of these quantities can be computed from s -parameter data.

The vector network analyzer (VNA) is the instrument of choice for small signal characterization of high-frequency components. [Figure 126.12](#) illustrates a one-port vector network analyzer measurement. These measurements use a source with a well-defined impedance equal to the system impedance and all ports of the device under test (DUT) are terminated with the same impedance. This termination eliminates unwanted signal reflections during the measurement. The port being measured is terminated in the test channel of the network analyzer that has an input impedance equal to the system characteristic impedance. Measurement of system parameters with all ports terminated minimizes the problems caused

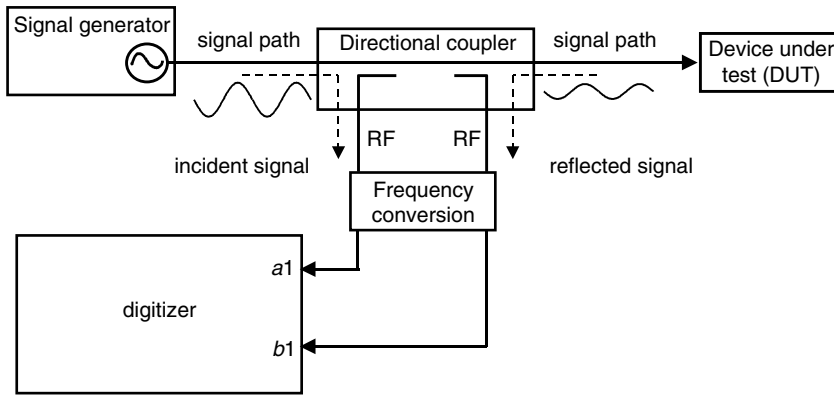

FIGURE 126.12 Vector network analyzer measurement configuration to determine s-parameters of a high-frequency device, component, or subsystem.

by short circuit, open circuit, and test circuit parasitics that cause considerable difficulty in the measurement of y- and h-parameters at very high frequencies. If desired, s-parameters can be converted to y- and h-parameters using analytical mathematical expressions.

The directional coupler shown in Figure 126.12 is a device for measuring the forward and reflected waves on a transmission line. During the network analyzer measurement, a signal is driven through the directional coupler to one port of the DUT. Part of the incident signal is sampled by the directional coupler. On arrival at the DUT port being measured, some of the incident signal will be reflected. This reflection is again sampled by the directional coupler. The sampled incident and reflected signals are then down-converted in frequency and digitized. The measurement configuration of Figure 126.12 shows only one-half of the equipment required to make full two-port s-parameter measurements. Figure 126.13 adds to this configuration to illustrate how two-port s-parameter measurements are accomplished. The s-parameters as defined in Equation (126.5) through Equation (126.18) are determined by analyzing the ratios of the digitized signal data.

For many applications, knowledge of the magnitude of the incident and reflected signals is sufficient. In these cases, the scalar network analyzer can be utilized in place of the vector network analyzer. The cost of the scalar network analyzer equipment is much less than VNA equipment and the calibration required for making accurate measurements is easier when phase information is not required. The scalar network analyzer measures reflection coefficient as defined in Equation (126.9) and Equation (126.10).

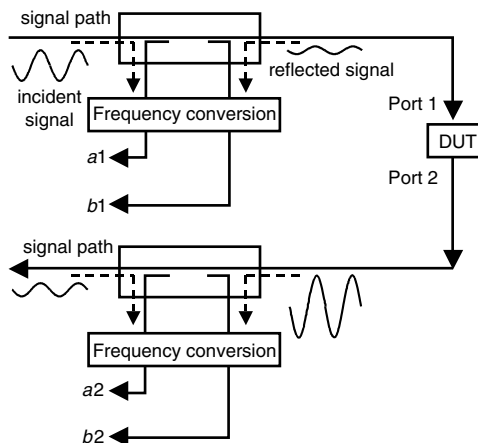

FIGURE 126.13 Full two-port s-parameter measurement configuration.

FIGURE 126.14 Output power versus input power at the fundamental frequency for a nonlinear circuit.

Large Signal

Virtually all physical systems exhibit some form of nonlinear behavior and microwave systems are no exception. Although powerful techniques and elaborate tools have been developed to characterize and analyze linear RF and microwave circuits, it is often the nonlinear characteristics that dominate microwave engineering efforts. Nonlinear effects are not all undesirable. Frequency conversion circuitry, for example, exploits nonlinearities in order to translate signals from one frequency to another. Nonlinear performance characteristics of interest in microwave design include harmonic distortion, gain compression, intermodulation distortion, phase distortion, and adjacent channel power. Numerous other nonlinear phenomena and nonlinear figures of merit are less commonly addressed, but can be important for some microwave systems.

Gain Compression

Figure 126.14 illustrates gain compression characteristics of a typical microwave amplifier with a plot of output power as a function of input power. At low power levels, a single frequency signal is increased in power level by the small signal gain of the amplifier ($P_{out} = G * P_{in}$). At lower power levels, this produces a linear P_{out} versus P_{in} plot with slope = 1 when the powers are plotted in dB units as shown in Figure 126.14. At higher power levels, nonlinearities in the amplifier begin to generate some power in the harmonics of the single frequency input signal and to compress the output signal. The result is decreased gain at higher power levels. This reduction in gain is referred to as *gain compression*. Gain compression is often characterized in terms of the power level when the large signal gain is 1 dB less than the small signal gain. The power level when this occurs is termed the *1dB compression point* and is also illustrated in Figure 126.14.

The microwave spectrum analyzer is the workhorse instrument of nonlinear microwave measurements. The instrument measures and displays power as a function of swept frequency. Combined with a variable power level signal source (or multiple combined or modulated sources), many nonlinear characteristics can be measured using the spectrum analyzer in the configuration illustrated in [Figure 126.15](#).

Harmonic Distortion

A fundamental result of nonlinear distortion in microwave devices is that power levels are produced at frequencies which are integer multiples of the applied signal frequency. These other frequency components are termed *harmonics* of the fundamental signal. Harmonic signal levels are usually specified and measured relative to the fundamental signal level. The harmonic level is expressed in dBc, which designates dB relative to the fundamental power level. Microwave system requirements often place a maximum

FIGURE 126.15 Measurement configuration to characterize gain compression and harmonic distortion. By replacing the signal generator with two combined signals at slightly offset frequencies, the configuration can also be used to measure intermodulation distortion.

acceptable level for individual harmonics. Typically, third and second harmonic levels are critical, but higher-order harmonics can also be important for many applications. The measurement configuration illustrated in Figure 126.15 can be used to directly measure harmonic distortion of a microwave device.

Intermodulation Distortion

When a microwave signal is comprised of power at multiple frequencies, a nonlinear circuit will produce *intermodulation distortion (IMD)*. The IMD characteristics of a microwave device are important because they can create unwanted interference in adjacent channels of a radio or radar system. The intermodulation products of two signals produce distortion signals not only at the harmonic frequencies of the two signals, but also at the sum and difference frequencies of all of the signal's harmonics. If the two signal frequencies are closely spaced at frequencies f_c and f_m , then the IMD products located at frequencies $2f_c - f_m$ and $2f_m - f_c$ will be located very close to the desired signals. This situation is illustrated in the signal spectrum of Figure 126.16. The IMD products at $2f_c - f_m$ and $2f_m - f_c$ are third order products of the desired signals, but are located so closely to f_c and f_m that filtering them out of the overall signal is difficult.

The spectrum of Figure 126.16 represents the nonlinear characteristics at a single power level. As power is increased and the device enters gain compression, however, harmonic power levels will grow more quickly than fundamental power levels. In general, the n^{th} order harmonic power level will increase at n times the fundamental. This is illustrated in the P_{out} versus P_{in} plot of Figure 126.17 where both the fundamental and the third order product are plotted. As in the case of the fundamental power, third-order IMD levels will compress at higher power levels. Intermodulation distortion is often characterized and specified in terms of the *third-order intercept point, IP3*. This point is the power level where the slope of the small signal gain and the slope of the low-power-level, third-order product characteristics cross as shown in Figure 126.17.

FIGURE 126.16 An illustration of signal spectrum due to intermodulation distortion from two signals at frequencies f_c and f_m .

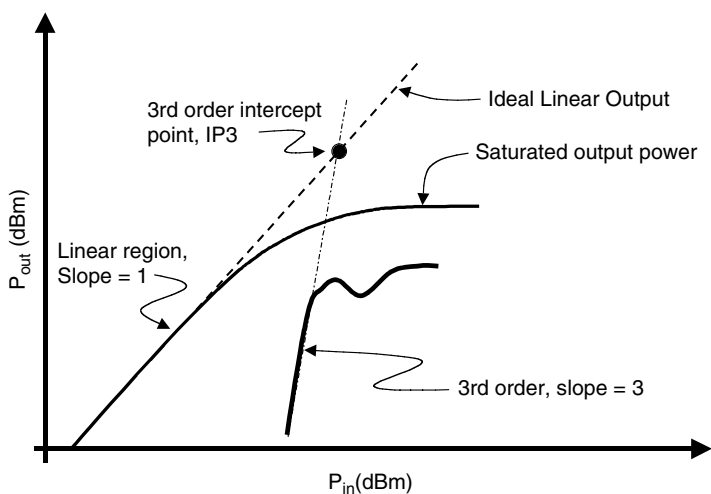

FIGURE 126.17 Relationship between signal output power and intermodulation distortion product levels.

Phase Distortion

Reactive elements in a microwave system give rise to time delays that are nonlinear. Such delays are referred to as *memory effects* and result in *AM-PM distortion* in a modulated signal. AM-PM distortion creates sidebands at harmonics of a modulating signal. These sidebands are similar to the IMD sidebands, but are repeated for multiple harmonics. AM-PM distortion can dominate the out-of-band interference in a radio. At lower power levels, the phase deviation of the signal is approximately linear and the slope of the deviation, referred to as the modulation index, is often used as a figure of merit for the characterization of this nonlinearity. The *modulation index* is measured in degrees per volt using a vector network analyzer. The phase deviation is typically measured at the 1-dB compression point in order to determine the modulation index. Because the vector network analyzer measures power, the computation of modulation index, k_ϕ , uses the formula

$$k_\phi = \frac{\Delta\Phi(P_{1dB})}{2Z_0\sqrt{P_{1dB}}} \quad (126.21)$$

where $\Delta\Phi(P_{1dB})$ is the phase deviation from small signals at the 1-dB compression point, Z_0 is the characteristic impedance of the system, and P_{1dB} is the 1-dB output compression point.

Adjacent Channel Power Ratio

Amplitude and phase distortion affect digitally modulated signals resulting in gain compression and phase deviation. The resulting signal, however, is far more complex than the simple one- or two-carrier results presented previously. Instead of IMD, *adjacent channel power ratio (ACPR)* is often specified for digitally modulated signals. ACPR is a measure of how much power leaks into adjacent channels of a radio due to the nonlinearities of the digitally modulated signal in a central channel. Measurement of ACPR is similar to measurement of IMD, but utilizes an appropriately modulated digital signal in place of a single tone signal generator.

Noise

Noise is a random process that can have many different sources such as thermally generated resistive noise, charge crossing a potential barrier, and generation-recombination (G-R) noise. Understanding noise is important in microwave systems because background noise levels limit the sensitivity, dynamic range, and accuracy of a radio or radar receiver.

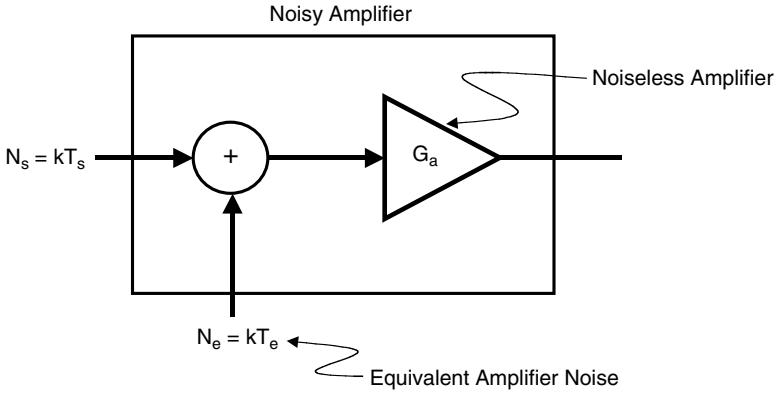

FIGURE 126.18 System view of amplifier noise.

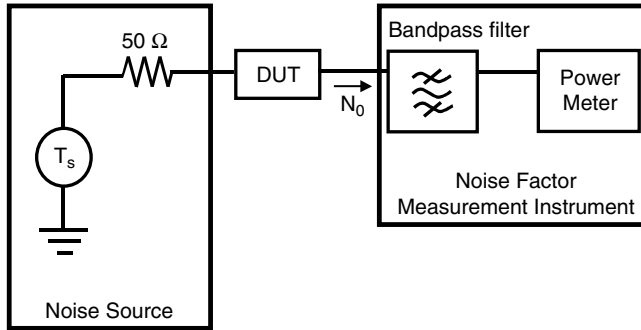

FIGURE 126.19 Measurement configuration for noise factor measurement.

Noise Figure

At microwave frequencies, noise characterization involves the measurement of noise power. The noise power of a linear device can be considered as concentrated at its input as shown in Figure 126.18. The figure considers an amplifier, but the analysis is easily generalized to other linear devices.

All of the amplifier noise generators can be lumped into an equivalent noise temperature with an equivalent input noise power per hertz of $N_e = kT_e$, where k is Boltzmann's constant $\cong 1.38 \times 10^{-23}\ \text{JK}^{-1}$ and T_e is the equivalent noise temperature. The noise power per hertz available from the noise source is $N_s = kT_s$ as shown in Figure 126.18. Since noise limits the system sensitivity and dynamic range, it is useful to examine **noise** as it is related to signal strength using a *signal-to-noise ratio* (SNR). A figure of merit for an amplifier, *noise factor* (F), describes the reduction in SNR of a signal as it passes through the linear device illustrated in Figure 126.18. The noise factor for an amplifier is derived from the figure to be

$$F = \frac{SNR_{IN}}{SNR_{OUT}} = 1 + \frac{T_e}{T_s} \quad (126.22)$$

Device noise factor can be measured as shown in Figure 126.19. To make the measurement, the source temperature is varied resulting in variation in the device noise output, N_0 . The device noise contribution, however, remains constant. As T_s changes, the noise power measured at the power meter changes according to

$$N_0(T_s) = (kT_sG + kT_eG)B \quad (126.23)$$

FIGURE 126.20 Typical phase noise spectrum observed on a spectrum analyzer.

where B is the bandwidth. The value of $N_0(T_S = 0)$ gives the noise power of the device alone. By using two known values of T_S , a value for $N_0(T_S = 0)$ can be computed.

In practice, the noise factor is usually given in decibels and called the *noise figure*, as follows:

$$NF = 10\log F \quad (126.24)$$

Phase Noise

When noise is referenced to a carrier frequency it modulates that carrier and causes amplitude and phase variations known as phase noise. Oscillator phase modulation noise (PM) is much larger than amplitude modulation noise (AM). The phase variations caused by this noise result in *jitter*, which is critical in the design and analysis of digital communication systems.

Phase noise is most easily measured using a spectrum analyzer. Figure 126.20 shows a typical oscillator source spectrum as measured directly on a spectrum analyzer. Characterization and analysis of phase noise are often described in terms of the power ratio of the noise at specific distances from the carrier frequency. This is illustrated in Figure 126.20.

Pulsed I-V

Although most of the measurements commonly utilized in RF and microwave engineering are frequency domain measurements, pulsed measurements are an important exception used to characterize high-frequency transistors. At RF and microwave frequencies, mechanisms known as *dispersion effects* become important to transistor operation. These effects reveal themselves as a difference in I-V characteristics obtained using a slow sweep as opposed to I-V characteristics obtained using a rapid pulse. The primary physical causes of I-V dispersion are thermal effects and carrier traps in the semiconductor. Figure 126.21 illustrates the characteristics of a microwave transistor under DC (solid lines) and pulsed (dashed lines) stimulation. In order to characterize dispersion effects, pulse rates must be shorter than the thermal and trapping time constants that are being monitored. Typically, for microwave transistors, that requires a pulse on the order of 100 ns or less. Similarly, the quiescent period between pulses should be long compared to the measured effects. Typical quiescent periods are on the order of 100 ms or more. The discrepancy between DC and pulsed characteristics is an indication of how severely the semiconductor traps and thermal effects will impact device performance.

FIGURE 126.21 Pulsed I-V characteristics of a microwave FET. Solid lines are DC characteristics while dashed lines are pulsed.

Another use for pulsed I-V measurement is the characterization of high-power transistors. Many high-power transistors (greater than approximately 30 watts) are only operated in a pulsed mode or at a bias level far below their maximum currents. If these devices are biased at higher current levels for a few milliseconds, the thermal dissipation through the transistor will cause catastrophic failure. This is a problem for transistor model development, since a large range of I-V curves — including high current settings — is needed to extract an accurate model. Pulsed I-V data can provide input for model development while avoiding unnecessary stress on the part being characterized.

126.4 Circuits and Circuit Technologies

Figure 126.22 illustrates a generalized radio architecture that is typical of the systems used in many wireless applications today. A signal is received by the antenna and routed via the duplexer to the receive path of the radio. A low noise amplifier (LNA) amplifies the signal before a mixer down-converts it to a lower frequency. The down-conversion is accomplished by mixing the received signal with an internally generated local oscillator (LO) signal. The ideal receiver rejects all unwanted noise and signals. It adds no noise or interference and converts the signal to a lower frequency that can be efficiently processed without adding distortion.

On the transmitter side, a modulated signal is first up-converted, and then amplified by the power amplifier (PA) before being routed to the antenna. The ideal transmitter boosts the power and frequency of a modulated signal to that required for the radio to achieve communication with the desired receiver. Ideally, this process is accomplished efficiently (minimum DC power requirements) and without distortion. It is especially important that the signal broadcast from the antenna include no undesirable frequency components.

To accomplish the required transmitter and receiver functions described above, RF and microwave components must be developed either individually or as part of an integrated circuit.

Low Noise Amplifier

The low noise amplifier is often most critical in determining the overall performance of the receiver chain of a wireless radio. The noise figure of the LNA has the greatest impact of any component on the overall receiver noise figure and receiver sensitivity. The LNA should minimize the system noise figure, provide sufficient gain, minimize nonlinearities, and ensure stable 50-ohm impedance with low power consump-

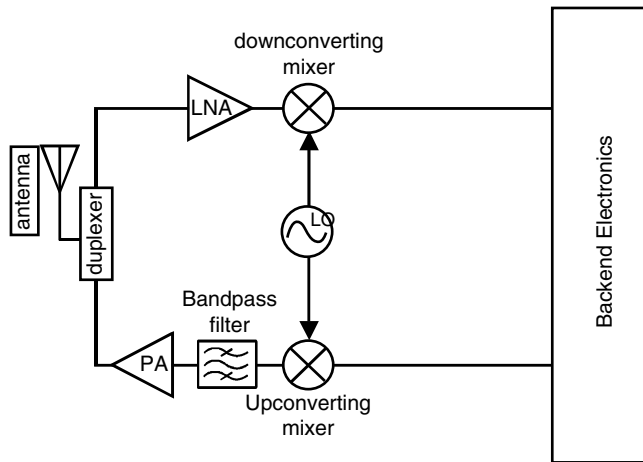

FIGURE 126.22 Generalized microwave radio architecture illustrating microwave components in both receiver and transmitter path. At present, most of the digital systems described in this section of the handbook are implemented in CMOS (complementary metal oxide semiconductor) technology. This technology allows for the fabrication of chips with wiring that is several times thinner than a human hair. Each system is packaged into an integrated circuit. The various layers of silicon and metal defining the circuit are then sent for fabrication. Copies of the same circuit, and sometimes different circuits, are fabricated on the same wafer, as shown here. (Photo courtesy of IBM.)

tion. The two performance specifications of primary importance to determine LNA quality are gain and noise figure.

In many radios, the LNA is part of a single chip design that includes a mixer and other receiver functions as well as the LNA. In these applications, the LNA may be realized using silicon, SiGe, GaAs, or another semiconductor technology. Si bipolar junction transistors and SiGe heterojunction bipolar transistors (HBTs) dominate the LNA business at frequencies below a couple of gigahertz because of their tremendous cost and integration advantages over compound semiconductor devices. Compound semiconductors are favored as frequency increases and noise figure requirements decrease. For applications that require extremely low noise figures, cooled compound semiconductor HEMTs are the favored device.

Power Amplifier

A power amplifier (PA) is required at the output of a transmitter to boost the signal to the power levels necessary for the radio to achieve a successful link with the desired receiver. PA components are often the most difficult and expensive part of microwave radio design. At high power levels, semiconductor nonlinearities such as breakdown voltage become critical design concerns. Thermal management issues related to dissipating heat from the RF transistor can dominate the design effort. Especially in the case of portable radio products, efficiency of the amplifier is critical. PA efficiency is essential to obtain long battery lifetime in a portable product. Critical primary design specifications for PAs include output power, gain, linearity, and efficiency.

Except in the case of very short-range, low-power radios, PA components tend to be discrete devices with minimal levels of integration. The unique semiconductor and thermal requirements of power amplifiers dictate the use of unique fabrication and manufacturing techniques in order to obtain required performance. The power and frequency requirements of the application typically dictate what device technology is required for the power amplifier. At frequencies as low as 1 GHz and power levels of 1 watt, compound semiconductor devices often compete with silicon and SiGe for power amplifier devices. As power and frequency increase from these levels, compound semiconductor HEMTs dominate in this application. Vacuum tube technology is still required to achieve performance for some extremely high-power or high-frequency applications.

Mixer

A mixer is essentially a multiplier and can be realized with any nonlinear device. If at least two signals are present in a nonlinear device, their products will be produced at the device output. The mixer is a frequency-translating device. Its purpose is to translate the incoming signal at frequency, f_{RB} to a different outgoing frequency, f_{IF} . The local oscillator (LO) port of the mixer is an input port and is used to *pump* the RF signal and create the IF signal.

Mixer characterization normally includes the following parameters:

- Input match (at the RF port)
- Output match (at the IF port)
- LO to RF leakage (from the LO to RF port)
- LO to IF leakage (from LO to IF port)
- Conversion Loss (from the RF port to the IF port)

The first four parameters are single frequency measurements similar to s-parameters S_{11} , S_{22} , S_{13} , and S_{23} . Conversion loss is similar to s-parameter S_{21} , but is made at the RF frequency at the input port and at the IF frequency at the output port.

Although a mixer can be made from any nonlinear device, many RF/microwave mixers utilize one or more diodes as the nonlinear element. FET mixers are also used for some applications. As in the case of amplifiers, the frequency of the application has a strong influence on whether silicon or compound semiconductor technologies are used.

RF Switch

RF switches are control elements required in many wireless applications. They are used to control and direct signals under stimulus from externally applied voltages or currents. Phones and other wireless communications devices utilize switches for duplexing and switching between frequency bands and modes.

Switches are ideally a linear device so can be characterized with standard s-parameters. Since they are typically bidirectional, $S_{21} = S_{12}$. Insertion loss (S_{21}) and reflection coefficient (S_{11} and S_{22}) are the primary characteristics of concern in an RF switch. Switches can be reflective (high impedance in the off state) or absorptive (matched in both on and off state).

The two major classes of technologies used to implement switches are PIN diodes and FETs. PIN diode switches are often capable of providing superior RF performance to FET switches but the performance can come at a cost of power efficiency. PIN diodes require a constant DC bias current in the on state while FET switches draw current only during the switching operation. Another important emerging technology for microwave switching is the micro-electro-mechanical systems (MEMS) switch. These integrated circuit devices use mechanical movement of integrated features to open and close signal paths.

Filter

Filters are frequency selective components that are central to the operation of a radio. The airwaves include signals from virtually every part of the electromagnetic spectrum. These signals are broadcast using various modulation strategies from TV and radio stations, cell phones, and base stations, wireless LANs, police radar, and so on. An antenna at the front end of a radio receives all these signals. In addition, many of the RF components in the radio are nonlinear, creating additional unwanted signals within the radio. In order to function properly, the radio hardware must be capable of selecting the specific signal of interest while suppressing all other unwanted signals. Filters are a critical part of this selectivity. An ideal filter would pass desired signals without attenuation while suppressing signals at all other frequencies to elimination.

Although Figure 126.22 shows only one filter in the microwave portion of the radio, filters are typically required at multiple points along both the transmit and receive signal paths. Further selectivity is often accomplished by the input- or output-matching circuitry of amplifier or mixer components.

Filter characteristics of interest include the bandwidth or passband frequencies and the insertion loss within the passband of the filter, as well as the signal suppression outside of the desired band. The quality factor, Q , of a filter is a measure of how sharply the performance characteristics transition between passband and out of band behavior.

At lower frequencies, filters are realized using lumped inductors and capacitors. Typical lumped components perform poorly at higher frequencies due to parasitic losses and stray capacitances. Special manufacturing techniques must be used to fabricate lumped inductors and capacitors for microwave applications. At frequencies above about 5 or 6 GHz, even specially manufactured lumped element components are often incapable of producing adequate performance. Instead, a variety of technologies are exploited to accomplish frequency selectivity. Open- and short-circuited transmission line segments are often realized in stripline, microstrip, or coplanar waveguide forms to achieve filtering. Dielectric resonators, small pucks of high dielectric material, can be placed in proximity to transmission lines to achieve frequency selectivity. Surface acoustic wave (SAW) filters are realized by coupling the electromagnetic signal into piezoelectric materials and tapping the resulting surface waves with appropriately spaced contacts. Bulk acoustic wave (BAW) filters make use of acoustic waves flowing vertically through bulk piezoelectric material. MEMS are integrated circuit devices that combine both electrical and mechanical components to achieve both frequency selectivity and switching.

Oscillator

Oscillators deliver power either within a narrow bandwidth, or over a frequency range (i.e., they are tunable). Fixed oscillators are used for everything from narrowband power sources to precision clocks. Tunable oscillators are used as swept sources for testing, FM sources in communication systems, and the controlled oscillator in a phase locked loop (PLL). Fixed tuned oscillators will have a power supply input and oscillator output, while tunable sources will have one or more additional inputs to change the oscillator frequency. The output power level, frequency of output signal and power consumption are primary characteristics that define oscillator performance. The quality factor, Q , is an extremely important figure of merit for oscillator resonators. Frequency stability (jitter) and tunability can also be critical for many applications.

The performance characteristics of an oscillator depend on the active device and resonator technologies used to fabricate and manufacture the component. Resonator technology primarily affects the oscillators cost, phase noise (jitter), vibration sensitivity, temperature sensitivity, and tuning speed. Device technology mainly affects the oscillator maximum operating frequency, output power, and phase noise (jitter).

Resonator choice is a compromise of stability, cost, and size. Generally the quality factor, Q , is proportional to volume, so cost and size tend to increase with Q . Technologies such as quartz, SAW, yttrium-iron-garnet (YIG), and dielectric resonators allow great reductions in size while achieving high Q by using acoustic, magnetic, and dielectric materials, respectively. Most materials change size with temperature, so temperature stable cavities have to be made of special materials. Quartz resonators are an extremely mature technology with excellent Q , temperature stability, and low cost. Most precision microwave sources use a quartz crystal to control a high-frequency tunable oscillator via a phase locked loop (PLL). Oscillator noise power, and jitter, is inversely proportional to Q^2 , making high resonator Q the most direct way to achieve a low noise oscillator.

Silicon bipolar transistors are used in most low noise oscillators below about 5 GHz. HBTs are common today and extend the bipolar range to as high as 100 GHz. These devices exhibit high gain and superior phase noise characteristics over most other semiconductor devices. For oscillator applications, complementary metal oxide semiconductor (CMOS) transistors are poor performers relative to bipolar transistors, but offer levels of integration that are superior to any other device technology. Above several GHz, compound semiconductor MESFETs and HEMTs become attractive for integrated circuit applications. Unfortunately, these devices tend to exhibit high phase-noise characteristics when used to fabricate oscillators. Transit time diodes are used at the highest frequencies where a solid-state device can be used. IMPATT and Gunn diodes are the most common types of transit time diodes available. The IMPATT

diode produces power at frequencies approaching 400 GHz, but the avalanche breakdown mechanism inherent to its operation causes the device to be very noisy. In contrast, Gunn diodes tend to exhibit very clean signals at frequencies as high as 100 GHz.

- 127.3 INVERTER Circuits
- 127.4 NAND Gates
- 127.5 NOR Gates

Logic devices as discussed in this chapter are of the electronic type and are also called **digital circuits and switching circuits**. Electronic logic devices that are manufactured today are primarily transistor-transistor logic (TTL) circuits and complementary metal oxide semiconductor (CMOS) circuits. Specialized electronic design engineers called *digital circuit designers* design TTL and CMOS switching circuits. *Logic and system designers* gain familiarity with available logic devices via manufacturer's catalogs.

The AND gate, the OR gate, the INVERTER circuit, the NAND gate, and the NOR gate are the fundamental building blocks of practically all electronic manufactured switching circuits. From these fundamental logic devices, larger blocks such as counters, state machines, microprocessors, and computers are constructed. Construction of larger logic devices is accomplished using the mathematics introduced in 1854 by an English mathematician named George Boole [Boole, 1954]. The algebra he invented is appropriately called *Boolean algebra*. It was not until 1938 that Claude Shannon [Shannon, 1938], a research assistant at Massachusetts Institute of Technology (MIT), showed the world how to use Boolean algebra to design switching circuits.

In the following sections the building blocks for the fundamental logic device are discussed, and their truth table functions and Boolean equations are presented.

127.1 AND Gates

The AND logic device is referred to as an *AND gate*. The function it performs is the AND function. The function is most easily represented by a table of truth called a *truth table*, as illustrated in [Table 127.1](#).

The values in the truth table are ones and zeroes, but they could just as easily be trues and falses, highs and lows, ups and downs, or any other symbolic entries that are easily distinguished. The output F is 1 only when both inputs A and B are 1, as illustrated in [Table 127.1](#). For all other input values of A and B the output values of F are 0. [Figure 127.1\(a\)](#) shows the logic symbol for an AND gate with two inputs [ANSI/IEEE Std 91-1984]. The Boolean equation that represents the function performed by the AND gate is written as

$$F = A \text{ AND } B \quad \text{or} \quad F = A \cdot B \quad (127.1)$$

TABLE 127.1 AND Gate Truth Table Function

| <i>A</i> | <i>B</i> | <i>F</i> |
|----------|----------|----------|
| 0 | 0 | 0 |

| 1 | 0 | 0 |
| 1 | 1 | 1 |

FIGURE 127.1 (a) AND gate logic symbol with two inputs; (b) logic symbol for a 3-input AND gate; (c) logic symbol for a 4-input AND gate.

The raised dot represents the AND operator and signifies the operation to be performed on the input variables *A* and *B*, with the result assigned to *F*. For *n* input **switching variables** there are 2^n rows in the truth table and output values for the switching variable *F*. An AND gate can consist of 2 or more inputs. Standard off-the-shelf TTL AND gate devices [Texas Instruments, 1984] have as many as 4 inputs. **Programmable logic devices** (PLDs) that are used to configure larger circuits [Advanced Micro Devices, 1988] either by fuses or by stored charge movement electrically have AND gates with 32 or more inputs. Figure 127.1(b) and Figure 127.1(c) show the logic symbols for a 3-input AND gate and a 4-input AND gate, respectively.

127.2 OR Gates

The OR logic device is referred to as an *OR gate*. The function it performs is the OR function. The truth table function for a 2-input OR gate is shown in Table 127.2.

Like the AND gate, the OR gate can have many inputs. The output *F* for the OR gate is 1 any time one of the inputs *A* or *B* is 1, as illustrated in Table 127.2. When the input values of *A* and *B* are both 0, the output value of *F* is 0. Figure 127.2(a) shows the logic symbol for an OR gate with two inputs. The Boolean equation that represents the function performed by the OR gate is written as

$$F = A \text{ OR } B \quad \text{or} \quad F = A + B \tag{127.2}$$

The plus sign represents the OR operator and signifies the operation to be performed on the input variables *A* and *B*, with the result assigned to *F*. Standard off-the-shelf TTL AND gate devices are generally limited to 2 inputs. Programmable logic devices (PLDs) that are used to configure larger circuits either by fuses or by stored charge movement electrically have OR gates with as many as 9 or more inputs. Figure 127.2(b) shows a logic symbol for a 9-input OR gate. Figure 127.2(c) shows a simplified logic symbol for a 9-input OR gate.

FIGURE 127.2 (a) OR gate logic symbol with two inputs; (b) logic symbol for a 9-input OR gate; (c) simplified logic symbol for a 9-input OR gate.

127.3 INVERTER Circuits

The INVERTER circuit, sometimes called the NOT circuit, is the simplest circuit of the fundamental logic devices because it only has one input. Its truth table function is shown in Table 127.3.

Notice in Table 127.3 that each output value of F is just the opposite of each input value for A . This inverting property provides a simple means of establishing a 1 output when a 0 input is supplied and a 0 output when a 1 input is supplied.

Larger circuits are often formed by connecting the outputs of two or more AND gates to the inputs of an OR gate. This form of configuration is called a **sum-of-products (SOP) form** since the AND gates perform a logic product and the OR gate performs a logic sum — hence the name *sum of products*. Figure 127.3(a) shows the sum-of-products form for a very common logic circuit that performs **modulo 2 addition** called an *exclusive OR*. Observe that the logic symbol for the INVERTER circuit — that is, the triangular symbol with the small circle at the output — is used in two places in the circuit for the exclusive OR. The switching variable A is inverted to obtain \bar{A} by one INVERTER circuit, and B is inverted to obtain \bar{B} by the second INVERTER circuit. The logic symbol for the exclusive OR circuit is shown in Fig. 127.3(b). The truth table function for the Exclusive OR circuit is illustrated in Table 127.4.

The Boolean equation for the exclusive OR circuit is

$$F = A \cdot \bar{B} + \bar{A} \cdot B \quad \text{or} \quad F = A \oplus B \quad (127.3)$$

The circled + symbol is the exclusive OR operator, which allows the functions to be expressed in a simpler form than the first form, which uses the AND operator (the raised dot), the OR operator (the plus symbol), and the INVERTER operator (the overbar).

| 0 | 1 | 1 |
| 1 | 0 | 1 |
| 1 | 1 | 0 |

127.4 NAND Gates

The NAND gate — where NAND stands for NOT AND — is the basic gate perhaps most frequently used. It consists of an AND gate followed by an INVERTER circuit. An off-the-shelf NAND gate is simpler to design, costs less to manufacture, and provides less **propagation delay time** than the equivalent connection of an AND gate followed by an INVERTER circuit. The NAND gate performs the NAND function. The truth table function for a NAND gate with two inputs is shown in Table 127.5.

The output *F* is 0 only when both inputs *A* and *B* are 1, and for all other input values of *A* and *B* the output values of *F* are 1. As might be expected, the output values of *F* in the truth table function for the NAND gate, Table 127.5, are each inverted from those in the truth table function for the AND gate, Table 127.1. The Boolean equation for the NAND gate, Equation (127.4), is the same as the Boolean equation for the AND gate, Equation (127.1), with an added overbar to indicate that the output is inverted:

$$F = A \text{ NAND } B \quad \text{or} \quad F = \overline{A \cdot B} \tag{127.4}$$

Figure 127.4(a) illustrates the logic symbol for a NAND gate with two inputs. Notice that the NAND gate logic symbol simply consists of the AND gate logic symbol with a small circle attached to its output. The small circle indicates inversion like the small circle used in the logic symbol for the INVERTER circuit.

Off-the-shelf TTL NAND gates are available with up to 13 inputs, as illustrated by the logic symbol shown in Figure 127.4(b) for a 13-input NAND gate.

TABLE 127.5 NAND Gate Truth Table Function

| 1 | 0 | 0 |
| 1 | 1 | 0 |

**FIGURE 127.5** (a) NOR gate logic symbol with two inputs.

127.5 NOR Gates

The NOR gate consists of an OR gate followed by an INVERTER circuit. NOR is a contraction of NOT OR. Like the NAND gate, an off-the-shelf NOR gate is simpler to design, costs less to manufacture, and provides less propagation delay time than the equivalent connection of an OR gate followed by an INVERTER circuit. The NOR gate truth table function for two inputs is represented in Table 127.6.

The output F is 1 only when both inputs A and B are 0, and for all other input values of A and B the output values of F are 0. The output values of F in the truth table function for the NOR gate, Table 127.6, are each inverted from those in the truth table function for the OR gate, Table 127.2. The Boolean equation for the NOR gate, Equation (127.5), is the same as the Boolean equation for the OR gate, Equation (127.2), with an added overbar to indicate that the output is inverted.

$$F = A \text{ NOR } B \quad \text{or} \quad F = \overline{A + B} \quad (127.5)$$

The logic symbol for a NOR gate with two inputs is shown in Figure 127.5. The NOR gate logic symbol is represented by the OR gate logic symbol with a small circle attached to its output. As mentioned earlier, the small circle indicates inversion. Off-the-shelf TTL NOR gates are available with up to 5 inputs.

Example. Suppose a three-person digital voting circuit is needed to allow three judges to make a decision on a proposition, and their decision must be indicated as soon as all votes are made. For three judges there must be $2^3 = 8$ rows in the truth table such that each row represents a different combination of judges' votes. The entry 101 would represent judge 1 voting yes, judge 2 voting no, and judge 3 voting yes; the decision for this row would be 1, showing a majority ruling, and the proposition would pass. For the case of 001 the decision for the row would be a 0, showing that a majority was not achieved, and the proposition would fail. The complete truth table function for a three-person voting circuit is shown in Table 127.7.

TABLE 127.7 Truth Table Function for a Three-Person Voting Circuit

| Judge 1 | Judge 2 | Judge 3 | Decision |
|---------|---------|---------|----------|
| 0 | 0 | 0 | 0 |
| 0 | 0 | 1 | 0 |
| 0 | 1 | 0 | 0 |
| 0 | 1 | 1 | 1 |
| 1 | 0 | 0 | 0 |
| 1 | 0 | 1 | 1 |
| 1 | 1 | 0 | 1 |
| 1 | 1 | 1 | 1 |

FIGURE 127.6 (a) Three-person voting circuit in SOP form.

The truth table function for the three-person voting circuit cannot be represented by one of the fundamental logic devices. The circuit requires a combination of the fundamental logic devices. By closely observing the truth table entries, we can write the following Boolean equation for the decision in terms of the three judges' inputs:

$$\begin{aligned} \text{Decision} = & (\text{judge 2 AND judge 3}) \text{ OR } (\text{judge 1 AND judge 3}) \\ & \text{OR } (\text{judge 1 AND judge 2}) \end{aligned} \quad (127.6)$$

which can be written more simply as

$$\text{Decision} = (\text{judge 2} \cdot \text{judge 3}) + (\text{judge 1} \cdot \text{judge 3}) + (\text{judge 1} \cdot \text{judge 2}) \quad (127.7)$$

The circuit for this Boolean equation in SOP form is shown in Figure 127.6. Each input to the circuit can be supplied by an on/off switch that represent a yes/no vote, respectively, and the output can be set up to drive a light *on* (lighted) or *off* (not lighted) to indicate the decision of the voting — where *on* represents a proposition has passed and *off* represents a proposition has failed. Other circuit designs are carried out in a similar manner by logic designers and system designers to build larger circuits and systems.

Logic devices are operated with voltages, so voltage values are sometimes used for the two distinct values, that is, the 1 and 0 discussed earlier. Each symbolic entry in a truth table thus represents a range of voltages. Logic circuits of the same family, such as TTL or CMOS, are designed to be used in combination with other devices of the same family without the user worrying about actual voltages required other than V_{cc} and GND. Most switching circuits today are operated from a 5-volt supply source; however, newer switching circuits are rapidly appearing on the market requiring a 3-volt supply source. Logic devices utilizing a smaller voltage require less power to operate, and portable equipment manufacturers are the first to benefit from this trend in device technology.

Defining Terms

Digital circuits and switching circuits — A class of electronic circuits that operates with two distinct levels.

Modulo 2 addition — Binary addition of two single binary digits, as expressed in Table 118.4.

Programmable logic devices — Logic devices that are either one time programmable by blowing or leaving fuses intact or many times programmable by moving stored charges electrically.

Propagation delay time — Delay time through a logic device from input to output.

Sum-of-products (SOP form) — Very popular form of Boolean equation representation for a switching circuit, also called AND/OR form, since AND gates feed into an OR gate.

Switching variable — Another name for an input variable, output variable, or signal name that can take on only two distinct values.

V_{cc} and GND — Power supply connections required of all electronic devices. For a 5-volt logic device, the 5-volt power supply terminal is connected to the V_{cc} terminal of the device and the power supply ground terminal is connected to the GND terminal of the device.

Charlotte

[128.1 Binary Counters](#)

[128.2 Arbitrary Code Counters](#)

[128.3 Counter Design](#)

[128.4 State Machines](#)

[128.5 State Diagrams](#)

[128.6 State Diagrams Using Transition Expressions](#)

A *counter* is a logic circuit whose outputs follow a defined repeating sequence. After the final number in the sequence is reached, the counter outputs return to the first number. To cause the outputs to change from one number in the sequence to the next, a clock signal is applied to the circuit. A *clock signal* is a logic signal that changes from a logic 0 to a logic 1 and from a logic 1 to a logic 0 at regular intervals. The counter outputs change at one of the transitions of the clock signal, either a 0-to-1 transition or a 1-to-0 transition, depending on the design of the counter and logic components used. Counters are widely used in logic systems to generate control signal sequences and to count events.

128.1 Binary Counters

A common counter is the *binary counter*, whose outputs follow a linearly increasing or decreasing binary number sequence. A *binary-up counter* has outputs that follow a linearly increasing sequence. For example, a 4-bit binary-up counter (a binary-up counter with four outputs) has outputs that follow the sequence: 0000, 0001, 0010, 0011, 0100, 0101, 0110, 0111, 1000, 1001, 1010, 1011, 1100, 1101, 1110, 1111, 0000, ... (i.e., 0, 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15, 0, ... in decimal). A *binary-down counter* is a counter whose outputs follow a counting sequence in reverse order, such as 1111, 1110, 1101, 1100, 1011, 1010, 1001, 1000, 0111, 0110, 0101, 0100, 0011, 0010, 0001, 0000, 1111, ... (i.e., 15, 14, 13, 12, 11, 10, 9, 8, 7, 6, 5, 4, 3, 2, 1, 0, 15, ... in decimal). A *bidirectional counter* is a counter that can count upwards or downwards depending on control signals applied to the circuit. The control signals specify whether the counter is to count up or down.

128.2 Arbitrary Code Counters

Counters can also be designed to follow other sequences. Examples include binary counters that count up to a specific number. For example, a 4-bit binary counter could be designed to count from 0 to 4 repeatedly, rather than from 0 to 15 repeatedly. Such counters can be binary counter designs with additional circuitry to reset the counter after the maximum value required has been reached. A *ring counter*

generates a sequence in which a 1 moves from one position to the next position in the output pattern. For example, the outputs of a 5-bit ring counter follow the sequence: 10000, 01000, 00100, 00010, 00001, 10000, ... A *Johnson counter* or *twisted ring counter* is a ring counter whose final output is “twisted” before being fed back to the first stage, so that when the final output is a 1 the next value of the first output is a 0, and when the final output is a 0 the next value of the first output is a 1. The sequence for a 5-bit Johnson counter is 10000, 11000, 11100, 11110, 11111, 01111, 00111, 00011, 00001, 10000, ... Johnson counters have the characteristic that only one digit changes from one number in the sequence to the next number. This characteristic is particularly convenient in eliminating *logic glitches* that can occur in logic circuits using counter outputs. Logic glitches are unwanted logic pulses of very short duration.

128.3 Counter Design

Most counters are based upon *D-type* or *J-K flip-flops*. *J-K* flops are particularly convenient as they can be made to “toggle” (i.e., change from 0 to 1, or from 1 to 0) if a logic 1 is applied permanently to the *J* output and to the *K* input of the flip-flop. Hence a single *J-K* flip-flop can behave as a one-bit binary counter whose output follows the sequence 0, 1, 0, ... as shown in Figure 128.1. We will describe counter designs using the toggle action of *J-K* flip-flops. In Figure 128.1 the flip-flop output changes on a 1-to-0 transition of the clock signal — that is, a negative *edge-triggered* flip-flop is being used. We shall assume such flip-flops in our designs.

Figure 128.2 shows idealized waveforms of a binary-up counter whose outputs are *A*, *B*, *C*, and *D*. Such counter outputs can be created in one of several ways. There will be one flip-flop for each output and four flip-flops for a 4-bit counter.

FIGURE 128.1 One-bit counter using a *J-K* flip-flop: (a) circuit; (b) output waveform.

FIGURE 128.2 Binary-up counter outputs.

FIGURE 128.3 Asynchronous binary counter.

Counter designs can be classified as synchronous or asynchronous. The key characteristic of any *asynchronous counter* is that the output of one stage is used to activate the next stage. A 4-bit asynchronous binary (up) counter is shown in Figure 128.3. Output A is the least significant bit of the sequence, and output D is the most significant bit. We can understand the operation of this counter by referring to the required counter waveforms shown in Figure 128.2. Output A is to change when there is a 1-to-0 transition on the clock input signal. Output B is to change when there is a 1-to-0 transition on output A. Output C is to change when there is a 1-to-0 transition on output B. Output D is to change when there is a 1-to-0 transition on output C. These transitions are achieved with the connections shown.

The circuit arrangement can be extended to any number of stages. The counter is asynchronous in nature because each output depends on a change in the previous output. Consequently, there will be a small delay between changes in successive outputs. The delays are cumulative, and the overall delay between the first output change and the last output change could be significant, for example, from 1111 to 0000. This delay will limit the rate at which clock pulses can be applied (the maximum frequency of operation). Asynchronous binary counters are sometimes called *ripple counters* because the clock “ripples” through the circuit.

In the *synchronous counter*, we try to avoid delays between successive outputs by synchronizing flip-flop actions. This step is done by connecting the clock signal to all the flip-flop clock inputs. Consequently, when outputs of flip-flops change, the changes occur simultaneously (ignoring variations between flip-flops). Logic is attached to the flip-flop inputs to produce the required sequence. Figure 128.4 shows one design of a synchronous binary (up) counter. We can understand this design also by examining the counter waveforms of Figure 128.2. The first stage is the same as the asynchronous counter, and output changes occur on every activating clock transition. The second stage should toggle if, at the time of the activating clock transition, the A output is a 1. The third stage should toggle if, at the time of the activating clock transition, the A output and the B output are both 1. The fourth stage should toggle if, at the time of the activating clock transition, the A output, the B output, and the C output are all 1. These transitions are achieved by applying A to the J-K inputs of the second stage, the logic functions $A \cdot B$ (i.e., A AND B) to the third stage, and the logic function $A \cdot B \cdot C$ (i.e., A AND B AND C) to the fourth stage. In each case, an AND gate is used in Figure 128.4. The toggle action for a fifth stage occurs when all of A, B, C, and D are a 1, and hence requires a four-input AND gate. Similarly, the sixth stage requires a five-input AND gate, and so on. An alternative implementation that reduces the number of inputs of the gates to two inputs is shown in Figure 128.5. However, this particular implementation has the disadvantage that

FIGURE 128.4 Synchronous binary counter.

FIGURE 128.5 Synchronous binary counter using two-input AND gates.

signals may have to pass through several gates to reach the inputs of flip-flops, which will limit the speed of operation of the counter.

128.4 State Machines

Counters are in the logic classification called *sequential circuits*. The outputs of sequential circuits depend on present inputs and past output values, as opposed to *combinational circuits*, in which the outputs depend only on a particular combination of the present input values. Sequential circuits exist in defined *states*. The state of the circuit changes to another state on application of new input values. Such circuits are called *state machines*. Since in all practical circuits there will be a finite number of states, practical state machines are more accurately called *finite state machines*.

A counter is clearly a circuit that exists in defined states; each state corresponds to one output pattern. Other sequential circuits include circuits that detect particular sequences of input patterns (*sequence detectors*). As parts of the required input pattern are received, the circuit state changes from one state to the next, finally reaching the state corresponding to the complete input pattern being received.

Using *state variables*, each state is assigned a unique binary number, which is stored internally. An n -bit state variable can be used to represent 2^n states. In *one-hot assignment* each state is assigned one unique state variable, which is a 1 when the system is in that state. All other state variables are zero for that state. Hence, with n states, n state variables would be needed. Although the one-hot assignment leads to more state variables, it usually requires less complicated logic.

128.5 State Diagrams

A *state diagram* is a graphical representation of the logical operation of circuits, such as counters, and sequential circuits in general. A state diagram indicates the various states that the circuit can enter and the required input/output conditions necessary to enter the next state. A state diagram of a 3-bit binary (up) counter is shown in Figure 128.6. States are shown by circles. The state number for the state, as given by the state variables, is shown inside each circle. In a counter, the state variables and the counter outputs are the same. Lines between the state circles indicate transitions from one state to the next state, which occurs for a counter circuit on application of the activating clock transition.

Other sequential circuits may have data inputs. For example, a J - K flip-flop is a sequential circuit in its own right, and has J and K inputs as well as a clock input. In that case, we mark the lines between

FIGURE 128.6 State diagram of a binary counter.

FIGURE 128.7 State diagrams of a J - K flip-flop: (a) Moore model state diagram; (b) Mealy model state diagram.

the states in the state diagram with the required input values to cause the state transition. There are two common forms of state diagram for circuits incorporating data inputs — the *Moore model state diagram* and the *Mealy model state diagram*. In both models, the inputs that cause a new state are shown next to the lines. The effects of all combinations of input values must be considered in each state. A line that returns to the same state forms a “sling” and indicates that the state does not change with the particular input values. In the Moore model, the outputs are associated with the states and are shown inside the circles. In the Mealy model, the outputs are associated with input values and resultant states and are shown next to the transition lines between states. Figure 128.7 shows the Moore model state diagram and the Mealy model state diagram for a J - K flip-flop. The fundamental difference between the Moore model state diagram and the Mealy model state diagram is that, in the Moore model state diagram, each state always generates a defined output, whereas in the Mealy model state diagram, states can generate various outputs depending upon present input values. Each model can represent any sequential circuit, although the number of states may be greater in the Moore model state diagram than in the Mealy model state diagram. The information given in the state diagram can be produced in a table called a *state table*.

128.6 State Diagrams Using Transition Expressions

An alternative form of state diagram that is particularly suitable for a state machine with a large number of states marks each line with a Boolean expression that must be true for the transition to occur. All expressions associated with each node must be exclusive of each other (i.e., no combinations of values must make more than one expression true). Also, the set of expressions must cover all combinations of variables. This form of state diagram for a J - K flip-flop is shown in Figure 128.8. In this diagram we can see clearly that the transition from state 1 to state 2 depends only on J being a 1, and the transition from state 2 to state 1 depends only on K being a 1.

FIGURE 128.8 State diagram of a J - K flip-flop using transition expressions.

Defining Terms

Asynchronous sequential logic circuit — A sequential circuit in which a clock signal does not synchronize changes. In an asynchronous sequential logic circuit, changes in more than one output do not necessarily occur simultaneously. Changes in outputs may depend on other output changes.

Combinational logic circuit — A logic circuit whose outputs depend only on present input values.

Edge triggering — A mechanism for activating a flip-flop. In positive edge triggering the output changes after a 0-to-1 logic transition on the clock input. In negative edge triggering the output changes after a 1-to-0 logic transition on the clock input.

Flip-flop — A basic logic circuit that can maintain its output at either 0 or 1 permanently, but whose output can “flip” from 0 to 1 or “flop” from 1 to 0 on application of specific input values. Common flip-flops are the *S-R* flip-flop, the *J-K* flip-flop, and the *D*-type flip-flop. The names are derived from the letters used for the inputs.

Programmable logic sequencers — A logic circuit in the family of programmable logic devices (PLDs) containing the components to implement a synchronous sequential circuit. A programmable logic sequencer has gates and flip-flops with user-selectable feedback connections. See *PAL@ Device Data Book Bipolar and CMOS*, Advanced Micro Devices, Inc., Sunnyvale, CA, 1990; *Digital System Design Using Programmable Logic Devices* by P. Lala, Prentice Hall, Englewood Cliffs, NJ, 1990; or *Programmable Logic*, Intel Corp., Mt. Prospect, IL, 1994, for further details.

Propagation delay — The very short time period in a basic logic circuit between the application of a new input value and the generation of the resultant output.

Sequential logic circuit — A logic circuit whose outputs depend on previous output values and present input values. Sequential circuits have memory to maintain the output values.

Synchronous sequential logic circuit — A sequential circuit in which a clock signal initiates all changes in state.

Further Information

The topic of counters and state machines can be found in most logic design books, a sample of which is listed in the reference section. *Contemporary Logic Design* by Katz is very readable and thorough for the electrical engineer. Other logic design books include:

- Prosser, F. P. and Winkel, D. E. 1987. *The Art of Digital Design*, 2nd ed. Prentice Hall, Englewood Cliffs, NJ.
McCalla, T. R. 1992. *Digital Logic and Computer Design*. Macmillan, New York.

Some books, such as the book by McCalla, integrate logic design with computer design because logic design is used in the design of computers.

129.4 Applications of Microcontrollers

Michael A. Soderstrand

University of California, Davis, and
Oklahoma State University

Every year since 1928, *Time Magazine* has announced in its first issue of the new year the “Man of the Year” for the previous year. Occasionally the “Man of the Year” was a group: *U.S. Fighting Men* in 1951, *U.S. Scientists* in 1961, *Those Under 25* in 1967, *Middle Americans* in 1970, and *American Women* in 1976 [1]. But in the June 3, 1983 issue, *Time Magazine* broke with all tradition with the announcement that the “Man of the Year” for 1982 was not a person at all, but rather *The Machine of the Year: The Computer Moves In* [2]. This was an extraordinary testimonial to a revolution in the making that had its roots in the astonishing development of the microprocessor chip that has revolutionized life throughout the world and invaded, for good or for bad, every aspect of human life. The article quotes an Apple Computer advertisement of the time:

“The ad provides not merely an answer, but 100 of them. A personal computer, it says, can send letters at the speed of light, diagnose a sick poodle, custom-tailor an insurance program in minutes, test recipes for beer. Testimonials abound. Michael Lamb of Tucson figured out how a personal computer could monitor anesthesia during surgery; the rock group Earth, Wind and Fire uses one to explode smoke bombs onstage during concerts; the Rev. Ron Jaenisch of Sunnysvale, Calif., programmed his machine so it can recite an entire wedding ceremony” [2].

The article also reports on a telephone survey of 1019 registered voters conducted December 8 and 9, 1982, with a sampling error of plus or minus 3%:

“A new poll for TIME by Yankelovich, Skelly and White indicates that nearly 80% of Americans expect that in the fairly near future, home computers will be as commonplace as television sets or dishwashers.

Although they see dangers of unemployment and dehumanization, solid majorities feel that the computer revolution will ultimately raise production and therefore living standards (67%), and that it will improve the quality of their children's education (68%)” [2].

Events since 1983 have not only confirmed, but exceeded the expectations outlined in the *Time Magazine* poll. The microprocessor that was and is the heart of the personal computers of 1982 has now expanded into every aspect of life, not just in the United States, but all over the world. Microprocessors, microcomputers, and microcontrollers are now everywhere, and it is virtually impossible to escape their influence. In this brief discussion, we cannot hope to cover but a very small part of the microprocessor story. However, we will provide an introduction to the topic through some critical definitions, a brief history, a review of the key features of microprocessors, a review of microprocessor applications, and finally a few words on where to go to get further information on this important topic.

129.1 Definitions

Figure 129.1 shows the basic architecture (i.e., basic components and their layout) for any computer system. There are four basic components in Figure 129.1: central processing unit (CPU), arithmetic logic unit (ALU), random-access memory (RAM), and input/output devices (I/O).

The CPU is essentially a controller for the operation of the computer. The CPU receives a clock signal (square wave in voltage, digitally this is alternating ones and zeros at the CPU clock frequency). On each cycle of the clock signal, the CPU steps through a standard sequence of operations as follows:

1. Fetch the next instruction from RAM memory.
2. Decode the instruction (i.e., determine what the instruction is asking the computer to do.)

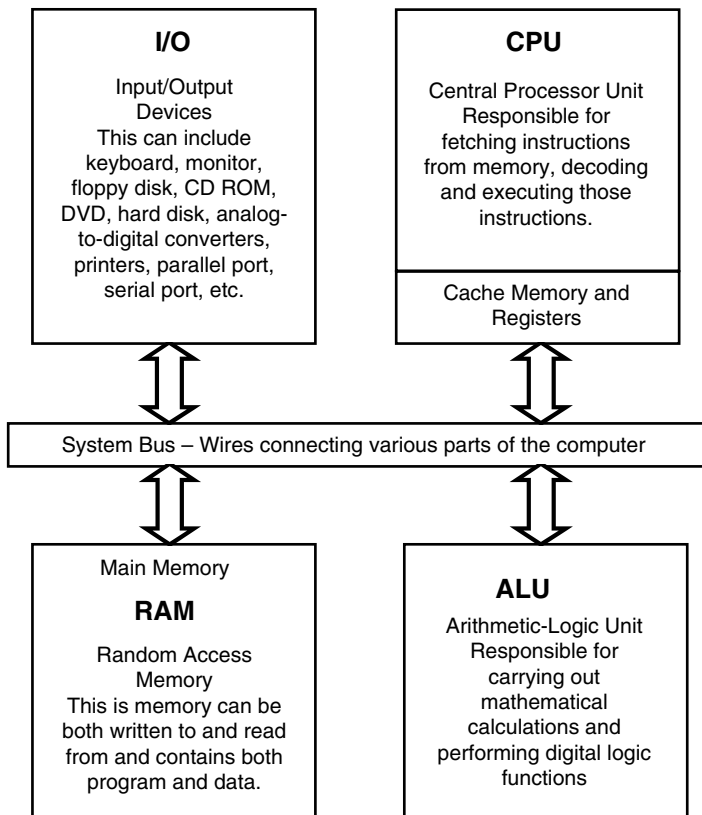

FIGURE 129.1 Architecture of a typical computer.

3. Fetch any data needed for the execution of the instruction from RAM memory and/or from the I/O devices. These data are stored in the CPU registers and/or the ALU.
4. Execute the instruction using the ALU if necessary.
5. Store the results of executing the instruction in RAM memory or send it to the I/O devices. (Note: Some instructions may only affect the CPU, registers or ALU.)

These basic five steps are repeated over and over again. The power of the computer is in the fact that we can store these instructions in RAM memory; hence, we can create very complicated programs that can do significant computing and this computing can be done very fast. For example, modern CPU clocks run in the low gigahertz range (1 billion cycles per second). With a 5-GHz CPU clock, the complete cycle of five steps can be completed 1 billion times every second!

The simple computer architecture of [Figure 129.1](#) represents virtually all computers over the last 5 decades [3]. While modern computers do optimize the various parts of the computer, the basic structure remains intact. There are two significant improvements to this architecture that are worth mentioning, however. The first is the called a reduced instruction set computer (RISC). Initially these computers tried to reduce the number of instructions that the computer had to perform in order to optimize the hardware for fast execution of these instructions. However, the real advantage of RISC turned out to be in regularizing the instructions so that hardware could be designed more efficiently. The opposite of a RISC computer is a complex instruction set computer (CISC). The primary difference between modern RISC and CISC computers is not in the number of instructions, but rather that RISC computers generally take exactly the same amount of time to execute each instruction while CISC computer instructions generally take different amounts of time to execute. A more significant improvement in computer performance comes from the idea of pipelining the steps that the CPU goes through. Pipelining is like an assembly line where parallel hardware executes each of the five steps in assembly line fashion such that it would take five CPU clock cycles for the first instruction to be completed, but after that one instruction per CPU clock cycle will be completed as the other instructions were entered into the pipeline on each subsequent CPU clock. This concept is at the heart of the superscalar computers, which tend to be the fastest-executing modern computers.

Definition of a Microcomputer

In the old days, there were three major categories of computer: mainframe computer, minicomputer, and microcomputer. Generally, mainframe computers were made from discrete components, minicomputers made significant use of very large-scale integrated (VLSI) circuits, and microcomputers used single-chip VLSI circuits for the CPU. No one speaks much of mainframe or minicomputers anymore. Modern computers are more likely to be categorized as supercomputers, workstations, or microcomputers. Supercomputers are special-purpose computers designed for scientific applications (e.g., number crunching) and are typically the fastest computers available today. Workstations are used as servers and high-end personal computers. Microcomputers generally fall into two classes: personal computers designed for use primarily by a single user and special-purpose computers designed to do a particular function, such as control a home appliance or a scientific instrument [4].

Definition of a Microprocessor

A microprocessor is a single-chip VLSI circuit that contains the CPU, registers, cache memory, and part of all of the ALU of [Figure 129.1](#) on a single chip. By definition, a microprocessor does not contain memory or I/O [4].

Definition of a Microcontroller

A single-chip VLSI circuit that contains all of the elements of [Figure 129.1](#) is called a microcontroller. A microcontroller is sometimes defined as a microprocessor with significant amounts of RAM memory and I/O on chip. Microcomputers consist of personal computers (PCs) and microcontrollers. PCs usually

are built from microprocessors with the RAM memory and I/O off chip. Microcontrollers, in contrast, are complete microcomputers of [Figure 129.1](#) on a single VLSI chip [4].

Microcontrollers are single-chip computers that are designed for use in controlling some process. The modern world is full of microcontrollers. They are used in many of our home appliances, home electronics, automobiles, scientific instruments, airplanes, and many other places. On a single chip, modern microcontrollers contain the following:

1. The CPU and ALU or microprocessor
2. Read-only memory (ROM, PROM, or EPROM)
3. Read/write memory (RAM)
4. Input/output devices (serial port, parallel port, analog-to-digital converters [ADCs], digital-to-analog converters [DACs], and so on)
5. On-chip timers
6. Interrupt controller

129.2 Historical Development

In 1971, Intel introduced the Intel 4004 4-bit microprocessor on a single chip. This is generally recognized as the first microprocessor [3]. It was not very powerful; all it could do was add and subtract and it did that with only 4-bit numbers. But it did become the basis for a hand-held portable four-function electronic calculator. In 1972, Intel introduced the 8008, an 8-bit version of the Intel 4004. It too could only add and subtract, but now with 8-bit numbers. However, the really significant breakthrough was the introduction in 1974 of the Intel 8080 microprocessor. The 8080 did not offer much advancement in arithmetic functions over the 8008. It could still only add and subtract 8-bit numbers. But what it did add was a complete computer instruction set including memory reference, input/output control, and bit manipulation and logic functions. The Intel 8080 was to revolutionize the computer industry.

The First Personal Computer — The Mark-8

Researchers at the University of California, Davis, Computer Museum believe that the first personal computer was constructed with the Intel 8008 microprocessor. This computer was called the Mark 8 Computer with 256 bytes of RAM. About 1000 to 2000 of these were marketed starting in July 1974 [5]. The July 1974 issue of *Radio Electronics* featured the Mark 8 Computer on its cover [6,7].

The first portable computer was probably the IBM 5100 which was marketed primarily for business use and introduced by IBM in 1975 [8]. The IBM 5100 had 64 Kbytes of memory, and an integrated 5-inch CRT that could display 16 lines of 64 characters. For about \$20,000, the IBM 5100 included an IBM 5103 dot-matrix printer and an IBM 5106 external tape drive for program storage. It could be programmed in the IBM APL language or in Basic. It had a serial I/O port and a communications adaptor. The CPU was based on an IBM controller called the PALM (put all logic in microcode). The PALM was technically not a microprocessor, but rather a computer controller that executed microcode in order to interpret a higher-level language like APL or Basic [9].

The First Commercially Successful Personal Computer

The first commercially successful personal computer was the Altair 8800 invented and marketed by Ed Roberts, the father of personal computing [8,10,11]. Roberts was a graduate of Oklahoma State University and a personal acquaintance of the author of this article. When the July 1974 issue of *Radio Electronics* featured the Mark-8 computer, Les Solomon, editor of *Popular Electronics*, was desperate to get something on homebrew computers into the magazine. He received a lot of potential articles, but he wanted to feature a personal computer built around the more powerful Intel 8080 or Motorola 6800 microprocessor. Roberts, through his company Micro Instrumentation Telemetry Systems (MITS), was making calculator kits, but exploring the potential of marketing a computer kit based on the Intel 8080. He had a great

deal with Intel getting the \$360 Intel 8080 microprocessor for only \$75 in bulk. MITS initially marketed the basic computer kit with an Intel 8080 microprocessor, 256 bytes of RAM, front panel switches and LEDs, and power supply for \$400, only \$40 more than Intel's price for the microprocessor alone. Solomon's daughter Lauren actually provided the name Altair after the name of a galaxy that the "Star Trek" crew was headed for in one episode. The January 1975 issue of *Popular Electronics* featured the MITS Altair 8800 on the front cover. Roberts hoped to sell about 200 units, but was overwhelmed with orders, ultimately selling over 10,000 Altair 8800 computers in both kit and assembled form. It was this article in *Popular Electronics* that caught the attention of Bill Gates and Steve Jobs, who decided to leave Harvard and come to Albuquerque, New Mexico, to produce software for the Altair 8800. At the time, Roberts had Paul Allen working on software for the Altair, so when Bill Gates showed up in Albuquerque (Jobs stayed in Massachusetts), Ed put all three on the task of building an operating system and a Basic language for the Altair 8800. This eventually led to Jobs forming Apple Computers and Gates and Allen forming Microsoft [11].

Apple and Microsoft

Apple Computers was founded by Steve Jobs, Steve Wozniak, and Ron Wayne in April 1976. The Apple I computer, based on the MOSTek 6502 microprocessor, was first introduced in kit form at the homebrew computer club in Palo Alto, California, in May 1976. Paul Terrell of The Byte Shop was so impressed he ordered 50 units at \$500 apiece [12].

In early 1977, plans were made for the first West Coast Computer Faire, originally scheduled for a small venue in San Francisco. As preregistration increased, the show venue was moved twice, first to a major San Francisco hotel, and then when it outgrew those facilities, to the San Francisco convention center. These moves were all necessary to keep up with the companies that wanted to show their computers at the show and the number of people who wanted to attend. Apple and Commodore were the stars of the show. Apple introduced the Apple II, an extraordinary computer for 1977. It featured a built-in keyboard, a color graphics display (yes, color!), eight expansion slots, and Basic built into a ROM with built-in high-level language graphics commands [8]. The Commodore PET (Personal Electronic Transactor) was also introduced at the 1977 first West Coast Computer Faire. This was the first of a long line of inexpensive computers from Commodore that brought computers to the masses. The Commodore VIC-20 was the first personal computer to sell 1 million units [8].

The IBM-PC and the Information Age

The landmark decision of IBM, the leading business mainframe computer manufacturer, to enter the personal computer market with the announcement of the IBM-PC in 1981 is generally considered to be the dawn of the information age [8]. The IBM-PC made desktop computing a legitimate and eventually essential part of business computing. The original IBM-PC was based on the Intel 8088 chip, a hybrid chip with a 16-bit internal bus and an 8-bit external bus. IBM obtained their operating system for the IBM-PC from Microsoft and bundled in Lotus 1-2-3 business software as part of the package. As was noted in the 1983 *Time Magazine* article [2], this was a significant turning point in the personal computer market and in the dawning of the information age.

Microprocessor Advancement from 1970 to Present

Table 129.1 through Table 129.4 provide data on the advance of microprocessors used by the two major personal computer manufacturers, Apple and Intel. Intel, of course, produced its own chips that were used in IBM-PCs and PC clones (personal computers made by other manufacturers that were compatible with the IBM-PC). Apple, on the other hand, produced some chips of its own, but also purchased chips from various manufacturers. The microprocessors of the 1970s were primarily 8-bit machines implemented in three-micron integrated circuit (IC) technology with clock speeds in the low megahertz range and capable of only about 300,000 to 600,000 instructions per second. The microprocessors of the 1980s

were primarily 16-bit machines implemented in one-micron technology with clock speeds in the 5- to 50-MHz range and capable of 1 to 20 million instructions per second. The microprocessors of the 1990s were primarily 32-bit microprocessors, often with a 64-bit bus, implemented in submicron technology with clock speeds of 50 MHz to 1 GHz and capable of 100 million to a billion instructions per second. The microprocessors of the early 2000s are 64-bit processors in 0.13-micron technology running at clock speeds in the 2- to 5-GHz range and capable of nearly 3 billion instructions per second. The number of transistors on the microprocessor chip increased dramatically from only a few thousand in the early 1970s to 77 million in the early 2000s [13–15].

Microprocessors and Microcontrollers

From Table 129.1 through Table 129.4, we see that the PC market is continually striving for improved performance in microprocessors. These microprocessors for the PC market tend to be relatively expensive (\$500 price range) when they first come out, but then as they are replaced by more powerful microprocessors the prices plummet (usually to less than \$5). Initially, the microcontroller market was comprised primarily of older microprocessors whose values had plummeted so that the price of the microprocessor was so low that they became much more economical in control applications than discrete logic. Applications for the outdated Intel 8080, 8086, and the Motorola 6800, among others, soared as the cost of the processors plummeted. Applications were found in home appliances, intercoms, telephone systems, security systems, garage door openers, answering machines, FAX machines, TVs, cable TV tuners, VCRs,

camcorders, remote controls, video games, cellular phones, musical instruments, sewing machines, lighting controls, pagers, cameras, pinball machines, exercise equipment, microwaves, copiers, printers, automobile trip counters, automobile engine controls, air bags, instrumentation, electronic entertainment equipment, climate control, keyless entry, and a host of others. Microprocessor manufacturers quickly realized that there was a huge market for microcontrollers and quickly modified some of their older

(a)

(b)

microprocessors to include on-chip RAM and ROM, serial and parallel I/O, timers, A/D and D/A converters and other support for control applications revamping the old microprocessors into microcomputers marketed as microcontrollers for embedded systems. Figure 129.2 shows a comparison of microprocessor (MPU) and microcontroller (MCU) sales during the 1990s. Figure 129.2(a) depicts worldwide dollar sales, and Figure 129.2(b) worldwide unit sales. Several things become very clear from Figure 129.2. First, Figure 129.2(a) shows that microprocessor (MPU) sales have grown only slightly, hovering around 200 million units per year while microcontroller (MCU) sales have grown dramatically from 1.7 billion units in 1991 to over 3 billion units in 1995. In 1995, about 15 microcontrollers were sold for every microprocessor sold. Of course, the microprocessors are much more expensive and hence constitute significant dollar sales. Figure 129.2(b) compares the dollar sales of microprocessors (MPU) vs. microcontrollers (MCU). Despite the soaring unit price of microprocessors and the relatively low price of microcontrollers, the dollar sales track very well with over \$10 billion in sales of microcontrollers in 1995 and around \$14 billion sales in microprocessors [17].

Figure 129.3 compares the types of microcontrollers sold during the 1990s. Figure 129.3(a) plots the total sales of microprocessors plus microcontrollers, increasing from \$6 billion in 1990 to \$18 billion in 2000. Figure 129.3(b) looks at microcontroller dollar sales for 4-bit, 8-bit, and 16/32-bit microcontrollers. One sees a relatively constant market for the very inexpensive 4-bit processors (just under \$2 billion per year), strong growth in the 8-bit microcontrollers (from \$2 billion in 1990 to \$10 billion in 2000) and

(a)

(b)

FIGURE 129.3 MPU and MCU sales: (a) total sales of MPU and MCU in billions of dollars; (b) sales of 4-bit, 8-bit and 16/32-bit MCUs's in billions of dollars.

an exponential growth in 16/32-bit processors starting from nearly nothing in 1990 and growing to nearly \$5 billion in 2000 [18].

129.3 Key Features of Modern Microprocessors and Microcontrollers

Both microprocessors and microcontrollers implement part or all of [Figure 129.1](#). However, the microprocessors emphasize the CPU and ALU functions, while microcontrollers balance CPU and ALU functions against RAM, ROM, and particularly I/O functions. [Table 129.1](#) through [Table 129.4](#) chart the progress of microprocessors over 4 decades. The clear trend is increasing power of the processor with faster CPU clocks, larger data widths, powerful floating-point ALUs, and more instructions per second. On the other hand, the most popular microcontrollers are based on older microprocessors such as the 8080, 8086, or 80186. By adding such things as a ROM containing a basic interpreter, RAM for program and data storage, A/D, D/A, serial and parallel I/O, and a set of timers, these older microprocessors are transformed into microcontrollers that are very low priced (average \$3 per unit) and very well suited for embedded processor applications. [Table 129.5](#) lists some of the major producers of microcontrollers and their 4-bit, 8-bit, 16-bit, and 32-bit lines.

The Most Popular Microcontroller: The 8051 (Intel and Others)

The 8051 was originally released by Intel in 1980 and quickly became the most popular microcontroller for embedded applications. Today many variants of the 8051 are available from multiple manufacturers. The 8051 is an 8-bit microprocessor with reasonable power at very low price. The 8051 is a modified Harvard architecture that has a separate memory for data and instructions allowing a single-cycle fetch of both instruction and data. The 8051 has a CPU with a Boolean processor, features five or six interrupts and two or three 16-bit timer counters. The I/O contains a full-duplex serial port and four 8-bit parallel ports. It comes with both on-chip RAM and EPROM. Strong points of the 8051 are its simple interrupt structure and the Boolean processor that allows for very simple bit testing and manipulation. The addressing structure is somewhat confusing, but very powerful.

The 8051 has the widest range of variants of any microcontroller. Atmel makes the smallest device, Dallas makes the fastest device and Siemens makes the most powerful. Unit costs for 8051 variants range from as low as \$3.30 to as high as \$40 depending on the features. The 8051 supports four separate memories: on-board RAM (only 128 or 256 bytes); external RAM (up to 64 Kbytes); on board EPROM (4 Kbytes or 8 Kbytes); and external EPROM (64 Kbytes).

Old PC Microprocessor Often Used as Microcontroller: The Z80 (Zilog)

In July 1976, Zilog introduced the Z80 microprocessor chip to compete with Intel's 8080 and 8085. The Z80 can execute 8080 code but includes powerful extension to the code. Many personal computers of the late 1970s and early 1980s were based on the Z80. Today the Z80 and its family (Z8 and Z180) are very popular as microcontrollers because of their very low cost (less than \$1) and powerful instruction set. The Z80 is an 8-bit CPU with 16-bit addresses that can address 64 Kbytes of memory. Zilog's Z180, 84013, and 14015, Hitachi's 64180, and Toshiba's 84013 and 84015 are enhanced versions of the Z80 that integrate many of the traditional peripheral functions onto the chip while maintaining upgrade compatibility with the Z80 but with much lower power requirements. They also add additional features, such as watchdog timers, clock generators, and additional 16-bit parallel I/O ports.

A Microcontroller for Hobbyists and Robotics: The 68HC11 (Motorola and Others)

Motorola introduced the 6800 series of 8-bit microprocessors back in 1975 to compete with the Intel 8080. The 68HC11 is an upgraded version of the 6800 series that integrates many peripheral functions

onto the chip. Like the Intel 8051, the 68HC11 has an 8-bit CPU with 16-bit address lines that can address 64 Kbytes of memory. However, the 68HC11 has a common memory structure where data, instructions, I/O and timers all share the same memory space. Part of the reason for the popularity of the 68HC11 with hobbyists and robotics is the fact that various models of the microprocessor come with EPROM, RAM, I/O timers, A/D converters, and PWM generators are all on chip. Typical current draw for the 68HC11 is a low 20 ma.

The Simplest Microcontroller: The PIC5 Series (Microchip)

The roots of the PIC microprocessor go back to 1975 and a Department of Defense (DOD) contract with Harvard University that developed the Harvard architecture. However, the DOD went with a simpler and at the time more reliable single memory architecture proposed by Princeton University. In 1978, Signetics picked up the basic architecture and used it in the Signetics 8x300 Peripheral Interface Controller (PIC). Around 1985 Signetics spun off its microelectronics division to Arizona-based Microchip Technologies with their main product the PIC microcontroller. The PIC was the first RISC microcontroller featuring only 33 instructions compared to over 90 in the Intel 8048. Microchip has developed a line of PIC microprocessors with a large variety of features integrated onto the chip while maintaining extremely low cost (\$1 to \$10 per unit).

129.4 Applications of Microcontrollers

Microcontrollers are primarily used in embedded systems. This means that the microcontroller is connected directly to sensory inputs and control outputs that allow it to sense information about its environment and exert control over a device through its control outputs. An example in home electronics might be the microcontroller in your microwave that responds to the buttons pressed on the console and then performs the function desired including such tasks as thawing frozen items by adjusting the microwave energy and sensing the temperature of the food to adjust the microwave power levels. An example in automobile electronics might be the cruise control that senses the speed and then adjusts the throttle to maintain the speed or to increase and decrease the speed in response to user input to the cruise control buttons. An example of a hobbyist project might be the design of a robot to search through a model house for a flame and then extinguish that flame. In each of these examples, the microcontroller is responsible for the control of the system and is embedded within the system as an integral part of the product.

The popularity of the microcontroller families discussed in the previous section is primarily due to the availability of excellent development tools for these microcontrollers. Figure 129.4 shows the setup of the 8052-BASIC development system that is very popular for use with the 8081 line of microcontrollers. The development system consists of a board with the 8052 microprocessor with a BASIC interpreter in its on-chip ROM, with either on-chip or external RAM, peripheral chips to support the 8052, and an RS-232 serial port to connect to a host computer. The host computer is used to download instructions in BASIC to the RAM where they are then interpreted by the BASIC interpreter and cause the 8052 to perform the desired function. The RS-232 serial port provides the host computer full access to the 8052 to examine registers, debug software code, set and test various features of the chip, and view what is

FIGURE 129.4 Typical microcontroller development system.

stored in all the registers and the memory of the 8052 chip. Once the program has been written and debugged to carry out the desired functions, the host computer can download the final program to EPROM (usually not to RAM as it would be lost should the power fail) and then the RS-232 cable can be removed and the 8052 can function independently of the host computer. Often the 8052-BASIC development board can be directly embedded into the system and become part of the integrated system. In other instances, the 8052-BASIC development system is used only to program and debug the 8052 microcontroller and then the microcontroller is unplugged from the development system and plugged into the embedded system where it will perform the desired function. There are lots of excellent development tools available both from commercial sources and in the form of freeware that make the use of microcontrollers in embedded systems very easy. Most designers find that they can learn very quickly the process to program the microcontroller and use it in their system.

Further Information

This chapter is intended to be a brief overview of microprocessors and microcontrollers. While it is not feasible to provide in this brief chapter the details needed to use these microprocessors and microcontrollers, this introduction should prepare the reader well for taking the next step of obtaining a microcontroller development system such as the one of [Figure 129.4](#) and taking the first step in programming a microcontroller for an embedded application. The Internet is an excellent source of information on how to do this and is also a source for both commercial and freeware that can be used to program or to simulate various microprocessors. A good overview and introduction to microprocessors and microcontrollers can be found in Brain [3] and Rongen [4]. A particularly good starting point for the beginner wishing to build an embedded system is the Microchip PIC website, which does a pretty good job of leading one by the hand through the steps necessary to choose the correct PIC microprocessor and associated development tools and then how to use those tools to develop an embedded system [19]. There are also a very large number of books available aimed at both the beginner and the more advanced designer [20–25].

Richard S. Sandige

University of Wyoming

This chapter deals primarily with relatively fast electronic memory systems. Slower magnetic media, other storage media, and input/output (I/O) interfaces are only briefly discussed. Read/write memory, read-only memory, static memory, dynamic memory, cache memory, volatility of memory, relative speed of memory, and applications of memory are the major topics discussed. Tradeoffs, advantages, and disadvantages are considered for various memory systems in the following sections. This approach provides insight as to the applications for which each type of memory system is used and why.

130.1 CPU, Memory, and I/O Interface Connections

Most applications that employ memory systems contain a processor or a central processing unit (CPU). The CPU carries out basic instructions that require moving data between internal registers and memory or between internal registers and an I/O interface. Accomplishing this task usually requires a minimum of three types of buses, as illustrated in [Figure 130.1](#). The CPU provides the locations or addresses where the data must come from during a memory-read cycle or go to during a memory-write cycle. The bus that conveys these locations to the memory and I/O interface is called the *address bus*. For an address bus of n bits there are $2n$ storage locations available. When the memory and I/O interface are both accessed via the same address lines and the same control lines, as illustrated in [Figure 130.1](#), the interface is called *memory-mapped I/O*.

When the I/O interface is accessed as an address space separate from the memory address space, the address bus lines are interpreted as port addresses of the CPU, and separate control bus lines exist between the CPU and the I/O interface to direct data into or out of requested ports on the CPU via special I/O instructions. In the case of processors that have separate I/O and memory control signals, memory-mapped I/O can always be used by ignoring both the separate I/O control signals and the special I/O instructions and using only those processor instructions that relate to memory. Using only memory instructions to access both memory and I/O in the memory space of the CPU generally increases the flexibility of the overall system and also makes the system easier to program. A necessary requirement for the programmer of a memory-mapped I/O memory system is a **memory map** that shows where all device locations exist.

Data, the contents of an address in a memory-mapped I/O system as illustrated in [Figure 130.1](#), are read from the memory space on a CPU memory-read cycle and written to the memory space on a CPU

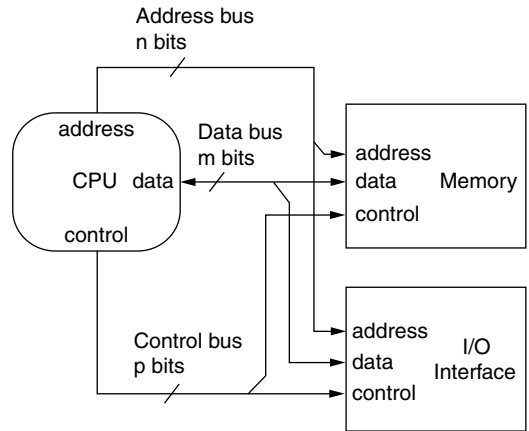

FIGURE 130.1 CPU, memory, and I/O interface for a memory-mapped I/O architecture.

memory-write cycle. An example of a memory-read cycle and a memory-write cycle timing diagram for a static RAM device will be presented later. Data travel on the **bidirectional data bus** in one direction at a time. The number of bits (data bus lines) associated with the data bus is dependent on the design of the CPU and ranges from a minimum of 4 bits for early microprocessors to as many as 32 bits for current microprocessors. Since heavy competition exists between major companies that manufacture microprocessors such as Motorola, Intel, IBM, Hewlett-Packard, and others, the push for 64 data bits and beyond for newer designs is underway. A larger number of data bits usually allows programs to be written more efficiently and also provides speed improvements in program execution since more bytes of data can be moved with fewer memory-read or -write cycles.

The control bus lines in a memory-mapped I/O system are routed to the memory and the I/O interface as illustrated in Figure 130.1. The I/O interface provides a data path for reading and writing data to the outside world that is beyond the system's existing memory system. The number of bits associated with the control bus is dependent on the architectural design of the complete system.

130.2 CPU Memory Systems Overview

A few of the various types of memory devices that can be connected to a CPU are illustrated in the memory systems connected to the CPU in Figure 130.2. The interconnections (all possible interconnections are not shown) must each have an address bus, a data bus, and a control bus, as discussed earlier. The **cache memory** block closest to the CPU usually contains static random access memory (RAM). Static RAM can also be used for primary memory; however, primary memory is usually designed with

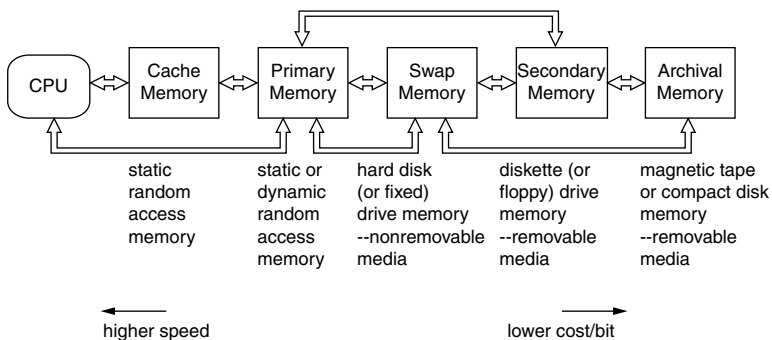

FIGURE 130.2 Overview of a CPU memory system.

dynamic RAM, which operates at a slower speed and is less expensive than static RAM. Dynamic RAM must be constantly refreshed (about every 2 to 8 milliseconds) or stored data are lost. Only one transistor per storage location is required in a dynamic RAM, compared to several transistors per storage location in a static RAM, where refresh is not required. Figure 130.2 also provides a general indication of where other types of memory such as hard (or fixed) drive memory, diskette (or floppy) drive memory, and magnetic tape or compact disk memory fit into a memory system relative to speed and cost/bit. Both static and dynamic RAMs are volatile types of memory. When power is removed, the content of the data in all storage locations is lost. The memory devices used for swap memory, secondary memory, and archival memory shown in Figure 130.2 are all nonvolatile memory. When power is removed from nonvolatile memory, the content of the data in all storage locations is preserved. Swap, secondary, and archival memories are all slower and cost less per bit than static and dynamic memories. This chapter will concentrate only on the faster or higher-speed types of static and dynamic memories that are contained in blocks closer to the CPU.

130.3 Common and Separate I/O Data Buses

Memory system blocks that consist of RAMs either utilize RAM devices that provide the input and output data lines via a common I/O data bus, as shown in Figure 130.3(a), or utilize RAM devices that provide the input and output data lines on separate I/O data buses, as shown in Figure 130.3(b). Memory systems that use memory blocks with a common I/O data bus have the advantage of costing less and taking up less printed circuit (PC) board space than those that use memory blocks with separate I/O data buses. Systems that use memory blocks with separate I/O data buses, however, have the advantage that **three-state buffers** can be added to the separate output data bus to eliminate **bus contention**, a problem in high-speed designs. Memory blocks that use either a common I/O bus or separate I/O buses are referred to as *single-port memory blocks* since data can only be accessed sequentially via a memory-read cycle or a memory-write cycle.

Some memory system blocks utilize dual-port memory devices, which allow data to be written to an input port while other data are read at a separate output port at the same time. The video memory of fast computer workstations is often designed using dual-port static memory devices called VRAMs (video random access memory). VRAMs have two ways to access data simultaneously. Data can be accessed

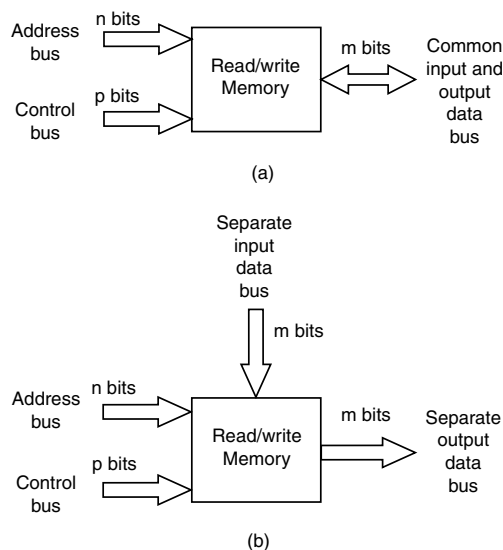

FIGURE 130.3 (a) Memory block with a common I/O data bus; (b) memory block with separate I/O data buses.

through a parallel RAM port and through a serial access memory (SAM) port. VRAMs are specialized devices that are specifically designed for use as display memories in **bit-mapped** graphic systems. Because of their multiple-access capability and functional flexibility, VRAM devices are usually the most expensive memory devices. It is also common in high-speed designs to have a dedicated video processor that issues video commands to speed up the video memory system.

130.4 Single-Port RAM Devices

Figure 130.4(a) shows a block diagram of a static RAM device with a common I/O data bus. A block diagram of a static RAM device with separate I/O data buses is shown in Figure 130.4(b). In both types of RAM devices, an address **decoder** is required to decode the n bits of address to determine one among the 2^n location in the memory array where data are stored (written) or retrieved (read). Both types of RAM devices also can contain a chip select line, a read/write line, and an output enable line. Output

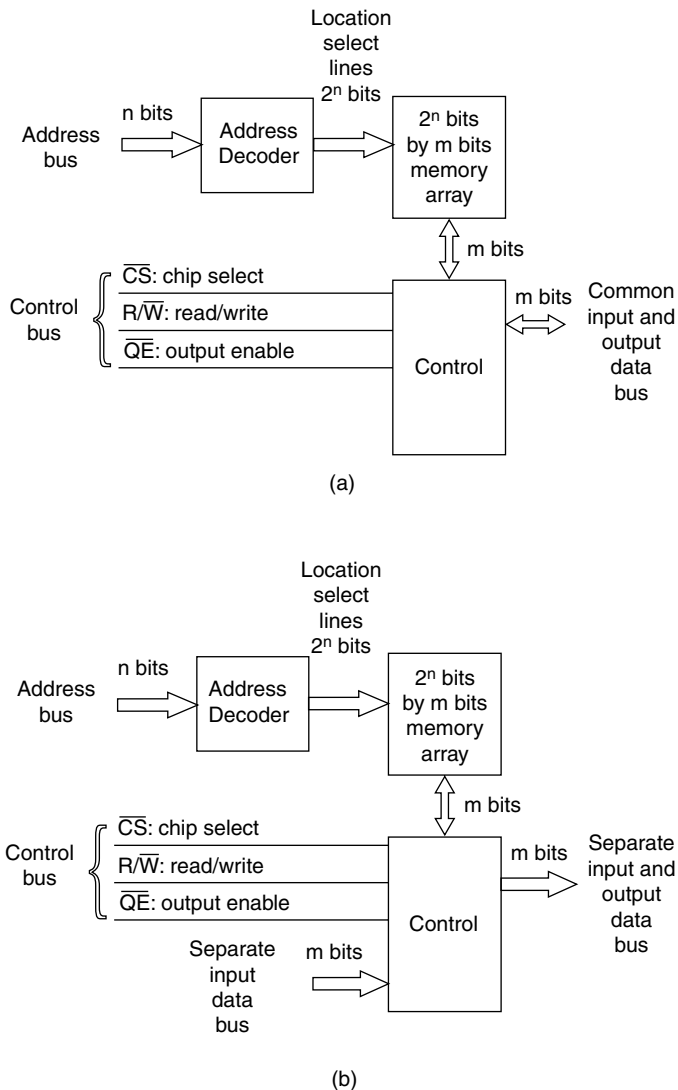

FIGURE 130.4 (a) Static RAM device with a common I/O data bus; (b) static RAM device with separate I/O data buses.

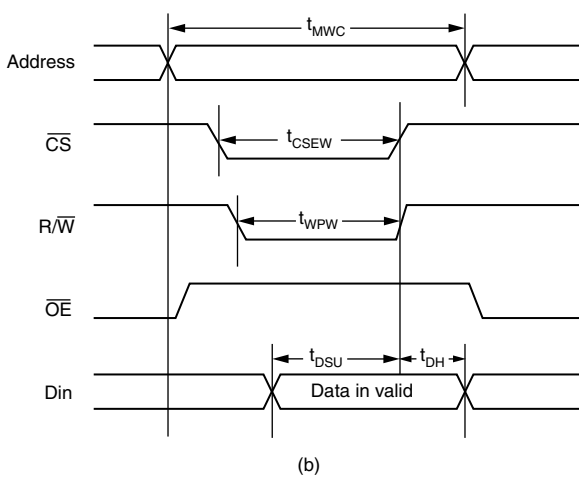

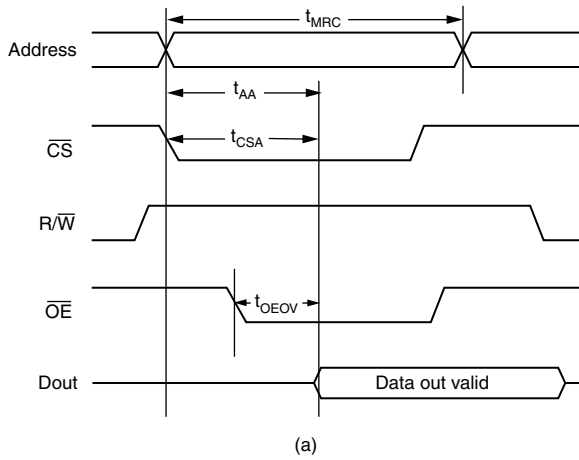

FIGURE 130.5 (a) Simplified timing diagram for a memory-read cycle; (b) simplified timing diagram for a memory-write cycle.

data are read from a static RAM device via the data bus — that is, data out valid — when the chip select line (\overline{CS}) is activated, the read/write control line (R/\overline{W}) is activated for read, and output enable line (\overline{OE}) is activated. These details are illustrated in the simplified timing diagram for the memory-read cycle of a static RAM device as shown in Figure 130.5(a). The \overline{CS} and \overline{OE} lines must both be pulled to a low-voltage logic state to be activated, since they both contain an overbar. The R/\overline{W} line must be pulled to a high-voltage logic state to be activated for read (no overbar over R). Abbreviations in the memory-read cycle timing diagram are provided in Table 130.1.

TABLE 130.1 Abbreviations for the Memory-Read Cycle Timing Diagram

| Abbreviation | Meaning |
|--------------|------------------------------------|
| t_{MRC} | Memory-read cycle time |
| t_{AA} | Address access time |
| t_{CSA} | Chip select access time |
| t_{OEOV} | Output enable to output valid time |

TABLE 130.2 Abbreviations for the Memory-Write Cycle Timing Diagram

| Abbreviation | Meaning |
|--------------|----------------------------------|
| t_{MWC} | Memory-write cycle time |
| t_{CSEW} | Chip select to end of write time |
| t_{WPW} | Write pulse width time |
| t_{DSU} | Data setup time |
| t_{DH} | Data hold time |

Input data are written to a static RAM device via the data bus — that is, data in valid — when the chip select line (\overline{CS}) is activated, the read/write line (R/\overline{W}) is activated for write (pulled to a low-voltage logic state), and the output enable line (\overline{OE}) is not activated (pulled to a high-voltage logic state). These details are illustrated in the simplified timing diagram for the memory-write cycle of a static RAM device as shown in [Figure 130.5\(b\)](#). Abbreviations in the memory-write cycle timing diagram are provided in Table 130.2.

130.5 Additional Types of Memory Devices

Other types of memory devices that can be located close to the CPU are **read-only memories** (ROMs), programmable read-only memories (PROMs), ultraviolet read-only memories (UV PROMs), and electrically erasable read-only memories (EEPROMs). Note that all of these devices are read-only devices in normal operation. Data can be stored permanently in the case of the ROM and PROM devices, or can be restored up to about 100 times in the case of the UV PROM and EEPROM devices. ROMs are programmed at the factory by metallic masks and cannot be reprogrammed by the user. PROMs are generally programmed in the field using a **universal programmer** by blowing or leaving fuses intact; these are called *one-time-programmable* (OTP) devices. UV PROMs are programmed in the field using a universal programmer, and programmed data can be erased using an ultraviolet light source through a quartz window located on top of the chip. The time it takes to erase the device is about 15 to 45 minutes, depending on the intensity of the light source. Once erased, the UV PROM can be reprogrammed. EEPROMs, the latest technology, can be programmed using a universal programmer, and then they can be erased by electrical pulses in less than a minute.

When developing a ROM-based system, engineers often use EEPROMs, since the turnaround time (the time for erasing and reprogramming) is very small to fix mistakes in programmed bit patterns. Engineers usually prefer to work with EEPROMs, until all the bugs are ironed out of a design, before committing to a ROM or PROM for the final design. ROMs are used in memory systems in computers to store information that needs to be accessed fast at power-up (such as the boot ROM that starts a PC system). EEPROMs are also used to store information that does not change very often, such as date, time, and configuration information.

ROMs and PROMs are permanently nonvolatile, whereas UV PROMs and EEPROMs are nonvolatile for approximately 10 years after being programmed. ROMs are very inexpensive per part after an upfront high cost is paid to the manufacturer for making the mask. To program PROMs, UV PROMs, and EEPROMs requires the user to purchase a universal programmer. A high-end universal programmer can run a few thousand dollars, whereas a programmer that programs only certain types of PROMs can cost as little as \$400 or \$500. PROMs are a little more expensive per part compared to ROMs and require that the user purchase a programmer. The next most expensive devices are UV PROMs and EEPROMs. Erasing UV PROMs requires that the user purchase an ultraviolet light source in addition to a universal programmer. EEPROMs can be programmed and erased with a universal programmer.

Speeds of the various devices are generally given with the ROM as the fastest, the PROM the next fastest, and the UV PROM and EEPROM much slower. [Table 130.3](#) provides a quick reference concerning cost/part, speed, and so forth for ROM and PROM-type devices.

TABLE 130.3 Summary of ROM and PROM-Type Devices

| Device | Cost/Part | Speed | Nonvolatile | Programmer |
|--------|---------------------|---------|------------------------------|-----------------------|
| ROM | Lowest ^a | Fastest | Permanently | N/A |
| PROM | Low | Fast | Permanently | Required |
| UVPROM | Higher | Slow | Semipermanently ^b | Required ^c |
| EEPROM | Higher | Slow | Semipermanently ^b | Required |

^a Up-front high cost must be paid to manufacturer for making the mask.

^b Stores data for approximately 10 years.

^c An ultraviolet light source is also required to erase these devices.

The timing diagram of interest for ROM users and the various PROM devices is the memory-read cycle. The universal programmer provides the required memory-write cycle for data storage for PROM devices. The memory-read cycle is basically the same as the memory-read cycle shown in Figure 130.5(a). The R/W signal for PROM devices is replaced by a program signal PGM used to perform a memory-write cycle. After the device is programmed the program signal PGM is disabled or not activated (pulled to a high-voltage logic state) so that the device can only be read.

130.6 Design Examples

In general, a cache memory system and a primary memory system often require a larger number of address bits and data bits than single-chip RAM devices can supply. This condition requires that several RAM devices be connected together to form the design for a cache or primary memory system.

Figures 130.6 and 130.7 illustrate the designs for two separate memory system blocks using static RAM devices. The first memory system design shown in Figure 130.6 addresses 1024 addresses each 8 bits wide. The RAM devices used in this design have only 256 addresses with a common I/O 4-bit-wide data bus. This situation requires using a decoder to decode four ranges of addresses and two RAM devices simultaneously. The decoder requires 2 bits from the address bus to select the four different address ranges. Output enable for the two RAMs that are selected for a memory-read cycle is obtained by ANDing the read/write signal with the decoder output that selects the required address range. Each RAM device requires 8 bits from the address bus to select among the 256 locations in its memory. Each RAM device only provides 4 bits of content at each memory location from 0 through 1023, thus requiring two RAM devices for each address.

Figure 130.7 illustrates a simpler memory system design that also addresses 1024 locations each 8 bits wide. In this design, 1024-bit RAM devices organized as 1024 words of 1 bit are used. Eight RAM devices must be used to obtain 8 bits of data. The address bus supplies all the RAM devices simultaneously without the need for an external address decoder, thus simplifying the design. Expanding the memory to 8192 addresses using instances of this design requires an external address decoder for chip select logic.

The simplest design for a memory system that addresses 1024 locations each 8 bits wide uses a single 8192-bit RAM device organized as 1024 words of 8 bits. In this design, the address bus and the data bus are connected directly to the RAM device. Cost, speed, printed circuit board space, and so forth are factors that need to be considered in choosing the best memory system design for a particular application.

Defining Terms

Bus contention — A condition that occurs on a bus when two or more devices try to output opposite logic levels on the same bus line.

Bidirectional data bus — A bus that allows data to flow in either direction.

Bit mapped — A graphic display that has 1 bit (or more) of display memory for each possible pixel or dot on the display.

Cache memory — A high-speed memory that can contain small segments of a program that can be accessed faster than primary or bulk memory.

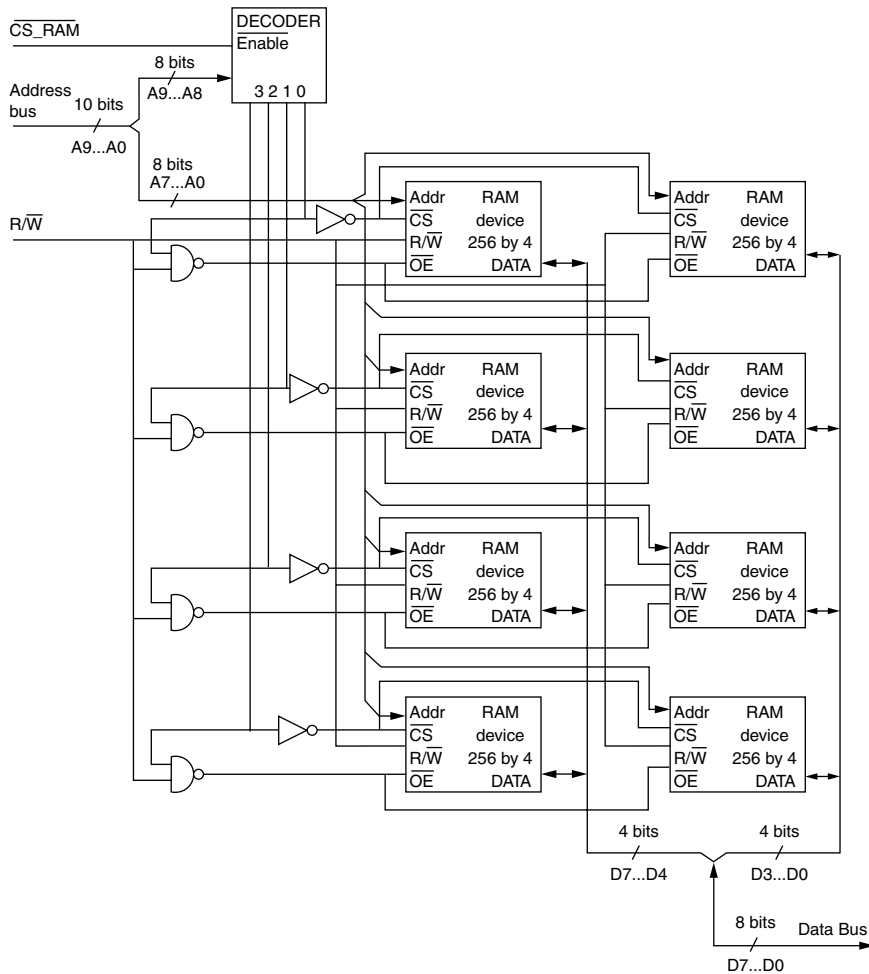

FIGURE 130.6 A 1024 × 8-bit static RAM memory system using 256 × 4-bit RAM devices with a common I/O data bus.

Decoder — A logic device that converts a binary code applied to i -input lines to 2^i different output lines.

Memory map — A table that specifies the location or address of every memory or I/O device that a CPU can access.

Read-only memories — Memories that are preprogrammed with data that can only be read under normal operation.

Three-state buffers — Buffers that have a third output state — that is, a state that is off, or high impedance, to effectively disconnect the outputs — in addition to the normal high- and low-voltage output states.

Universal programmer — A programming unit that can program various types of PROMs, erase EEPROMs, and program programmable logic array and programmable array logic devices.

FIGURE 130.7 A 1024 × 8-bit static RAM memory system using 1024 × 1-bit RAM devices with a common I/O data bus.

The size and complexity of very large-scale integrated (VLSI) circuits preclude manual design. Designers of VLSI circuits typically use specialized software tools in a workstation-based interactive environment. This chapter reviews important aspects of computer-aided circuit design and simulation and presents an introduction of the use of hardware description languages for design description and design simulation/verification of digital circuits. Digital simulation of analog circuits is also introduced.

131.1 Design Flow

The design flow of a methodology for designing VLSI circuits consists of a structured sequence of steps, beginning with design entry and culminating in the generation of a database containing geometric detail of the masks that will be used to fabricate the design. These steps can be summarized as follows:

1. Create a description of the design (design entry).
2. Establish testability of the design.
3. Verify the functionality of the design (simulation).
4. Develop a gate-level realization of the design.
5. Verify the timing specifications.
6. Place and route the design.
7. Evaluate the timing performance of the routed design.
8. Produce database for mask generation.

Multiple passes may be necessary through all or part of this flow. Other design flows are possible, and this design flow can be modified depending on the particular technology that is being used. For example, formal verification tools may be used in place of simulation, and a synthesis tool may be used to produce the gate-level realization.

Design specifications summarize the functional behavior and timing requirements of the design. They may include power and area constraints and additional information that is relevant to the task.

FIGURE 131.1 Schematic of a half-adder.

Design entry is the step of encapsulating a representation of the design. This representation may be in a variety of forms, such as a schematic. The testability of the design is generally addressed early in the design process to allow detection of untestable circuitry. The addition of hardware might be required, such as the insertion of a scan path into a sequential circuit. If the design is already in a form that is bound to a particular hardware realization, the timing specifications of the design can be verified by a static analysis of the paths in the circuit or by simulation. The place and route step may involve a full-custom layout of high-performance circuitry or semicustom layout of standard cells or gate arrays (field- or mask-programmable). In either case, the physical layout must be re-verified to confirm that the implementation not only realizes the desired functional behavior but also meets the externally imposed timing constraints of the design and the timing constraints imposed by storage elements (flip-flops) used in the design itself.

This chapter will focus on two steps in the overall design flow: design entry and simulation. *Design entry* is the process by which a description of the design is encapsulated in a database that serves all subsequent steps in the design flow. A designer may perform this step by drawing paper-and-pencil schematics, using a schematic entry tool, using a *hardware description language* (HDL), or selecting and interconnecting high-level macros representing hardware functional components. The two modes of entry that are of interest here are schematics and hardware description languages.

131.2 Schematic Entry

A schematic entry tool allows the designer to select and interconnect schematic symbols (icons) representing hardware components. Connections are made by graphical wires and buses representing physical signals in a circuit. The schematic entry software creates and manages a database containing the topological and incidental information created at the schematic, and this software also creates interfaces that will allow other design flow steps to access the database. For example, the information in the topological description can be used by a simulation tool to establish a database for simulating the design represented by the schematic. Figure 131.1 shows a simple schematic of a half-adder logic circuit generated by a schematic entry tool. Schematic entry tools have become popular during the past 10 years as the computational power of desktop interactive computer graphics has become capable of supporting complex design tasks at reasonable speeds.

131.3 Hardware Description Languages

Schematic entry focuses attention on structural detail of the design and is an appealing mode of entry because engineers are familiar with this traditional visual format. The objects in a schematic representation are high-level blocks and/or gate-level circuits. Structural modeling consists of interconnecting these objects to create a structure that has a desired behavior. An HDL is a computer-based programming language having special constructs and semantics to model, represent, and simulate the functional behavior and timing of digital hardware. An HDL supports structural, behavioral, and mixed descriptions of a design. Unlike schematic-based design, behavioral modeling uses HDL-based constructs and/or procedural code to describe the desired behavior without explicit binding to hardware.

Recently developed HDLs, such as Verilog [Thomas and Moorby, 1991; Sternheim, 1993] and VHDL [Navabi, 1993], provide an alternative mode of design entry by allowing the designer to create a text description of the circuit without relying on a schematic. The text itself can be generated on an ordinary terminal and is very portable. Some examples of Verilog descriptions are given as follows:

```

module Flip_flop(q,data_in,clk,rst);
input data_in,clk,rst;
output q;
always @ (posedge clk)
begin
if (rst == 1) q = 0;
else q = data_in;
end
endmodule

```

The basic element of design encapsulation in Verilog is a “module.” The code in the flip-flop module declared here updates the value of the output *q* whenever the clock has a positive (rising) edge, provided that the reset line is not asserted.

Verilog also supports a *register transfer logic* (RTL) description with several built-in-language operators. The use of RTL is illustrated as follows:

```

module bitwise_or (y,A,B); // RTL model
input [7:0] A,B;
output [7:0] y;
assign y = A | B;
endmodule

```

This bitwise_or module uses the built-in operator, |, to implement the “bitwise or” of the data words. The “assign” keyword effects an event-scheduling rule that updates the value of *y* whenever *A* or *B* changes. An event is said to occur whenever a signal changes value. Note that the Verilog language operators used in RTL design (such as the | operator) have implied logic. Their use simplifies the task of writing Verilog descriptions of behavior.

The text that follows declares a model of a half-adder circuit (see [Figure 131.1](#)) as a structural connection of CMOS standard cells xorf201, nanf201, and invf101.

```

module Add_half_structural (S,C,A,B,);
output S,C;
input A, B;
wire C_bar;

xorf201 G1 (S,A,B);
nanf201 G2 (C_bar,A,B);
invf101 G3 (C,C_bar);
endmodule

```

The description declares the name of the module, the input and output ports of the module, a wire that is used internally for a connection, and a list of instantiations of the library cells/modules. The arguments of the instantiated modules correspond directly to the physical wires that would interconnect their hardware counterparts.

HDLs allow a design to be represented abstractly or behaviorally without any binding to particular hardware elements. The fragments of text that follow show two alternative descriptions of a half-adder. The first fragment uses built-in language operators in an RTL style to implement a 4-bit-slice adder. (Here {} denotes a concatenation operator, which in this example creates a 5-bit wide data path from operations on the 4-bit buses and the *c_in* bit.) Verilog features built-in data types and operators that make this style of modeling very easy to implement.

```

module adder_4_RTL (sum, c_out, a,b,c_in);
output [3:0] sum;
output c_out;
input [3:0] a,b;

```

```

    assign {c_out,sum} = a + b + c_in
endmodule

```

The next description is a fragment of procedural code that implements a behavioral model of a carry look-ahead adder [Sternheim, 1993].

```

module add_4_CLA (sum, c_out, a,b,c_in);
    output [3:0] sum;
    output c_out;
    input [3:0] a,b;
    reg [3:0] carrychain;
    wire [3:0] gen = a & b; //bitwise and (carry generate);
    wire [3:0] prop = a ^ b;// bitwise xor (carry propagate);
    always @ a or b or c_in // event "or"
        begin: carry_generation_block
            integer i;
            carrychain[0] = gen[0] + (prop[0] & c_in);
            for(i = 1; i <= 3; i = i + 1)
                begin
                    #0 carrychain[i] = gen[i] + (prop[i] & carrychain[i-1]);
                end
            end
        end
    wire [4:0] shiftedcarry = {carrychain, c_in};
    wire [3:0] sum = prop ^ shiftedcarry;
    wire c_out = shiftedcarry[4];
endmodule

```

A module that is modeled by procedural code has no predetermined binding to hardware. Admittedly, built-in language operators, such as +, have an implicit binding to hardware, but this binding can be deferred to later in the design flow. This allows the designer to focus on functionality rather than implementation. Both Verilog and VHDL support algorithmic description of behavior through the mechanism of procedural code, which executes serially.

CAD/CAE software vendors provide development and debug environments supporting the designer of HDL-based descriptions of a design. These may include text editors and interactive debuggers.

VHDL, the VHSIC (very high-speed integrated circuit) HDL, was created under the auspices of the Department of Defense and is now an IEEE standard (IEEE 1076-1987). Verilog was created as a proprietary language, became very popular as a widely used industry tool, and then was placed in the public domain in 1990. It is presently in the final stages of becoming an IEEE standard [IEEE 1364]. Both languages support high-level abstract descriptions of digital systems; Verilog also has built-in gate-level and switch-level functional primitives.

Simulation of HDL-Modeled Circuits

Simulators are available for simulating the behavior of digital circuit described by either Verilog or VHDL. These simulators provide a fast, efficient, visual representation of the behavior of a digital circuit. Logic simulation is usually done on event-driven simulators, which exploit the topological latency that is characteristic of digital circuits.

Simulation of a circuit that has been modeled by an HDL requires that a *design unit test bench* (DUTB) be developed to apply stimulus to the unit under test (UUT). A test bench for a nand latch (cross-coupled nand primitives) module is given in the following:

```

module DUTB_Nand_latch;
    reg preset, clear;

```

```

wire q, qbar;
Nand_latch(q, qbar, preset, clear); // Instantiate the UUT
initial
begin // Create stimulus to UUT
$monitor ($time,, "preset =%b clear =%b q =%b qbar =%b,"
preset, clear,q,qbar);
    #10 preset = 0; clear = 1;
    #10 preset = 1;
    #10 clear = 0;
    #10 clear = 1;
    #10 preset = 0;
    #10 $finish;
end
endmodule

```

This DUTB applies stimuli to the inputs of the nand latch at intervals of ten simulation units. The \$monitor system task effects a listing of the output shown below. (Note: In this example the nand latch has a unit delay between an event on one of its inputs and the resulting event on its output. The value x denotes an unknown logic value.)

| | | | | |
|----|------------|-----------|-------|----------|
| 0 | preset = x | clear = x | q = x | qbar = x |
| 10 | preset = 0 | clear = 1 | q = x | qbar = x |
| 11 | preset = 0 | clear = 1 | q = 1 | qbar = x |
| 12 | preset = 0 | clear = 1 | q = 1 | qbar = 0 |
| 20 | preset = 1 | clear = 1 | q = 1 | qbar = 0 |
| 30 | preset = 1 | clear = 0 | q = 1 | qbar = 0 |
| 31 | preset = 1 | clear = 0 | q = 1 | qbar = 1 |
| 32 | preset = 1 | clear = 0 | q = 0 | qbar = 1 |
| 40 | preset = 1 | clear = 1 | q = 0 | qbar = 1 |

In addition to providing the standard output listing, a variety of tools offered by vendors of CAD/CAE software provide graphical output of simulation results.

131.4 Tradeoffs between HDLs and Schematic Entry

There are some tradeoffs that can be noted between schematic entry and HDL-based design entry. From the standpoint of support, a schematic-driven paradigm requires a color-graphic workstation (or suitably enhanced PC); language-based entry is easily done at a terminal, and an engineer can work at a remote site without requiring local support.

Editing a design that is described by an HDL can be shorter and simpler than the task of editing a design described by schematics. The task of removing, relocating, and rebinding schematic objects can be time consuming if the schematic itself is very dense and/or complex.

HDLs support a higher level of abstraction than can be described by schematics. A schematic can certainly have a symbol of any functional unit, but this must eventually be represented in terms of lower-level detail that is ultimately expressed as a structural description. An HDL can embody a behavior with no reference whatsoever to structural detail.

Schematic entry focuses the designer's attention on structural detail; a designer using an HDL can focus on structural detail, functional behavior, or a mixture of the two. HDLs support a top-down design methodology (TDM), in which a design is hierarchically decomposed in simpler, hierarchically organized functional units. In Verilog, the nested instantiation of modules is the mechanism by which hierarchical decomposition of a design is accomplished. The actual partitioning may be done according to functionality, but no restriction is implied by the language itself. In a TDM, the design is created in a top-down

fashion; it is verified in a bottom-up sequence, beginning with verification of the lowest levels of the hierarchy and proceeding to verification of the integrated design. The hierarchical decomposition of a 4-bit adder is given below. The top-level module contains four instantiations of full adders, which themselves contain instantiations of half-adders and glue logic; the half-adders are defined in terms of modules declared in the cell library.

```

module Add_rca_4 (Sum, C_out, A, B, C_in);
  output Sum,C_out;
  input A,B,C_in;
  wire [3:0] Sum,A,B;
  wire C_out,C_in4,C_in3,C_in2,C_in;
  Add_full G1 (Sum[3],C_out,A[3],B[3],C_in4);
  Add_full G2 (Sum[2],C_in4,A[2],B[2],C_in3);
  Add_full G2 (Sum[1],C_in3,A[1],B[1],C_in2);
  Add_full G4 (Sum[0],C_in2,A[0],B[0],C_in);
endmodule

module Add_full (S,C_out,A,B,C_in);
  output S,C_out;
  input A,B,C_in;
  wire S1,C1,C2,C_out_bar;
  Add_half G1 (S1,C1,A,B);
  Add_half G2 (S,C2,S1,C_in);
  norf201 G3 (C_out_bar,C1,C2);
  invf101 G4 (C_out,C_out_bar);
endmodule

module Add_half(S,C,A,B);
  output S,C;
  input A,B;
  wire C_bar;
  xorf201 G1 (S,A,B);
  nanf201 G2 (C_bar,A,B);
  invf101 G3 (C,C_bar);
endmodule

```

HDLs support rapid prototyping of a design by allowing a designer to focus attention on the functionality of a design rather than its physical/structural implementation. This factor dramatically shortens the time required to create and verify a design. Shortening the design cycle allows more changes to be made in less time, thereby increasing the likelihood that a design error will be found before its effects become widespread. The ease of considering design alternatives in an HDL context can stimulate and encourage consideration of design alternatives.

Tools now exist that automatically create a schematic from the HDL description, resulting in another attractive feature of HDLs. Thus, a schematic is actually a by-product of the HDL design flow. This approach to design greatly shortens the design cycle. The designer must, however, conform to a style that ensures synthesizable results.

131.5 HDLs and Synthesis

The Verilog HDL is a key element in modern design flows that incorporate logic synthesis tools. These tools begin with a behavioral description of the functionality of the design and then create an optimal logic-level description. This description can then be mapped onto a particular technology to meet timing and area constraints.

FIGURE 131.2 Low-pass filter section.

131.6 Transistor-Level Design and Simulation

Digital simulation of a circuit's analog waveforms has been popular for decades, especially since the creation of SPICE [Tuinenga, 1988]. This tool uses mathematical descriptions of active and passive circuit elements such as transistors and other components. These models provide a closer approximation of the actual analog waveforms that will be generated in the physical circuit. This additional resolution/detail comes at the price of greatly increased simulation times and memory requirements. The underlying models of the devices themselves are typically more complex than those used to support digital simulation.

Transistor-level simulators rely on numerical integration techniques, such as the Newton–Raphson method, and exploit the sparsity of the underlying matrices that result from applying Kirchhoff's laws to the possibly nonlinear circuit. In practice these simulators are used effectively to verify the timing performance of critical subcircuits, such as a detailed transient analysis of a memory design, rather than that of an entire system. The text that follows shows a fragment of SPICE code that describes the simple double-pole low-pass filter section shown in Figure 131.2.

```
Vgen 1 0 AC 1
R1 1 2 500
L1 2 3 10 mH
C1 3 0 1 uF
.AC DEC 100 100 HZ 10 KHz
.PROBE
.END
```

The first line of the code specifies an independent AC voltage source connected between node 1 and the reference node 0. This source has a level of 1. Each of the next three lines begins with a label specifying the type and identity index of a component, the indices of a pair of nodes to which the component is connected, and the value of the component in default or specified physical units. Then the AC source is specified to have a logarithmic sweep in decades from 100 Hz to 10 kHz in steps of 100 Hz. The .PROBE command is a PSpice [Tuinenga, 1988] statement that creates a database from simulation of the circuit. This database can then be examined to view various features of the response of the circuit. In this example, a Bode plot of the filter response will be created.

The following code describes a transient analysis of the same circuit that was considered earlier:

```
Vgen 1 0 pw1(0,0.1m,1 5.1m, 0)
R1 1 2 500
L1 2 3 10 mH
C1 3 0 1 uF
.TRAN 1m 10m
.PROBE
.END
```

Here, the source is programmed as a piecewise linear waveform describing a pulse that has a 0.1-ms transition from 0 to 1 and lasts for 5 ms. The .TRAN statement specifies that the transient waveform should be plotted in steps of 1 ms beginning at time = 0 (default) and ending at time 10 ms.

SPICE-like software typically supports the following analysis tasks:

- Transient analysis
- Steady state analysis
- Temperature analysis
- Frequency response
- Small-signal transfer function
- Sensitivity analysis
- Thevenin equivalent circuit
- Monte Carlo analysis
- Group delay analysis

Many variations of SPICE are available from CAD/CAE software vendors.

131.7 Conclusions

Powerful software tools exist to support circuit designers. These tools offer substantial gains in productivity in the overall engineering effort.

Defining Terms

Hardware description language (HDL) — A computer-based programming language having special constructs and semantics to model, represent, and simulate the functional behavior and timing of digital hardware.

SPICE — A software language used to create digital simulations of analog circuits. The acronym stands for *simulation program with integrated circuit emphasis*. SPICE was developed at the University of California, Berkeley; it is a public domain tool.

Verilog — An HDL that is widely used in industry to describe and simulate digital systems. It is in the final stages of becoming an IEEE standard. It supports hierarchical decomposition, switch- and gate-level structural modeling, register transfer logic/data flow modeling, and procedural modeling, including concurrent activity flows. It has built-in data types.

VHDL — An HDL that was developed under the support of the Department of Defense and is an IEEE standard. It supports hierarchical decomposition, data flow, and procedural modeling. It has user-defined data types.

A Paradox

Several types of equipment are used to verify and test digital circuits. The type depends on the design itself and the stage at which it is tested. Logic analyzers are “testers” that combine general-purpose characteristics with ease of use. They allow engineers to measure digital signals in a fashion similar to oscilloscopes; the x axis represents the time, and the y axis the voltage sampled. Logic analyzers evolved from oscilloscopes in the early 1970s; in a later section, we will distinguish between the use of analyzers and the use of oscilloscopes. Logic analyzers come in various sizes and with a variety of features. They may be used to measure one signal or several signals simultaneously. To explain how they work, it is important to present some basic concepts. The following sections will first describe the nature of digital signals, and then explain what an analyzer is and how it is used in testing digital circuits.

132.1 Nature of Digital Signals

Digital signals are waveforms that assume either a low-limit V_L (logic state 0) or a high-limit V_H (logic state 1). The exact values of these two limits are technology dependent. An example of a digital signal is shown in [Figure 132.1](#). In its ideal form it is a square wave but not necessarily periodic. Due to delays within the devices and interconnect, the rise and fall of the signal are not instantaneous. For a typical pulse, the rate of rise (or fall) is usually called the *slew rate*. The higher the slew rate is, the faster the operation of the circuit. Proper operation of digital circuits is dependent on the arrival of the waveform at various nodes of the circuit at the appropriate time.

Verifying the correctness of a digital signal involves state and timing measurement. The state is the value of the signal at any time, either state 0 or state 1. If the signal is above a certain reference V , it is logic 1; if it is below this reference, it is logic 0. This is illustrated in [Figure 132.2](#). For the logic analyzer to reconstruct the waveform examined, measurements need to be taken at various time instants. The collection of such measurements forms a sample that is interpreted by the analyzer, displayed, and possibly stored for further analysis. This process is called **sampling** and is done at various sampling points. In a sense, sampling is like taking snapshots of the waveform. Sampling also serves in time analysis. In the remainder of this chapter, we describe how the analyzer works in both state and timing capacities, but first let us discuss sampling and its importance in logic analyzer operations.

FIGURE 132.1 Digital signals: ideal vs. actual.

FIGURE 132.2 Sampling a waveform and reconstructing it.

132.2 Signal Sampling

Figure 132.2 shows a digital waveform, the sampling points, and the possible displays of the analyzer. The collected sample is stored in a buffer and used to reconstruct the waveform as illustrated in the figure. Sampling is a very important process in the operation of logic analyzers. If the signal is changing at 1 MHz, then it alternates between high and low every $T = 0.5 \mu\text{s}$. To accurately reconstruct this signal, we must sample it at least every $0.5 \mu\text{s}$. That is, the sampling rate has to be at least double that of the rate at which the signal is changing. The size of the sample is limited to the size of the buffer. A normal buffer size contains 1 K (1024) sample points. For a sample rate of 2 megasamples per second, the buffer will hold data for $512 \mu\text{s}$.

The logic analyzer is always sampling. When the user triggers it for display, it will show the waveform before and after the **trigger**. The triggering is done in one of two modes: level and edge. Both modes will be described later in conjunction with timing and state analysis.

132.3 Timing Analysis

Time analysis is very crucial to the performance of digital circuits. For proper functioning of a circuit, the signal must arrive at various nodes at precise times within a tolerance. Whenever the state changes from 0 to 1 or vice versa for two consecutive sampling points, the analyzer recognizes that the signal went through a transition during the period between these two points. This transition is then interpreted as having occurred at the second sampling instant, as illustrated in [Figure 132.3](#). However, there is uncertainty about where the transition has really occurred. The first transition, 0 to 1, occurred just after sample point 1, but it is only recorded at sample point 2. Similarly, the transition from 1 to 0 occurred right before sample point 4, where it was recorded. Since $\delta_1 > \delta_2$, the recording at sample point 4 is more accurate than at point 2.

The interval of time between two sample points, the *sampling period*, denoted in the figure by Δ , is the maximum uncertainty in timing measurement. Thus, the shorter the sampling period is, the higher is the resolution. This period has to be smaller than any pulse width measured by the logic analyzer. Otherwise, the pulse may not be recorded at all, or it might be recorded as having the sampling period as its width. Both cases are shown in Figure 132.3 for the pulses b and c.

Increasing the sampling rate for a certain **buffer depth** results in a narrower window. Alternately, keeping the same window requires a *deeper buffer*. It is possible to reduce the buffer depth by storing

FIGURE 132.3 Sampling accuracy.

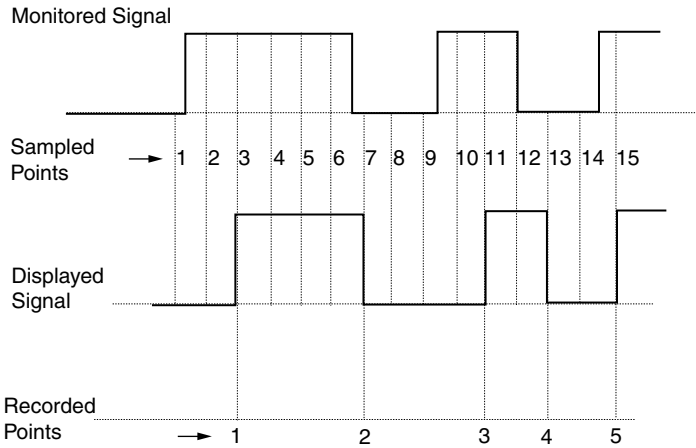

FIGURE 132.4 Transitional sampling.

only the sample points following transitions, as illustrated in Figure 132.4. Of all 15 sample points, only five are stored. Since the analyzer is sampling digital data, only the transition is relevant. This scheme is called **transitional sampling**.

Logic analyzers are not intended as parametric measuring instruments. They are used to determine timing relationship. We will consider such use of logic analyzers later in the chapter. Next, we examine the second type of analysis — state analysis.

132.4 State Analysis

In an earlier section, we used the term *state* to refer to the value of the signal on a certain node of the circuit. However, the advantage of the logic analyzer is in providing a means to determine the signal value on several nodes of the circuit. The **state** of a certain circuit is the collection of signals (0 or 1) on some lines of the circuit. The set of nodes may be the lines of a bus or the output of a counter.

The operation of the majority of digital circuits is synchronized by one signal called the *clock*. As the clock transitions from 0 to 1 (positive edge) or from 1 to 0 (negative edge), the signals propagate through the circuit and stabilize before the next clock edge. The clock is usually periodic, with duty cycle less than 50%. Thus, to observe the state of a circuit, it is convenient to use the system clock as the reference. The logic analyzer will capture the state of the circuit as the edge of the clock occurs. This mode of operation is called *edge triggering*.

Consider the example shown in Figure 132.5 for a 4-bit binary counter. The count is read on $Q_1Q_2Q_3Q_4$. These nodes form the state of the counter. Displayed also are the system clock and an asynchronous clear that returns the counter to 0 whenever asserted.

FIGURE 132.5 Edge and level trigger.

FIGURE 132.6 Components of a logic analyzer. Hair-thin fibers of ultrapure glass are now transmitting voice, data, and video communications in many parts of the globe in the form of digital pulses emitted by semiconductor lasers the size of a grain of salt. Such fiber-optic systems are now capable of transmitting a half-million simultaneous conversations. (Photo courtesy of AT&T Bell Laboratories.)

It is also possible to request the data when the circuit is in a certain state, say 1010. In such a case, a *level trigger* — specification of a level to start the capture of the data — is used. Every signal of the state — here, 4 — is measured by a channel. Besides observing the display, users may need to examine the values. For this 4-bit counter, using binary notations is manageable. It would be difficult, though, to use this representation for a 32-bit bus; instead, hexadecimal numbers would be used.

Now that we are familiar with the operation of logic analyzers, we briefly describe its components.

132.5 Components of a Logic Analyzer

A logic analyzer consists of the functional blocks shown in Figure 132.6: data acquisition block, data analyzer block that is part of the CPU, memory, display, and several ports that allow connection to a PC, printer, and other instruments. The interface between the data acquisition and the unit under test (UUT) is called the *pod*. The CPU is microprocessor based, but the data acquisition is usually an application-specific integrated circuit (ASIC). As IC technology advances the size and the cost of analyzers decreases. Portable analyzers may be used for on-site testing.

132.6 Advanced Features of Logic Analyzers

- Modern logic analyzers interface with PCs for postprocessing of the data. These data can be edited by the PC editor and also exported to a spreadsheet for further analysis.

- A logic analyzer can be bundled with a digitizing oscilloscope and thus work as three instruments in one, for timing analysis, state analysis, and parametric measurements. For intermodule analysis the data are viewed simultaneously by the three modules.
- Utilities are also available to translate state analysis files into test-pattern generation files to minimize time-consuming data entries.

132.7 Applications of Logic Analyzers

Although logic analyzers bear resemblance to digitizing oscilloscopes, their applications are not identical. Scopes are usually used when high fidelity is necessary in replicating every variation, no matter how small, in the waveform, and when timing between two or more events needs to be measured with high accuracy. The scope is suitable for parametric measurements.

Logic analyzers, on the other hand, are not as accurate in measuring time and voltages. They do have, however, many other equally important assets that have helped advance the state of the art of digital design. In the digital domain the signal is either high or low; the ripples in the waveform profile are of no consequence to proper operation of the product. It is more important to show that the actual waveforms of the circuit are as the designer expected. Logic analyzers are also useful in determining timing relationships among data lines of a bus or any group of various nodes in the UUT. This fact was illustrated earlier with the example of the 4-bit counter.

Logic analyzers are used for design verification during the development and integration cycle of digital systems. They are also useful in production testing. The product itself may be a microprocessor-based circuit or an ASIC.

The effectiveness of the logic analyzer depends on its characteristics. For example, analyzers with only a few channels are not efficient for testing a large circuit. If the maximum speed of an analyzer is under that of the UUT, it is useless for such a UUT. Also, logic analyzers must have sufficient capacity for data acquisition.

A Paradox

Logic analyzers are built of digital ICs that need to function at a speed higher than that of the UUT. They are used to develop tomorrow's ICs that are supposed to have higher performance than the products of today. To build a design tool for a customer who uses state-of-the-art devices, one must have the next-generation devices to make the tool effective for the present generation. And that is physically impossible.

Defining Terms

Buffer depth — The size of the acquisition memory.

Sampling — The process of recording signals at specific moments, called *sample points*, over a period of time.

State — The logic values of a collection of nodes in the circuit that depend on the transition in the clock of the circuit.

Transitional sampling — Storing samples indicating change of level.

Trigger — Signal entered by the user to flag the acquisition.

133.1 Fourier Transforms

One method used extensively calls for replacing the continuous Fourier transform by an equivalent *discrete Fourier transform* (DFT) and then evaluating the DFT using the discrete data. But evaluating a DFT with 512 samples (a small number in most cases) requires more than $1.5 \cdot 10^6$ mathematical operations. It was the development of the **fast Fourier transform (FFT)**, a computational technique that reduces the number of mathematical operations in the evaluation of the DFT to $N \log_2(N)$ (approximately $2.5 \cdot 10^4$ operations for the 512-point case mentioned above), that made DFT an extremely useful tool in almost all fields of science and engineering.

A data sequence is available only within a finite time window from $n = 0$ to $n = N - 1$. The transform is discretized for N values by taking samples at the frequencies $2\pi/N T$, where T is the time interval between sample points. Hence, we define the DFT of a sequence of N samples for $0 \leq k \leq N - 1$ by the relation

$$\begin{aligned}
 F(k\Omega) &\doteq F_d\{f(nT)\} = T \sum_{n=0}^{N-1} f(nT)e^{-j2\pi nkT/NT} \\
 &= T \sum_{n=0}^{N-1} f(nT)e^{-j\Omega Tnk}, \quad n = 0, 1, \dots, N - 1
 \end{aligned}
 \tag{133.1}$$

where

N = number of sample values

T = sampling time interval

$(N - 1)T$ = signal length

$f(nT)$ = sampled form of $f(t)$ at points nT

$$\Omega = \frac{2\pi}{T} \frac{1}{N} = \frac{\omega_s}{N} = \text{the frequency sampling interval}$$

$$e^{-j\Omega T} = N\text{th principal root of unity}$$

$$j = \sqrt{-1}$$

The inverse IDFT is given by

$$f(nT) \doteq F_d^{-1}\{F(k\Omega)\} = \frac{1}{NT} \sum_{k=0}^{N-1} F(k\Omega) e^{j2\pi nkT/NT}$$

$$= \frac{1}{NT} \sum_{k=0}^{N-1} F(k\Omega) e^{j\Omega Tnk}$$
(133.2)

The sequence $f(nT)$ can be viewed as representing N consecutive samples $f(n)$ of the continuous signal, whereas the sequence $F(k\Omega)$ can be considered as representing N consecutive samples $F(k)$ in the frequency domain. Therefore, Equation (133.1) and Equation (133.2) take the compact form

$$F(k) \doteq F_d\{f(n)\}$$

$$= \sum_{n=0}^{N-1} f(n) e^{-j2\pi nk/N} = \sum_{n=0}^{N-1} f(n) W_N^{nk}, \quad k = 0, \dots, N-1$$
(133.3)

$$f(n) \doteq F_d^{-1}\{F(k)\}$$

$$= \frac{1}{N} \sum_{k=0}^{N-1} F(k) e^{j2\pi nk/N} = \sum_{k=0}^{N-1} F(k) W_N^{-nk}, \quad n = 0, \dots, N-1$$
(133.4)

where $W_N = e^{-j2\pi/N}$, and $j = \sqrt{-1}$. An important property of the DFT is that $f(n)$ and $F(k)$ are uniquely related by the transform pair in Equation (133.3) and Equation (133.4).

We observe that the functions W^{kn} are N -periodic, that is,

$$W_N^{kn} = W_N^{(k+N)n} = W_N^{k(n+N)}, \quad k, n = 0, \pm 1, \pm 2, \dots$$
(133.5)

As a consequence, the sequence $f(n)$ and $F(k)$ as defined by Equation (133.3) and Equation (133.4) are also N -periodic.

It is generally convenient to adopt the convention

$$\{f(n)\} \longleftrightarrow \{F(k)\}$$
(133.6)

to represent the transform pair in Equations (133.3) and (133.4).

Properties of the DFT

A detailed discussion of the properties of DFT can be found in the references cited at the end of this chapter. The following list gives a few of these properties that are of value for the development of the fast Fourier transform.

1. Linearity

$$\{af(n) + by(n)\} \longleftrightarrow \{aF(k) + bY(k)\}$$
(133.7a)

2. *Complex conjugate.* If $N/2$ is an integer and $\{f(n)\} \longleftrightarrow \{F(k)\}$, then

$$F\left(\frac{N}{2} + \ell\right) = F^*\left(\frac{N}{2} - \ell\right), \quad \ell = 0, 1, \dots, \frac{N}{2} \quad (133.7b)$$

where $F^*(k)$ denotes the complex conjugate of $F(k)$. This identity shows the folding property of the DFT.

3. *Reversal*

$$\{f(-n)\} \longleftrightarrow \{F(-k)\} \quad (133.8)$$

4. *Time shifting*

$$\{f(n + \ell)\} \longleftrightarrow \{W^{-\ell k} F(k)\} \quad (133.9)$$

5. *Convolution of real sequences.* If

$$y(n) = \frac{1}{N} \sum_{\ell=0}^{N-1} f(\ell)h(n-\ell), \quad n = 0, 1, \dots, N-1 \quad (133.10)$$

then

$$\{y(n)\} \longleftrightarrow \{F(k)H(k)\} \quad (133.11)$$

6. *Correlation of real sequences.* If

$$y(n) = \frac{1}{N} \sum_{\ell=0}^{N-1} f(\ell)h(n+\ell), \quad n = 0, 1, \dots, N-1 \quad (133.12)$$

then

$$\{y(n)\} \longleftrightarrow \{F(k)H^*(k)\} \quad (133.13)$$

7. *Symmetry*

$$\left\{\frac{1}{N} F(n)\right\} \longleftrightarrow \{f(-k)\} \quad (133.14)$$

8. *Parseval's theorem*

$$\sum_{n=0}^{N-1} f^2(n) = \frac{1}{N} \sum_{k=0}^{N-1} |F(k)|^2 \quad (133.15)$$

where $|F(k)| = F(k)F^*(k)$.

Example 133.1 Verify Parseval's theorem for the sequence $\{f(n)\} = \{1, 2, -1, 3\}$.

Solution. With the help of Equation (133.3) we obtain

$$\begin{aligned}
 F(k)\Big|_{k=0} = F(0) &= \sum_{n=0}^3 f(n)e^{-j\frac{2\pi}{4}kn} \Big|_{k=0} \\
 &= (1e^{-j\frac{\pi}{2}\cdot 0\cdot 0} + 2e^{-j\frac{\pi}{2}\cdot 0\cdot 1} - e^{-j\frac{\pi}{2}\cdot 0\cdot 2} + 3e^{-j\frac{\pi}{2}\cdot 0\cdot 3}) = 5
 \end{aligned}$$

Similarly, we find

$$F(1) = 2 + j; F(2) = -5; F(3) = 2 - j$$

Introducing these values in Equation (133.15) we obtain

$$1^2 + 2^2 + (-1)^2 + 3^2 = \frac{1}{4}[5^2 + (2+j)(2-j) + 5^2 + (2-j)(2+j)] \text{ or } 15 = \frac{60}{4}$$

which is an identity as it should have been.

Relation between DFT and Fourier Transform

The sampled form of a continuous function $f(t)$ can be represented by the N equally spaced sampled values $f(n)$ such that

$$f(n) = f(nT), \quad n = 0, 1, \dots, N-1 \quad (133.16)$$

where T is the sampling interval. The length of the continuous function is $L = NT$, where $f(N) = f(0)$.

We denote the sampled version of $f(t)$ by $f_s(t)$, which can be represented by the expression

$$f_s(t) = \sum_{n=0}^{N-1} [Tf(n)]\delta(t - nT) \quad (133.17)$$

where $\delta(t)$ is the Dirac or impulse function.

Taking the Fourier transform of $f_s(t)$ in Equation (133.17) we obtain

$$\begin{aligned}
 F_s(\omega) &= T \int_{-\infty}^{\infty} \sum_{n=0}^{N-1} f(n)\delta(t - nT)e^{-j\omega t} dt \\
 &= T \sum_{n=0}^{N-1} f(n) \int_{-\infty}^{\infty} \delta(t - nT)e^{-j\omega t} dt = T \sum_{n=0}^{N-1} f(n)e^{-j\omega nT}
 \end{aligned} \quad (133.18)$$

Equation (133.18) yields $F_s(\omega)$ for all values of ω . However, if we are interested only in values of $F_s(\omega)$ at a set of discrete equidistant points, then Equation (133.18) is expressed in the form [see also Equation (133.1)]

$$F_s(k\Omega) = T \sum_{n=0}^{N-1} f(n)e^{-jk\Omega nT}, \quad k = 0, \pm 1, \pm 2, \dots, \pm \frac{N}{2} \quad (133.19)$$

where $\Omega = 2\pi/L = 2\pi/NT$. Therefore, comparing Equation (133.3) and Equation (133.19), we observe that we can find $F(\omega)$ from $F_s(\omega)$ using the relation

$$F(k) = F_s(\omega)\Big|_{\omega=k\Omega} \quad (133.20)$$

Power, Amplitude, and Phase Spectra

If $f(t)$ represents voltage or current waveform supplying a load of 1 ohm, the left-hand side of Parseval's theorem [Equation (133.15)] represents the power dissipated in the 1-ohm resistor. Therefore, the right-hand side represents the power contributed by each harmonic of the spectrum. Thus, the DFT **power spectrum** is defined as

$$P(k) = F(k)F^*(k) = |F(k)|^2, \quad k = 0, 1, \dots, N-1 \quad (133.21)$$

For real $f(n)$, there are only $(N/2 + 1)$ independent DFT spectral points as the complex conjugate property shows [Equation (133.7)]. Hence, we write

$$P(k) = |F(k)|^2, \quad k = 0, 1, \dots, \frac{N}{2} \quad (133.22)$$

The *amplitude spectrum* is readily found from that of a power spectrum, and it is defined as

$$A(k) = |F(k)|, \quad k = 0, 1, \dots, N-1 \quad (133.23)$$

The power and amplitude spectra are invariant with respect to shifts of the data sequence $\{f(n)\}$.

The **phase spectrum** of a sequence $\{f(n)\}$ is defined as

$$\phi_f(k) = \tan^{-1} \left[\frac{\text{Im}\{F(k)\}}{\text{Re}\{F(k)\}} \right], \quad k = 0, 1, \dots, N-1 \quad (133.24)$$

As in the case of the power spectrum, only $(N/2 + 1)$ of the DFT phase spectral points are independent for real $\{f(n)\}$. For a real sequence $\{f(n)\}$, the power spectrum is an *even function* about the point $k = N/2$ and the phase spectrum is an *odd function* about the point $k = N/2$.

Observations

1. The frequency spacing $\Delta\omega$ between coefficients is

$$\Delta\omega = \Omega = \frac{2\pi}{NT} = \frac{\omega_s}{N} \quad \text{or} \quad \Delta f = \frac{1}{NT} = \frac{f_s}{N} = \frac{1}{T_o} \quad (133.25)$$

2. The reciprocal of the record length defines the frequency resolution.
3. If the number of samples N are fixed and the sampling time is increased, the record length and the precision of frequency resolution is increased. When the sampling time is decreased, the opposite is true.
4. If the record length is fixed and the sampling time is decreased (N increases), the resolution stays the same and the computed accuracy of $F(n\Omega)$ increases.
5. If the record length is fixed and the sampling time is increased (N decreases), the resolution stays the same and the computed accuracy of $F(n\Omega)$ decreases.

Data Windowing

To produce more accurate frequency spectra, it is recommended that the data are weighted by a **window** function $\{w(n)\}$. Hence, the new data set will be of the form $\{f(n)w(n)\}$. The following are the most commonly used windows:

1. Triangle (Fejer, Bartlet) window

$$w(n) = \begin{cases} \frac{n}{N/2}, & n = 0, 1, \dots, \frac{N}{2} \\ w(N-n), & n = \frac{N}{2}, \dots, N-1 \end{cases} \quad (133.26)$$

2. $\cos^\alpha(x)$ window

$$\begin{aligned} w(n) &= \sin^2\left(\frac{n}{N}\pi\right), \quad n = 0, 1, \dots, N-1, \quad \alpha = 2 \\ &= 0.5 \left[1 - \cos\left(\frac{2n}{N}\pi\right) \right] \end{aligned} \quad (133.27)$$

This window is also called the *raised cosine* or *Hann window*.

3. Hamming window

$$w(n) = 0.54 - 0.46 \cos\left(\frac{2\pi}{N}n\right), \quad n = 0, 1, \dots, N-1 \quad (133.28)$$

4. Blackman window

$$w(n) = \sum_{m=0}^K (-1)^m a_m \cos\left(2\pi m \frac{n}{N}\right), \quad n = 0, 1, \dots, N-1, \quad K \leq \frac{N}{2} \quad (133.29)$$

For $K = 2$, $a_0 = 0.42$, $a_1 = 0.50$, and $a_2 = 0.08$.

5. *Blackman-Harris window*. Harris used a gradient search technique to find three- and four-term expansions of Equation (133.29) that either minimized the maximum side-lobe level for fixed main-lobe width or traded main-lobe width for minimum side-lobe level (see Table 133.1).

6. Centered Gaussian window

$$w(n) = \exp\left[-\frac{1}{2}\alpha\left(\frac{n}{N/2}\right)^2\right], \quad 0 \leq |n| \leq \frac{N}{2}, \quad \alpha = 2, 3, \dots \quad (133.30)$$

As α increases, the main lobe of the frequency spectrum becomes broader and the side-lobe peaks become lower.

TABLE 133.1 Blackman–Harris Window Parameters

| Number of Terms in Equation (133.29) | Parameter Values | | | |
|---|------------------|---------|---------|---------|
| | 3 | 3 | 4 | 4 |
| Minimum side lobe (dB) | -70.83 | -62.05 | -92 | -74.39 |
| Parameter | | | | |
| a_0 | 0.42323 | 0.44959 | 0.35875 | 0.40217 |
| a_1 | 0.49755 | 0.49364 | 0.48829 | 0.49703 |
| a_2 | 0.07922 | 0.05677 | 0.14128 | 0.09892 |
| a_3 | — | — | 0.01168 | 0.00188 |

7. Centered Kaiser-Bessel window

$$w(n) = I_0 \left[\pi \alpha \sqrt{1.0 - \left(\frac{n}{N/2} \right)^2} \right] / I_0[\pi \alpha], \quad 0 \leq |n| \leq \frac{N}{2} \quad (133.31)$$

where

$I_0(x)$ = zero-order modified Bessel function

$$= \sum_{k=0}^{\infty} \left(\frac{(x/2)^k}{k!} \right)^2 \quad (133.32)$$

$$k! = 1 \times 2 \times 3 \times \dots \times k$$

$$\alpha = 2, 2.5, 3 \quad (\text{typical values})$$

Fast Fourier Transform

One of the approaches to speed the computation of the DFT of a sequence is the *decimation-in-time method*. This approach involves breaking the N -point transform into two $(N/2)$ -point transforms, then breaking each $(N/2)$ -point transform into two $(N/4)$ -point transforms, and continuing the above process until the two-point transform is obtained. We start with the DFT expression and factor it into two DFTs of length $N/2$:

$$F(k) = \sum_{n=0}^{N-2} f(n) W_N^{kn} \quad n \text{ even} \quad (133.33)$$

$$+ \sum_{n=1}^{N-1} f(n) W_N^{kn} \quad n \text{ odd}$$

Letting $n = 2m$ in the first sum and $n = 2m + 1$ in the second, Equation (133.33) becomes

$$F(k) = \sum_{m=0}^{(N/2)-1} f(2m) W_N^{2mk} + \sum_{m=0}^{(N/2)-1} f(2m+1) W_N^{(2m+1)k} \quad (133.34)$$

However, because of the following identities,

$$W_N^{2mk} = (W_N^2)^{mk} = e^{-\frac{2\pi}{N} 2mk} = e^{-j \frac{2\pi}{N/2} mk} = W_{N/2}^{mk} \quad (133.35)$$

and the substitution $f(2m) = f_1(m)$ and $f(2m + 1) = f_2(m)$, $m = 0, 1, \dots, N/2 - 1$, Equation (133.33) takes the form

$$F(k) = \sum_{m=0}^{(N/2)-1} f_1(m) W_{N/2}^{mk} \quad (N/2) = \text{point DFT of even indexed sequence}$$

$$+ W_N^k \sum_{m=0}^{(N/2)-1} f_2(m) W_{N/2}^{mk} \quad (N/2) = \text{point DFT of odd indexed sequence} \quad (133.36)$$

$$k = 0, \dots, N/2 - 1$$

FIGURE 133.1 Illustration of Example 133.1. (Source: Dorf, R. C., Ed. 1993. *The Electrical Engineering Handbook*. CRC Press, Boca Raton, FL.)

We can also write Equation (133.36) in the form

$$\begin{aligned}
 F(k) &= F_1(k) + W_N^k F_2(k), & k = 0, 1, \dots, N/2 - 1 \\
 F\left(k + \frac{N}{2}\right) &= F_1(k) + W_N^{k+N/2} F_2(k) \\
 &= F_1(k) - W_N^k F_2(k), & k = 0, 1, \dots, N/2 - 1
 \end{aligned} \tag{133.37}$$

where $W_N^{k+N/2} = -W_N^k$ and $W_{N/2}^{m(k+N/2)} = W_{N/2}^{mk}$. Since the DFT is periodic, $F_1(k) = F_1(k + N/2)$ and $F_2(k) = F_2(k + N/2)$.

Next, we apply the same procedure to each $N/2$ sample, where $f_{11}(m) = f_1(2m)$ and $f_{21}(m) = f_2(2m + 1)$, $m = 0, 1, \dots, (N/4) - 1$. Hence,

$$\begin{aligned}
 F_1(k) &= \sum_{m=0}^{(N/4)-1} f_{11}(m) W_{N/4}^{mk} + W_N^{2k} \sum_{m=0}^{(N/4)-1} f_{21}(m) W_{N/4}^{mk} \\
 & & k = 0, 1, \dots, \frac{N}{4} - 1
 \end{aligned} \tag{133.38}$$

or

$$\begin{aligned}
 F_1(k) &= F_{11}(k) + W_N^{2k} F_{21}(k) \\
 F_1\left(k + \frac{N}{4}\right) &= F_{11}(k) - W_N^{2k} F_{21}(k), & k = 0, 1, \dots, \frac{N}{4} - 1
 \end{aligned} \tag{133.39}$$

Therefore, each of the sequences f_1 and f_2 have been split into two DFTs of length $N/4$.

Example 133.2 To find the EFT of the sequence $\{2, 3, 4, 5\}$ we first bit-reverse the elements from position $\{00, 01, 10, 11\}$ to position $\{00, 10, 01, 11\}$. The new sequence is $\{2, 4, 3, 5\}$ (see also Figure 133.1). Using Equation (133.36) and Equation (133.37) we obtain

$$F_1(0) = \sum_{m=0}^1 f_1(m)W_2^{m \cdot 0} = f_1(0)W_2^0 + f_1(1)W_2^0 = f(0) \cdot 1 + f(2) \cdot 1$$

$$F_1(1) = \sum_{m=0}^1 f_1(m)W_2^{m \cdot 1} = f_1(0)W_2^{0 \cdot 1} + f_1(1)W_2^1 = f(0) + f(2)(-j)$$

$$F_2(0) = W_4^0 \sum_{m=0}^1 f_2(m)W_2^{m \cdot 0} = f_2(0)W_2^0 + f_2(1)W_2^0 = f(1) + f(3)$$

$$\begin{aligned} F_2(1) &= W_4^1 \sum_{m=0}^1 f_2(m)W_2^{m \cdot 1} = W_4^1 [f(1)W_2^0 + f(3)W_2^1] \\ &= W_4^1 f(1) - W_4^1 f(3) \end{aligned}$$

From Equation (133.37) the output is $F(0) = F_1(0) + W_4^0 F_2(0)$, $F(1) = F_1(1) + W_4^1 F_2(1)$, $F(2) = F_1(0) - W_4^0 F_2(0)$, and $F(3) = F_1(1) - W_4^1 F_2(1)$ Figure 133.2 shows an eight-point decimation-in-time FFT. (See also Table 133.2.)

Computation of the Inverse DFT

To find the inverse of FFT using an FFT algorithm, we use the relation

$$f(n) = [\text{FFT}(F^*(k))]^*/N \tag{133.40}$$

FIGURE 133.2 An eight-point decimation-in-time fast Fourier transform.

133.2 Walsh–Hadamard Transform

Walsh Functions

In 1923, Walsh developed a complete orthogonal set of rectangular functions known as Walsh functions. The first eight functions are shown in [Figure 133.3](#). These signals have been widely used to perform

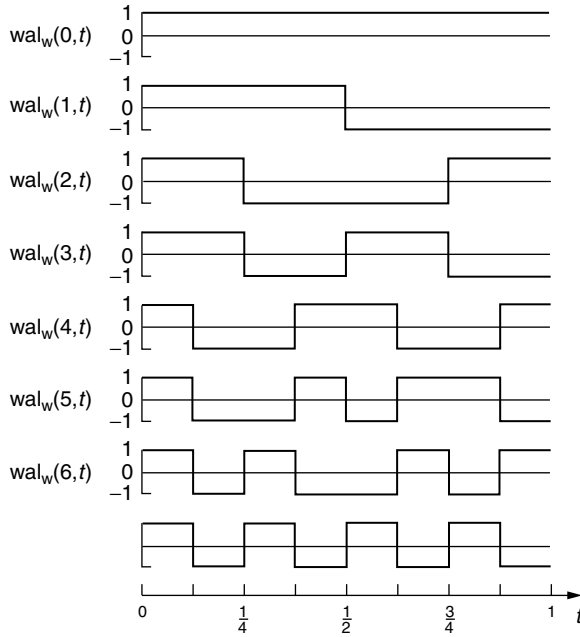

FIGURE 133.3 Walsh functions.

nonsinusoidal orthogonal transforms in various digital-signal processing applications since they can essentially be computed using addition and subtraction only.

Every signal $f(t)$ absolutely integrable in $0 \leq t \leq 1$ can be equated in a series of the form

$$f(t) = \sum_{k=0}^{\infty} d_k \text{Wal}_w(k, t) \quad (133.41)$$

where

$$d_k = \int_0^1 f(t) \text{Wal}_w(k, t) dt, \quad k = 0, 1, 2, \dots \quad (133.42)$$

The above series converges uniformly to $f(t)$ if it is continuous in $0 \leq t \leq 1$ and converges in the mean where $f(t)$ is discontinuous.

The Walsh–Hadamard transforms are analogous to the discrete Fourier transform. The basis functions are sampled Walsh functions, which can be expressed in terms of the Hadamard matrices $\underline{H}_w(n)$. An $\underline{H}_w(3)$ is shown in Figure 133.4, where $n = \log_2 N$.

Let u_i and v_i be the i th bits in the binary representation of the integers u and v , respectively; then

$$(u)_{\text{decimal}} = (u_{n-1}, u_{n-2}, \dots, u_1 u_0)_{\text{binary}}$$

$$(v)_{\text{decimal}} = (v_{n-1}, v_{n-2}, \dots, v_1 v_0)_{\text{binary}}$$

The Walsh-ordering Hadamard matrix elements are given by

$$h_{uv}^{(w)} = (-1)^{\sum_{i=0}^{n-2} r_i(u)v_i}, \quad u, v = 0, 1, \dots, N-1 \quad (133.43)$$

$$H_w(3) = \begin{bmatrix} 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 \\ 1 & 1 & 1 & 1 & -1 & -1 & -1 & -1 \\ 1 & 1 & -1 & -1 & -1 & -1 & 1 & 1 \\ 1 & 1 & -1 & -1 & 1 & 1 & -1 & -1 \\ 1 & -1 & -1 & 1 & 1 & -1 & -1 & 1 \\ 1 & -1 & -1 & 1 & -1 & 1 & 1 & -1 \\ 1 & -1 & 1 & -1 & -1 & 1 & -1 & 1 \\ 1 & -1 & 1 & -1 & 1 & -1 & 1 & -1 \end{bmatrix}$$

FIGURE 133.4 Hadamard matrix.

where

$$\begin{aligned} r_0(u) &= u_{n-1} \\ r_1(u) &= u_{n-1} + u_{n-2} \\ r_2(u) &= u_{n-2} + u_{n-3} \\ &\vdots \\ r_{n-1}(u) &= u_1 + u_0 \end{aligned}$$

The Hadamard matrices have the following properties:

1. $\underline{H}_w(k)$ is a symmetric matrix:

$$\underline{H}_w(k) = \underline{H}_w(k)^T \quad (133.44)$$

T stands for transpose.

2. $\underline{H}_w(k)$ are orthogonal:

$$\underline{H}_w(k)\underline{H}_w(k)^T = 2^k \underline{I}(k) \quad (133.45)$$

where $\underline{I}(k)$ is a $(2^k \times 2^k)$ identity matrix.

3. The inverse of $\underline{H}_w(k)$ is proportional to itself:

$$[\underline{H}_w(k)]^{-1} = (1/2^k)\underline{H}_w(k) \quad (133.46)$$

where $[\underline{H}_w(k)]^{-1}$ defines the inverse of $\underline{H}_w(k)$.

Walsh-Ordered Walsh-Hadamard Transform (WHT_w)

The WHT_w of the data sequence $\{x(n)\} = \{x(0), x(1), \dots, x(N-1)\}$ is defined by

$$\underline{X}(n) = \frac{1}{N} \underline{H}_w(n)x(n) \quad (133.47)$$

where $\underline{X}(n)$ is the k th WHT_w coefficient and

$$\underline{X}(n)^T = [X(0), X(1), \dots, X(N-1)] \quad (133.48)$$

Since $\underline{H}_w(n)$ is orthogonal and symmetric, we find that the inverse Walsh-ordered Hadamard transform IWHT_w is given by

$$x(n) = H_w(n)X(n) \quad (133.49)$$

Example 133.3 Let $\{x(n)\} = \{1, 2, 2, 1\}$. To evaluate $\underline{X}(n)$ for $k = 0, 1, 2, 3$ we use Equation (133.47). Hence,

$$\begin{bmatrix} X(0) \\ X(1) \\ X(2) \\ X(3) \end{bmatrix} = \frac{1}{4} \begin{bmatrix} 1 & 1 & 1 & 1 \\ 1 & 1 & -1 & -1 \\ 1 & -1 & -1 & 1 \\ 1 & -1 & 1 & -1 \end{bmatrix} \begin{bmatrix} 1 \\ 2 \\ 2 \\ 1 \end{bmatrix} = \begin{bmatrix} 6/4 \\ 0 \\ -2/4 \\ 0 \end{bmatrix}$$

From the above example, we observe that N^2 additions and/or subtractions are required to compute the WHT_w coefficients $\underline{X}(n)$, $n = 0, 1, \dots, N - 1$.

Fast Walsh-Ordered Walsh-Hadamard Transform (FWHT_w)

Manz [1972] introduced an FWHT_w that has the following steps:

1. Bit-reverse the input sequence and order it in ascending index. For example, if $\{x(n)\} = \{x(1), x(2), x(3)\} = \{1, 2, 3\}$, the sequence becomes $\{\hat{x}(n)\} = \{1, 3, 2\} = \{\hat{x}(0), \hat{x}(1), \hat{x}(2)\}$.
2. Define a reversal, which is best illustrated by the simple case shown in Figure 133.5.

FIGURE 133.5 Reversal and nonreversal steps.

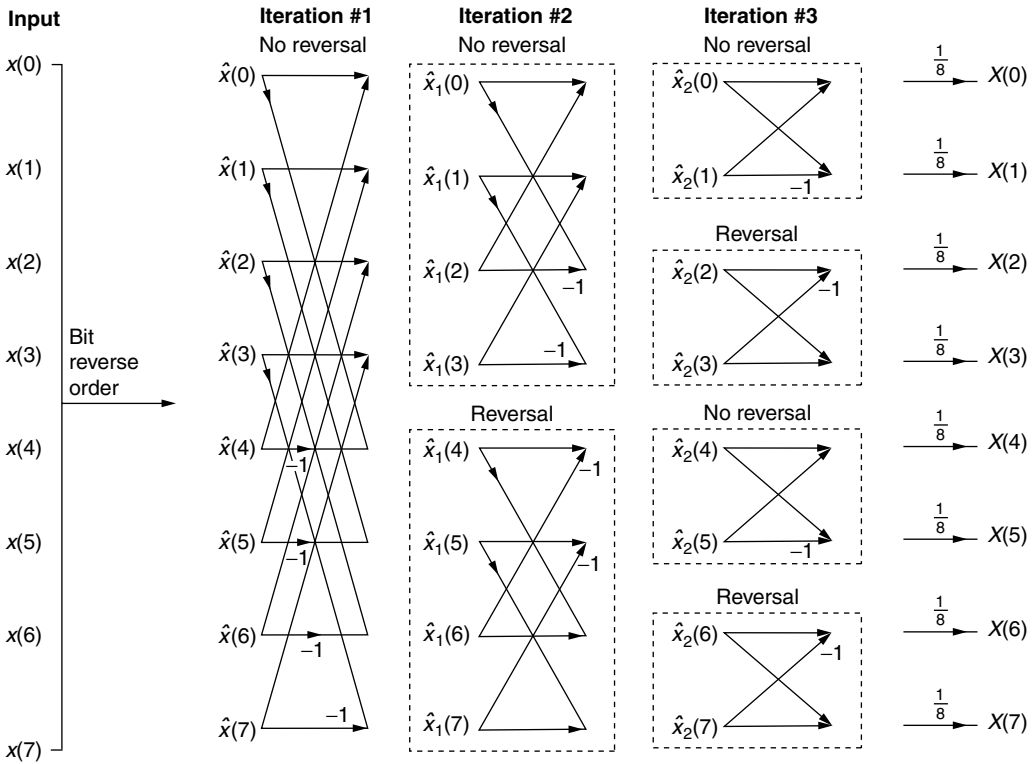

FIGURE 133.6 Fast Walsh-Hadamard transform.

3. Define the blocks that are reversed and nonreversed. Figure 133.6 shows the positions of blocks for an FWHT_w flow graph for $N = 8$.

Example 133.4 To find the WHT_w of the sequencing $\{x(n)\} = \{11213213\}$, we proceed as follows:

| | | | | | |
|------------|------------------------------|------------------------|------------------------|------------------------|-----------------------------------|
| $x(0) = 1$ | $\hat{x}(0)[000] = x(0) = 1$ | $x_1(0) = 1 + 1 = 2$ | $x_2(0) = 2 + 3 = 5$ | $x_3(0) = 5 + 9 = 14$ | $\frac{1}{8} X(0) = \frac{14}{8}$ |
| $x(1) = 1$ | $\hat{x}(1)[100] = x(4) = 1$ | $x_1(1) = 3 + 2 = 5$ | $x_2(1) = 5 + 4 = 9$ | $x_3(1) = -9 + 5 = -4$ | $\frac{1}{8} X(1) = -\frac{4}{8}$ |
| $x(2) = 2$ | $\hat{x}(2)[010] = x(2) = 2$ | $x_1(2) = 2 + 1 = 3$ | $x_2(2) = -3 + 2 = -1$ | $x_3(2) = -1 - 1 = -2$ | $\frac{1}{8} X(2) = -\frac{2}{8}$ |
| $x(3) = 1$ | $\hat{x}(3)[110] = x(6) = 1$ | $x_1(3) = 1 + 3 = 4$ | $x_2(3) = -4 + 5 = 1$ | $x_3(3) = 1 - 1 = 0$ | $\frac{1}{8} X(3) = \frac{0}{8}$ |
| $x(4) = 3$ | $\hat{x}(4)[001] = x(1) = 1$ | $x_1(4) = -1 + 1 = 0$ | $x_2(4) = 0 - 1 = -1$ | $x_3(4) = -1 + 3 = 2$ | $\frac{1}{8} X(4) = \frac{2}{8}$ |
| $x(5) = 2$ | $\hat{x}(5)[101] = x(5) = 2$ | $x_1(5) = -2 + 3 = 1$ | $x_2(5) = 1 + 2 = 3$ | $x_3(5) = -3 - 1 = -4$ | $\frac{1}{8} X(5) = -\frac{4}{8}$ |
| $x(6) = 1$ | $\hat{x}(6)[011] = x(3) = 1$ | $x_1(6) = -1 + 2 = 1$ | $x_2(6) = 1 + 0 = 1$ | $x_3(6) = 1 + 1 = 2$ | $\frac{1}{8} X(6) = \frac{2}{8}$ |
| $x(7) = 3$ | $\hat{x}(7)[111] = x(7) = 3$ | $x_1(7) = -3 + 1 = -2$ | $x_2(7) = -2 + 1 = -1$ | $x_3(7) = -1 + 1 = 0$ | $\frac{1}{8} X(7) = \frac{0}{8}$ |

The power spectrum of WHT_w is given by

$$P_w = X^2(0)$$

$$P_w(s) = X^2(2s-1) + X^2(2s), \quad s = 1, 2, \dots, \frac{N}{2} - 1$$

$$P_w\left(\frac{N}{2}\right) = X^2(N-1)$$

Defining Terms

Fast Fourier transform (FFT) — A computational technique that reduced the number of mathematical operations in the evaluation of the discrete Fourier transform (DFT) to $N \log_2(N)$.

Phase spectrum — All phases associated with the spectrum harmonics constitute the phase spectrum.

Power spectrum — A power contributed by each harmonic of the spectrum.

Window — Any appropriate function that multiplies that data with the intent of minimizing the distortion of the Fourier spectra.

[134.3 Digital Filter Implementation](#)

Digital filtering is concerned with the manipulation of **discrete data sequences** to remove noise or extract certain desired information. Discrete or digital signals are somewhat intuitive to human beings despite their rarity in nature. That is, people tend to make and tabulate measurements of physical entities in sets of data values with limited precision, while the entities being measured vary continuously both in their functional dependence and their value.

Although an infinite number of numerical manipulations can be applied to discrete data (e.g., finding the mean value, forming a histogram), the primary objective of digital filtering is to form a discrete output sequence $y(n)$ from a discrete input sequence $x(n)$. In some manner, each output data sample is computed from the input data sequence — not just from any one sample, but from many, in fact, possibly from all the input samples.

The reader may already be familiar with a few processing schemes. For example, computing a moving average is sometimes used as a means of reducing measurement uncertainty or noise in data. In a three-point symmetric scheme the output sequence is found by

$$y(n) = \frac{x(n-1) + x(n) + x(n+1)}{3}$$

Note that the output sequence in this case is a sum of products of the input sample values with certain coefficients. (In this case the coefficients all have the same value of $1/3$.)

To make some headway in analyzing digital filters, it is necessary to restrict in two ways the types of filters being considered. First, a given filter is restricted to being linear. This means that the response of the filter to a sum of inputs is the sum of the outputs corresponding to the inputs individually and that, if the input to the filter is scaled by a multiplicative factor, the output is scaled by the same factor.

The second restriction placed on the types of filters being analyzed is that they be shift-invariant. This property states that for any given input $x(n)$ producing output $y(n)$, the response of the filter to the shifted input $x(n - n_0)$ produces the same output sequence of values shifted by the same amount, namely, $y(n - n_0)$. Note that the moving average processing scheme satisfies these restrictions. However, a much larger class of processing algorithms also falls into the category of linear shift-invariant filters.

The output of a digital filter to any input can be determined from a formula known as the *convolution sum*. To derive this relation, consider first the unit impulse sequence defined as

$$\delta(n) = \begin{cases} 1 & \text{for } n = 0 \\ 0 & \text{otherwise} \end{cases}$$

By use of this special sequence any discrete sequence can be written

$$x(n) = \sum_{m=-\infty}^{\infty} x(m)\delta(n-m)$$

Suppose this sequence were input to a linear shift-invariant digital filter. Since the filter is linear, the output will be a linear combination of the outputs resulting from shifted unit impulse inputs. Since the filter is shift-invariant, the outputs will also be shifted by the same amounts. Thus, if the output of the filter in response to a single unit impulse at $n = 0$ is the sequence $h(n)$, the output of the filter to the input $x(n)$ will be the linear combination of shifted $h(n)$ sequences weighted with the coefficients of the $x(n)$ sequence:

$$y(n) = \sum_{m=-\infty}^{\infty} x(m)h(n-m)$$

By a change of dummy index of summation, it is easily shown that this can also be written as

$$y(n) = \sum_{m=-\infty}^{\infty} h(m)x(n-m)$$

These equations are known as the **convolution summation** and describe the output of the filter to any arbitrary input. Thus, in theory, the response of a given filter to any input can be computed from knowledge of the sequence $h(n)$, which is referred to as the *impulse response* of the filter. It is a sequence that is of extreme importance in digital filtering, since it completely describes the filter.

A digital filter is often conveniently described in terms of its frequency characteristics, which are given by the Fourier transform of its impulse response. The impulse response and frequency response make up the Fourier transform pair,

$$H(e^{j\omega}) = \sum_{n=-\infty}^{\infty} h(n)e^{-j\omega n}, \quad -\pi \leq \omega \leq \pi$$

$$h(n) = \frac{1}{2\pi} \int_{-\pi}^{\pi} H(e^{j\omega})e^{j\omega n}d\omega, \quad -\infty \leq n \leq \infty$$

where ω is the digital radian frequency. The discrete-time Fourier transform is expressed as a function of $e^{j\omega}$ rather than simply as a function of ω to distinguish the discrete-time transform from its continuous-time counterpart. The radian frequency ranging from $\omega = 0$ to $\omega = \pi$ corresponds to the “real-world” frequency range from 0 to $F_s/2$, where F_s is the sample rate of the discrete-time data. For example, if the sample rate of data into a digital filter is 2 kHz, then the frequency 100 Hz corresponds to $\omega = 0.1 \pi$.

Just as in the analysis of continuous-time systems, the operation of convolution is equivalent to the product of Fourier transforms in the frequency domain, $Y(e^{j\omega}) = H(e^{j\omega})X(e^{j\omega})$. Therefore, $H(e^{j\omega})$ may be treated as the *transfer function* of the digital filter since it relates the input Fourier transform to the Fourier transform of the output, specifying how each frequency component in the filter input is altered by the filter.

Closely related to the Fourier transform of $h(n)$ is the z transform defined by

$$H(z) = \sum_{n=-\infty}^{\infty} h(n)z^{-n}$$

$H(z)$ is referred to as the z -domain transfer function of the filter. The Fourier transform is then the z transform evaluated on the unit circle in the z plane ($z = e^{j\omega}$). An important property of the z transform is that $z^{-1}H(z)$ corresponds to $h(n-1)$, so z^{-1} represents a one-sample delay, termed a *unit delay*.

In this chapter, the focus will be restricted to **filter design** and **filter implementation** of frequency-selective filters. These filters are intended to pass frequency components of the input sequence in a given band of the spectrum while blocking the rest. Typical frequency-selective filter types are low-pass, high-pass, band-pass, and band-reject filters. Other special-purpose filters exist; however, their design is an advanced topic that will not be addressed here. In addition, special attention is given to causal filters for which the impulse response is identically zero for negative n and which can thus be implemented in real time.

134.1 Finite Impulse Response Filter Design

The objective of **finite impulse response (FIR) digital filter** design is to determine $N + 1$ coefficients

$$h(0), h(1), \dots, h(N)$$

so that the transfer function $H(e^{j\omega})$ approximates a desired frequency characteristic $H_d(e^{j\omega})$. All other impulse response coefficients are zero. An important property of FIR filters for practical applications is that they can be designed to be *linear phase*; that is, the transfer function has the form

$$H(e^{j\omega}) = A(e^{j\omega})e^{-j\omega N/2}$$

where the amplitude $A(e^{j\omega})$ is a real function of frequency. The desired transfer function can be similarly written

$$H_d(e^{j\omega}) = A_d(e^{j\omega})e^{-j\omega N/2}$$

where $A_d(e^{j\omega})$ describes the amplitude of the desired frequency-selective characteristics. For example, the amplitude frequency characteristics of an ideal low-pass filter are given by

$$A_d(e^{j\omega}) = \begin{cases} 1 & \text{for } |\omega| \leq \omega_c \\ 0 & \text{otherwise} \end{cases}$$

where ω_c is the *cutoff frequency* of the filter.

A linear phase characteristic ensures that a filter has a constant delay independent of frequency. Thus, all frequency components in the signal are delayed by the same amount, and the only signal distortion introduced is that imposed by the filter's frequency-selective characteristics.

Since an FIR filter can only approximate a desired frequency-selective characteristic, some measures of the accuracy of approximation are needed to describe the quality of the design. These are the *passband ripple* δ_p , the *stopband attenuation* δ_s , and the *transition bandwidth* $\Delta\omega$. These quantities are illustrated in [Figure 134.1](#) for a prototype low-pass filter. The passband ripple gives the maximum deviation from the desired amplitude (typically unity) in the region where the input signal spectral components are desired to be passed unattenuated. The stopband attenuation gives the maximum deviation from zero in the region where the input signal spectral components are desired to be blocked. The transition bandwidth

FIGURE 134.1 Amplitude frequency characteristics of an FIR low-pass filter showing definitions of passband ripple δ_p , stopband attenuation δ_s , and transition bandwidth $\Delta\omega$. (Source: Dorf, R. C., Ed. 1993. *The Electrical Engineering Handbook*. CRC Press, Boca Raton, FL, p. 240.)

gives the width of the spectral region in which the frequency characteristics of the transfer function change from the passband to the stopband values. Passband ripple and stopband attenuation are often specified in decibels, in which case their values are related to the quantities, δ_p and δ_s by the following:

$$\text{Passband ripple in dB} = P = -20\log_{10}(1 - \delta_p)$$

$$\text{Stopband attenuation in dB} = S = -20\log_{10} \delta_s$$

FIR Filter Design by Windowing

The windowing design method is a computationally efficient technique for producing nonoptimal filters. Filters designed in this manner have equal passband ripple and stopband attenuation:

$$\delta_p = \delta_s = \delta$$

The method begins by finding the impulse response of the desired filter from

$$h_d(n) = \frac{1}{2\pi} \int_{-\pi}^{\pi} A_d(e^{j\omega}) e^{j\omega(n - N/2)} d\omega$$

For ideal low-pass, high-pass, band-pass, and band-reject frequency-selective filters, the integral can be solved in closed form. The impulse response of the filter is then found by multiplying this ideal impulse response with a window $w(n)$ that is identically zero for $n < 0$ and for $n > N$:

$$h(n) = h_d(n)w(n), \quad n = 0, 1, \dots, N$$

Some commonly used windows are defined as follows:

Rectangular (truncation)

$$w(n) = \begin{cases} 1 & \text{for } 0 \leq n \leq N \\ 0 & \text{otherwise} \end{cases}$$

Hamming

$$w(n) = \begin{cases} 0.54 - 0.46 \cos(2\pi n / N) & \text{for } 0 \leq n \leq N \\ 0 & \text{otherwise} \end{cases}$$

Kaiser

$$w(n) = \begin{cases} I_0\left(\beta \sqrt{1 - [(2n - N) / N]^2}\right) / I_0(\beta) & \text{for } 0 \leq n \leq N \\ 0 & \text{otherwise} \end{cases}$$

In general, windows that slowly taper the impulse response to zero result in lower passband ripple and a wider transition bandwidth. Other windows (e.g., Hanning, Blackman) are also sometimes used, but not as often as those shown above.

Of particular note is the Kaiser window where $I_0(\cdot)$ is the 0th-order modified Bessel function of the first kind, and β is a shape parameter. The proper choice of N and β allows the designer to meet given passband ripple, stopband attenuation, and transition bandwidth specifications. Specifically, using S , the stopband attenuation in dB, the filter order must satisfy

$$N = \frac{S - 8}{2.285 \Delta \omega}$$

Then the required value of the shape parameter is given by

$$\beta = \begin{cases} 0 & \text{for } S < 21 \\ 0.5842(S - 21)^{0.4} + 0.07886(S - 21) & \text{for } 21 \leq S \leq 50 \\ 0.1102(S - 8.7) & \text{for } S > 50 \end{cases}$$

Consider as an example of this design technique a low-pass filter with a cutoff frequency of $\omega_c = 0.4\pi$. The ideal impulse response for this filter is given by

$$h_d(n) = \frac{\sin[0.4\pi(n - N/2)]}{\pi(n - N/2)}$$

Choosing $N = 8$ and a Kaiser window with shape parameter of $\beta = 0.5$ yields the following impulse response coefficients:

$$h(0) = h(8) = -0.07568267$$

$$h(1) = h(7) = -0.06236596$$

$$h(2) = h(6) = 0.09354892$$

$$h(3) = h(5) = 0.30273070$$

$$h(4) = 0.40000000$$

Design of Optimal FIR Filters

The accepted standard criterion for the design of optimal FIR filters is to minimize the maximum value of the error function

$$E(e^{j\omega}) = W_d(e^{j\omega}) |A_d(e^{j\omega}) - A(e^{j\omega})|$$

over the full range of $-\pi \leq \omega \leq \pi$. $W_d(e^{j\omega})$ is a desired weighting function used to emphasize specifications in a given frequency band. The ratio of the deviation in any two bands is inversely proportional to the ratio of their respective weighting.

A consequence of this optimization criterion is that the frequency characteristics of optimal filters are *equiripple*: although the maximum deviation from the desired characteristic is minimized, it is reached several times in each band. Thus, the passband and stopband deviations oscillate about the desired values with equal amplitude in each band. Such approximations are frequently referred to as *mini-max* or *Chebyshev* approximations. In contrast, the maximum deviations occur near the band edges for filters designed by windowing.

Equiripple FIR filters are usually designed using the *Parks–McClellan* computer program [Antoniou, 1979], which uses the *Remez exchange algorithm* to determine iteratively the *extremal frequencies* at which the maximum deviations in the error function occur. A listing of this program along with a detailed description of its use is available in several references, including Parks and Burrus [1987] and DSP Committee [1979]. The program is executed by specifying as inputs the desired band edges, gain for each band (usually 0 or 1), band weighting, and filter impulse response length. If the resulting filter has too much ripple in some bands, those bands can be weighted more heavily and the filter redesigned. Details on this design procedure are discussed in Rabiner [1973] along with approximate design relationships that aid in selecting the filter length needed to meet a given set of specifications.

Although we have focused on the design of frequency-selective filters, other types of FIR filters exist. For example, the Parks–McClellan program will also design linear-phase FIR filters for differentiating broadband signals and for approximating the Hilbert transform of such signals.

For practice in the principles of equiripple filter design, consider an eighth-order low-pass filter with a passband $0 \leq \omega \leq 0.3\pi$, a stopband $0.5\pi \leq \omega \leq \pi$, and equal weighting for each band. The impulse response coefficients generated by the Parks–McClellan program are as follows:

$$h(0) = h(8) = -0.063\ 678\ 59$$

$$h(1) = h(7) = -0.069\ 122\ 76$$

$$h(2) = h(6) = 0.101\ 043\ 60$$

$$h(3) = h(5) = 0.285\ 749\ 90$$

$$h(4) = 0.410\ 730\ 00$$

These values can be compared to those for the similarly specified filter designed in the previous section using the windowing method.

134.2 Infinite Impulse Response Filter Design

An **infinite impulse response (IIR) digital filter** requires less computation to implement than an FIR digital filter with a corresponding frequency response. However, IIR filters cannot generally achieve a perfect linear phase response.

Techniques for the design of infinite impulse response analog filters are well established. For this reason, the most important class of IIR digital filter design techniques is based on forcing a digital filter to behave like a reference analog filter. For frequency-selective filters, this is generally done by attempting to match

frequency responses. This task is complicated by the fact that the analog filter response is defined for an infinite range of frequencies ($\Omega = 0$ to ∞), whereas the digital filter response is defined for a finite range of frequencies ($\omega = 0$ to π). Therefore, a method for mapping the infinite range of analog frequencies, Ω , into the finite range from $\omega = 0$ to π known as the *bilinear transform* is employed.

Let $H_a(s)$ be the Laplace transform transfer function of an analog filter with frequency response $H_a(j\Omega)$ (Ω in radians/s). The bilinear transform method obtains the digital filter transfer function $H(z)$ from $H_a(s)$ using the substitution

$$s = \frac{2}{T} \frac{1 - z^{-1}}{1 + z^{-1}}$$

that is,

$$H(z) = H_a(s) \Big|_{s=(2/T)(1-z^{-1})/(1+z^{-1})}$$

This transformation maps analog frequency Ω to digital frequency ω according to

$$\omega = 2 \tan^{-1} \left(\frac{\Omega T}{2} \right)$$

thereby warping the frequency response $H_a(j\Omega)$ and forcing it to lie between 0 and π for $H(e^{j\omega})$. Therefore, to obtain a digital filter with a cutoff frequency of ω_c , it is necessary to design an analog filter with cutoff frequency

$$\Omega_c = \frac{2}{T} \tan \left(\frac{\omega_c}{2} \right)$$

This process is referred to as *prewarping* the analog filter frequency response to compensate for the warping of the bilinear transform. Applying the bilinear transform substitution to this analog filter will then give a digital filter that has the desired cutoff frequency.

Analog filters and hence IIR digital filters are typically specified in a slightly different fashion than are FIR filters. Figure 134.2 illustrates how analog and IIR digital filters are usually specified. Note that by

FIGURE 134.2 Frequency characteristics of an IIR digital low-pass filter showing definitions of passband ripple δ_p , stopband attenuation δ_s , and transition bandwidth $\Delta\omega$. (Source: Dorf, R. C., Ed. 1993. *The Electrical Engineering Handbook*. CRC Press, Boca Raton, FL, p. 244.)

comparing to Figure 134.1 that the passband ripple in this case never goes above unity, where in the FIR case the passband ripple is specified about unity.

Four basic types of analog filters are generally used to design digital filters: (1) Butterworth filters, which are maximally flat in the passband and decrease monotonically outside the passband; (2) Chebyshev filters, which are equiripple in the passband and decrease monotonically outside the passband; (3) inverse Chebyshev filters, which are flat in the passband and equiripple in the stopband; and (4) elliptic filters, which are equiripple in both the passband and stopband. Techniques for designing these analog filters are covered elsewhere [e.g., Van Valkenberg (1982)] and will not be considered here.

To illustrate the design of an IIR digital filter using the bilinear transform, consider the design of a second-order Chebyshev low-pass filter with 0.5 dB of passband ripple and a cutoff frequency of $\omega_c = 0.4\pi$. The sample rate of the digital filter is to be 5 Hz, giving $T = 0.2$ seconds. To design this filter, we first design an analog Chebyshev low-pass filter with a cutoff frequency of

$$\Omega_c = \frac{2}{0.2} \tan(0.2\pi) = 7.2654 \text{ rad/s}$$

This filter has a transfer function

$$H(s) = \frac{0.9441}{1 + 0.1249s + 0.01249s^2}$$

Substituting

$$s = \frac{2}{0.2} \frac{z-1}{z+1}$$

gives

$$H(z) = \frac{0.2665(z+1)^2}{z^2 - 0.1406z + 0.2695}$$

Computer programs are available that accept specifications on a digital filter and carry out all steps required to design the filter, including prewarping the frequencies, designing the analog filter, and performing the bilinear transform. Two such programs are given in Parks and Burrus [1987] and Antoniou [1979].

Notch Filters

An important special type of IIR filter is the notch filter. Such filters can remove a very narrow band of frequencies and are useful for applications like removing 60-Hz noise from data. The following second-order z -domain transfer function realizes a notch filter at frequency ω_0 :

$$H(z) = \frac{1 - 2\cos\omega_0 z^{-1} + z^{-2}}{1 - 2r \cos\omega_0 z^{-1} + r^2 z^{-2}}$$

The parameter r is restricted to the range $0 < r < 1$. Substituting $z = e^{j\omega}$, multiplying the numerator and denominator by $e^{j\omega}$, and applying some trigonometric identities yields the following frequency response for the filter:

$$H(e^{j\omega}) = \frac{2\cos\omega - 2\cos\omega_0}{(1+r^2)\cos\omega - 2r\cos\omega_0 + j(1-r^2)\sin\omega}$$

From this expression it can easily be seen that the response of the filter at $\omega = \omega_0$ is exactly zero. Another property is that, for $r \cong 1$ and $\omega \neq \omega_0$, the numerator and denominator are very nearly equal, and so the response is approximately unity. Overall, this is a very good approximation of an ideal notch filter as $r \rightarrow 1$.

134.3 Digital Filter Implementation

For FIR filters the convolution sum represents a computable process, and so filters can be implemented by directly programming the arithmetic operations

$$y(n) = h(0)x(n) + h(1)x(n-1) + \dots + h(N)x(n-N)$$

However, for an IIR filter the convolution sum does not represent a computable process. Therefore, it is necessary to examine the general transfer function, which is given by

$$H(z) = \frac{Y(z)}{X(z)} = \frac{\gamma_0 + \gamma_1 z^{-1} + \gamma_2 z^{-2} + \dots + \gamma_M z^{-M}}{1 + \beta_1 z^{-1} + \beta_2 z^{-2} + \dots + \beta_N z^{-N}}$$

where $Y(z)$ is the z transform of the filter output, $y(n)$, and where $X(z)$ is the z transform of the filter input, $x(n)$. The unit-delay characteristic of z^{-1} then gives the following **difference equation** for implementing the filter

$$y(n) = \gamma_0 x(n) + \gamma_1 x(n-1) + \dots + \gamma_M x(n-M) - \beta_1 y(n-1) - \dots - \beta_N y(n-N)$$

In calculations of $y(0)$, the values of $y(-1)$, $y(-2)$, ..., $y(-N)$ represent initial conditions on the filter. If the filter is started in an initially relaxed state, then these initial conditions are zero.

Defining Terms

Convolution summation — A possibly infinite summation expressing the output of a digital filter in terms of the impulse response coefficients of the filter and present and past values of the input to the filter. For finite-impulse-response filters, this summation represents a way of implementing the filter.

Difference equation — An equation expressing the output of a digital filter in terms of present and past values of the filter input and past values of the filter output. For infinite-impulse-response filters, a difference equation must be used to implement the filter since the convolution summation is infinite.

Discrete data sequence — A set of values constituting a signal whose values are known only at distinct sampled points.

Filter design — The process of determining the impulse response coefficients or coefficients of a difference equation to meet a given frequency or time response characteristic.

Filter implementation — The numerical method or algorithm by which the output sequence of a digital filter is computed from the input sequence.

Finite impulse response (FIR) digital filter — A filter whose output in response to a unit impulse function is identically zero after a given bounded number of samples.

Infinite impulse response (IIR) digital filter — A filter whose output in response to a unit impulse function remains nonzero for an indefinite number of samples.

135.1 Introduction

The objective in communications is to reproduce a source output (or, message signal) at a destination. Depending on the type of the message signal and the modulation scheme employed, communication systems can be classified as analog or digital. Examples of analog communication systems include commercial radio and television broadcast, first generation cellular systems such as advanced mobile phone service (AMPS) in the U.S., among others. On the other hand, most current telephone systems, second and third generation cellular systems such as GSM, and magnetic recording systems represent examples of digital communications systems.

The basic block diagram of an analog communication system is shown in [Figure 135.1](#). The message signal is modulated, and sent over the channel by the transmitter. There are several objectives in modulation. For example, the channel may not be suitable for the transmission of the original message signal directly either due to the physical channel characteristics, or due to the frequency allocation mandated by a regulatory body. Furthermore, through modulation, multiple messages can be transmitted over the same medium, and also, depending on the specific modulation scheme, the signal quality can be improved at the receiver.

The channel block represents the physical medium over which transmission takes place. Examples include the atmosphere, telephone lines, optical fiber, and coaxial cables. The channel corrupts the transmitted signal by introducing attenuation, interference, multipath fading, additive noise, etc. The simplest, but useful, model to capture some of these effects is that of an additive white Gaussian noise (AWGN) channel where the transmitted signal is attenuated in a deterministic manner, and white Gaussian noise is added on it. For simplicity, we limit our attention to this channel model throughout the chapter. At the receiver side, the channel output is demodulated to obtain an estimate of the original message signal.

FIGURE 135.1 Block diagram of an analog communication system.

FIGURE 135.2 Block diagram of a digital communication system.

Some messages, such as computer files and text messages, are by nature digital, meaning that they are represented by a sequence of M -ary symbols. Furthermore, if an analog message signal is bandlimited, which is the case for almost all message signals, it can be sampled and quantized, and thus converted to a digital form. Therefore, it is also of importance to address the transmission of digital messages. In fact, digital communications offer various advantages over many analog communication techniques, for example, in terms of the performance in noise, cost, power, and bandwidth requirements as will become clear later in the chapter.

The block diagram of a general digital communication system is illustrated in Figure 135.2. The message sequence is first passed to a source encoder which removes the redundancy in the sequence, i.e., compresses it. This is very similar to the operation of the “zip” programs used to compress computer files. After the redundancy is removed, the information sequence is fed to a channel encoder block, which effectively adds “controlled” redundancy to protect the transmitted data against the channel impairments. The channel coded data is then modulated using a digital modulation technique which converts the sequence of symbols to a form that can be transmitted over the channel, for example, to an electrical signal for the case of telephony.

At the receiver side, the channel output is first demodulated and estimates of the channel coded symbols are obtained. Then, these symbols are passed through the channel decoder and the source decoder to obtain the message sequence at the destination.

This chapter reviews the basic blocks of both analog and digital communication systems. Emphasis is given to the description of the various modulation schemes. The chapter is organized as follows. Section 135.2 deals with analog modulation. Both amplitude modulation and angle modulation schemes are discussed, and the effects of noise on the performance are explained. Section 135.3 presents the basics of digital modulation techniques. Section 135.4 deals with the transmission of different messages over the same medium, and finally, Section 135.5 provides a brief summary.

135.2 Analog Communications

Before we present the details of various analog modulation techniques, we start with a review of the concept of frequency and present basic mathematical tools that will be necessary. We then review the amplitude modulation schemes where the signal is embedded in the amplitude of a carrier signal. We next describe the angle modulation schemes where the information is embedded in the phase or the frequency of the carrier. We conclude the section with a review of the effects of noise in analog modulation schemes.

Concept of Frequency and Fourier Transform

Frequency of a signal is a measure of how fast the signal is changing. In Figure 135.3, three sample signals are given. The first one is clearly changing more slowly than the second, and the second one is changing more slowly than the third. This is illustrated by the statement that the first signal is a “low” frequency signal, the second one is a “medium” frequency signal, and the last one is a “high” frequency signal. We

| $\Pi(t) = \begin{cases} 1 & t \leq 1/2 \\ 0 & \text{otherwise} \end{cases}$ | $\frac{\sin(\pi f)}{\pi f}$ |
| $\sin(\pi t) / \pi t$ | $\Pi(f)$ |
| $e^{-\alpha t} u_{-1}(t), \alpha > 0$ | $\frac{1}{\alpha + j2\pi f}$ |
| $\text{sgn}(t) = \begin{cases} 1 & t > 0 \\ -1 & t < 0 \\ 0 & t = 0 \end{cases}$ | $\frac{1}{j\pi f}$ |

note that usually the message signals (e.g., speech signals) are low frequency signals, whereas the modulated signals are “high” frequency ones.

Fourier transform represents a convenient mathematical tool that can be used to study the frequency content of a signal. The Fourier transform of a signal $x(t)$ is defined (under certain regulatory conditions) as

$$X(f) = \int_{-\infty}^{\infty} x(t)e^{-j2\pi ft} dt \tag{135.1}$$

where $j = \sqrt{-1}$ and the dummy variable “ f ” denotes the frequency. The inverse Fourier transform can be obtained as

$$x(t) = \int_{-\infty}^{\infty} X(f)e^{j2\pi ft} df \tag{135.2}$$

Some common signals and their Fourier transforms are given in Table 135.1

In Figure 135.4, three example Fourier transforms are shown. The signal on the left is referred to as a baseband signal because it contains only low-frequency components, i.e., the frequency content is concentrated around $f = 0$. For the other two, the Fourier transforms are concentrated around some higher frequencies and therefore are referred to as “bandpass” signals. An important characteristic of a signal is its bandwidth (W), which is measured as the positive frequency content of its Fourier transform which is also illustrated in Figure 135.4.

There are a number of important properties of the Fourier transform. For example, Fourier transform is linear. Also, it is easy to show that convolution in time domain is equivalent to multiplication in

FIGURE 135.4 Sample “low”, “medium”, and “high” frequency signals in frequency domain.

frequency domain, and vice versa. Furthermore, shift in time results in a multiplication by a complex exponential in the frequency domain. For a detailed discussion of these and other properties of the Fourier transform, the reader is referred to the references at the end of the chapter.

The response of a system to a given input is important to study various aspects of communications. A system is called linear if

$$\mathcal{L}\{ax_1(t) + bx_2(t)\} = a\mathcal{L}\{x_1(t)\} + b\mathcal{L}\{x_2(t)\} \quad (135.3)$$

for all scalar a and b . And, it is called time invariant if

$$y(t - t_0) = \mathcal{L}\{x(t - t_0)\} \quad (135.4)$$

for any t_0 , where $y(t)$ is the response of the system to the input $x(t)$.

Linear time invariant (LTI) systems are useful to describe the effects of many communications channels, as well as the filters that are needed in the implementation of communication systems. An LTI system is completely characterized by its impulse response, denoted by $h(t)$, which is nothing but the response of the system to an impulse applied at $t = 0$. The output of the LTI system to an input $x(t)$ is given by the convolution integral

$$y(t) = x(t) * h(t) \quad (135.5)$$

$$= \int_{-\infty}^{\infty} x(\tau)h(t - \tau)d\tau \quad (135.6)$$

The Fourier transform of the impulse response, $H(f)$, is referred to as the transfer function of the system. With this definition, the input/output relationship of the LTI system (in the frequency domain) can be conveniently written as

$$Y(f) = X(f)H(f). \quad (135.7)$$

Amplitude Modulation

In amplitude modulation (AM), the message signal $m(t)$ is embedded in the amplitude of the carrier $c(t) = A_c \cos(2\pi f_c t + \phi_c)$ where A_c is the amplitude, ϕ_c is the phase and f_c is the frequency of the carrier signal. There are several amplitude modulation techniques, namely, double sideband suppressed carrier (DSB-SC) AM, conventional AM, single sideband (SSB) AM, and vestigial sideband (VSB) AM.

DSB-SC AM

For DSB-SC AM, the modulated signal is given by

$$u(t) = m(t)c(t) \quad (135.8)$$

$$= A_c m(t) \cos(2\pi f_c t + \phi_c). \quad (135.9)$$

It is easy to show that in the frequency domain we have

$$U(f) = M(f) * C(f) \quad (135.10)$$

$$= \frac{A_c}{2} e^{j\phi_c} M(f - f_c) + \frac{A_c}{2} e^{-j\phi_c} M(f + f_c). \quad (135.11)$$

FIGURE 135.5 A typical message signal and its DSB-SC AM modulated version.

FIGURE 135.6 Demodulation of DSB-SC AM modulated signals.

Figure 135.5 illustrates the magnitude spectrum of a typical message signal, and the DSB-SC AM modulated signal. It is clear that the modulator simply “translates” the frequency content of the (base-band) message signal to the carrier frequency, which is selected to make sure that the transmitted signal matches the channel characteristics. In this case, both upper and lower sidebands of the modulated signal (shown in the figure) are transmitted. Therefore, the bandwidth of the modulated signal (i.e., the transmission bandwidth necessary) is twice the bandwidth of the message signal (W).

The demodulation of a DSB-SC AM modulated signal is performed as follows. A reference carrier signal is obtained using a phase locked loop circuit, then the received signal is mixed with the reference carrier signal, the resulting signal is passed through a low-pass filter whose bandwidth is the same as the original message bandwidth. The reference signal can also be obtained through the transmission of a small carrier component (i.e., pilot tone) along with the message signal. Figure 135.6 illustrates the demodulation process. In the absence of channel noise, i.e., when the received signal is identical to the transmitted signal, assuming that there is no estimation error in the phase of the carrier, it is easy to see that the receiver output is proportional to $m(t)$, thus the message signal is recovered.

Conventional AM

For DSB-SC AM, a phase-locked loop is needed to reproduce the carrier signal to be used in the demodulation process. However, this circuit is usually expensive, and thus not appropriate for certain applications such as broadcasting where a very cheap receiving circuit is required. With this motivation, in conventional AM, a large carrier component along with the amplitude modulated signal is transmitted. Mathematically, the modulated signal is given by

$$u(t) = A_c(1 + am_n(t))\cos(2\pi f_c t + \phi_c) \quad (135.12)$$

where the $m_n(t)$ is the normalized message signal, i.e.,

$$m_n(t) = \frac{m(t)}{\max |m(t)|}$$

and a is the modulation index. We usually select $a \leq 1$, otherwise, the signal is over-modulated.

FIGURE 135.7 A typical message signal and its conventional AM modulated version.

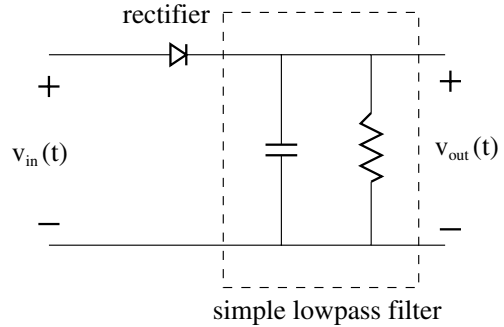

FIGURE 135.8 Envelop detector used to demodulate conventional AM modulated signals.

In the frequency domain, we have

$$U(f) = \frac{A_c}{2} e^{j\omega_c t} (M(f - f_c) + \delta(f - f_c)) + \frac{A_c}{2} e^{-j\omega_c t} (M(f + f_c) + \delta(f + f_c)). \quad (135.13)$$

Figure 135.7 illustrates a typical conventional AM modulated signal in the frequency domain. The bandwidth required for transmission is the same as the one for DSB-SC AM, i.e., $2W$.

As long as the signal is not over-modulated, a simple envelop detector circuit can be used for demodulation, which is nothing but a rectifier and a low-pass filter as shown in Figure 135.8. Clearly, a synchronous demodulator can also be used; however, this will unnecessarily complicate the implementation.

SSB and VSB AM

For DSB-SC AM, both the lower sideband and the upper sideband of the modulated signal are transmitted as shown in Figure 135.5. However, only one of the sidebands is sufficient for the proper demodulation of the message signal at the receiver. SSB AM transmits only one of the sidebands to reduce the bandwidth requirement to W (as compared to $2W$). The SSB AM signal can simply be obtained by bandpass filtering the DSB AM signal, and can be demodulated in exactly the same way.

In practice, the strict requirements for the bandpass filter make the implementation of the SSB AM expensive. As a remedy, another filter that keeps a “vestige” of the other sideband along with the sideband being transmitted can also be used. The resulting modulation scheme is the VSB AM. In this case, the bandwidth required to transmit the modulated signal is only slightly larger than W , and the scheme is much easier to implement. As long as the filter is selected such that $H(f - f_c) + H(f + f_c)$ is constant for $|f| \leq W$, the message signal can be demodulated in exactly the same way as in DSB-SC AM and SSB AM. VSB AM finds applications in, for example, TV broadcasting.

Angle Modulation

In angle modulation, the message signal is transmitted in the “angle” (i.e., frequency or phase) of the carrier signal as opposed to its amplitude. There are two main angle modulation schemes, namely, frequency modulation (FM) and phase modulation (PM).

The modulated signal is given by

$$u(t) = A_c \cos(2\pi f_c t + \phi(t)) \quad (135.14)$$

where k_p and k_f are constants. For PM, we select $\phi(t) = k_p m(t)$, and for FM we choose $\phi(t) = 2\pi k_f \int_{-\infty}^t m(\tau) d\tau$.

The modulation index is defined as $\beta_p = k_p \max |m(t)|$ for PM, and $\beta_f = \frac{k_f \max |m(t)|}{W}$ for FM, where k_p and k_f are constants.

Frequency domain analysis for angle modulation schemes is very difficult except for some very simple cases. However, there is a simple rule called Carson's rule that can be used to determine the required transmission bandwidth. Carson's rule simply states that the effective bandwidth of the modulated signal which contains more than 98% of the total signal power is $B_c = 2(\beta + 1)W$ where β is the modulation index. Clearly, depending on the modulation index used, this may be significantly more than the required bandwidth for the amplitude modulation schemes.

Frequency discriminator which is composed of a differentiator and an envelop detector can be used for demodulation. For example, for an FM signal, the output of the differentiator is simply proportional to $f_c + k_f m(t)$, and since f_c is usually very large, this quantity is always non-negative, and the message signal can be recovered by the envelop detector. One can also use a phase locked loop circuit to demodulate the angle-modulated signals. The latter is more expensive to implement, but it offers a better performance (when there is noise present).

Noise in Analog Communications

As mentioned in the introductory section, the received signal is corrupted by channel noise which degrades the demodulated signal quality at the output of the receiver. Signal to noise ratio (SNR) is usually used as such a measure. A detailed mathematical treatment of noise and the resulting SNR is beyond the scope of this chapter; however, some observations are in order.

Amplitude modulation schemes cannot improve the signal quality (compared to the baseband system, i.e., no modulation). Specifically, it can be shown that DSB-SC AM and SSB AM result in the same output SNR as the reference baseband system. SNR for the VSB AM depends on the characteristics of the filter used, however, it is very similar to the SSB AM case. On the other hand, for conventional AM together with the message signal, a large carrier component – which contains no information – is transmitted. The modulation index should be selected as close to 1 as possible to maximize the SNR; however, even for $a = 1$, at least 50% of the power is spent on the carrier component. Therefore, in order to achieve the same output SNR, the transmission power must be increased considerably, resulting in an inferior output SNR compared to that of the baseband system, and the other amplitude-modulation schemes.

On the other hand, the significant bandwidth expansion introduced by the angle modulation schemes helps improve the signal quality at the receiver output considerably. In general, the larger the modulation index (for the angle-modulation scheme), the higher the resulting output SNR. However, the modulation index cannot be made arbitrarily large to increase the output SNR, as a phenomenon called “threshold effect” occurs. If the baseband SNR reduces below a threshold (which increases with the modulation index), the receiver output cannot be distinguished from noise. Therefore, for a given background noise level, there is an upper limit on the modulation index that can be used. The output signal fidelity can further be improved by the use of pre-emphasis/de-emphasis filtering, which effectively uses FM for the low-frequency components of the message signal, and PM for the high-frequency components. Finally, we note that the demodulation scheme being used affects the output signal-to-noise ratio that can be obtained. The receivers which have feedback (e.g., a phase-locked loop) result in a significantly larger output SNR compared to the other alternatives (e.g., frequency discriminator).

Regardless of the specific modulation scheme employed, transmitted signal gets attenuated over the communication link. For example, for free space, the received signal power is inversely proportional to the square of the transmitter/receiver separation. Therefore, if the transmitter/receiver separation is large, the signal power at the receiver input is small, resulting in a significant loss in the SNR. One way to combat attenuation is to boost the transmit signal power; however, this is not an efficient way. For example, for free space, if the separation is increased tenfold, the transmit power should be increased 100 times to ensure the same signal-to-noise ratio is achieved. A more efficient way to counteract the harmful effects of signal attenuation is to use “analog repeaters” between the source and the destination. An analog repeater simply amplifies the signal it receives, and relays it to the destination. It can be shown that even though amplifiers used may have an internal noise that “corrupts” the signal before retransmission, they can be very effective in reducing the overall power requirements of the transmitter.

135.3 Digital Communications

This section deals with the transmission of digital information as opposed to the analog sources considered in the previous section. Before we proceed, we should note that there are many advantages of digital communications over analog communication techniques. For example, with digital communications, the received signal fidelity can be improved significantly. Also, digital transmitters require less power consumption, less bandwidth (by exploiting the redundancy in the data), and are inexpensive to build. Furthermore, data transmission is possible, and also secure communications can be accomplished with relative ease.

The section is organized as follows. We first review digital information sources in brief, and consider analog to digital conversion. We then give an overview of various baseband and carrier modulation techniques. We consider the optimal receiver in the presence of additive white Gaussian noise, and comment on the effects of noise on the performance of the system.

Digital Sources and Analog to Digital Conversion

As opposed to analog sources such as a speech signal, many information sources, such as text messages or data files, are digital. That is, they are represented by sequences of M -ary symbols. For the case of $M = 2$, the resulting source is said to be a binary information source, and the alphabet used is simply $\{0,1\}$. This is probably the most common way of representing digital information sources.

Even though a source output may be analog to start with, it can be converted to digital with negligible loss of fidelity provided that the analog to digital (A/D) conversion is carried out properly. This conversion is done by sampling and quantization. Sampling theorem states that, if the message signal is bandlimited to W , we can reconstruct it from its samples provided that the samples are taken at a rate greater than or equal to the Nyquist rate, i.e., $2W$. For example, a telephone-quality speech signal is bandlimited to $W = 3.4$ KHz. Therefore, if we sample the signal using a sampling frequency of 6.8 KHz (i.e., 6800 samples per second) or more, the samples are theoretically sufficient to represent the original message signal. We note that there is no loss in signal fidelity in this step.

The second step in A/D conversion is quantization. The samples of the analog message signal usually take on a continuum of values, thus it is impossible to represent them with infinite accuracy digitally. Instead, each sample is represented by a finite number of bits by employing a quantizer which maps the signal value to the closest allowable quantization level. For example, for a speech source, if 8 bit (256 level) quantization is used, and 8 KHz sampling frequency is employed, the original source is represented by 64 K bits/sec. We note that the quantization operation results in a “loss” in signal quality. However, this loss may be reduced by selecting the number of quantization levels sufficiently large.

Pulse Code Modulation

Pulse Code Modulation (PCM) whose block diagram is given in [Figure 135.9](#) represents a popular method of analog-to-digital conversion. The analog signal is first sampled at a rate greater than the Nyquist rate,

FIGURE 135.9 Block diagram of a uniform pulse code modulation scheme.

the samples are quantized using a uniform quantizer, and then represented by using binary digits. Uniform quantization means that the quantization regions are selected to be of equal length. The number of quantization levels is usually selected to be a power of 2 so that a ν -bit quantizer can be used effectively. A popular application of PCM is digital telephony.

In order to transmit one bit per second, the minimum bandwidth needed (with binary modulation) is $1/2$ Hz (although, in practice a higher bandwidth may be necessary due to practical limitations). If the source is sampled at a rate f_s samples/sec, the data rate is $f_s \nu$ bits/sec. Therefore, the minimum bandwidth needed to transmit the PCM signal is $f_s \nu/2$ Hz. Furthermore, if the sampling frequency is selected to be equal to the Nyquist rate (i.e., $f_s = 2W$), the minimum bandwidth needed is found to be $W\nu$. Therefore, if the number of quantization levels is increased in an attempt to make the quantization loss small, a larger transmission bandwidth will be required. For example, increasing the number of bits per sample by 1 increases the signal to quantization noise ratio by approximately 6 dB while requiring an additional bandwidth of W Hz for transmission.

For many sources, the source outputs are not uniformly distributed on their full range. For example, for speech sources, the low amplitude levels are more likely than the higher amplitude levels. Therefore, it will be beneficial if, effectively, a larger number of quantization levels (resulting in finer quantization) are used for the more likely amplitude levels. One way to accomplish this is to use a nonuniform quantizer instead of the uniform one in the PCM scheme. However, this is unnecessarily expensive. This motivates the use of a nonuniform PCM which is obtained by using a compressor/expander pair (usually referred as a compander) together with a uniform PCM scheme. A compressor is an invertible nonlinear mapping that maps the range of the more likely outputs to a wider region, and compresses the less likely ones. A compressor is used before sampling the analog signal, and its inverse (corresponding expander) is used at the receiver end after the signal is converted to analog. A μ -law compander and an A -law compander are used for digital telephony in North America and in Europe, respectively. The use of nonuniform PCM results in significant increase in the signal quality.

By exploiting the properties of typical analog sources (e.g., speech sources), other variations of “waveform coding” techniques, such as differential PCM, Delta Modulation, and Adaptive Delta Modulation are also used in practice.

Digital Modulation Techniques

Many different modulation methods can be used to convert the digital information (i.e., the sequence of M -ary symbols) to a form suitable for transmission over the channel. In this section, we review several important digital baseband and carrier modulation schemes.

Digital Baseband Transmission

An example of a digital baseband modulation scheme is the baseband pulse amplitude modulation (PAM) where the M -ary symbols are transmitted in the amplitude of a basic pulse. More specifically, the transmitted signal corresponding to the symbol m is given by

$$s_m(t) = A_m g(t) \leq t \leq T \quad (135.15)$$

where $A_m = 2m + 1 - M$, $m \in \{0, 1, 2, \dots, M-1\}$, and $g(t)$ is the baseband pulse. For the case of binary transmission ($M = 2$), “0” is transmitted using $s_0(t) = -g(t)$, and “1” is transmitted with $s_1(t) = g(t)$.

FIGURE 135.10 Signal constellations for PAM and OOK.

FIGURE 135.11 Transmitted 4-ary PAM and 4-ary PPM signals corresponding to the sequence $\{2,0,1,3,2\}$.

Another baseband modulation scheme is on-off keying (OOK) where “1” is transmitted using a basic pulse $s_1(t) = g(t)$, “0” is transmitted using $s_0(t) = 0$.

If $g(t)$ is used as a basis function, the PAM- and OOK-modulated signals can conveniently be represented in vector form. For PAM the vector representation is then $s_m = A_m$, and for OOK, $s_0 = 0$ and $s_1 = 1$. This representation leads to a convenient representation for the signal constellation for PAM and OOK as shown in Figure 135.10.

Pulse position modulation (PPM) is another method of digital baseband modulation. As opposed to the PAM and OOK, in this case, the information is transmitted in the relative position of a pulse within the bit duration. For example, if a rectangular pulse is used and the bit duration is T , the symbol m is transmitted using

$$s_m(t) = \begin{cases} 1 & \text{if } \frac{mT}{M} \leq t \leq \frac{(m+1)T}{M} \\ 0 & \text{otherwise} \end{cases} \quad (135.16)$$

As an example, consider a 4-ary communication scheme. The transmitted signal with 4-ary PAM (using a rectangular pulse), and 4-ary PPM are shown in Figure 135.11 for the information sequence of $\{2,0,1,3,2\}$.

Digital Carrier Modulation

For many communication systems, digital baseband transmission is not possible due to the physical characteristics of the channel or due to regulatory reasons. Therefore, suitable digital carrier modulation techniques are also developed. Different carrier modulation techniques include amplitude shift keying (ASK), phase shift keying (PSK), frequency shift keying (FSK), and quadrature amplitude modulation (QAM).

ASK (also called carrier modulated PAM) is very similar to baseband PAM, that is, information is embedded in the amplitude of a basic signal. The m^{th} symbol is transmitted using

$$s_m(t) = A_m g(t) \cos(2\pi f_c t) \quad 0 \leq t \leq T \quad (135.17)$$

where $A_m = 2m + 1 - M$, $g(t)$ is a shaping pulse and f_c is the carrier frequency. Using a similar vector representation, the signal constellation for ASK can be shown to be the same as the case of PAM (shown in Figure 135.10). We note that this scheme transmits both upper and lower sidebands of the modulated signal (as in DSB AM). As an alternative, in order to obtain a more bandwidth efficient version of ASK, an SSB ASK scheme (similar to SSB AM) can be employed.

In PSK, the information is impressed in the phase of the carrier signal. The m th symbol is transmitted using

$$s_m(t) = g(t) \cos\left(2\pi f_c t + (m-1) \frac{2\pi}{M}\right) \tag{135.18}$$

$$= \cos\left((m-1) \frac{2\pi}{M}\right) g(t) \cos(2\pi f_c t) - \sin\left((m-1) \frac{2\pi}{M}\right) g(t) \sin(2\pi f_c t) \tag{135.19}$$

For $M = 2$, binary PSK (BPSK) is obtained.

In QAM, the information is transmitted both in the amplitude and the phase of the carrier signal. Mathematically, the transmitted signal is given by

$$s_m(t) = A_{mc} g(t) \cos(2\pi f_c t) - A_{ms} g(t) \sin(2\pi f_c t) \tag{135.20}$$

where A_{mc} and A_{ms} are selected as the amplitudes of the in-phase and quadrature components of the transmitted signal.

For PSK and QAM, two orthogonal functions $g(t) \cos(2\pi f_c t)$ and $-g(t) \sin(2\pi f_c t)$ can be used as the basis functions to represent the transmitted signals in vector form. For PSK, we can write

$$\underline{s}_m = \left[\cos\left((m-1) \frac{2\pi}{M}\right) \quad \sin\left((m-1) \frac{2\pi}{M}\right) \right].$$

Similarly, for QAM, we obtain $\underline{s}_m = [A_{mc} \quad A_{ms}]$. In Figure

135.12, the signal constellations for 4 PSK, 8 PSK and (rectangular) 16 QAM are shown.

Finally, in FSK, different signals are transmitted using carriers with different frequencies as opposed to the different amplitudes and phases.

Bandwidth Requirements

Roughly speaking, a pulse of duration T occupies an approximate bandwidth of $1/T$. Since with PAM each symbol is transmitted using exactly one of these pulses, in order to transmit at a rate of 1 symbol/sec, a bandwidth of 1 Hz is needed.¹ This is the same for the two-dimensional modulation schemes (e.g., PSK

FIGURE 135.12 4 PSK, 8 PSK, and 16 QAM signal constellations.

¹In fact, if single side band modulation is used, each bit would require $1/2$ Hz.

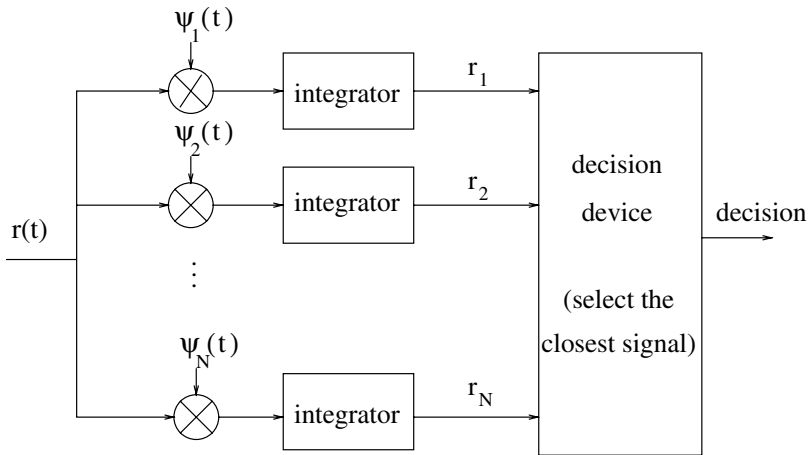

FIGURE 135.13 Block diagram of the ML receiver.

and QAM) described earlier since the in-phase and quadrature components of the signal occupy the same frequency band. Therefore, with PAM, PSK, and QAM, the spectral efficiency achieved is $\log_2 M$ bits/sec/Hz. That is, when the constellation size is increased, a more efficient use of the frequency band is achieved. This improvement is obtained at the expense of an increase in the error rate, as we will see shortly.

Receiver Design in AWGN

For an AWGN channel (which is one of the simplest channel models for practical communication systems), ignoring the channel attenuation, the received signal is nothing but the transmitted signal corrupted by the additive white Gaussian noise. That is,

$$r(t) = s(t) + \eta(t) \quad (135.21)$$

where $s(t)$ is the transmitted signal, and $\eta(t)$ is a white Gaussian noise process. The receiver has to make a decision on the symbol transmitted based on this noisy observation. We now describe this process in some detail.

Assume that the transmitted signal is represented in vector form by $\underline{s} = [s_1 s_2 \dots s_N]$ using orthonormal basis functions¹ denoted by $\{\psi_1(t), \psi_2(t), \dots, \psi_N(t)\}$. Further assume that all the symbols are equally likely to be transmitted, and are independent from one symbol to the next. With this assumption (which characterizes “uncoded” communication systems appropriately), symbol by symbol maximum likelihood (ML) decoding becomes optimal, i.e., minimizes the probability of symbol error.

For ML decoding, the receiver first demodulates the received signal $r(t)$ using a bank of correlators, that is, it obtains the component of the received signal in the signal space denoted by \underline{r} . \underline{r} is nothing but the vector representation of $r(t)$ with respect to the orthonormal basis functions defined in the previous paragraph. Although $r(t)$ may not lie in that space completely, its component outside of this space is not important for making a decision on the transmitted symbol. Then, this vector is fed to a decision device which declares the closest signal vector (i.e., the corresponding symbol) to the received vector in the Euclidean distance sense as its decision. This process is illustrated in Figure 135.13.

Each correlator can be replaced by a filter matched to the corresponding basis function $\psi(t)$ and a sampler sampling at $t = T$. The impulse response of the filter matched to $\psi(t)$ is given by $\psi(T-t)$. With this modification, the matched filter type receiver is obtained as shown in Figure 135.14.

¹That is, the basis functions are normalized and orthogonal to each other.

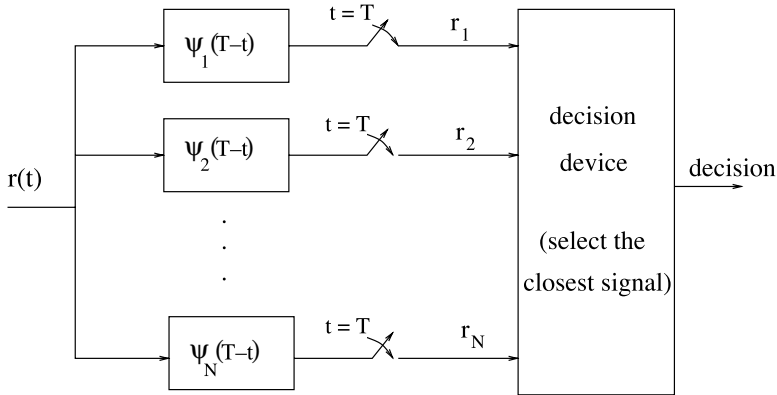

FIGURE 135.14 Block diagram of the matched filter type ML receiver.

FIGURE 135.15 ML receiver for BPSK modulation.

Furthermore, the ML receiver can be simplified considerably for the specific modulation schemes described in the previous section. As an example, let us consider the case of BPSK modulation. In this case, the (matched filter type) ML receiver can be obtained by a single matched filter, and a simple threshold detector as illustrated in Figure 135.15.

Effects of Noise in Digital Transmission

Due to the additive noise present in the system, the receiver will make some errors in its decisions. A thorough treatment of the noise in digital communications is beyond the scope of this chapter; however, we will make some observations.

Assume that a certain modulation scheme with a given constellation is employed, and a specific constellation point (i.e., the corresponding symbol or signal) is transmitted. The receiver will fail to make the correct decision if the received vector is closer to another constellation point due to the channel noise. The most common types of errors will be due to the signal “closest” to the transmitted symbol (in the Euclidean distance sense). This is particularly true if the noise variance is small, or the signal-to-noise ratio is high, meaning that the performance of the modulation scheme is determined by the distance between the closest constellation points for large SNRs. Therefore, in order to compare the performance of two different modulation schemes, assuming that the energy of the constellation is normalized, we can use this minimum distance as a metric. The smaller the minimum distance, the more the modulation scheme is error prone.

As an example, let us compare the performance of BPSK with OOK. To maintain the same distance between the two constellation points in both schemes, it is easy to see that the energy of the OOK scheme should be doubled. That is, the signal-to-noise ratio should be increased by a factor of 2, i.e., approximately 3 dB. Therefore, we say that BPSK is 3 dB better than OOK in terms of power efficiency. Similar comparisons can be made for other modulation schemes as well. In general, when the constellation size is increased in an attempt to improve the spectral efficiency of the system, the power efficiency of the system reduces. In other words, there is a trade-off between the power consumption and the bandwidth efficiency.

In order to combat the effects of significant signal attenuation with the distance (both in wireless and wireline signal transmission), just as in the case of analog communication, repeaters can be employed.

For the case of digital transmission, the repeaters can be used to “amplify and forward” the intermediate signal, or to demodulate the transmitted digital information, and retransmit it. It can be shown that the latter scheme (also called regenerative repeaters) is a better choice in terms of the bit error rates achievable by the end-to-end system.

135.4 Multiplexing and Multiple Access

In many analog or digital communication systems, the communication medium is used to transmit different messages. This is accomplished through “multiplexing techniques” if the messages belong to the same user, and through “multiple-access techniques” if the messages belong to different users.

A straightforward multiplexing technique is what is called “quadrature carrier multiplexing.” In this case, two messages (of bandwidth W) are transmitted using a double sideband AM modulation scheme employing two orthogonal carriers of the same frequency, i.e., $\cos(2\pi f_c t)$ and $\sin(2\pi f_c t)$. Since both messages occupy the same frequency band, two messages are transmitted using a bandwidth of $2W$, resulting in the same spectral efficiency as the single sideband AM.

Frequency division multiplexing (FDM) and frequency division multiple access (FDMA) use different nonoverlapping frequency bands to transmit the different signals over the same medium as illustrated in Figure 135.16. The underlying transmission may be analog or digital. Since the transmitted signals do not overlap in frequency domain, they can be easily recovered at the receiver by the help of bandpass filters. Commercial AM, FM radio transmission, and TV broadcast are all communication systems employing FDMA; cable TV is a good example of a system employing FDM.

Time division multiplexing (TDM), or time division multiple access (TDMA) use different time “intervals” to accommodate the transmission of different messages. A typical time frame (suitable for the transmission of K different messages) is shown in Figure 135.17. In this case, the messages do not overlap in time allowing proper communication. Clearly, unlike frequency division multiplexing or multiple access, TDM or TDMA are only suitable for digital communications. A good example of a TDM system is digital telephony where the “bits” of different users are multiplexed by the “central office” before transmission over a common medium. A good example of a TDMA scheme is the GSM system commonly used for second and third generation cellular telephony in the U.S. and Europe.

(only the positive frequency contents are shown)

FIGURE 135.16 FDM or FDMA illustrated in the frequency domain.

FIGURE 135.17 TDM or TDMA time frame.

There are other multiple access schemes such as code division multiple access (CDMA) or space division multiple access (SDMA) that are beyond the scope of this chapter.

135.5 Summary and Further Reading

We have presented a brief overview of analog and digital communication techniques. We have illustrated some of the main communications principles without going into the mathematical details involved.

In addition to the details of analog and digital modulation techniques not presented here, there are many issues that remain in particular for digital communications. For example, we have not talked about the timing and synchronization issues, detailed descriptions of source and channel coding techniques, signaling for other practical communication channels such as channels with intersymbol interference (ISI), and fading channels, other modulation schemes including spread spectrum communications, and multiple access techniques such as code division multiple access (CDMA). For these important more advanced topics and the details of analog and digital communication systems the reader is referred to the textbooks on communications such as References [1] through [8].

136.1 Block Codes
136.2 Convolutional Codes
136.3 Trellis-Coded Modulation

Error correction coding involves adding redundant symbols to a data stream in order to allow for reliable transmission in the presence of channel errors. Error correction codes fall into two main classes: block codes and convolutional codes. In block codes, the code word is only a function of the current data input, whereas in convolutional codes the current output is a function of not only the current data input but also of previous data inputs. Thus, a convolutional code has memory, whereas a block code is memoryless. Codes can also be classified according to their code rate, symbol alphabet size, error detection/correction capability, and complexity. The code rate determines the extra bandwidth needed and also the reduction in energy per transmitted symbol relative to an uncoded system. The alphabet size is usually either two (binary) or a power of two. When the alphabet size is binary, the symbol is called a bit. Codes can be made either to detect or to correct errors or some combination of both and also can be made to detect/correct either random errors or burst errors. The complexity of a code is usually a function of the decoding procedure that is used, so the most popular codes are those that can be decoded in a relatively simple manner and still provide good error correction capability.

136.1 Block Codes

An (n, k) block code is a mapping of a k symbol information word into an n symbol code word. The code is said to be systematic if the first k symbols in the code word are the information word. In an (n, k) code, $n - k$ symbols are redundant and are often referred to as *parity symbols*. The code rate, R , is defined as $R = k/n$. An important parameter of a block code is its minimum distance, d_{\min} , which is defined as the minimum Hamming distance between any two code words. (Hamming distance is the number of places in which two code words disagree.) A code with a minimum distance of d_{\min} can guarantee to correct any pattern of $t = \lfloor (d_{\min} - 1) / 2 \rfloor$ or fewer errors. Alternatively, the code can guarantee to detect any error pattern consisting of $s = d_{\min} - 1$ or fewer errors. If simultaneous error detection and correction is desired, the minimum distance of the code must be such that $d_{\min} \geq s + t + 1$.

Most block codes used in practice are linear (or group) codes. In a linear code the set of code words must form a mathematical group. Most importantly, the sum of any two code words must itself be a code word. Encoding of linear block codes is accomplished by multiplying the k symbol information word by an $n \times k$ matrix (known as a generator matrix) forming an n symbol code word. To decode, a received word is multiplied by an $n \times (n - k)$ matrix (known as a *parity check matrix*) to form an $n - k$ symbol vector known as the *syndrome*. A look-up table is then used to find the error pattern that corresponds to the given syndrome and that error pattern is subtracted from the received word to form the decoded word. The parity (redundant) symbols are then removed to form the decoded information

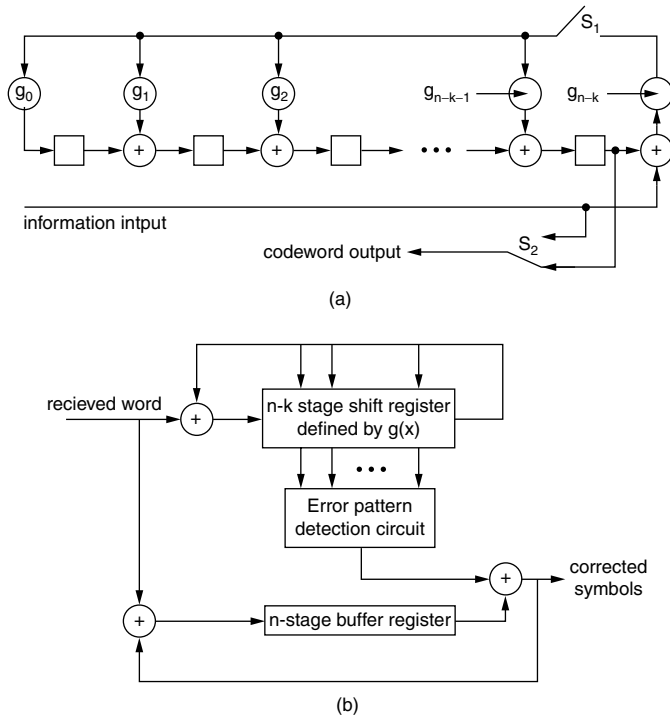

FIGURE 136.1 (a) Encoder for a cyclic group code; (b) Meggitt decoder for cyclic group codes.

word. In general, unless the number of parity symbols ($n - k$) of a linear code is very small, syndrome decoding is too complicated and so codes with a simpler decoding procedure are used.

A cyclic code is a group code that has the additional property that any cyclic shift of a code word produces another code word. A cyclic code is specified by a generator polynomial, which is a polynomial of order $n - k$ of the form $g(x) = g_0 + g_1x + \dots + g_{n-k}x^{n-k}$, or by its parity check polynomial, $h(x)$, which is related to $g(x)$ by $g(x)h(x) = x^n - 1$. The code is encoded with a division circuit (a linear feedback shift register) as shown in Figure 136.1(a). In that circuit, switches S_1 and S_2 are in the closed and up positions, respectively, until the k data symbols are clocked in. After that, the two switches are flipped and the parity symbols are read out. The received sequence can be decoded using a similar circuit known as the *Meggitt decoder*, shown in Figure 136.1(b). Most of the complexity of the decoder is in the error pattern detector, which must recognize all correctable error patterns with errors in the last position. For a single-error correcting code this can be implemented with a multiple-input AND gate, but for codes with large error correction capability the number of error patterns that must be recognized becomes unfeasible.

A technique known as *error-trapping decoding* can be used to simplify the error pattern detector of the Meggitt decoder, but again, this technique only works for short codes with low error-correcting capability. Error trapping is quite effective for decoding burst error correcting codes and also works nicely on the well-known Golay code. When longer codes with high error correction capability are needed, it is common to consider various subclasses of cyclic group codes that lead to implementable decoding algorithms. One such subclass that is extremely popular comprises the BCH codes. Since BCH codes are cyclic codes, they can be encoded with the same general encoder shown in Figure 136.1(a). In addition, a well-known technique called the *Berlekamp algorithm* can be used to decode BCH codes. The Berlekamp algorithm is fast and easy to implement, but it is not a maximum likelihood decoding technique, and so it does not always take advantage of the full error-correcting capability of the code. In addition, it is often desirable for a demodulator to feed soft decisions on to the decoder. This will usually enable the decoder to make a more reliable decision about which symbols are in error. A demodulator is said to make soft decisions when it quantizes its output into an alphabet size larger than the size of the transmitted symbol

set. All of the standard techniques for decoding block codes suffer from the fact that they cannot be used on soft decisions; this is the main reason why convolutional codes are often preferred.

For a memoryless channel with an error rate of p , the probability of decoding error, P_d , for an (n, k) t -error correcting code is given by

$$P_d = \sum_{i=t+1}^n \binom{n}{i} p^i (1-p)^{n-i} = 1 - \sum_{i=0}^t \binom{n}{i} p^i (1-p)^{n-i}$$

Finding exact expressions for the probability of a symbol error, P_s (i.e., probability of bit error or bit-error rate for the case of binary symbols) is generally not tractable, but the following bounds work quite well:

$$\frac{d_{\min}}{n} P_d \leq P_s \leq \sum_{i=t+1}^n \binom{n}{i} \frac{i+t}{n} p^i (1-p)^{n-i}$$

Another method of specifying the performance of an error correction coding scheme focuses on coding gain. Coding gain is the reduction in dB of required signal-to-noise ratio needed to achieve a given error rate relative to an uncoded system. Specifically, if an uncoded system needs an energy per bit of $E_u(P_s)$ to achieve a symbol error rate of P_s , and a coded system requires $E_c(P_s)$, the coding gain is

$$\gamma(P_s) = 10 \log \{ [E_u(P_s)] / [E_c(P_s)] \} \text{ dB}$$

The asymptotic coding gain is the coding gain measured in the limit as P_s goes to zero and is given for a Gaussian noise channel by

$$\gamma = \lim_{P_s \rightarrow 0} \gamma(P_s) = 10 \log \left(\frac{k}{n} (t+1) \right) \text{ dB}$$

136.2 Convolutional Codes

In a convolutional code, as in a block code, for each k information symbols, $n - k$ redundant symbols are added to produce n code symbols and the ratio of k/n is referred to as the code rate, R . The mapping, however, is not memoryless, and each group of n code symbols is a function of not only the current k input symbols but also the previous $K - 1$ blocks of k input symbols. The parameter K is known as the *constraint length*. The parameters n and k are usually small and the code word length is arbitrary (and potentially infinite). As with block codes, the ability to correct errors is determined by d_{\min} , but in the case of convolutional codes this quantity is generally referred to as the *free distance*, d_{free} . Although the error correction capability, t , has the same relationship to d_{free} as in block codes, this quantity has little significance in the context of convolutional codes.

A convolutional code is generated using a feed-forward shift register. An example of the structure for the convolutional encoder is shown in Figure 136.2(a) for a code with $R = 1/2$ and $K = 3$. In general, for each group of k symbols input to the encoder, n symbols are taken from the output. A convolutional code can be described graphically in terms of a state diagram or a trellis diagram, as shown in Figure 136.2(b) and Figure 136.2(c) for the encoder of Figure 136.2(a). The state diagram represents the operation of the encoder, whereas the trellis diagram illustrates all the possible code sequences. The states in both the state and trellis diagrams represent the contents of the shift register in the encoder, and the branches are labeled with the code output corresponding to that state transition.

The optimum (maximum likelihood) method for decoding convolutional codes is the Viterbi algorithm, which is nothing more than an efficient way to search through the trellis diagram for the most likely transmitted code word. This technique can be used equally well with either hard or soft

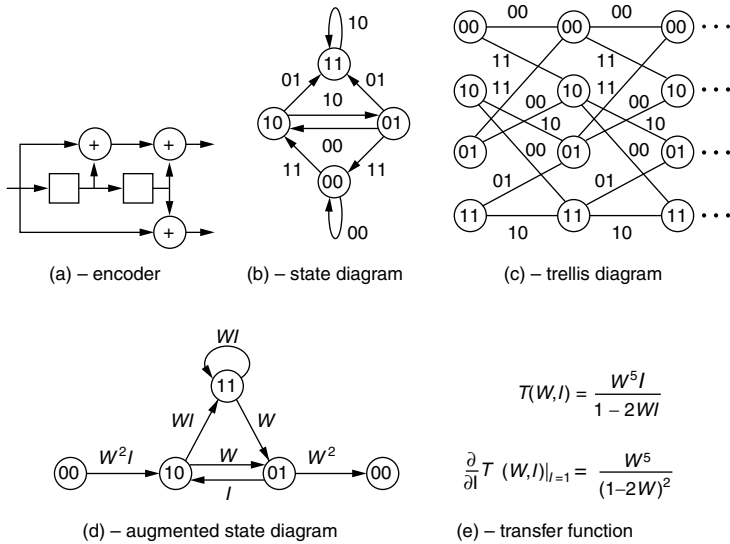

FIGURE 136.2 A rate 1/2, $K = 3$ convolutional encoder.

channel decisions and has a complexity that is exponential in the constraint length. As a result, the Viterbi algorithm can be used only on codes with a moderate constraint length (currently about $K \leq 10$). For most applications, this limit on K is not too severe and so Viterbi decoding is used almost exclusively. If a larger constraint length is needed, several suboptimal decoding algorithms exist whose complexities do not depend on the constraint length. Sequential decoding techniques such as the Stack and Fano algorithms are generally nearly optimum in terms of performance and faster than Viterbi decoding, whereas majority logic decoding is very fast, but generally gives substantially worse performance.

The performance of a convolutionally encoded system is specified in terms of the decoded symbol error probability or in terms of a coding gain, as defined in Section 136.1. An exact result for the error probability cannot be easily found but a good upper bound is provided through the use of transfer functions. To find the transfer function for a given code, an augmented state diagram is produced from the original state diagram of the code by splitting the all-zero state into a starting and ending state and labeling each branch with $W^w I^i$, where w is the Hamming weight of the output sequence on that branch, i is the Hamming weight of the input that caused that transition, and W and I are dummy variables. The transfer function of the code is then given by applying Mason's gain formula to the augmented state diagram. The augmented state diagram and the transfer function for the encoder in Figure 136.2(a) are shown in Figure 136.2(d) and Figure 136.2(e). The probability of decoded symbol error can be found from the transfer function by

$$P_e \leq \frac{1}{k} \frac{\partial}{\partial I} T(W, I) \Big|_{I=1, W=Z}$$

The parameter Z that appears in this equation is a function of the channel being used. For a binary symmetric channel (BSC), $Z = \sqrt{4p(1-p)}$, where p is the crossover probability of the channel; for an additive white Gaussian noise (AWGN) channel with antipodal signaling, $Z = \exp(-E_s/N_0)$, where E_s is the average energy per symbol, and $N_0/2$ is the two-sided power spectral density of the noise.

Although the given bound is convenient because it is general, it is often not very tight. A tighter bound can be obtained for various channel models. For example, for the AWGN channel, a tighter bound is

FIGURE 136.3 Bit-error-rate comparison of block and convolutional codes.

$$P_e \leq \frac{1}{k} \exp\left(\frac{d_{\text{free}} E_s}{N_0}\right) Q\left(\sqrt{\frac{2d_{\text{free}} E_s}{N_0}}\right) \left. \frac{\partial}{\partial I} T(W, I) \right|_{I=1, W=\exp(-E_s/N_0)}$$

This bound generally gives a good estimate of the true error probability, at least for high values of E_s/N_0 . For complex codes (long constraint length), calculating the transfer function can be tedious. In that case, it is common to use a lower bound that involves just the first term in the Taylor series expansion of the transfer function, resulting in

$$P_e \geq \frac{B_{d_{\text{free}}}}{k} Q\left(\sqrt{\frac{2d_{\text{free}} E_s}{N_0}}\right)$$

where $B_{d_{\text{free}}}$ is the sum of the input Hamming weights of all paths with an output Hamming weight of d_{free} . In many cases $B_{d_{\text{free}}} = 1$, and this can always be used as a lower bound. This expression can also be used to obtain the expression for asymptotic coding gain:

$$\gamma = 10 \log\left(\frac{kd_{\text{free}}}{2n}\right) \text{ dB}$$

This result is very similar to the expression for asymptotic coding gain for block codes.

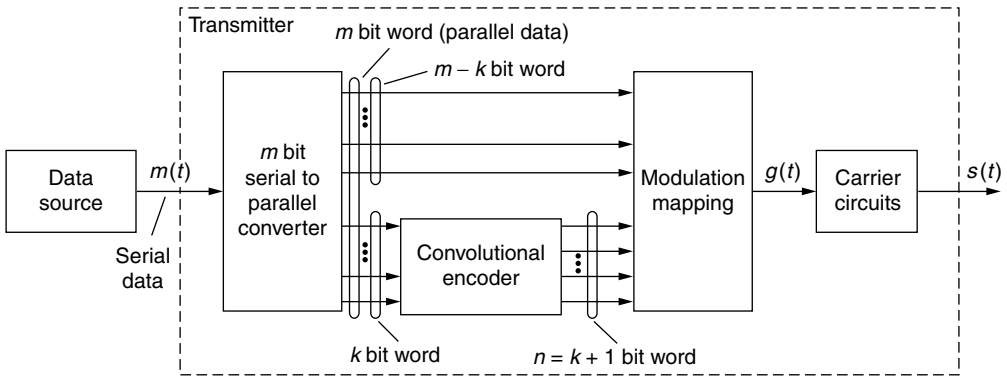

Finally, Figure 136.3 shows a performance comparison of the rate 1/2, $K = 3$ convolutional code depicted in Figure 136.2 with several block codes whose code rates are nearly equal to 1/2. The bit-error rate is plotted as a function of E_b/N_0 (energy per bit divided by noise spectral density). For all cases the assumed modulation is BPSK. Note that even this simple convolutional code with soft decisions can perform as well as a fairly long (and hence complex) block code.

136.3 Trellis-Coded Modulation

In both block and convolutional coding a savings in power (coding gain) is obtained at the cost of extra bandwidth. In order to provide the redundancy, extra symbols are added to the information stream. Accommodating these symbols without sacrificing information rate requires a shorter symbol duration or, equivalently, a larger bandwidth. The bandwidth expansion relative to an uncoded system is equal to $1/R = n/k$. Thus, coding is used when power is at a premium but bandwidth is available — that is, a power-limited environment. When power savings is not so crucial and bandwidth is at a premium (a bandwidth-limited environment), spectrum can be conserved by using a multilevel signaling scheme (some form of M -ary PSK or M -ary quadrature amplitude modulation is popular in this case). When

(a) Conventional Coding Technique

(b) Trellis-Coded Modulation Technique

FIGURE 136.4 Block diagram of transmitter for TCM. (Source: Couch, L. W. 1993. *Digital and Analog Communication Systems*, 4th ed. Macmillan, New York. With permission.)

both bandwidth and power are tightly constrained, trellis-coded modulation (TCM) provides power savings with no bandwidth expansion. Redundancy is added to the data stream through the expansion of the size of the signal set. For example, binary data could be sent using a QPSK signal set. Since a QPSK constellation has four points and thus could represent two bits, each QPSK signal would represent one data bit and one parity bit (a rate $1/2$ code). Alternatively, one could use 8-PSK with a rate $2/3$ code and send two bits of information per symbol. As a general rule of thumb, if it is desired to send m bits of information per channel symbol, the size of the signal set is doubled and a rate $m/(m + 1)$ code is used.

A general block diagram of a TCM encoder is shown in Figure 136.4. Data bits are grouped into m bit blocks. These blocks are then input to a rate $m/(m + 1)$ binary convolutional encoder. The $m + 1$ output bits are then used to select a signal from an $M = 2^{m+1}$ -ary constellation. The constellation is usually restricted to being one- or two-dimensional in order to save bandwidth. The encoding is often done in a systematic manner as indicated in Figure 136.4, where $m - k$ of the input bits are left uncoded and the remaining k bits are encoded using a rate $k/(k + 1)$ encoder. As with convolutional codes, the TCM scheme is designed to maximize the free distance of the code, but in this case distance is measured as Euclidean distance in the signal constellation. Each path through the trellis diagram now represents a sequence of signals from the constellation, and performance is mainly determined by the minimum Euclidean distance between any two distinct sequences of signals.

At the receiver, the received signal is demodulated using soft decisions and then decoded using the Viterbi algorithm. Performance is determined in a manner very similar to that for a convolutional code. Bounds on the bit-error rate can be found using transfer function techniques, although the method to obtain these transfer functions can be more complicated if the signal constellation does not exhibit a great deal of symmetry. Also, a coding gain relative to an uncoded system can be calculated as

$$\gamma = 20 \log \left(\frac{d_{\text{free}}}{d_{\text{uncoded}}} \right) \text{ dB}$$

FIGURE 136.5 Free distance of binary convolution codes with 4-PSK modulation, and TCM with a variety of two-dimensional modulation schemes. (Source: Ungerboeck, G. 1987. Trellis-coded modulation with redundant signal sets, Part I: Introduction. *IEEE Comm. Mag.*, 25(2):5–11. ©1987 IEEE. With permission.)

where d_{uncoded} is the Euclidean distance between nearest neighbors in the uncoded systems signal constellation. Figure 136.5 shows some coding gains that can be achieved using TCM. To calculate coding gain relative to an uncoded system using this figure, pick the desired spectral efficiency, r (measured in bits/second/Hz), on the horizontal axis and then measure the vertical distance between the uncoded scheme and the TCM scheme. For example, if it is desired to send three bits per channel symbol, an uncoded 8-PSK signal constellation could be used. Using TCM with 16-QASK (i.e., 16-QAM) would give about 4.4 to 7.4 dB coding gain depending on the number of states in the TCM scheme, and the spectral efficiency would be 3 bits/second/Hz in both cases.

Defining Terms

Block code — A memoryless mapping from k input symbols to n output symbols.

Code rate — The ratio of the number of input symbols to the number of output symbols for a block or convolutional encoder.

Constraint length — The number of input blocks that affect a current output block in a convolutional encoder. It is also a measure of the complexity of the code.

Convolutional code — A mapping from k input symbols to n output symbols that is not memoryless. The current output depends on current and past inputs.

Cyclic code — A block code for which every cyclic shift of a code word produces another code word.

Group code — A block code for which any linear combination of two code words produces another code word. Also known as a *linear code*.

Trellis-coded modulation — A combination of traditional modulation and convolutional coding techniques whereby redundancy is added through the expansion of the size of the signal constellation.

J. N. Daigle

University of Mississippi

Over the last decade, computer communication networks have evolved from the domain of research and business tools for the few into the mainstream of public life. We have seen continued explosive growth of the Internet, a worldwide interconnection of computer communication networks that allows low-latency person-to-person communications on a global basis. Advancements in *firewall* technology have made it possible to conduct business using the Internet with significantly reduced fear of compromise of important private information, and broad deployment of *World Wide Web*, or simply *Web*, technology has facilitated the creation of new network-based businesses that span the globe. Significant steps have been taken to extend networking services to the mobile consumer. Perhaps more significantly, the introduction of high-speed Internet access to homes and the introduction of the point-to-point protocol (PPP) have made it possible to extend the Internet to every home that has at least a basic twisted-pair telephone line.

The potential for using networking technology as a vehicle for delivering multimedia — voice, data, image, and video — presentations, and indeed multiparty, multimedia conferencing service, has been demonstrated, and the important problems that must be solved in order to realize this potential are rapidly being defined and focused upon. User-friendly applications that facilitate navigation within the Web have been developed and made available to networking users on a non-fee basis via network servers, thus facilitating virtually instantaneous search and retrieval of information on a global basis. For example, it is now common for users to access broadcasts of exciting events, such as Le Tour de France, in real time over the Internet using only a dial-up telephone connection. Access to details concerning events of all kinds to all people is unprecedented in history.

By definition, a *computer communication network* is a collection of applications hosted on different machines and interconnected by an infrastructure that provides communications among the communicating entities. While the applications are generally understood to be computer programs, the generic model includes the human being as an application, an example being the people involved in a telephone call.

This article summarizes the major characteristics of computer communication networks. Our objective is to provide a concise introduction that will allow the reader to gain an understanding of the key distinguishing characteristics of the major classes of networks that exist today and some of the issues involved in the introduction of emerging technologies.

There are a significant number of well-recognized books in this area. Among these are the excellent texts by Schwartz [1987] and Spragins [1991], and more recently Kurose and Ross [2001], which have enjoyed wide acceptance both by students and practicing engineers and cover most of the general aspects of computer communication networks. Other books found to be especially useful by many practitioners are Rose [1990], Black [1991], and Bertsekas and Gallager [1987].

The latest developments are, of course, covered in the current literature, conference proceedings, formal standards documents, and the notes of standards meetings. A pedagogically oriented magazine that specializes in computer communications networks is *IEEE Network*, but *IEEE Communications* and *IEEE Computer* often contain interesting articles in this area. *ACM Communications Review*, in addition to presenting pedagogically oriented articles, often presents very useful summaries of the latest standards activities. Major conferences that specialize in computer communications include the IEEE INFOCOM and ACM SIGCOMM series, which are held annually. It is becoming common at this time to have more and more discussion about personal communication systems, and the mobility issues involved in communication networks are often discussed in *IEEE Network* and *IEEE Personal Communication Systems*. There are also numerous journals, magazines, and conferences specializing in subsets of computer communications technologies.

We begin our discussion with a brief statement of how computer networking came about and a capsule description of the networks that resulted from early efforts. Networks of this generic class, called *wide area networks* (WANs) are broadly deployed today and there are still a large number of unanswered questions with respect to their design. The issues involved in the design of those networks are basic to the design of most networks, whether wide area or otherwise. In the process of introducing these early systems, we describe and contrast three basic types of communication switching: circuit, message, and packet.

We next turn to a discussion of computer communication *architecture*, which describes the structure of communication-oriented processing software within a communication-processing system. We introduce the International Standards Organization/Open Systems Interconnection (ISO/OSI) reference model (ISORM). Initially, the ISORM model was intended to guide the development of protocols, but its most important contribution seems to have been the provision of a framework for discussion of issues and developments across the communications field in general and communication networking in particular. We then present the Internet reference model, which parallels the Internet protocol stack that has evolved, and we base our discussion of protocols on selections from the Internet protocol suite. This discussion is necessarily simplified in the extreme, as thorough coverage requires hundreds of pages, but we hope that our brief description will enable the reader to appreciate some of the issues.

Having introduced the basic architectural structure of communication networks, we next turn to a discussion of an important variation on this architectural scheme: the *local area network* (LAN). Discussion of this topic is important because it helps to illustrate what a reference model is and what it is not. Specifically, early network architectures anticipate networks in which individual node pairs are interconnected via a single link, and connections through the network are formed by concatenating node-to-node connections.

LAN architectures, on the other hand, anticipate all nodes being interconnected in some fashion over the same communication link (or medium). This, then, introduces the concept of adaption layers in a natural way. It also illustrates that if the services provided by an architectural layer are carefully defined, then the services can be used to implement virtually any service desired by the user, possibly at the price of some inefficiency.

Next, we discuss asynchronous transfer mode and frame relay, two important link-layer technologies. We conclude with a brief discussion of recent developments.

137.1 General Networking Concepts

Data communication networks have existed since about 1950. The early networks existed primarily for the purpose of connecting users of a large computer to the computer itself, with additional capability to provide communications between computers of the same variety and having the same operating software. The

FIGURE 137.1 Generic computer communication network.

Lessons learned during the first 20 or so years of operation of these types of networks have been valuable in preparing the way for modern networks. For the purposes of our current discussion, however, we think of communication networks as being networks whose purpose is to interconnect a set of applications that are implemented on hosts manufactured by possibly different vendors and managed by a variety of operating systems. Networking capability is provided by software systems that implement standardized interfaces specifically designed for the exchange of information among heterogeneous computers.

The earliest effort to develop large-scale, general-purpose networking capability based on packet switching was led by the Advanced Research Projects Agency (ARPA) of the Department of the Army in the late 1960s; this effort resulted in the computer communication network called ARPANET. The end results of the ARPA networking effort, its derivatives, and the early initiatives of many companies such as AT&T, DATAPOINT, DEC, IBM, and NCR have been far-reaching in the extreme. We will concentrate on the most visible product of these efforts, which is a collection of programs that allows applications running on different computers to intercommunicate. Before turning to our discussion of the software, however, we provide a brief description of a generic computer communication network.

Figure 137.1 shows a diagram of a generic computer communication network. The most visible components of the network are the *terminals*, *access lines*, *trunks*, and *switching nodes*. Work is accomplished when the users of the network, the terminals, exchange messages over the network.

The terminals, which are usually referred to as end systems, represent the set of communication-terminating equipment communicating over the network. Equipment in this class includes, but is not limited to, user terminals, general-purpose computers, and database systems. This equipment, either through software or human interaction, provides the functions required for information exchange between pairs of application programs or between application programs and people. The functions include, but are not limited to, call setup, session management, and message transmission control. Examples of applications include electronic mail transfer, WWW browsing, and playback of audio streams. An extensive discussion of applications is provided in Kurose and Ross [2001].

Access lines provide for data transmission between the terminals and the network switching nodes. These connections may be set up on a permanent basis or they may be switched connections, and there are numerous transmission schemes and protocols available to manage these connections. The essence of these connections, however, from our point of view is a channel that provides data transmission at some number of bits per second (bps), called the channel capacity, C . The access line capacities may range from a few hundred bps to in excess of millions of bps, and they are usually not the same for all terminating equipments of a given network. The actual information-carrying capacity of the link depends on the protocols employed to effect the transfer; the interested reader is referred to Bertsekas and Gallager [1987], especially [chapter 2](#), for a general discussion of the issues involved in data transmission over communication links.

Trunks, or internodal trunks, are the transmission facilities that provide for transmission of data between pairs of communication switches. These are analogous to access lines, and from our point of view, they simply provide a communication path at some capacity specified in bps.

There are three basic switching paradigms: circuit, message, and packet switching. *Circuit switching* and *packet switching* are transmission technologies, while message switching is a service technology. In circuit switching, a call connection between two terminating equipments corresponds to the allocation of a prescribed set of physical facilities that provide a transmission path of a certain bandwidth or transmission capacity. These facilities are dedicated to the users for the duration of the call. The primary performance issues, other than those related to quality of transmission, are related to whether or not a transmission path is available at call setup time and how calls are handled if facilities are not available.

Message switching is similar in concept to the postal system. When a user wants to send a message to one or more recipients, the user forms the message and addresses it. The message switching system reads the address and forwards the complete message to the next switch in the path. The message moves asynchronously through the network on a message switch-to-message switch basis until it reaches its destination. Message switching systems offer services such as mailboxes, multiple destination delivery, automatic verification of message delivery, and bulletin boards. Communication links between the message switches may be established using circuit or packet switching networks as is the case with most other networking applications. An example of a message-switching protocol that has been used to build message-switching systems is the simple mail-transfer protocol (SMTP).

In the circuit-switching case, there is a one-to-one correspondence between the number of trunks between nodes and the number of simultaneous calls that can be carried. That is, a trunk is a facility between two switches that can service exactly one call, and it does not matter how this transmission facility is derived. Major design issues include the specification of the number of trunks between node pairs and the routing strategy used to determine the path through a network in order to achieve a given call-blocking probability. When blocked calls are queued, the number of calls that may be queued is also a design question.

A packet-switched communication system exchanges messages among users by transmitting sequences of packets comprising the messages. That is, the sending terminal equipment partitions a message into a sequence of packets, the packets are transmitted across the network, and the receiving terminal equipment reassembles the packets into messages. The transmission facility interconnecting a given node pair is viewed as a single trunk, and the transmission capacity of this trunk is shared among all users whose packets traverse both nodes. While the trunk capacity is specified in bps, the packet-handling capacity of a node pair depends both upon the trunk capacity and the nodal-processing power.

In some packet-switched networks, the path traversed by a packet through the network is established during a call-setup procedure, and the network is referred to as a virtual circuit-packet-switching network. Other networks provide datagram service, which allows users to transmit individually addressed packets without the need for call setup. Datagram networks have the advantage of not having to establish connections before communications take place, but have the disadvantage that every packet must contain complete addressing information. Virtual-circuit networks have the advantage that addressing information is not required in each packet, but have the disadvantage that a call setup must take place before communications can occur. The datagram is an example of *connectionless service*, while virtual circuit is an example of *connection-oriented service*.

Prior to the late 1970s, signaling for circuit establishment was in-band. That is, in order to set up a call through the network, the call-setup information was sent sequentially from switch to switch using the actual circuit that would eventually become the circuit used to connect the end users. In an extreme case, this amounted to trying to find a path through a maze, sometimes having to retrace one's steps before finally emerging at the destination or just simply giving up when no path could be found. This had two negative characteristics: first, the rate of signaling-information transfer was limited to the circuit speed, and second, the circuits that could have been used for accomplishing the end objective were being consumed simply to find a path between the endpoints. This resulted in tremendous bottlenecks on major holidays, which were solved by virtually disallowing alternate routes through the toll-switching network.

An alternate out-of-band signaling system, usually called *common channel interoffice signaling* (CCIS), was developed primarily to solve this problem. Signaling now takes place over a signaling network that is partitioned from the network that carries the user traffic. This principle is incorporated into the concept of integrated services digital networks (ISDNs), which is described thoroughly in Helgert [1991]. The basic idea of ISDN is to offer to the user some number of 64 Kbps access lines plus a 16-Kbps access line through which the user can describe to an ISDN how the user wishes to use each of the 64-Kbps circuits at any given time. The channels formed by concatenating the access lines with the network inter-switch trunks having the requested characteristics are established using an out-of-band signaling system, the most modern of which is known as *signaling system#7* (SS#7).

In either virtual circuit or *datagram networks*, packets from a large number of users may simultaneously need transmission services between nodes. Packets arrive to a given node at random times. The switching node determines the next node in the transmission path, and then places the packet in a queue for transmission over a trunk facility to the next node. Packet-arrival processes tend to be bursty, that is, the number of packet arrivals over fixed-length intervals of time has a large variance. Because of the burstiness of the arrival process, packets may experience significant delays at the trunks. Queues may also build due to the difference in transmission capacities of the various trunks and access lines and delays result. Processing is also a source of delay, and the essence of packet-switching technology is to trade delay for efficiency in resource utilization.

Protocol design efforts, which seek to improve network efficiencies and application performance, are frequent topics of discussion at both general conferences in communications and those specialized to networking. The reader is encouraged to consult the proceedings of the conferences mentioned earlier for a better appreciation of the range of issues and the diversity of the proposed solutions to the issues.

137.2 Computer Communication Network Architecture

In this section, we begin with a brief, high-level, definition of the ISORM, which is discussed in significant detail in Black [1991], and then we turn to a more detailed discussion of a practical Internet reference model (PIRM). The ISORM has seven layers, none of which can be bypassed conceptually. In general, a layer is defined by the types of services it provides to its users and the quality of those services. For each layer in the ISO/OSI architecture, the user of a layer is the next layer up in the hierarchy, except for the highest layer for which the user is an application. Clearly, when a layered architecture is implemented under this philosophy, then the quality of service obtained by the end user, the application, is a function of the quality of service provided by all of the layers.

Figure 137.2, adapted from Spragins [1991], shows the basic structure of the OSI architecture and how this architecture is envisaged to provide for exchange of information between applications. As shown in the figure, there are seven layers: application, presentation, session, transport, network, data link, and physical. Brief definitions of the layers are now given, but the reader should bear in mind that substantial further study will be required to develop an understanding of the practical implications of the definitions.

Physical layer: Provides electrical, functional, and procedural characteristics to activate, maintain, and deactivate physical data links that transparently pass the bit stream for communication between data link *entities*.

Data link layer: Provides functional and procedural means to transfer data between network entities; provides for activation, maintenance, and deactivation of data link connections, character and frame synchronization, grouping of bits into characters and frames, error control, media access control, and flow control.

Network layer: Provides switching and routing functions to establish, maintain, and terminate network layer connections and transfer data between transport layers.

Transport layer: Provides host-to-host, cost-effective, transparent transfer of data, end-to-end flow control, and end-to-end quality of service as required by applications.

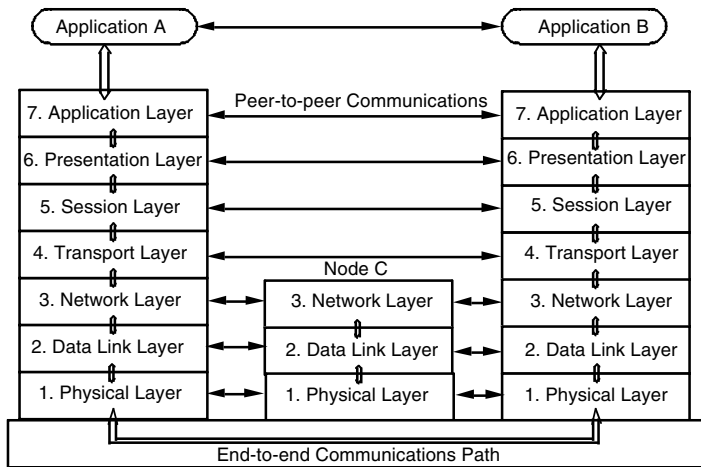

FIGURE 137.2 ISO reference model. (Adapted from Spragins, J. D. *Telecommunications: Protocols and Design*. Addison-Wesley, Reading, MA, 1991. With permission.)

Session layer: Provides mechanisms for organizing and structuring dialogues between application processes.

Presentation layer: Provides for independent data representation and syntax selection by each communicating application and conversion between selected contexts and the internal architecture standard.

Application layer: Provides applications with access to the ISO/OSI communication stack and certain distributed information services.

As we have mentioned previously, a layer is defined by the types of services it provides to its users. In the case of a request or a response, these services are provided via invocation of *service primitives* of the layer in question by the layer that wants the service performed. In the case of an indication or a confirm, these services are provided via invocation of service primitives of the layer in question by the same layer that wants the service performed.

The process of invoking a service primitive is not unlike a user of a programming system calling a subroutine from a scientific subroutine package in order to obtain a service, say, matrix inversion or memory allocation. For example, a request is analogous to a CALL statement in a FORTRAN program, and a response is analogous to the RETURN statement in the subroutine that has been called. The requests for services are generated asynchronously by all of the users of all of the services and these join (typically prioritized) queues along with other requests and responses while awaiting servicing by the processor or other resource such as a transmission line.

The service primitives fall into four basic types, which are as follows: request, indication, response, and confirm. These types are defined as follows:

Request: A primitive sent by layer $(N + 1)$ to layer N to request a service.

Indication: A primitive sent by layer N to layer $(N + 1)$ to indicate that a service has been requested of layer N by a different layer $(N + 1)$ entity.

Response: A primitive sent by $(N + 1)$ to layer N in response to an *indication primitive*.

Confirm: A primitive sent by layer N to layer $(N + 1)$ to indicate that a response to an earlier *request primitive* has been received.

To understand the basic ideas of a network, it is useful to first ask the question: “What functionality would be needed in a point-to-point connection between two computers that are hard-wired together?” We would find that we need everything except the functions provided by layer 3; there is no need for switching and routing functions. Thus, it is natural to think of the networking aspect of a computer

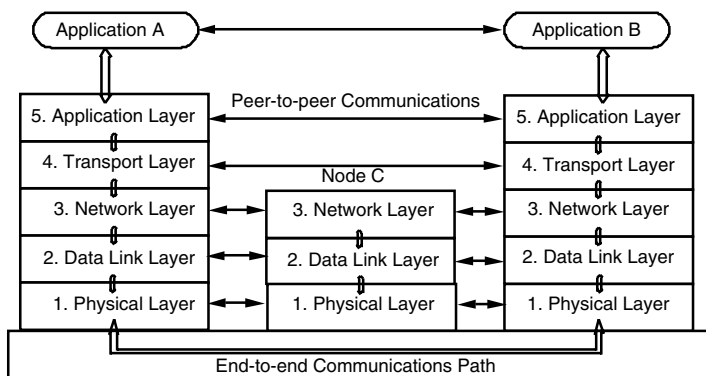

FIGURE 137.3 Practical Internet reference model.

communication network as the interconnection of layer three entities. In fact, we can think of the network as the collection of layer 3 entities. Everything above layer 3 facilitates activities that are taking place over the network, and everything below layer 3 is there simply for the purpose of connecting the layer 3 entities together.

As a practical matter, networking has evolved such that the more realistic reference model has five, rather than seven, layers. In essence, the session and presentation layers are absorbed into the application layer, with the resulting reference model as shown in Figure 137.3.

In order to be more specific about how communications takes place, we now turn to a brief discussion of Internet protocol (IP), which is the network layer protocol of the Internet. The IP protocol provides a datagram delivery service to the transport layer. In order to do this, IP provides exactly one primitive to its upper layer protocol (ULP): SEND.

As mentioned earlier, an upper layer protocol issuing a primitive is equivalent to a computer program calling a subroutine or procedure. A *primitive* has an associated set of *formal parameters*, which are analogous to the formal parameters of a procedure in a programming language. In this case, the parameters for the SEND.request primitive are the source address, the destination address, the type-of-service parameter set, the data length, options parameters, and the data. These parameters provide all the information needed by IP to deliver data to the required destination. The data itself is the entity that the ULP wants sent. The source address is the Internet address of the ULP requesting the SEND service and the destination address is the Internet address of the ULP to which the data is to be sent. The type of service and options parameters give IP information about how the delivery is to be handled, such as the priority of the send action. The data length parameter tells IP how much data it has to send.

In general, communications take place between peer layer protocols by the exchange of *protocol data units* (PDUs), which contain all of the information required for the receiving protocol *entity* to provide the required service. For the PIRM, we say that applications exchange *messages*, layer 4 entities exchange *segments*, layer 3 entities exchange *datagrams*, layer 2 entities exchange *frames*, and layer 1 protocols exchange *1-PDUs*. It should be mentioned that datagrams are packets that traverse networks using connectionless layer 3 protocols. Equivalently, we can say that the packet-switched Internet is a datagram network because IP is the only layer 3 protocol, and it provides connectionless service.

In order to exchange PDUs, entities of a given layer use the services of the next lower layer. To make things concrete, assume that the ULP sending the information is a transmission control protocol (TCP) entity in Host A and the ULP to which the information is being sent is the TCP entity in Host B. In the case of the SEND discussed previously, the TCP entity in Host A is using the SEND service to send the information in the data field to its peer destination TCP entity in Host B; the content of this data field is the PDU and it is called a segment since TCP is a layer 4 protocol. At the destination, Host B, IP uses its DELIVER primitive to deliver the packet to the TCP entity in Host B. Thus, the TCP's packet is the data contained in the data field of its SEND request. The destination TCP entity must be able to determine

what to do with any packet it receives. Therefore, the PDUs, or packets, must be structured in a standard way so that a computer program can examine the data received and take the appropriate actions. The structure that must be adhered to is specified in the protocol standard for the protocol. For example, TCP is specified in Request for Comments RFC 793.

Similarly, the IP entity in Host A forms a PDU that is sent to its peer IP entity in another mode. The IP layer PDU, which is called a *datagram* since IP is a layer 3 protocol, is formed by using information provided in the service request issued by the TCP entity and other information available in the IP layer entity itself. Instructive information is packed into the header of the IP datagram while the data part, or sometimes a subset of the data part, of the TCP request forms the data part of the IP datagram.

Some protocols are connection oriented and some are connectionless, meaning that the service they provide is connection oriented or connectionless. For example, IP provides a connectionless service while TCP is connection oriented. For connection mode communications, a connection must be established between two peer entities before they can exchange PDUs. Therefore, connection-oriented protocols must provide primitives that facilitate establishment of a connection. For example, TCP has several forms of OPEN primitives that an application can use initiate connections, and TCP also has CLOSE and ABORT primitives that an application can use to terminate connections.

Once a connection is established, data exchange between the two application layer entities can take place; that is, the entities can exchange PDUs. For example, if an application layer entity in Host A wishes to send a PDU to an application layer entity in Host B, the application layer entity in Host A would issue a T_SEND.request to the appropriate transport link layer entity in Host A. This entity would package the PDU together with appropriate control information into a transport service data unit (TSDU) and send it to its peer transport layer entity in Host B. In order to do this, the transport layer would invoke the services of the network layer. In turn, the network layer would invoke the services of the data link layer and so on. Specifically, the network layer entity in Host A would issue a DL_DATA.request to the appropriate data link layer entity in Host A. This entity would package the PDU together with appropriate control information into a data link service data unit (DLSDU) and send it to its peer at C. The peer data link entity at C would extract the layer-3 PDU deliver it to the network entity at C, which would forward it to the data link entity in C providing the connection to Host B. This entity would then send the DLSDU to its peer in Host B, and this data link entity would extract the layer 3 PDU and pass it to the Host B network entity via a DL_DATA.indication. The receiving network layer entity would extract the SDU and forward it to the transport layer in Host C using the N_Data.indication.

Now, network layer PDUs are called packets and DL layer PDUs are called frames. But, the data link layer does not know that the information it is transmitting is a packet; to the DL layer entity, the packet is simply user information. From the perspective of a data link entity, it is not necessary to have a network layer. The network layer exists to add value for the user of the network layer to the services provided by the DL layer. In the example above, the network layer added value by providing a relaying capability since Hosts A and C were not directly connected. Similarly, the DL layer functions on a hop-by-hop basis, each hop being completely unaware that there are any other hops involved in the communication. We will see later that the data link need not be limited to a single physical connection.

We now turn to a discussion of LANs, which have inherent properties that make the use of sublayers particularly attractive.

137.3 Local Area Networks and Internets

In this section, we discuss the organization of communications software for LANs. In addition, we introduce the idea of internets, which were brought about to a large extent by the advent of LANs. We discuss the types of networks only briefly and refer the reader to the many excellent texts on the subject. Layers 4 and 5 for local area communications networks are identical to those of wide area networks. However, because the hosts communicating over a LAN share a single physical transmission facility, the routing functions provided by the network layer, layer 3, are not necessary. Thus, the functionality of a layer 3 within a single LAN can be substantially simplified without loss of utility. On the other hand, a

DL layer entity must now manage many simultaneous DL layer connections because all connections entering and leaving a host on a single LAN do so over a single physical link. Thus, in the case of connection-oriented communications, the software must manage several virtual connections over a single physical link.

There were several basic types of transmission schemes used in early local area networks. Three of these received serious consideration for standardization: the *token ring*, *token bus*, and *carrier sense multiple access* (CSMA). All three access methods became IEEE standards (the IEEE 802 series), and eventually became ISO standards (ISO 8802 series) because all merited standardization. On the other hand, all existed for the express purpose of exchanging information among peers, and it was recognized at the outset that the upper end of the data link layer could be shared by all three access techniques. The decision to use a common logical link control (LLC) sublayer for all of the LAN protocols and develop a separate sublayer for each of the different media apparently ushered in the idea of adaption sublayers, in this case, the media access control (MAC) sublayer. The most dominant today is the CDMA-based version, which is known as Ethernet or IEEE 802.3.

The idea of sublayering has proven to be valuable, as new types of technologies have become available. For example, the new fiber-distributed digital interface (FDDI) uses the LLC of all other LAN protocols, but its MAC is completely different from the token ring MAC even though FDDI is a token ring protocol. A thorough discussion of FDDI and related technologies is given in Jain [1994].

Metropolitan area networks (MANs) have been deployed for the interconnection of LANs within a metropolitan area. The primary media configuration for MANs is a dual bus configuration, and it is implemented via the distributed queue, dual bus (DQDB) protocol, also known as IEEE 802.6. The net effect of this protocol is to use the dual bus configuration to provide service approaching the FCFS service discipline to the traffic entering the FDDI network, which is remarkable considering that the LANs being interconnected are geographically dispersed. Interestingly, DQDB concepts have recently also been adapted to provide wide area communications. Specifically, structures have been defined for transmitting DQDB frames over standard DS-1 (1.544 megabits per second) and DS-3 (6.312 megabits per second) facilities, and these have been used as the basis for a service offering called switched multimegabit data services (SMDS).

One of the more interesting consequences of the advent of local area networking is that many traditional computer communication networks became internets overnight. LAN technology was used to connect stations to a host computer, and these host computers were already on a WAN. It was then a simple matter to provide a relaying, or bridging, service at the host in order to provide wide area interconnection of stations on LANs to each other. In short, the previously established WANs became networks for interconnection of LANs; that is, they were interconnecting networks rather than stations. Internet performance suddenly became a primary concern in the design of networks; a new business developed to provide specialized equipment, routers, to provide interconnection among networks.

Over the last decade, wireless LANs, which are local area networks in which radio or photonic links serve as cable replacements, have become common. Indeed, wireless LAN technology is now widely deployed in homes as well as in offices. Most of this technology features spread-spectrum wireless transmission with the media access technology being in the IEEE 802.11 family.

We now describe two broadly deployed technologies that provide link-layer connections in communication networks: *frame relay* (FR) technology, which is described in Braun [1994] and *asynchronous transfer mode* (ATM) technology, which is described in McDysan and Spohn [1994] and Pildush [2000].

As we have mentioned previously, there is really no requirement that the physical media between two adjacent data link layers be composed of a single link. In fact, if a path through the network is initially established between two data link entities, there is no reason that DLC protocols need to be executed at intermediate nodes. Through the introduction of adaption layers and an elementary routing layer at the top of the DL layer, DLC frames can be relayed across the physical links of the connection without performing the error checking, flow control, and retransmission functions of the DLC layer on a link-by-link basis. The motivation is that since link transmission is becoming more reliable, extensive error checking and flow control are not needed across individual links; an end-to-end check should be suffi-

cient. Meanwhile, the savings in processing due to not processing at the network layer can be applied to frame processing, which allows interconnection of the switches at higher line speeds. Since bps costs decrease with increased line speed, service providers can offer savings to their customers through FRNs. Significant issues are frame loss probability and retransmission delay. Such factors will determine the retransmission strategy deployed in the network. The extensive deployment of FR technology at this time suggests that this technology provides improvements over standard packet technology.

Another recent innovation is the ATM. The idea of ATM is to partition a user's data into many small segments, called cells, for transmission over the network. Independent of the data's origin, the cell size is 53 octets, of which 5 octets are for use by the network itself for routing and error control. Users of the ATM are responsible for segmentation and reassembly of their data. Any control information required for this purpose must be included in the 48 octets of user information in each cell. In the usual case, these cells would be transmitted over networks that provide users with 135 Mbps or more data transmission capacity (with user overhead included in the capacity).

The segmentation of units of data into cells introduces tremendous flexibility for handling different types of information, such as voice, data, image, and video, over a single transmission facility. As a result, there has been a tremendous investment in developing implementation agreements that will enable a large number of vendors to independently develop interoperable equipment. This effort is focused primarily in the ATM Forum, a private, not-for-profit consortium of over 500 companies of which more than 150 are principal members and active contributors.

LANs, WANs, and MANs based on the ATM paradigm are being deployed as described in Pildush [2000], for example. ATM is an excellent technology for providing worldwide Ethernet LAN interconnection at a full rate of 10 or 100 megabits per second. Originally, numerous vendors were planning to have ATM capabilities at the back plane in much the same way that Ethernet has been provided, but the bulk of deployment of ATM today is at the link layer between IP routers.

137.4 ATM and Frame Relay

ATM technology was initially developed in hopes of extending ISDN technology toward the concept of a broadband integrated services data network that would provide bandwidth on demand to end users. The ATM architecture consists of three sublayers: the ATM adaptation layer (AAL), the ATM layer, and the physical media dependent (PMD) layer. It is convenient for the purposes of this discussion to think of services as falling into two categories: circuit mode and packet mode, where a circuit mode service, such as voice, is a service that is naturally implemented over a circuit switched facility and a packet-mode service, such as e-mail, is a service that is more naturally implemented over a packet-switched connection. From many perspectives, it is natural to implement circuit-mode services directly over ATM while it is more natural to implement packet-mode services at the Internet (or packet) layer.

The implication of this partitioning of service types is that any service that has been developed for deployment over an IP network would naturally be deployed over an ATM network by simply using the ATM network as a packet delivery network. Each packet would traverse the network as a sequence of cells over an end-to-end virtual connection. If the flow control and resource management procedures can be worked out, the net effect of this deployment strategy would be, for example, that an application designed to be deployed over an Ethernet segment could be deployed on a nationwide (or even global) network without a noticeable performance degradation. The implications of this type of capability are obvious as well as mind-boggling.

137.5 Recent Developments

Broad deployment of networking technologies and wireless communications devices are the big story in recent times. A typical home deployment of networking technology today includes a router, which is at the interface of the home network and the outside world. Typically, the router has an IEEE 802.3

(Ethernet) port of the 100-Mbps variety as well as an IEEE 802.11 wireless LAN port facing the in-home side of the network. The connection from the home may be one of many technologies, ranging from a traditional relatively low-speed dialed connection over a phone line to relatively high-speed connection based on some form of digital subscriber loop (DSL) technology, such as asymmetric DSL (ADSL), which delivers service to the home in the range of hundreds of kilobytes per second to low megabytes per second. Connected together to form a network within a home may be a number of computers and a print server having an attached printer. A number of additional computers may be attached to the same network via wireless IEEE 802.11 connections. The router itself is usually connected to an Internet service provider (ISP) over the point-to-point protocol (PPP). All Internet applications running on all end systems (computers) in the home share the same PPP link-layer connection to the ISP port to the Internet.

Many of the services that network users enjoy today are the result of enhancements to the development of multimedia applications and protocols that are integrated into Web browsers. The Web browsers allow users to access search engines through which they can find interesting Web content. Once the content is found, the user can generally access the content quickly by simply clicking on a URL. When the object arrives at the user's system, the Web browser automatically invokes the services of a helper application, which renders the object to the user. For example, in the event that the object is a JPEG file, the Web browser will invoke an application that can display a picture that is stored in JPEG format.

At the time of this writing, networking technologies are being extended to the wireless domain as discussed in Lin and Chlamtac [2001] and Garg [2002]. The intention is to make all networking services available to mobile end systems using essentially the same infrastructure as the cellular telephone system. Alternatively stated, the intention is to evolve the wireless cellular phone system to a point where it is just part of the Internet. Meanwhile the intention is to evolve the Internet to the point where it handles all types of communications services. Thus, over the long term it is expected that communications types will be available over the Internet and that access to the Internet will be available to users at any time and place, whether the user is mobile or stationary. We are all looking forward to the end objective, the universal personal communications services (UPCS).

Defining Terms

Access line — A communication line that connects a user's terminal equipment to a switching node.

Adaption sublayer — Software that is added between two protocol layers to allow the upper layer to take advantage of the services offered by the lower layer in situations where the upper layer is not specifically designed to interface directly to the lower layer.

Architecture — The set of protocols defining a computer communication network.

Asynchronous transfer mode (ATM) — A mode of communication in which communication takes place through the exchange of tiny units of information called *cells*.

Broadband Integrated Services Digital Network (B-ISDN) — A generic term that generally refers to the future network infrastructure that will provide ubiquitous availability of integrated voice, data, imagery, and video services.

Carrier sense multiple access — A random access method of sharing a bus-type communication medium in which a potential user of the medium listens before beginning to transmit.

Circuit Switching — A method of communication in which a physical circuit is established between two terminating equipments before communication begins to take place. This is analogous to an ordinary phone call.

Common channel interoffice signaling — Use of a special network dedicated to signaling to establish a path through a communication network, which is dedicated to the transfer of user information.

Computer communication network — Collection of applications hosted on different machines and interconnected by an infrastructure that provides intercommunications.

Connectionless service — A mode of packet switching in which packets are exchanged without first establishing a connection. Conceptually, this is very close to message switching, except that if the destination node is not active, then the packet is lost.

- Connection-oriented service** — A mode of packet switching in which a call is established prior to any information exchange taking place. This is analogous to an ordinary phone call, except that no physical resources need be allocated.
- Entity** — A software process that implements a part of a protocol in a computer communication.
- Formal parameters** — The parameters passed during the invocation of a service primitive; similar to the arguments passed in a subroutine call in a computer program.
- Fast packet networks** — Networks in which packets are transferred by switching at the frame layer rather than the packet layer. Such networks are sometimes called frame relay networks. At this time, it is becoming vogue to think of frame relay as a service, rather than transmission, technology.
- Firewall** — Computer communication network hardware and software introduced into an internet at the boundary of the public network and a private network for the purpose of protecting the confidential information and network reliability of the private network.
- International Standards Organization Reference Model** — A model, established by the International Standards Organization (ISO), that organizes the functions required by a complete communication network into seven layers.
- Internet** — A network formed by the interconnection of networks.
- Local area networks** — A computer communication network spanning a limited geographic area, such as a building or college campus.
- Media access control** — A sublayer of the link layer protocol whose implementation is specific to the type of physical medium over which communication takes place and controls access that medium.
- Message switching** — A service-oriented class of communication in which messages are exchanged among terminating equipments by traversing a set of switching nodes in a store and forward manner. This is analogous to an ordinary postal system. The destination terminal need not be active at the same time as the originator in order that the message exchange take place.
- Metropolitan area networks** — A computer communication network spanning a limited geographic area, such as a city; sometimes features interconnection of LANs.
- Packet switching** — A method of communication in which messages are exchanged between terminating equipments via the exchange of a sequence of fragments of the message called packets.
- Protocol data unit** — The unit of exchange of protocol information between entities. Typically, a protocol data unit (PDU) is analogous to a structure in C or a record in Pascal; the protocol is executed by processing a sequence of PDUs.
- Service primitive** — The name of a procedure that provides a service; similar to the name of a subroutine or procedure in a scientific subroutine library.
- Switching node** — A computer or computing equipment that provides access to networking services.
- Token bus** — A method of sharing a bus-type communications medium that uses a token to schedule access to the medium. When a particular station has completed its use of the token, it broadcasts the token on the bus, and the station to which it is addressed takes control of the medium.
- Token ring** — A method of sharing a ring-type communications medium that uses a token to schedule access to the medium. When a particular station has completed its use of the token, it transmits the token on the bus, and the station that is physically next on the ring takes control.
- Trunk** — A communication line between two switching nodes.
- Wide area networks** — A computer communication network spanning a broad geographic area, such as a state or country.
- World Wide Web** — A collection of hypertext-style servers interconnected via Internet services.

Further Information

There are many conferences and workshops that provide up-to-date coverage in the computer communications area. Among these are the IEEE INFOCOM and ACM SIGCOMM conferences and the IEEE Computer Communications Workshop, which are specialized in computer communications and are held annually. In addition, IEEE GLOBECOM (annual), IEEE ICC (annual), IFIPS ICC (biannual), and the International Telecommunications Congress (biannual) regularly feature a substantial number of paper and panel sessions in networking.

The *ACM Communications Review*, a quarterly, specializes in computer communications and often presents summaries of the latest standards activities. *IEEE Network*, a bimonthly, specializes in tutorially oriented articles across the entire breadth of computer communications and includes a regular column on books related to the discipline. Additionally, monthly magazines *IEEE Communications* and *IEEE Computer* frequently have articles on specific aspects of networking. Also, see *IEEE Personal Communication Systems*, a quarterly magazine, for information on wireless networking technology.

For those who wish to be involved in the most up-to-date activities, there are many interest groups on the Internet that specialize in some aspect of networking. Searching for information on the Internet has become greatly simplified with the advent of the World Wide Web and the deployment of a number of search engines. For example, you can go to www.google.com and then enter *mobile IP* as the search keyword, and Google will return ten pages of references on the topic, including the set of standards relating to the topic.

138.1 Communications Satellite Services and Frequency Allocation

An agency of the United Nations, the International Telecommunications Union (ITU), issues the radio regulations that have treaty status among the ITU members. The services of interest in satellite communications include the fixed satellite service, mobile satellite service (including maritime, aeronautical, and land mobile vehicles), broadcast satellite service, and intersatellite service. Most commercial communications satellites operating in the fixed satellite service use the C band (6 GHz up, 4 GHz down) or the Ku band (14 GHz up, 12 GHz down). At higher frequencies, the 30-GHz (Ka band) and 50-GHz satellites are under development. The mobile satellite services operate primarily in the L band (1.6 GHz up, 1.5 GHz down). Exact frequencies and permitted signal characteristics are contained in the radio regulations and tables of frequency allocations issued by the ITU in Geneva, Switzerland.

138.2 Information Transfer and Link Margins — Ground to Space (Up-Link)

A transmitter with an output power of P_t , transmitting through an antenna with a gain of G_t , will provide a power flux density, ϕ , at a range of r_u , according to the formula

$$\phi = \frac{P_t G_t}{4\pi r_u^2} \quad (138.1)$$

The satellite receiver antenna with an effective aperture of A_r , located at a range from the ground transmitter will have a received power level, P_r , given by

$$P_r = \phi A_r = \frac{\phi G_u \lambda_u^2}{4\pi} \quad (138.2)$$

where λ_u is the wavelength of the up-link, and G_u is the gain of the receiving antenna.

The signal is received in the presence of thermal noise from the receiver plus external noise. The total noise power density is $N_0 = kT_s$, where $k = 1.38 \cdot 10^{-23}$ J/K (joules per kelvin) is Boltzmann's constant, and T_s is the system temperature. The noise power in the radio frequency (RF) transmission bandwidth, B , is $N = N_0 B$.

The up-link signal-to-noise power ratio is

$$P_u/N_u = (P_t G_t G_u / k T_s B) (\lambda / 4\pi r)^2 \quad (138.3)$$

In decibels,

$$\begin{aligned} P_u / N_u = 10 \log P_t G_t - 20 \log (\lambda / 4\pi r_u) - 10 \log B \\ + 10 \log (G / T) - 10 \log k \end{aligned} \quad (138.4)$$

The terms of this equation represent the earth station effective isotropic radiated power (EIRP) in dB W; free space loss in dB; RF channel bandwidth in dB Hz; satellite G/T ratio in dB/K, and Boltzmann's constant, which is -228.6 dBW/Hz K.

Similarly, the signal-to-noise power ratio of the space-to-earth link, or down-link (P_d/N_d), yields

$$P_d/N_d = (P_s G_s G_e / k T_e B) (\lambda_d / 4\pi r_d)^2 \quad (138.5)$$

where P_s is the power of the satellite transmitter, G_s is the gain of the satellite transmitting antenna, G_e is the gain of the earth station receiving antenna, k is Boltzmann's constant, T_e is the temperature of the earth station receiver, B is the bandwidth, λ_d is the wavelength of the down-link, and r_d is the range of the down-link.

The overall system power-to-noise ratio (P_s/N_s) is given by

$$\frac{1}{P_s / N_s} = \frac{1}{P_u / N_u} + \frac{1}{P_d / N_d} \quad (138.6)$$

Signals relayed via communications satellites include voice channels (singly, or in groups or supergroups), data channels, and video channels. Signals from multiple sources are multiplexed onto a composite baseband signal. The signals relayed via communications satellites include voice channels (singly, or in groups or supergroups), data techniques used to modulate these signals so that they can be kept separate use a physical domain such as frequency, time, space (separate antenna beams), or encoding. Access can be preassigned or assigned on demand. The three principal modes of multiple access include the following:

Frequency-demand multiple access (FDMA) isolates signals by filtering different frequencies.

Time-demand multiple access (TDMA) isolates signals by switching time slots.

Code-division multiple access (CDMA) isolates signals by correlation.

138.3 Communication Satellite Orbits

Earth-orbiting satellite trajectories are conic sections with the earth's center of mass located at one focus. The simplest orbit is circular, wherein the centrifugal force on the satellite is balanced by the gravitational force:

$$F_c = F_g \quad (138.7)$$

$$\frac{mv^2}{r} = \frac{GMm}{r^2} \quad (138.8)$$

where v is the satellite's velocity, r is the distance from the earth's center to the satellite, m is the satellite's mass, M is the earth's mass, and G is the constant of universal gravitation. Solving for v gives

$$v = \sqrt{\frac{GM}{r}} \quad (138.9)$$

$$(GM = 3.9858 \cdot 10^5 \text{ km}^3 / \text{s}^2) \quad (138.10)$$

If the satellite is in an elliptical orbit, with the semimajor axis of the ellipse given by a , the velocity at any point is given by the "vis-viva" equation:

$$v = \sqrt{GM \left(\frac{2}{r} - \frac{1}{a} \right)} \quad (138.11)$$

The maximum distance from the earth's center is known as the *apogee radius* (A), and the minimum distance is known as the *perigee radius* (P). The eccentricity (e) of the ellipse is given by

$$e = \frac{A - P}{A + P} \quad (138.12)$$

The velocity at apogee v_A is give by

$$v_A = \sqrt{\frac{GM}{A}(1 - e)} \quad (138.13)$$

and at perigee

$$v_P = \sqrt{\frac{GM}{P}(1 + e)} \quad (138.14)$$

The orbit period (T) is given by

$$T = 2\pi \sqrt{\frac{a^3}{GM}} \quad (138.15)$$

Most communications satellites are in geostationary orbits, which are in the equatorial plane with a period equal to one (sidereal) day, which is approximately 4 minutes shorter than a solar day. These satellites have an altitude of approximately 36,000 km.

Geostationary satellites appear to be stationary to observers (and antennas) on earth. The antennas are not required to track such a stationary target. Low-gain antennas with broad beams do not need to track satellites, and many of the satellites designed to operate with small mobile terminals use orbits with lower altitudes than the geostationary satellites. These orbits usually have high inclinations to the equatorial plane to provide coverage of the earth's surface to high latitudes.

TABLE 138.1 Launch Site Locations

| Site | Latitude | Longitude |
|---------------------------------------|----------|-----------|
| Kourou, French Guiana | 5°N | 53°W |
| Cape Canaveral, Florida | 28°N | 81°W |
| Vandenberg Air Force Base, California | 35°N | 121°W |
| Baikonur (Tyuratam), Kazakhstan | 46°N | 63°E |
| Plesetsk, Russia | 63°N | 35°E |
| Xiachang, People's Republic of China | 28°N | 102°E |
| Tanegashima, Japan | 30°N | 131°E |

138.4 Launch Vehicles

Launch services that were once the province of government organizations have become commercial enterprises. Practically all commercial launches to date have been to geostationary orbit.

Recently, the most popular launch provider has been Arianespace, which launches from Kourou, French Guiana, on the Atlantic coast of South America. Three launch vehicles used for commercial launches in the U.S. are McDonnell Douglas's Delta and Martin Marietta's Atlas and Titan. In the U.S., all eastward launches are conducted from Cape Canaveral; the polar and nearpolar launches use Vandenberg Air Force Base in California. Russia provides launches using the Proton and Zenit launch vehicles from Baikonur (Tyuratam) in Kazakhstan and from Plesetsk in Russia. China's Great Wall Trading Co. provides launches on the Long March launch vehicle from Xichang, China. Japan launches from Tanegashima, Japan, using the H-1 and H-2 launch vehicles. Locations of these launch sites are given in Table 138.1.

The velocity increment (v) gained by a launch vehicle when a propellant is burned to depletion is given by the equation

$$v = c \log_e M \quad (138.16)$$

The term c is the characteristic velocity of the propellants and is often expressed as

$$c = I_{sp} g \quad (138.17)$$

where I_{sp} is the specific impulse of the propellants (typically, $I_{sp} = 300$ s for lox/kerosene propellants in space) and g is the acceleration due to gravity. The mass ratio (M) can be expressed as

$$M = \frac{\text{Propellants} + \text{structure} + \text{payload}}{\text{Structure} + \text{payload}} \quad (138.18)$$

This velocity increment assumes that the vehicle doesn't change altitude appreciably during the propellant burn or experience significant aerodynamic drag.

138.5 Spacecraft Design

The primary subsystem in a communications satellite is the payload, which is the communications subsystem. The supporting subsystems include structure; electrical power; thermal control; attitude control; propulsion; and telemetry, tracking, and control (TT&C).

The communications subsystem includes the receiving antennas, receivers, transponders, and transmitting antennas. This payload makes up 35 to 60% of the mass of the spacecraft. The communications capability of the satellite is measured by the antenna gain (G), receiver sensitivity (T_r), transmit power (P_t), and signal bandwidth (B). Sensitivity is often expressed as G_r/T_r , and radiated power (EIRP) as $G_r P_r$.

Early models of communications satellites used antennas with broad beams and little directivity. These beams were spread over the whole earth and required large, highly directional antennas on the ground to pick up the weak satellite signals.

Improvements in satellite attitude control subsystems and in launch vehicle capabilities have enabled satellites to carry large antennas with multiple feeds to provide narrow beams that “spotlight” the desired coverage area (“footprint”) on earth. These footprints can be focused and contoured to cover designated areas on earth. The narrow beams also permit multiple reuse of the same frequency allocations.

Antenna gain G is given by

$$G = 4\pi A\eta/\lambda^2 \quad (138.19)$$

where A is the effective cross-sectional area, η is the antenna efficiency (typically 55 to 80%), and λ is the wavelength. At the Ku band down-link (12 GHz), where $\lambda = 2.5$ cm, a 1-m diameter antenna can provide a gain of 40 dB. The half-power beam width in degrees θ is given approximately by

$$\theta \approx 21/fD \quad (138.20)$$

where f is the frequency in gigahertz and D is the antenna diameter in meters. In this example the beam width $\theta = 1.75^\circ$. Using the same antenna reflector on the Ku band up-link (14 GHz), the beam width would be slightly narrower (1.5°) if the reflector is fully illuminated.

Transponders are satellite-borne microwave repeaters. A typical C-band transponder is composed of filters and low-noise amplifiers to select and amplify the received (6 GHz) signal. Local oscillators are fed into mixers along with the incoming signal to produce intermediate frequency (IF) signals, which are further amplified before mixing with another local oscillator to produce the down-link signal. This signal is fed to a high-power amplifier (HPA). Traveling wave tubes were used originally as HPAs but have been replaced by solid-state power amplifiers (SSPAs) at C band. The amplified signal is fed to the transmitting antenna for transmission to earth on the down-link (4 GHz).

Geostationary communications satellites operating at C band usually carry 24 transponders with 40 MHz of separation between them. Dual polarizations permit double use of the 500-MHz frequency allocation.

Without onboard processing the transponders are usually “transparent,” in that they receive the incoming (up-link) signals, amplify them, and change the carrier frequency before transmitting the down-link signals. Transparent transponders provide no signal processing other than amplification and changing the carrier frequency (heterodyning). These transponders can relay any signals that are within the transponders’ bandwidth. Other types of transponders can demodulate the incoming signals and remodulate them on the down-link carrier frequencies.

The spacecraft structure must support the payload and the subsystems through the propulsion phases as well as in orbit. The accelerations can be as high as 6 to 8 g during the launch phases. In orbit the structure must permit deployment and alignment of solar cell arrays and antenna reflectors. The spacecraft utilization factor, U , is defined as

$$U = \frac{M_u}{M} \quad (138.21)$$

where M_u is the mass of the communications payload and power subsystems, and M is the total spacecraft mass in orbit.

Representative values of U range from 0.35 to 0.60. Typical large geostationary communications satellites have a mass of 2000 kg in orbit.

The electric power subsystem uses solar cell arrays to provide electric power. The transmitters of the communications subsystem consume most of this power. Increasing demands for electric power led to large deployable solar arrays composed of silicon solar cells. Typically, power demand is for 2 kW of 28 V DC power. Power-conditioning units maintain the voltage levels within prescribed specifications. Rechargeable batteries (nickel-cadmium or nickel-hydrogen) provide power in emergencies and during solar eclipses.

The thermal control subsystem must maintain the specified temperature for all components of the spacecraft. Heat sources include incident sunlight and internal electrical heat sources (especially the HPAs). The only way to eliminate heat is to radiate it into space. The Stefan–Boltzmann law of radiation

gives the radiated heat (q) as $q = \epsilon A \sigma T^4$ where ϵ is the emissivity, which is between 0 and 1 (a black body has $\epsilon = 1$); A is the surface area; σ is the Stefan–Boltzmann constant ($= 5.760 \pm 0.007 \cdot 10^{-8} \text{ W/m}^2\text{K}^4$); and T is the absolute temperature.

The temperature of a passive black sphere in geostationary orbit around the earth in sunlight is between 275 and 280 K. The incident solar flux density (S) is approximately 1.37 kW/m². Preventing absorption of this heat energy requires the spacecraft to have a low absorptivity (α). A designer can control the temperature by controlling the absorptivity/emissivity ratio and by using spacecraft radiators.

The satellite's average temperature is given by

$$T = \frac{1}{\sigma} \left(\frac{\alpha a S}{\epsilon A} + \frac{Q}{\epsilon A} \right) \quad (138.22)$$

where a is the projected area (facing the sun), A is the total surface area, and Q is the internal heat dissipation.

Satellites need attitude control and station-keeping subsystems to maintain their orientation so that the antenna beams will illuminate the desired coverage areas on earth, the solar arrays will intercept the sun's rays, and velocity increments from the onboard propulsion subsystem will keep the satellite in its desired location. Onboard sensors can be used to detect the earth's horizon, the sun, and reference stars. Radio-frequency sensors are also used to detect beacons from earth stations.

Inertial measurements from onboard gyroscopes are used to detect attitude changes. These changes can be made using onboard reaction wheels, which transfer angular momentum between the spacecraft and the wheel, or by the reaction jets on the attitude control system.

Communications satellites are usually held to accuracies of approximately 0.1° or less in all three axes (yaw, pitch, and roll). The onboard propulsion system can provide velocity for the initial insertion in orbit and subsequent station-keeping velocity increments, as well as attitude control.

A typical communications satellite has propellant tanks containing monopropellant hydrazine (N₂H₄). On command, this fuel will flow through a valve to a thruster that contains a catalyst bed, combustion chamber, and nozzle. The resulting force from the thruster is used in velocity corrections needed for station keeping or for attitude control. This force is given by

$$F = \dot{W} I_{sp} \quad (138.23)$$

where \dot{W} is the propellant weight flow rate, and I_{sp} is the specific impulse, which is about 230 s for the example described.

By using electrically heated thrusters and bipropellant systems, the specific impulse can be raised to 300 s or more. Some communications satellites have such large propellant tanks that velocity increments of several kilometers per second can be achieved.

TT&C subsystems are provided for satellites in order to determine the status, performance, position, and velocity of the satellite, as well as to control it. Data from onboard sensors are transmitted by telemetry transmitters to ground control for monitoring the status of the satellite. Beacons are tracked in range and angle to determine position and velocity. Ground commands are received, demodulated, and processed by command receivers onboard the satellite. TT&C subsystems include high-power transmitters and omnidirectional antennas that can provide communications even if attitude control is lost and the spacecraft is tumbling. Link margins are similar to those described for the communications payload, but with more robust signal-to-noise ratios.

138.6 Propagation

Free space is transparent to electromagnetic waves; however, waves undergo refraction and absorption when passing through the troposphere and the ionosphere. The most important effect on satellite communications is the clear sky attenuation caused by the molecular resonance absorption bands. The

FIGURE 138.1 Atmospheric path losses at sea level.

clear sky attenuation per kilometer is plotted versus frequency in Figure 138.1. Resonance of water vapor molecules reaches 0.15 dB/km at 25 GHz. During heavy rainstorms, this attenuation can increase significantly, as shown in Figure 138.1.

Below 10 GHz, the atmosphere is transparent, but the resonant peaks shown for various molecules in the atmosphere can cause serious attenuation in the K band. The use of this band may be hampered by heavy rainstorms, which can cause depolarization as well as attenuation. One technique used to overcome this problem is to use diverse ground stations, spaced 5 to 10 km apart, to avoid transmission through localized thunderstorms.

138.7 Earth Stations

Earth stations are located on the ground segment of satellite communications systems. They provide communications with the satellites and interconnections to terrestrial communications systems. A simplified block diagram is shown in Figure 138.2.

The antennas, the most prominent subsystems, focus beams to enhance the sensitivity of the receivers, enhance the radiated power of the transmitters, and discriminate against radio interference from transmitters located outside the narrow antenna beam.

Both fixed and mobile earth stations have been developed for lower- and higher-frequency satellites.

138.8 Ka Band Satellites

With wider bandwidth availability, higher-frequency satellites have been conceived. In 2003 there were about 95 orbital slots assigned and planned Ka band satellites operated in the 20- to 30-GHz region. However, some satellite systems came and went before become operational. As mentioned in Section 138.6 and Figure 138.1, attenuation increases as frequency increase. Thus, transmission characteristics

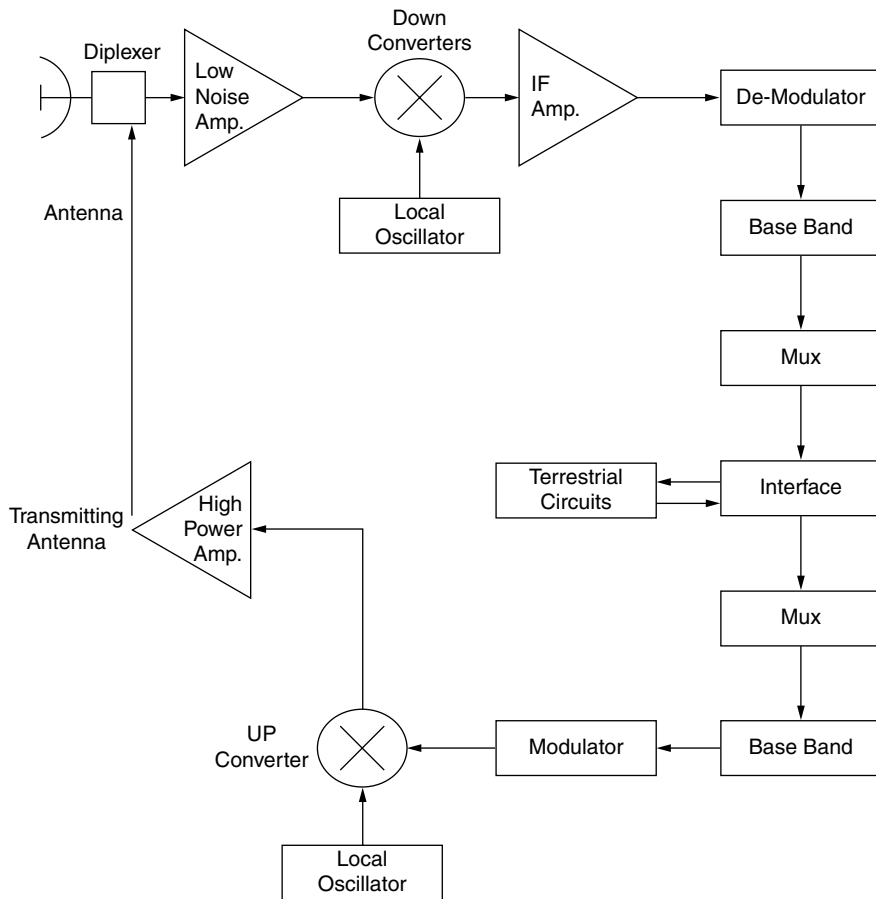

FIGURE 138.2 Earth station block diagram.

of such satellite operations become significant particular for small mobile terminals (Christopher, 1999; Pinck and Rice, 1995; Slack and Rice, 1996).

138.9 Satellites and the Internet

“Internet in the sky” has been announced by a number of satellite operators or would-be operators. In general, Internet and satellites are not compatible. Even with onboard processing, satellites are bottlenecks and cannot provide the optimal freedom of multiple-path flexibility as in terrestrial Internet operations. For recent developments in this area, see Hu and Li (2001), Allman et al. (1997), and publications by the Internet Protocols over Satellite Working Group.

Internet Protocols over Satellite (IpoS) Working Group is the concise name for the TIA-SCD-CIS-Internet Protocol Working Group (TR34.1.1), which is within the Telecommunications Industry Association-Satellite Communications Division (TR43), Communications and Interoperability Section (TR43.1). The IpoS Group is concerned with developing enhancements of Internet protocols to facilitate integration between Internet and satellite technologies.

138.10 Consultative Committee for Space Data Systems

Originated by NASA, the Consultative Committee for Space Data Systems (CCSDS) is now a multinational satellite and space communications standards organization that addresses both space and ground

segments. The space segments consist of spacecraft platforms, onboard systems, and space-qualified devices. The ground segments consist of ground networks and command, and telemetry data processing. Active members include the British National Space Centre (BNSC)/United Kingdom; Canadian Space Agency; Centre National d'Etudes Spatiales (CNES)/France; Deutsches Zentrum für Luft- und Raumfahrt e.V (DLR)/Germany; European Space Agency (ESA); Instituto Nacional de Pesquisas Espaciais (INPE)/Brazil; NASA; National Space Development Agency of Japan (NASDA); and Russian Space Agency (RSA)/Russian Federation. In addition, there are 25 satellite- and space-related organizations worldwide that belong to CCSDS as observer members.

- 139.3 [Summary and Conclusions](#)

All over the world, wireless communications services have enjoyed phenomenal growth over the past two decades. It was only in late 1983 that the first commercial cellular telephone system in the U.S. was deployed by Ameritech in the Chicago area. This was the analog service called Advanced Mobile Telephone System (AMPS). Today, cellular telephone services, most of them digital, are available throughout the world, and are beginning to rival fixed-line telephone services both in terms of availability and number of users. In a span of less than 20 years, the number of mobile wireless subscribers worldwide has grown from zero to over a billion users. This remarkable growth demonstrates not only the strong desire of people around the world to communicate to one another while on the move, but also the tremendous strides that technology has made in both fulfilling and further fueling this need. While the ability to communicate using radio signals was demonstrated by Marconi more than a century ago, it was the remarkable developments during the past few decades in RF circuit fabrication, digital signal processing, and several miniaturization technologies that made it possible to deploy and deliver wireless communication services at the scale and scope that we see today.

While a vast majority of subscribers today use wireless systems for voice telephony, we have begun to see the adoption of wireless data services as well. Short Messaging Service (SMS), which allows users to send text messages of size 160 characters or less using their cellular handsets, was first deployed in Europe in 1991, and has risen to a worldwide volume of several billions of messages per month in less than a decade. Operators are now beginning to offer Multi-media Messaging Service (MMS), which allows users to add pictures, sound, and other contents to their messages.

In addition to messaging, wireless data services include information services such as the delivery of news, stock quotes, weather, directions, etc. Due to the limitations in data rate and available space for display in handheld devices, specialized technologies such as the Wireless Access Protocol (WAP) and i-mode were developed to tailor and deliver Internet content to handheld devices. WAP is an open global specification that has so far had limited success, and i-mode is a proprietary technology developed by NTT DoCoMo that has enjoyed greater success in Japan since its introduction in February 1999.

Wireless data applications also include wireless access to the Internet and corporate Intranets. These applications are typically experienced in a laptop computer environment, where wireless connectivity is provided through a wireless adapter card. Currently available wireless Internet access services are limited to data rates in the order of tens of kilobits per second, with user experience comparable to the traditional dial-up services available over telephone lines. Future wireless services such as the third generation (3G) services promises greater throughputs on the order of several hundred kilobits per second. The evolution of newer and richer wireless data applications is accompanied by a migration of cellular wireless networks from a traditional circuit switched platform toward an all-IP packet switched network.

In this chapter we cover the fundamental aspects of wireless communications technology and provide a brief introduction to several existing and emerging wireless communication systems and standards. We begin by outlining the major technical challenges to providing wireless communications services, and provide an overview of the various techniques that have been developed to meet these challenges. Since the wireless industry has evolved to support a multiplicity of standards and systems, we attempt to cover the prominent ones such as GSM and cdma2000 in brief detail in this chapter. While most of the focus is on wide area mobile communications systems, Wireless Local Area Networks (WLAN) is also briefly covered. While WLAN systems do not provide the ubiquitous wide area coverage or high-velocity mobility support that traditional cellular and personal communications networks do, they are an important component of the wireless connectivity solution for the end-users since they are capable of much greater data rates and provide untethered access to communication networks. We also envision the possibility of seamless roaming across multiple heterogeneous networks such as the cellular packet data networks and wireless LAN networks. A number of wireless LAN systems and technologies that are standardized in the IEEE 802.11 group are covered in this chapter.

There is a lot of research activity currently underway in the area of Personal Area Networking (PAN) that provides interconnectivity and networking among the devices carried by a user within a Personal Operating Space (POS) using short-range low-power radio technology. Bluetooth® is an example of a Personal Area Networking technology. Personal Area Networks are being standardized in the IEEE 802.15 standards group. Task Group 3a within the 802.15 body is exploring the use of ultra-wideband wireless technology to develop extremely high-data rate short-range connectivity solutions.

While the focus of this chapter is on mobile and portable radio communications, fixed wireless communications is also gaining a lot of traction. The IEEE 802.16 standards group has ratified a new standard for wireless broadband metropolitan area networking that provides a wireless alternative to wired solutions such as cable modems and Digital Subscriber Lines (DSL) for broadband access. These systems provide multi-megabits per second connectivity over distances of a few miles for stationary applications.

139.1 Technical Challenges to Wireless Communications

In this section we identify the major technical challenges that make the design of a wireless communication system uniquely different from that of traditional wired communication systems, and provide an overview of the various approaches that have been explored to overcome these challenges.

In wireless communications systems the transmission channel is simply the intervening space between the transmitter and the receiver. Unlike in wired communications channels, there is no physical connection (a copper wire or fiber optic cable) to guide the signal from one point to another. Instead wireless systems rely on the ability of radiowaves to propagate through space. The first challenge comes from the fact that the radio channel is a difficult and unpredictable media for communication. This is especially true of mobile radio channels where the end-user is moving at high-speeds. Developing a communication system that can reliably transport signals between a mobile user terminal and a fixed base station through this harsh media is a challenge that continues to excite wireless researchers.

The second challenge comes from the fact that the radio spectrum is a scarce resource. Government regulatory bodies around the world have allocated only a limited amount of spectrum for commercial use. While there is a large amount of spectrum for use in the low-power license-exempt bands, this is

not the case with licensed frequency bands. Being a scarce resource, operators around the world have paid billions of dollars in licensing fees to gain rights to use these frequency bands. The need to accommodate an ever-increasing number of users and providing them with applications that demand larger amounts of bandwidth within the allocated spectrum challenges the system designer to continuously search for solutions that use the spectrum more efficiently. Developing methods to improve the spectral efficiency of wireless communication systems is an area of keen interest for wireless researchers.

One particular challenge that can be thought of as resulting from the scarcity of spectral resources, but requiring special mention is the issue of multi-user channel access. In addition to the need to ensure that each user utilizes the spectrum as efficiently as possible, there is also the need to devise methods to share the resources among the multiple users in the most effective manner. Since spectrum constraints do not always permit the luxury of providing dedicated resources to each user, methods need to be developed to divide and allocate the spectrum resources to different users on demand and in an optimal manner.

The next two challenges result directly from the two fundamental differentiating value propositions that wireless communications systems attempt to bring to the end-user: mobility and portability. Mobility implies that (1) a user can send and receive data packets or voice calls wherever they are, and (2) a user can maintain a communication session without interruption while on the move. The first implication requires that the system provide the ability to identify the location of each user at any given time and develop routing and roaming methods. The second implication requires that the system provide a method of seamless handover between base stations as the user moves around the coverage area.

Portability implies that the communications device used by the end-user is battery powered and lightweight. Since terminal devices are battery powered, it is important that they consume as little power as possible. Given that in many industrialized countries the total power consumed by wireless networks and terminals is turning out to be a non-significant portion of the total national power consumption, power saving has also become a national macro-economic need. The requirement of low-power consumption challenges designers to look for power efficient transmission schemes, power saving protocols, and battery technologies with longer life.

Superimposed on all these challenges is the need to provide these services at a low cost in order to ensure mass market adoption. It is therefore imperative to understand that the wireless system designer often does not have the luxury of choosing the best possible technical solution, but is instead constrained by several practical and economic realities.

In the following subsection we discuss each of these challenges in more detail. We begin with the challenges imposed by the radio channel.

Radio Channel Impairments

Radio signals travel most effectively when there is a clear line-of-sight between the transmitter and receiver, and if the intervening area is free of clutter. In clear line-of-sight conditions, a radio signal simply experiences an exponential decay of power with distance. The requirements of modern communications systems such as cellular systems and wireless LAN systems, however, do not allow the luxury of line-of-sight communications, and have to work under much more unforgiving conditions. The several large and small obstructions in the channel, undulations in the terrain, relative motion between the transmitter and receiver, interference from other signals, and several other complicating factors together not only weaken but also delay and distort the signal in an unpredictable and time-varying fashion. Instead of a clean copy of the original signal, what is received at the far end is an unpredictable mess that often bears only a poor resemblance to the signal transmitted. Under these conditions it is a challenge not only to design signals that can withstand the vagaries of the wireless channel but also to build receivers capable of extracting the transmitted information buried deep within the distorted received signal. Any attempt to design a wireless system and build resilient signal sets and good receivers must begin with a thorough understanding of the wireless channel.

It is instructive to characterize the radio channel at three different levels of spatial scale. The first level of characterization is to develop a model that describes the median distance-dependent decay in power

that the signal undergoes as it traverses the channel. These large-scale models provide the systems engineer a rough estimate of the area that can be covered by a given radio transmitter. Since radio signal power tends to decay exponentially with distance, these models are typically linear on a logarithmic decibel scale with a slope and intercept that depend on the overall terrain and clutter environment. Widely-used large scale propagation models derived from empirical measurements include the Okumura-Hata Model [Hata, 1980], and the COST-231 Model [EURO-COST, 1991].

The next level of characterization is the variation in received signal power from the median distance-dependant value. These variations called large-scale fading are often caused by undulations in the terrain and large obstructions such as buildings, and depend largely on the diffraction losses that radio signals suffer as they get around these obstacles. Measurements have shown that these large-scale variations tend to have a log-normal distribution around the median value. The variance of this log-normal distribution dictates the amount of power margin that the system engineer needs to accommodate in the link budget to ensure adequate signal coverage at over 90–99% of the areas that need to be covered. This margin is often referred to as the shadow margin.

The final level of spatial scale at which the radio channel can be characterized is the variation in signal strength observed over small areas. Due to the phenomenon of multi-path propagation the amplitude of the received radio signal can vary significantly (several tens of dBs) over very small distances (on the order of wavelengths). These variations are called small-scale fading. A good understanding of the nature of small-scale fading is critical to the design of wireless modems.

Figure 139.1 illustrates the phenomenon of multi-path propagation experienced by signals traveling from a transmitter to a receiver via several reflecting and scattering objects. Each of the multiple paths experiences a different attenuation and time delay (and resulting phase offset). What is seen at the receiver is the superposition of these multiple waves. This superposition can cause constructive or destructive interference depending on the phase relationship among the different waves. Therefore the amplitude of the resultant received signal will depend on the particular multipath structure seen at the receiver. As the mobile receiver moves in space, the radio paths between the transmitter and receiver will change giving rise to a different multipath structure. This change in multipath structure changes the relative phase and amplitude of the received waves, and thereby changes the amplitude of the resultant signal. Therefore, as the receiver moves in space, the amplitude of the received signal varies depending on variation in the multipath structure. Thus, spatial variation in multipath structure is manifested as temporal variation in the received signal strength of a mobile receiver. This variation in received signal strength caused by multipath propagation is called **multipath fading**. Depending on the absence or presence of a dominant path (e.g., direct line of sight), the amplitude variation in the received signal caused by multi-path fading is often found to follow either a Rayleigh or Rician probability distribution, and therefore referred to as *Rayleigh fading* or *Rician fading*, respectively.

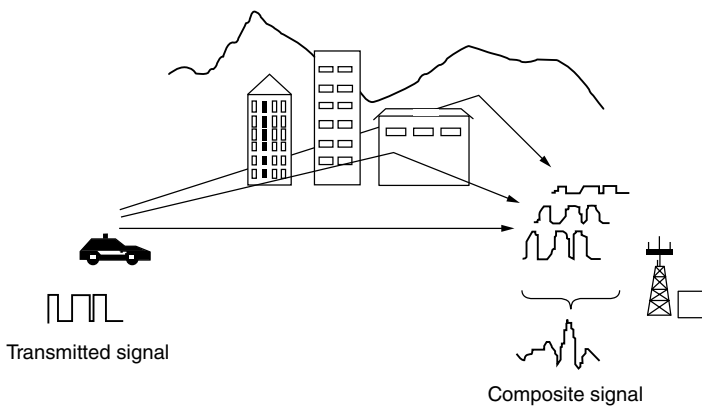

FIGURE 139.1 Illustration of multipath propagation in a wireless channel.

TABLE 139.1 Summary of Techniques to Mitigate Radio Channel Impairments

| Type of Fading | Mitigation Technique |
|----------------------------|--|
| Flat and Slow Fading | Obtain multiple uncorrelated copies of the same signal using some type of diversity. Examples include: Antenna or Space Diversity Error Correction Coding Time Diversity using Interleaving Frequency Diversity Polarization Diversity Other techniques include: Adaptive Modulation Automatic Repeat Request Increase Fade Margin in Link Budget |
| Frequency Selective Fading | Adaptive Equalization Multi-carrier modulation schemes such as Orthogonal Frequency Division Multiplexing (OFDM) Direct Sequence Spread Spectrum with RAKE Frequency Hopped Spread Spectrum Pilot Signal Antenna solutions such as distributed antenna systems, small cells, and directional antennas to reduce delay spread |
| Fast Fading | Non-coherent or Differentially Coherent Modulation Error Correction Coding Interleaving Increase Symbol Rate by adding signal redundancy |

While multi-path propagation is inherent to a mobile radio channel, the effect of it on a radio signal depends on the signal characteristics. The two main effects of multi-path propagation are *flat fading* and *frequency selective fading*. If the signal bandwidth is less than the channel bandwidth (band of frequencies over which the frequency response of the channel is nearly constant), flat fading results. Flat fading is manifested as large variations in signal amplitude, but does not cause signal distortion. If the signal bandwidth is larger than the channel bandwidth, frequency-selective fading results. Frequency-selective fading is manifested as time dispersion, which causes inter-symbol interference (ISI). Time dispersion caused by multipath delays is often quantified by a parameter called *rms delay spread*. Measurement results show that in outdoor cellular environments delay spread values are in the range of hundreds of nanoseconds to a few microseconds, and in indoor environments they range from a few nanoseconds to a few hundred nanoseconds.

The time-variation in the channel characteristics caused by the relative motion between the transmitter and receiver leads to carrier frequency dispersion called *Doppler Spread*. Doppler Spread is directly related to vehicle speed and carrier frequency. When the time-variations in channel conditions caused by motion is faster than the time-variations in the transmitted information signal, the effect is called *fast fading*. And conversely, when the channel characteristics vary slower than the information signal, the effect is called *slow fading*.

There are a variety of processing techniques that can be used to mitigate the effects of small-scale fading. Some of these techniques require processing at the transmitter, some at the receiver, some both. Channel coding, equalization, antenna diversity combining, etc. are examples of techniques to mitigate multipath effects. Some of the more advanced techniques do not seek to mitigate the challenges posed by multipath fading, instead see multipath as offering a richly diverse environment that can be cleverly exploited to gain capacity enhancements. Examples of such techniques include space division multiplexing using intelligent antennas and multi-user diversity that exploits the uncorrelated fades experienced by different users to make capacity gains. Table 139.1 summarizes several of these signal processing techniques to mitigate multipath fading.

Scarcity of Licensed Frequency Spectrum

Radio frequency spectrum is a scarce and expensive resource that needs to be managed carefully. This is especially true of the licensed spectrum allocated to provide cellular mobile voice and data services. As demand for wireless services have grown, a number of techniques have been developed and adopted to utilize the scarce spectrum resources more and more efficiently. One of the most basic techniques for efficiently managing the limited spectrum resource is called **frequency reuse**, which is the key to providing capacity and accommodating a growing subscriber base in cellular systems [MacDonald, 1979]. Frequency reuse is fundamental to the cellular radio concept.

Cellular and Frequency Reuse

Cellular radio systems rely on an intelligent allocation and reuse of the radio frequency spectrum throughout a coverage region. A subset of the spectrum is assigned to a small geographic area called a cell. Each cell is served by a base station that uses channels in the spectrum allocated to that cell. The power radiated by a base station is deliberately kept low, and antennas are located so as to achieve coverage within the particular cell. By limiting the coverage area within a cell, the same group of channels can be used to cover various cells that are separated from one another by distances large enough to keep the interference between them (termed co-channel interference) within tolerable limits. This replication of channels in separated geographic areas is termed frequency reuse.

Figure 139.2 shows a cellular layout where cells labeled with the same letter use the same group of channels (i.e., spectrum). Due to random propagation effects, actual cell coverage areas are amorphous in nature. It is, however, useful to visualize cells as hexagons for system design purposes.

To better understand the frequency reuse concept, consider a cellular system that has a total of S duplex channels available for use. If each cell is allocated a group of k channels ($k < S$), and if the S channels are divided among N cells into unique and disjoint channel groups with the same number of channels, the total number of available radio channels can be expressed as

$$S = kN \tag{139.1}$$

FIGURE 139.2 Illustration of the cellular concept. Cells labeled with the same letter use the same set of frequencies. A cell cluster is outlined in bold and is replicated over the coverage area. In this example the cluster size, N , is equal to 7, and each cell contains $1/7$ of the total number of available channels.

The factor N is called the cluster size and is typically equal to or less than 7. The N cells that use the complete set of frequencies are collectively called a cluster. If a cluster is replicated M times within the system, the total number of duplex channels, C , available to the system is given by

$$C = MkN = MS \quad (139.2)$$

As seen from Equation (139.2), the capacity of a cellular system is directly proportional to the number of times a cluster is replicated in a given service area. If the cluster size N is reduced, more clusters are used to cover a given area and hence more capacity (larger value of C) is achieved. The choice of N depends on the co-channel interference level that can be tolerated. For example, GSM systems typically can work well at $N = 4$, while CDMA systems can operate at $N = 1$.

To this point we have considered the use of omni-directional antennas at each base station. The co-channel interference of a cellular system can be further reduced (and thus capacity can be increased) if directional antennas are used at the base station. Each directional antenna covers a disjoint section of the cell and is assigned a fraction of the cell's channels. This technique is termed sectorization. Due to the use of directional antennas, a given sector will now interfere with (and be interfered by) a fraction of the co-channel cells. This fraction depends on the amount of sectoring used. Normally, sectoring is done either in thirds or sixths. As a result of the reduced co-channel interference, a smaller cluster size becomes allowable. This reduced cluster size results in higher capacity.

When sectorization is employed, the frequencies used in a particular cell are broken down into three or six groups and used only within a particular sector. The implementation is accomplished using fixed directional antennas. In the case of 120° sectors, the number of interferers in the first level is reduced from six to two. This is because only two of the six co-channel cells will be directing a particular frequency group towards the cell. The penalty paid for this improvement is an increased number of antennas as well as an increased number of necessary hand-offs. Additionally, the trunking efficiency is decreased.

Dynamic Channel Allocation

For efficient utilization of the radio spectrum, a frequency reuse scheme that is consistent with the objectives of increasing capacity and minimizing interference is required. In other words, a system designer needs to devise efficient channel assignment strategies. Channel assignment strategies can be classified as either fixed or dynamic. The particular type of channel assignment employed affects the performance of the system, particularly in how calls are managed when a mobile user travels from one cell to another [Tekinay and Jabbari, 1991].

The preceding discussion on the number of channels per cell assumes that traffic is uniformly distributed in the service area. In real systems, however, traffic is not uniformly distributed. Certain areas such as shopping malls or stadiums may experience higher traffic volume as compared to other areas. Such hot spots can be alleviated through cell-splitting or the use of micro-cells. However, if the traffic volume increases are temporary (e.g., during special events or during rush hour) a more effective means of servicing the increased demand is the use of dynamic channel allocation. A fixed channel allocation scheme permanently assigns channels (channel definitions depend on the multiple access scheme as will be discussed later) to a given sector or cell whereas a dynamic channel allocation scheme will associate channels and cells based on demand. Such a scheme requires careful assignment strategies to ensure reuse distances are not violated. However, the advantage is that it allows a system to adjust to non-uniform traffic patterns. Typically such schemes allow heavily loaded sectors (or cells) to borrow channels from neighboring cells which are lightly loaded.

In a fixed channel assignment strategy, each cell is allocated a predetermined set of channels. Any call attempt within the cell can be served only by the unoccupied channels in that particular cell. If all the channels in that cell are occupied, the call is blocked and the subscriber does not receive service. In dynamic channel assignment, channels are not allocated to various cells permanently. Instead, each time a call is attempted, the cell base station requests a channel from the MTSO, which allocates a channel based on an algorithm that minimizes the cost of channel allocation.

Intelligent Antennas

As mentioned in a previous section, directional antennas can increase system capacity by reducing co-channel interference thus allowing smaller reuse patterns. Theoretically, the capacity could be continually increased by further sectorization. However, practical constraints limit the amount of sectorization possible. For example, increased sectorization results in an increased handoff overhead and a higher risk of dropped calls. One potential solution to this situation is the concept of intelligent antennas [Buehrer et al., 1999]. Intelligent antennas can allow for reduced reuse patterns without increasing hand-offs. This is accomplished by using phased arrays or switched beams to direct energy over a more narrow part of the cell or sector without dividing the spectrum. By monitoring the received signal the antenna adapts to mobile movement within a sector or cell to maintain a narrow beam without requiring handoff. The downside to such a system is that it requires additional antenna hardware to form the narrow beams (either through antenna arrays or butler matrices). Unfortunately, RF hardware is among the more expensive components of the base station. Additionally, intelligent antenna systems require additional ASICs to run the appropriate algorithm which either adapts the phased array weights or switch the beams.

Multiple Access Strategies

A basic component of any wireless (or wired) communication system that involves multiple connections is the method by which different users access the medium. Since users must share a common medium in order to communicate, there must be some known method for accomplishing this. This is termed **multiple access**. We have already discussed the way in which geography is used in cellular systems to create isolated channels through frequency reuse patterns. Now we discuss how within a given cell (and thus specific frequency band) users must have some method of accessing or sharing the medium.

Multiple access methods are generally divided into two basic categories: random access and channelized access. In the former method there are no pre-assigned channels for each user. Instead, users must compete for the medium each time they have information to send. In the latter method users are assigned a specific channel which is dedicated for their use as long as they have information to transmit. Such a scheme requires significant overhead to set up the channels and thus is most applicable to constant rate applications such as voice. However, setting up dedicated channels is not particularly efficient when the information source is bursty (such as in computer data networks). In such cases it is much more efficient to allow users to randomly access the channel.

There are several general random access methods that are employed for data networks including ALOHA, slotted ALOHA, and carrier sense techniques. In each of these techniques users access a single channel whenever they have data to send. In the ALOHA system [Abramson, 1970], users simply transmit data as soon as it arrives. They can then listen (either to the channel or via feedback) and determine whether or not their data was received successfully. When two or more users access simultaneously, there will be a collision and the data will not be received correctly. However, if traffic is bursty and the number of users is not large, the frequency of collisions should be small. Further, if transmitters know when a collision occurs they can retransmit using a channel access protocol. When users are restricted to begin transmitting at fixed time intervals the system is called *Slotted ALOHA*. Slotted ALOHA, while requiring synchronization between users, provides an improvement in throughput, particularly at moderate to high offered traffic loads. This is because the probability of a collision is reduced by synchronizing transmissions.

The throughput of ALOHA and Slotted ALOHA is not particularly good since transmitters listen to the channel only after they have transmitted. Collisions can be reduced by listening before transmitting (a “look before you leap” approach). This is termed *Carrier Sense Multiple Access* or CSMA. In CSMA users simply monitor the channel and refrain from transmitting if there is current traffic. Collisions will still occur when two or more users sense the idle channel and transmit simultaneously. The throughput of CSMA can be much higher than ALOHA especially if it is used in conjunction with *Collision Detection* (CSMA/CD). In CSMA/CD users also listen for collisions and when a collision is detected a special jam signal is transmitted which informs all users that they should cease transmitting. Such a procedure reduces

FIGURE 139.3 Illustration of the three multiplexing techniques, and how multiple channels are provided without interfering with each other: (a) FDMA, (b) TDMA, and (c) CDMA.

the downtime of the channel and thus improves throughput. As discussed in the WLAN section CSMA/CD has limitations in a wireless channel, and therefore a Collision Avoidance (CA) scheme is used instead.

In voice systems, random access methods are not particularly useful since they cannot guarantee that a user will be able to transmit when necessary. Voice systems thus use channelized multiple access strategies where each user requests a channel and is given one for the duration of the call. There are three basic methods for creating channels in a communication system: frequency channels, time channels, and code channels. These correspond directly to *Frequency Division Multiple Access (FDMA)*, *Time Division Multiple Access (TDMA)*, and *Code Division Multiple Access (CDMA)*. In FDMA systems the medium is divided into frequency slots which are then used for specific channels. Each transmitter-receiver pair must know which frequency band to use and must then tune their receiver to detect that band. In a TDMA system all users share a common frequency band, but are restricted to transmitting in a particular time slot. Thus, only a single frequency band is needed, but the receiver must have accurate knowledge of the timing of the different transmissions in order to correctly receive the signal. Such a system has some advantages compared to FDMA when multiple data rates are used in the system. In many wireless systems, the medium is first divided into several frequency channels using FDMA, and then each frequency channel is further divided among multiple users using TDMA. Figure 139.3 provides an illustration of the three multiple access schemes.

CDMA is significantly different than FDMA and TDMA. CDMA systems rely on spread spectrum techniques, where all users can transmit in the same frequency band and at the same time. However, each transmitter-receiver pair uses a specific spreading waveform which is modulated by the information. The spreading waveforms of different users have very low cross correlation. Thus, while TDMA and FDMA provided ideally orthogonal multiple access schemes, CDMA is inherently interference limited. While it is theoretically possible to create an orthogonal CDMA system, it would require synchronous reception of all signals on both the uplink and downlink. This is clearly possible on the downlink, but extremely difficult on the uplink. Further, when there are multipath delays which are greater than a chip¹ duration, maintaining orthogonal reception upon synchronization is not possible. CDMA, while inferior

¹ A 'chip' is one symbol in a direct sequence spread spectrum signal.

to TDMA and FDMA in a single cell system with continuous transmission, provides certain advantages in a cellular voice system. First, CDMA allows for universal frequency reuse ($N = 1$), which improves the spectral efficiency of CDMA as compared to TDMA and FDMA. Second, CDMA allows for natural statistical multiplexing in voice systems simply by suppressing transmission when there is no voice present. Since voice activity is typically on the order of 40%, suppressing transmission during periods of silence reduces the interference level by ~60%. Since interference is the limiting factor in CDMA, this technique directly improves the system capacity. These two factors make CDMA generally more attractive than TDMA or FDMA methods for cellular voice despite the additional complication of power control that is required. This is evidenced by the fact that the vast majority of Third Generation (3G) standards for cellular are based on CDMA.

Mobility Management

Cellular and Personal Communications systems provide users with seamless connectivity while being on the move. Today, a typical wireless user can place a call successfully while walking down a street, traveling in his vehicle or commuting to work in a local train. Providing users with such an experience requires complex systems to be in place to manage and track the call. The challenge of communication networks to locate mobile terminals and maintain connectivity as they move from one location to the other is referred to as *mobility management*. Implementing a good mobility management scheme is critical to the overall performance of the network and providing a good user experience. As a result, the area of mobility management has gained considerable attention since the early days of the first wireless systems.

Functionally, mobility management may be divided into two categories — location management and handoff management. Location management protocols focus on issues like mobile registration, location updating, and paging while handoff management protocols allow users to maintain a seamless connection with the network as they move and change their location.

Location management involves both the identification of the mobile location and successful call delivery. In the identification stage, the mobile periodically registers with the network to identify its presence and location within the network. In the call delivery stage, the network is queried on the current location of the terminal device. In a nutshell, location management within the wireless network is a combination of several database queries and responses. These databases include Home Location Registers (HLR) and Visitor Location Registers (VLR), which store information about the local home users and the visiting users, respectively. For larger networks, the location of databases and network elements participating in the location management process is critical to the overall performance.

Today, there are two main standards that provide location management in cellular and personal communications systems. They are GSM's Mobile Application Part (MAP) and the EIA/TIA's Interim Standard IS-41. GSM MAP was developed as part of the GSM standard and the IS-41 protocol was primarily developed for wireless systems in North America.

Handoff management is the second aspect of mobility management. A proper handoff management mechanism is crucial to the overall performance of a wireless system that supports roaming and mobility. **Handoff** refers to the process where a data session or voice call is transferred from one base station to another. A successful handoff is executed by the close co-ordination and involvement of several network elements and multiple protocols within the wireless system. For example, in a GSM system, handoffs between two base stations involve the base stations, Base Station Controllers (BSC) and Mobile Switching Centers (MSC) [3GPP TS 05.08, 1997].

Processing handoffs is an important task in any cellular mobile system. Many system designs prioritize handoff requests over call initiation requests. It is required that every handoff be performed successfully and that they happen as infrequently and imperceptibly as possible. In cellular systems the signal strength on either the forward or reverse channel link is continuously monitored and, when the mobile signal begins to decrease (e.g., when the reverse channel signal strength drops to below between -90 dBm and -100 dBm at the base station), a handoff occurs. In first-generation analog cellular systems, the Mobile Telephone Switching Office (MTSO) monitored the signals of all active mobiles at frequent intervals to

obtain a rough estimate of their location and decide if a handoff was necessary. In second-generation systems handoff decisions are mobile assisted. In a mobile-assisted handoff (MAHO) the mobile stations take measurements of the received power from several surrounding base stations and continually report the results of these measurements to the base station in use, which initiates the handoff. The MAHO method provides faster handoff than first-generation analog cellular systems since the MTSO is not burdened with additional computation.

Handoffs may be classified based on the link layer establishment and termination process between the mobile terminal and the base station. Accordingly, there are two types that are referred to as “break-before-make,” or “make-before-break.” In a break-before-make handoff, the mobile breaks the link layer from one base station before establishing it with another. During the time of switchover between the base stations, the mobile terminal, for a fraction of a second, is not connected to either base station. Examples of wireless protocols supporting the break-before-make handoffs include AMPS, GSM, and IS-136. In the make-before-break handoff, the mobile terminal establishes concurrent link layer connections with all the base stations taking part in the handoff process. IS-95 and 1XRTT are examples of systems that support make-before-break handoffs.

As mobility management protocols provide end to end solutions, they operate across multiple physical and link layer connections (Layer 1 and 2). Hence, these protocols are generally designed to operate around the network layer (Layer 3). For example, in GSM mobility management is distributed across different network elements. Depending on the situation, different network elements participate in providing mobility management to the terminal. Examples of mobility management in GSM include GSM-MAP between the HLR and Mobile Switching Center (MSC) VLR, ISUP between MSCs, and BSSMAP between BSCs and MSCs.

The convergence of wireless technologies with the Internet has created a special need for providing mobility support in an Internet Protocol (IP) environment. Since the original Internet protocols were designed for stationary devices and most of the existing mobility protocols were meant for non-IP networks, newer protocols, such as Mobile IP (MIP), had to be developed to support mobility for an IP enabled device in a wireless and fixed-line environment.

Mobile IP (MIP) is a protocol that has gained great attention over the past few years. The protocol is being specified under the auspices of the Mobile IP Working Group (WG) at the Internet Engineering Task Force (IETF). The protocol attempts to offer a simple solution to the mobility problem for IP devices [Perkins, 2002]. IETF MIP WG has specified IP mobility solutions for networks based on IPv4 and IPv6. Since its inception, the WG has completed the development of the IPv4 based mobility protocol and is currently working on the IPv6 based mobility protocol. At the time of this writing, the IETF WG was working on the 21st draft for MIPv6. Some of the issues that have been addressed by the protocols include mobility management across heterogeneous IP based networks, triangular routing, and route optimization. As a consequence of MIP implementation in networks, we can expect to see devices successfully roaming across different wireless technologies. For example, a user can expect to surf the Internet with an Internet enable PDA device on an 802.11b network and handover the session to an UMTS network. To the user, the transition between the networks will be seamless and the application will not be interrupted.

Another important benefit that mobility management techniques offer wireless operators is the ability to off-load traffic from one network to the other. An operator may avoid congestion to its GSM/GPRS network by off-loading some of its traffic to the EGPRS or UMTS network. Of course, we are assuming that the mobile terminal has the ability to maintain link layer connectivity across all the technologies participating in the handover.

Low Power Requirements

Since wireless communications systems typically involve mobile and portable devices, it is of utmost importance that the systems be designed with low power consumption requirements of the user terminal device in mind. Greater efficient use of power in portable wireless devices not only increases the usage time of the devices, but also enhances the user experience. Charging one’s wireless device often can be

the most frustrating experience to any user. Since the early days of wireless communication, low power consumption for terminal devices has been an area of great focus and attention. It used to be that designers could allow for greater power consumption in order to get greater performance, but researchers are now looking to save power without compromising performance. Greater power savings may be achieved by using a combination of efficient signal processing techniques, better physical layer design, improvements in protocols, and superior materials in the device.

In wireless handsets, battery quality and performance plays an important role in the overall performance and usability of handsets. This issue becomes more critical with wireless terminals transmitting and receiving data. Keeping other parameters such as modulation, coding and channel conditions constant, the power consumed by the terminal device is directly proportional to the bit rate with which it is transmitting.

Development of high performance, low power wireless systems require designers to focus on coupling different areas of communications. Some of the most important areas include communications theory, integrated circuit fabrication, low power circuit design, digital signal processing techniques, and wireless protocol design.

Low-power consumption requirement drives physical layer design toward the direction of using power-efficient modulation schemes — signal sets that can be detected and decoded at lower signal levels. Unfortunately, power-efficient modulation and coding schemes tend to be less spectrally efficient. Since spectral efficiency is also a very important requirement for many wireless systems, it becomes challenging to pick the appropriate trade-off between power efficient and spectral efficient signal sets.

Protocol design is another important area which can be utilized to gain power efficiencies. Ensuring that the transmitter circuitry is turned on only when required, and on a demand basis, incorporating low-power sleep modes with methods to wake up when required, etc. are tricks that can be played to reduce the overall power consumption. Bluetooth is an example of a protocol that is designed with low-power consumption requirement being among the most important consideration.

Along with hardware designs that employ power efficient architectures, battery technologies play a vital role in the performance of terminals. Battery technologies that offer higher power densities over greater periods of time can compensate for some of the limitations in the hardware and software systems.

Most of the earlier handsets used Nickel Cadmium (NiCd) batteries. Although these batteries were widely used, and to a large extent are being currently used, they had a problem related to their charging levels. When a NiCd battery is charged from a partially charged level, it assumes its new uncharged level as the partially charged level at which it begins charging. This memory effect in the battery results in a reduction of the total power delivered with each charge. With the introduction of Nickel Metal Hydride (NiMH) batteries, the problem related to the memory-effect in batteries was solved. These batteries also had higher power levels in comparison with NiCd batteries. The latest battery technology involves Lithium Ion and contains a built in electronic charge and discharge circuitry. These batteries have superior performance characteristics and are more expensive than their NiCd and NiMH counterparts.

139.2 Evolution of Wireless Services and Standards

Wireless communication systems have come a long way since Marconi first showed how information could be transmitted over the wireless link. Since the early 1970s, commercial wireless systems have evolved considerably. Advances in digital signal processing, semiconductor technologies, and software systems have enabled the development of advanced wireless technologies that support services ranging from voice applications to real-time video applications. Presently, there are several wireless standards available; each supporting multiple services. Most of the countries around the world are at a stage of wireless maturity where wireless subscribers expect their handsets to work wherever they go. To a casual subscriber, this may not be a great achievement, but on closer look, one can easily appreciate the amount of effort and time that was put in to develop these global standards. Although today most of the standardization is achieved with the collective effort of companies and government bodies on a global scale, this was not so in the early stages of the development of wireless systems.

FIGURE 139.4 Evolution of the various mobile wireless technology standards and their data rate capabilities.

United States, Japan, and parts of Europe led the development of the first generation of wireless systems. The first generation systems were characterized by their analog modulation schemes and were geared primarily towards delivering voice. Examples of these technologies include the Advanced Mobile Phone System (AMPS) from the U.S. and the Nordic Mobile Telephone (NMT) from Norway, Sweden and Finland.

Improvements in processing abilities of hardware platforms over time enabled the development of the second generation (2G) wireless systems. These systems were also aimed primarily towards the voice market, but unlike the first generation systems, they used digital modulation schemes. Examples of 2G systems include the Global System of Communications (GSM), IS-95, and IS-136. GSM was adopted all over Europe and most of Asia, while North American market was fragmented between IS-95, IS-136, and GSM.

Although 2G systems offered consumers with superior voice quality over their first generation counterparts, they were aimed primarily towards delivering voice service. There was still the need to deliver data services over wireless. Keeping in mind that large quantities of money were spent in deploying the 2G networks, it was essential to upgrade 2G systems, at a minimal cost, to provide data. Such upgrades to 2G systems to support wireless data came to be commonly referred to as being the 2.5G systems. Examples of 2.5G systems include GPRS and IS-95b.

The International Telecommunications Union (ITU) in the 1990s invited contributions for third generation wireless systems, or 3G systems. Some of the main criteria to qualify as a 3G system included the ability to provide 144 kbps in a vehicular environment, 384 kbps for pedestrian users and 2 Mbps for stationary terminals. As part of its standardization process, ITU also identified spectrum segments for the use by 3G systems. Examples of 3G systems include WCDMA and cdma2000. One of the most interesting aspects of the 3G contributions was the choice of CDMA as the preferred access technique for the majority of 3G systems. Not only did the IS-95 camp propose evolution towards a CDMA based 3G technology, but the GSM camp offered its own version of CDMA, called W-CDMA. Figure 139.4 shows the evolutionary path for wireless data systems.

Advanced Mobile Phone Service (AMPS)

The Advance Mobile Phone Service, or AMPS, was developed by AT&T Bell Labs in the late 1970s and was first deployed commercially in 1983 in Chicago and its nearby suburbs. Unlike the cellular systems of today, the first system used large cell areas and omni-directional base station antennas. The system covered 2,100 square miles with only 10 base stations. Each base station had a height between 150 ft and 550 ft. A total of 136 voice channels were deployed unevenly among the 10 base stations on the basis of expected levels of traffic. The earliest systems were designed for a Carrier to Interference Ratio (CIR) of 18 dB for satisfactory voice performance, and were deployed in a 7 cell frequency reuse pattern with 3 sectors per cell.

Since its first deployment in Chicago, AMPS has been deployed in several countries in South America, Asia and North America. In the United States, the Federal Communications Commission assigned

spectrum in a manner that identified two AMPS operators for every market. These two operators were identified as being the A side and the B side operator. Each operator was assigned a total of 416 AMPS channels in each market. Of the 416 channels, 21 channels were designated for control information and the remaining 395 channels carried voice traffic.

AMPS base stations continuously transmit beacon information over a control channel known as the Forward Control Channel (FCC). This channel is transmitted using FSK modulation. An AMPS mobile listens to this beacon signal and locks on to the channel by which it is referred to as being “camped on” to the base station. As mentioned earlier, each operator has 21 channels dedicated for control. As a result, the mobile needs to scan only these 21 channels to identify the presence of an AMPS signal from a base station. Once the mobile camps-on to a base station, it can originate or receive a call. Mobiles camped to each base station transmit the Reverse Control Channel (RCC) that is monitored by the base station. The RCC is transmitted by all mobiles that are camped on to each base station. Just like the reverse link’s RCC, all the base stations transmit their FCCs out of the pool of 21 control channels. Hence, it is the responsibility of network providers to see that FCCs allocated to adjacent base stations are not a source of interference.

Once the mobile associates itself with a base station, it may originate a call by transmitting an origination message over the RCC. Details of the subscriber such as the Electronic Serial Number (ESN), Station Class Mark (SCM) and Mobile Identification Number (MIN) are also transmitted to the base station. On receiving these details of the mobile subscriber, the base station verifies the authenticity of the user by checking with the Mobile Telephone Switching Office (MTSO). On getting an approval from the MTSO, the call is routed to the Public Switched Telephone Network (PSTN) and on to the final destination.

During the course of an AMPS call, supervisory signals are used to make sure that the call between the mobile subscriber and base station is properly connected. The supervisory signals in the AMPS systems are the Supervisory Audio Tone (SAT) and the Signaling Tone (ST). The SAT is a range of three tones that are transmitted at 5970, 6000, and 6030 Hz. Each base station uses one of these three tones during a voice call. This signal is superimposed over the voice signal in the forward link and reverse link and is transmitted at levels that are barely audible to a user. In geographic areas where mobiles receive multiple co-channel signals from multiple base stations, the SAT provides a way of identifying the base station that is handling the call.

The ST is a burst of 10 kbps data stream that consists of a pattern of alternating 1’s and 0’s. The main function of the ST is to indicate the end of a call and is transmitted along with the SAT. When the mobile terminates a call, it sends the ST to the base station. On its reception, the base station is alerted of the call being terminated by the mobile station.

Though all operators have already deployed 2G digital systems, AMPS continues to be used in North America as a common fallback service available throughout the geography, and is often used in the context of providing roaming between different operator networks.

GSM and its Evolution

In the early 1990s, many European countries came together under the auspices of the Conference of European Posts and Telegraphs (CEPT) to develop and standardize a pan-European system for mobile services. The group was called the Groupe Spécial Mobile (GSM) and their main charter was to develop a system that can deliver inexpensive wireless voice services, and work all across Europe.

By 1989, the European Telecommunications Standards Institute (ETSI) took over the development of the GSM standard. The first version, called GSM Phase I, was released by the early 1990s and in a short period of time was deployed by several European operators. As GSM began gaining acceptance beyond Europe, the standard was renamed as the Global System for Mobile Communications.

Since the first commercial GSM deployment in Europe in 1991, GSM has gained widespread acceptance across the globe. Today GSM stands out from the rest of the technologies as the most popular standard in terms of volumes of terminals and operators deploying it.

TABLE 139.2 Summary of GPRS Radio Specifications

| Parameter | Specification |
|---|--|
| Downlink Frequency Band | 824–849 MHz, 1850–1910 MHz (U.S.) 880–915 MHz, 1710–1785 MHz (Europe) |
| Uplink Frequency Band | 869–894 MHz, 1930–1990 MHz (U.S.) 925–960 MHz, 1805–1880 MHz (Europe) |
| Transmitter/Receiver Frequency Separation | 45 MHz, 80 MHz (U.S.) 45 MHz, 95 MHz (Europe) |
| Multiple Access Technique | TDMA/FDMA |
| Duplexing Technique | FDD |
| Modulation Data Rate | 270.83333 Kbps |
| Channel Spacing | 200 kHz |
| Time Slot Period | .576 ms |
| Frame Period | 4.615 ms |
| Number of Timeslots per Frame | 8 |
| Bit Period Duration | 3.692 μs |
| Modulation | GMSK |

In Europe and other parts of the world GSM has been deployed in the 900 MHz and 1800 MHz bands while in the United States it has been deployed in the 850 MHz and 1900 MHz frequency bands. Table 139.2 shows details of the radio interface of a GSM system.

By the mid-1990s, ETSI introduced the GSM Packet Radio Systems (GPRS) as an evolutionary step for GSM systems toward higher data rates. Under favorable conditions, these systems can provide a maximum data rate of 160 kbps. GPRS and GSM systems share the same frequency bands, time slots, and signaling links. Figure 139.5 shows the architecture of a GSM/GPRS system. As shown in the diagram, a GSM system may be upgraded to a GPRS system by introducing new elements, such as the Serving GPRS Support Node (SGSN) and Gateway GPRS Support Node (GGSN), and upgrading existing network elements such as the BTS and HLR. SGSN provides mobility management and may be thought of as equivalent to the MSC for voice systems. GGSN provides the IP router functionality and connects the GPRS network to the Internet and other IP networks.

The GSM standard got a further boost in its data handling capabilities with the introduction of Enhanced Data Rate for GSM systems, or EDGE, in the early part of 1997. Although EDGE was developed for existing GSM systems, it can also be implemented as a stand-alone system that can be deployed by a non-GSM operator. Under favorable conditions, EDGE systems can provide users with a maximum data rate in the range of 400 kbps.

In the late 1990s ETSI submitted a proposal for a 3G system called Universal Mobile Telephone System (UMTS). UMTS included a CDMA-based air interface, called Wide-band CDMA (W-CDMA). Although the air interface was different from the air interface of GSM and EDGE, its back end network elements such as MSC, SGSN, and GGSN was backward compatible with the 2G and 2.5G system.

FIGURE 139.5 Block diagram representation of the GSM/GPRS network architecture.

IS-95 and its Evolution

The IS-95 standard based on CDMA for cellular telephony was introduced in 1993 as a voice-only system. The standard uses universal frequency reuse ($N = 1$) with direct sequence spread spectrum modulation using 64-ary Orthogonal Walsh codes on the uplink and QPSK on the downlink. Unlike TDMA/FDMA-based systems, CDMA requires strict power control. Thus, IS-95 includes fast (800Hz) power control on the reverse link and 50 Hz power control on the forward link. The original (IS-95A) system supported 9.6 kbps voice channels¹ and a single dedicated data channel at 9.6 kbps. The introduction of IS-95B allowed for multiple 9.6 kbps channels to be used simultaneously for a peak data rate of 76.8 kbps albeit at the cost of 8 voice channels. Further, in order to improve the efficiency of data transmission, burst (or packet) mode was introduced. The key benefits of CDMA-based cellular systems are universal frequency use and statistical multiplexing of voice traffic. The former benefit is directly enabled by the use of spread spectrum modulation. The latter benefit is the result of voice activity as discussed earlier. A third advantage of CDMA is the direct benefit of sectorized antennas.

In recent years the IS-95 family of standards (branded cdmaOne by the CDMA Development Group) has been upgraded via the Third Generation Partnership Project 2 to what is termed cdma2000. cdma2000 (also called 3G1X for third generation with one times the chip rate of IS-95) improves the capabilities of IS-95 to meet the standards set forth by the International Telecommunications Union (ITU) for International Mobile Telecommunications 2000 (IMT-2000). Specifically, the data capabilities were enhanced by adding separate logical channels termed *supplemental channels*. Each link can support a single fundamental channel (at 9.6 kbps) and multiple supplemental channels (up to 307 kbps). Further, the data rate can be increased up to 2 Mbps through the use of multiple carriers (3G3X). The link quality was improved by upgrading the uplink through the use of coherent modulation and the downlink through the addition of fast (800 Hz) power control to match the uplink. Advanced antenna capabilities were also integrated into the new standard through options for transmit diversity as well as supplemental pilot options for beam-steering. A key to these upgrades is that they are backward compatible. cdma2000 and IS-95A/B may be deployed on the same carrier allowing gradual deployment.

In order to both achieve higher data rates (up to 2 Mbps) as well as improve overall system throughput for packet data scenarios the 3G1X standard was also evolved to 3G1X-EVDO (*EVolution, Data Only*). As the name implies, the standard is applicable to data traffic only since there is no guarantee of real time service. The downside to this standard is that although it is backward compatible with the IS-95 radio characteristics, it cannot be deployed on the same carrier as 3G1X RTT or IS-95. This requires service providers to dedicate a single carrier to data services in order to deploy data. In order to allow providers to use the same carrier for both data and voice the IS-95 family of standards also includes 3G1x-EVDV (*EVolution, Data and Voice*). This standard combines EVDO packet data service with voice service on a single carrier.

Wireless Local Area Networks

The wireless standards and systems covered thus far are for providing cellular and personal communications services using wide area networks (WAN) that provide ubiquitous coverage to users. Wireless Local Area Networks (WLAN), on the other hand, are systems designed to provide wireless connectivity to a local wired network, typically located within a building. In most cases they provide a wireless extension to wired Ethernet networks using a wireless Access Point. An Access Point typically can provide radio coverage for about 100–200 feet. For a long time, the WLAN use was restricted to vertical niche market applications such as factory floors, health care clinics, and warehouses. This situation is rapidly changing with the adoption of new interoperable industry standard called Wi-Fi™. In addition to

¹ This was termed the fundamental rate and was dependent on the vocoder used. Some systems used a 14.4 kbps vocoder which meant that the data channel was also available at 14.4 kbps.

enterprise wireless networking, WLAN systems are now being used for applications such as home networking and wireless data access at targeted public locations.

The IEEE 802.11 is the predominant wireless LAN standard in the US. It took several years of work at the IEEE to complete its first version of the standard, thereby delaying the adoption of WLAN systems. After completing their first standard in June 1997, IEEE 802.11 committee worked very hard to quickly complete several revisions to the standard. The first one is the IEEE 802.11b, which is an 11 Mbps extension to the original IEEE 802.11, and operates in the 2.4 GHz ISM band. This is the standard that is currently trademarked as Wi-Fi™. The second one, the IEEE 802.11a is a higher speed alternative that operates in a 5 GHz U-NII band. Both of these standards were completed in a very short time. We now also have a new standard called IEEE 802.11g, which can be thought of as essentially IEEE 802.11a operating in the 2.4 GHz band, while at the same time also including backward compatibility with IEEE 802.11b. While the physical layer standard for each of these variations is different, they all have the same medium access control (MAC) layer specification.

The MAC layer is based on a variation of the Carrier Sense Multiple Access (CSMA) system used in Ethernet. While the traditional wired Ethernet uses Collision Detection (CD) along with CSMA, the 802.11 standard uses a collision avoidance (CA) mechanism. Collision Avoidance is used since Collision Detection cannot work properly in the wireless environment. Collision Detection requires that every node be able to hear every other node in the network. In a wireless environment, it is quite possible that a node A can hear a node B, and node B can hear a node C, while A and C cannot hear each other. This problem is often referred to as the “hidden node” problem. Collision Avoidance overcomes the hidden node problem, by using a simple Request to Send (RTS), Clear to Send (CTS) protocol that ensures that collisions do not occur very often. The MAC layer design philosophy is premised on supporting only best effort services. There are no good provisions made for QoS. There is, however, a new MAC layer standard called IEEE 802.11e being specified that will incorporate methods to accommodate service prioritization and QoS support.

The MAC layer also supports a rudimentary authentication and encryption scheme called Wired Equivalent Privacy (WEP). Efforts to improve the security offered in wireless LAN is underway in a task group within the IEEE (called IEEE 802.11i).

The IEEE 802.11b uses a Direct Sequence Spread Spectrum (DSSS) physical layer and operates in the 2.4 GHz ISM band. The DSSS signal occupies a relatively wide 22 MHz channel. There are a total of 11 channels defined in the IEEE 802.11b standard. Given that there is only a total of 80 MHz in the 2.4 GHz ISM band, out of the eleven channels one can only pick sets of three non-overlapping channels at a time. When two IEEE 802.11b systems operate in close proximity, it is important to ensure that they are operating in non-overlapping channels. Operating in the same channel or overlapping channel can degrade the throughput performance.

The IEEE 802.11b standard supports multiple data rates: 1, 2, 5.5, and 11 Mbps. Signaling at 1 Mbps and 2 Mbps is achieved using BPSK and QPSK modulation, respectively, and are fully backward compatible with the original 802.11 DSSS standard. The 5.5 Mbps and 11 Mbps signaling are achieved by adding a new coding scheme called complementary code keying (CCK) to the standard. CCK is able to deliver 5.5 Mbps and 11 Mbps without changing the bandwidth of the signal. CCK uses an “eight chip” code-spreading sequence and can operate at 11 Mbps in environments with delay spreads of 100 ns, and at 5.5 Mbps in environments with 250 ns delay spread. CCK does not actually change the modulation scheme used; it merely replaces the Barker code sequences used in the original IEEE 802.11 standard with a new set of CCK codes. Because there are 64 unique CCK code words that can be used to encode the signal, up to 6 bits can be represented by any one particular code word (instead of the 1 bit represented by a Barker symbol). The CCK code word is then modulated with the QPSK technology used in 2 Mbps wireless DSSS radios.

The need for higher speeds and the desire to move away from the crowded 2.4 GHz band led to the development of IEEE 802.11a standard. This standard offers up to 54 Mbps in the newly allocated 5 GHz U-NII band. The physical layer is not only at a different frequency, but also uses a completely different modulation scheme. Orthogonal Frequency Division Multiplexing (OFDM) is the radio technology

adopted by the IEEE 802.11a standard. OFDM offers superior performance both in terms of spectral efficiency (how many bits can be squeezed in a given bandwidth) and immunity to multi-path interference. IEEE 802.11a breaks the frequency band of 5.15–5.35 GHz into eight 20 MHz channels. Each of these 20 MHz channels is composed of 52 narrow-band carriers of 300 kHz bandwidth. OFDM sends data in parallel across all of these carriers and aggregates the throughput. Each carrier can transport 125 kbps of data. Of the 52 carriers, four are designated as pilot (for synchronization and control), and 48 are used for data transport. Thus, each 20 MHz channel yields an aggregate data rate of 6 Mbps. Now, using higher order modulation (64QAM) the channel capacity can be increased up to 54 Mbps.

Wireless LAN/WAN Integration

Telecommunications service providers and mobile operators around the world are recognizing the potential for a new high-speed wireless data service at targeted public locations called “hotspots” using wireless LAN technology. The rapid adoption and proliferation of Wi-Fi™ offers a compelling case to deploy broadband wireless services using this technology. Given that the range of these wireless systems is only 100–200 feet, it is not possible to provide ubiquitous wide area cellular-like coverage using this technology. It is, however, eminently possible (with significantly lower capital outlay) to provide service at targeted islands of coverage, called “hotspots,” which may be chosen carefully depending on the target market and type of service offering. Plausible hotspots include airports, hotels, convention centers, cafes, restaurants, bookstores, truck stops, MDUs, and other locations where people tend to congregate and/or are captive for a certain period of time. Some operators see the initial target market as the so-called “road-warrior” segment — business travelers with laptops — and offer services in airports and hotels. Other operators target local travelers like the real-estate agents and the general tech-savvy consumers and are offering this service at places such as cafes and restaurants.

As wireless LAN systems are used to deploy public communications service, there is an interest in integrating them with the existing and emerging wide area wireless data systems such as GPRS, and cdma2000 to provide users a seamless connectivity experience. Having a WLAN-based network in targeted locations can enable an operator to provide higher-speed services to customers at those locations, and could help off-load the traffic on the wide area network. Using WLAN-based networks for providing high-speed services in areas of high-traffic concentration, and within buildings appears very attractive. Providing a wireless LAN-based service can complement the mobility and ubiquity of the cellular networks with the offer of high bandwidth in a relatively limited and stationary or portable environment.

The LAN/WAN integration could happen at various levels. At one level, it would simply be a common authentication and billing between the two services. At the deeper level, the system would support seamless mobility between the two using Mobile IP-based technologies. Even tighter coupling between the two services will require developing interworking functions between the two. It is conceivable that future third-generation wireless data networks and wireless LAN networks could get fully integrated into a single IP-based network providing seamless handover functionality between the two.

139.3 Summary and Conclusions

Mobile and portable radio communication systems and services have enjoyed tremendous growth in the past two decades. Remarkable strides have been made in understanding the challenges to wireless mobile and portable communications and developing solutions to meet those challenges. In this chapter, we provided a brief introduction to wireless communications, and outlined some of the major challenges. While good quality mobile voice communications and low data rate wireless data communications are a reality today, there is still work to be done in wireless communications. Mobile radio communications continue to excite researchers around the world, who are driven by the powerful vision of providing affordable broadband multimedia communications to mobile users anywhere, anytime, and in a manner that is secure and easy to use.

Defining Terms

Multipath Fading — The variations in received signal level caused by the superimposition of multiple propagating radio waves impinging on the receiver.

Frequency reuse — The use of radio channels on the same carrier frequency to cover various areas that are separated from one another so that cochannel interference is not objectionable.

Multiple Access — The process and techniques by which a multiplicity of users gain access to the available channel resources from transmission and reception. The channel resources are typically shared among all the users on a demand basis.

Handoff — The process of transferring a mobile station from one channel to another. This transfer could be across adjacent sectors or base stations.

- 140.1 Optical Communications Systems Topologies
- 140.2 Fibers
- 140.3 Other Components
- 140.4 Signal Quality

Electronic communications over conducting wires or by atmospheric radio transmission began in the latter part of the 19th century and was highly developed by the mid-20th century. Widespread communication via beams of light traveling over thin glass fibers is a relative newcomer, beginning in the 1970s, reaching acceptance as a viable technology in the early 1980s, and continuing to evolve since then [Chaffee, 1988]. Fibers now form a major part of the infrastructure for a national telecommunications information highway in the U.S. and elsewhere.

The fundamentals of optical communications are covered in many textbooks [e.g., Palais, 1998; Keiser, 2000; Agrawal, 2002], which elaborate on the information presented in this chapter.

Optical communications refers to the transmission of messages over carrier waves that oscillate at optical frequencies. The frequency spectrum of electromagnetic waves can range from DC to beyond 10^{21} Hz. (A tabulation of units and prefixes used in this chapter appears in [Tables 140.1](#) and [140.2](#).) Optical waves oscillate much faster than radio waves or even microwaves. Their characteristically high frequencies (on the order of $3 \cdot 10^{14}$ Hz) allow vast amounts of information to be carried. An optical channel utilizing a bandwidth of just 1% of this center frequency would have an enormous bandwidth of $3 \cdot 10^{12}$ Hz. Numerous schemes exist for taking advantage of the vast bandwidths available. These include wavelength-division multiplexing (WDM) and optical frequency-division multiplexing (OFDM), which allocate various information channels to bands within the optical spectrum.

For historical reasons optical waves are usually described by their wavelengths rather than their frequencies. The two characteristics are related by

$$\lambda = c/f \tag{140.1}$$

where f is the frequency in hertz, λ is the wavelength, and c is the velocity of light in empty space ($3 \cdot 10^8$ m/s). A frequency of $3 \cdot 10^{14}$ Hz corresponds to a wavelength of 10^{-6} meters (or 1 μm , often called a *micron*). Wavelengths of most interest for optical communications cover the range from 0.8 to almost 1.7 microns.

The Gaussian beam profile is common in optical systems. Its intensity pattern in a plane transverse to the direction of wave travel is described by

TABLE 140.1 Units Used in Optical Communications

| Unit | Symbol | Measure |
|-----------------|--------|-----------|
| Meter | m | Length |
| Second | s | Time |
| Hertz | Hz | Frequency |
| Bits per second | b/s | Data rate |
| Watt | W | Power |

TABLE 140.2 Commonly Used Prefixes

| Prefix | Symbol | Multiplication Factor |
|--------|--------|-----------------------|
| Tera | T | 10^{12} |
| Giga | G | 10^9 |
| Mega | M | 10^6 |
| Kilo | k | 10^3 |
| Milli | m | 10^{-3} |
| Micro | μ | 10^{-6} |
| Nano | n | 10^{-9} |

$$I = I_0 e^{-2(r/w)^2} \quad (140.2)$$

where r is the polar radial coordinate and the factor w is called the *spot size*. This is the light pattern emitted by many lasers and is (approximately) the intensity distribution in a single-mode fiber.

Optical transmission through the atmosphere is possible, but it suffers serious liabilities. A fundamental limit is imposed by diffraction of the light beam as it propagates away from the transmitting station. The full divergence angle of a Gaussian beam is given by

$$\theta = 2\lambda/\pi w \quad (140.3)$$

Because of the continual beam enlargement with propagation distance, the amount of light captured by a finite receiving aperture diminishes with increasing path length. The resultant low received power limits the distances over which atmospheric optical systems are feasible.

The need for an unobstructed line-of-sight connection between transmitter and receiver and a clear atmosphere also limits the practicality of atmospheric optical links. Although atmospheric applications exist, the vast majority of optical communications is conducted over glass fiber.

A key development leading to fiber communications was the demonstration of the first laser in 1960. This discovery was quickly followed by plans for numerous laser applications. Progress on empty-space optical systems in the 1960s laid the groundwork for fiber communications in the 1970s. The first low-loss optical waveguide, the glass fiber, was produced in 1970. Soon after, multimode fiber transmission systems were being designed, tested, and installed. The mass production commercialization of the single-mode fiber in 1983 brought about the fiber revolution in the communications industry. Fibers are practical for a range of path lengths, from under a meter to as long as required on the earth's surface and beneath its oceans (e.g., almost 10,000 kilometers for transpacific links).

Fiber systems are limited in length by the bandwidth of their components (a fiber's bandwidth decreases with length) and by component losses (a fiber's loss increases with length). Loss is usually expressed in the decibel scale, which compares two power levels and is defined by

$$\text{dB} = 10\log(P_2/P_1) \quad (140.4)$$

140.1 Optical Communications Systems Topologies

Fibers find their greatest use in telephone networks, local area networks (LANs), and cable television networks. They are also useful for short data links, closed-circuit video links, and elsewhere.

A block diagram of a point-of-point fiber optical communications system appears in [Figure 140.1](#). This diagram represents the architecture typical of the telephone network. The fiber telephone network is digital, operating at levels indicated in [Table 140.3](#). Single fibers operating as high as 10 Gb/s are commonplace. At this rate, almost 130,000 digitized voice channels (each operating at 64 kb/s) can be transmitted along a single fiber using time-division multiplexing (TDM). Fiber systems operating at 40 Gb/s have been developed, further increasing the capacity of a single fiber operating at a single carrier

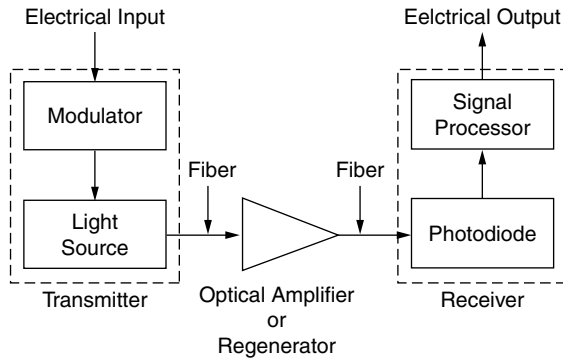

FIGURE 140.1 Point-to-point fiber transmission system.

wavelength. When the number of carrier wavelengths is increased using WDM (tens or even hundreds of channels), capacities of a single fiber enter the terabit/s range.

Because fiber cables may contain more than one fiber (in fact, some cables contain hundreds of fibers), the capacity for voice and data transmission within a single cable is enormous.

Telephone applications may be broken down into several distinct areas: transmission between telephone exchanges, long-distance links, undersea links, and distribution in the local loop (i.e., to subscribers). Although similarities exist among these systems, requirements are somewhat different. Between telephone exchanges, large numbers of calls must be transferred over moderate distances. Because of the moderate path lengths, optical amplifiers or regenerators are not required. Long-distance links, such as between major cities, require signal boosting of some sort (either regenerators or optical amplifiers). Undersea links (such as transatlantic or transpacific) require multiple boosts in the signal because of the long path lengths involved [Thiennot et al., 1993].

Fiber to the home (for broadband services, such as cable television distribution) does not involve long path lengths but does include division of the optical power in order to share fiber transmission paths over all but the last few tens of meters into the subscriber's premises. In many subscriber networks, the fibers terminate at optical-to-electrical conversion units located close to the subscriber. From that point, copper wires transmit the signals over the remaining short distance to the subscriber. Because of the power division, optical amplifiers are needed to keep the signal levels high enough for proper reception.

Cable television distribution remained mostly coaxial cable based for many years, which was partly due to the distortion produced by optical analog transmitters. Production of highly linear laser diodes (such as the distributed feedback [DFB] laser diode) permitted the design of practical television fiber distribution links.

Some applications, such as LANs, require distribution of the signals over shared transmission fiber. Topologies include the passive star, the active star, and the ring network [Hoss, 1990]. The passive star and the active ring are illustrated in Figure 140.2 and Figure 140.3. LANs are *broadcast systems* that allow all terminals to receive messages sent from any one transmitting terminal.

The star coupler distributes optical signals from any input port to all output ports. Its loss is simply

$$L = 10\log(1/N) \tag{140.5}$$

where N is the number of output ports on the star coupler.

TABLE 140.3 Digital Transmission Rates

| Designation | Data Rate (Mb/s) |
|-------------|------------------|
| DS-1 | 1.5444 |
| DS-3 | 44.736 |
| DS-4 | 274.175 |
| OC-1 | 51.84 |
| OC-3 | 155.52 |
| OC-12 | 622.08 |
| OC-24 | 1244.16 |
| OC-48 | 2488.32 |
| OC-192 | 9953.28 |
| OC-768 | 39813.12 |

Note: The DS levels refer to U.S. telephone signaling rates, whereas the OC levels are those of the SONET standard.

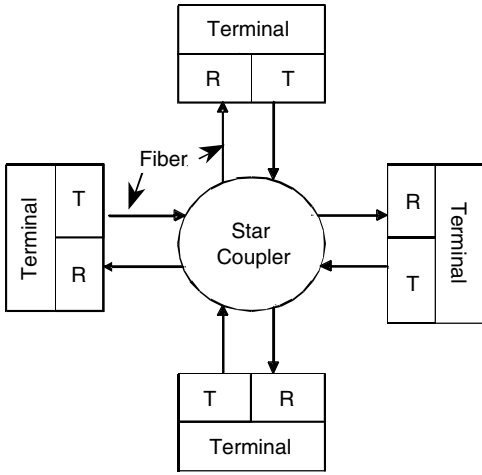

FIGURE 140.2 Star topology. Blocks T and R are, respectively, the optical transmitter and optical receiver.

FIGURE 140.3 Ring topology. Blocks T and R are, respectively, the optical transmitter and optical receiver.

In the ring each node acts as a regenerator. The ring is simply a series of connected point-to-point networks.

The major components found in optical communications systems are modulators, light sources, fibers, photodetectors, connectors, splices, star couplers, regenerators, and optical amplifiers.

140.2 Fibers

Silica glass fibers make up the majority of optical transmission lines. The wavelength regions around 850 nm and in the range from 1260 to 1675 nm have been heavily utilized because of their low losses. Losses are lower in the longer wavelengths, making them more suitable for long transmission paths. The nomenclature for the longer wavelength bands appears in Table 140.4. Selected properties of fibers are tabulated in Table 140.5.

Dispersion causes pulse spreading, leading to intersymbol interference. This interference limits the fiber's allowable data rate. The amount of pulse spreading is given by

$$\Delta\tau = ML\Delta\lambda \quad (140.6)$$

where M is the dispersion (a few values are given in Table 140.5), L is the fiber length, and $\Delta\lambda$ is the spectral width of the light source emission. Dispersion is created by the material and the waveguide structure, both of which have a wavelength-dependent pulse velocity.

Multimode fibers allow many modes to simultaneously traverse the fiber. This produces *multimode distortion* (resulting in additional pulse spreading) because the various modes travel at different speeds. For this reason, multimode fibers can only be used for applications in which the product of data rate (or modulation frequency) and path length is not high.

Because single-mode fibers eliminate multimode spreading, they have larger bandwidths and are used for all long-distance, high-rate links. Multimode fibers have relatively high loss and large dispersion in the 850-nm first window region. Applications are, therefore,

TABLE 140.4 Spectral Band Nomenclature

| Band | Descriptor | Range (nm) |
|--------|-----------------------|------------|
| O-band | Original | 1260–1360 |
| E-band | Extended | 1360–1460 |
| S-band | Short wavelength | 1460–1530 |
| C-band | Conventional | 1530–1565 |
| L-band | Long wavelength | 1565–1625 |
| U-band | Ultra-long wavelength | 1625–1675 |

TABLE 140.5 Typical Fiber Properties

| Wavelength (nm) | Loss (dB/km) | Dispersion (ps/nm · km) |
|-----------------|--------------|-------------------------|
| 800–900 | 3.0 | 120 |
| 1290–1330 | 0.35 | Nearly zero |
| 1520–1570 | 0.22 | 15 |

restricted to moderately short part lengths (typically less than a kilometer). Components in this window tend to be cheaper than those operating at the longer wavelengths.

At wavelengths close to 1300 nm, fibers exhibit low losses and nearly zero dispersion. Single-mode, nonrepeated paths up to 70 km or so are attainable at this wavelength. Here, multimode fiber is feasible for modest lengths required by LANs and campus-based networks, while single-mode fiber is better for longer point-to-point links.

Fiber systems in the 1550-nm region operate at the highest rates and longest unamplified, nonrepeated distances because of the low fiber attenuation. Unamplified lengths over 100 km are possible. Typically, only single-mode fibers are used in this region to eliminate capacity-limiting multimode distortion. Dispersion is managed using specially designed dispersion-shifted fibers that reduce it below the level given in Table 140.5.

140.3 Other Components

Most systems utilize semiconductor laser diodes (LD) or light-emitting diodes (LEDs) for the light source. These sources are typically modulated by controlling their driving currents. The conversion from current, i , to optical power, P , is given by

$$\begin{aligned} P &= a_1(i - I_{\text{th}}), & i > I_{\text{th}} \\ P &= 0, & i < I_{\text{th}} \end{aligned} \quad (140.7)$$

where a_1 is a constant and I_{th} is the turn-on threshold current for the diode. The threshold current for LEDs is zero and in the range of a few milliamperes to a few tens of milliamperes for LDs. For example, a_1 may be 0.1 mW/mA. Thus, the optical power waveform is a replica of the modulation current if the light source is operated above its threshold current.

Laser diodes are more coherent (i.e., they have smaller spectral widths) than LEDs, and thus produce less dispersion. In addition, LDs can be modulated at higher rates (above 10 GHz), whereas LEDs are limited to rates of just a few hundred MHz. LEDs have the advantage of lower cost and simpler circuitry requirements. For high modulation rates, external modulators replace direct modulation of the light source. These modulators follow the light source, rather than precede it as in [Figure 140.1](#). These modulators use the electrooptic effect in crystals or electroabsorption effects in semiconductors and take the form of integrated optic devices.

The photodetector converts the light beam back into an electrical signal. Semiconductor PIN photodiodes and avalanche photodiodes are normally used. The conversion for the PIN diode is given by the linear equation

$$i = \rho P \quad (140.8)$$

where i is the detected current, P is the incident optical power, and ρ is the photodetector's *responsivity*. Typical values of the responsivity are on the order of 0.5 A/W. The avalanche photodiode response follows this same equation but includes an amplification factor that can be as high as several hundred.

140.4 Signal Quality

Signal quality is measured by the signal-to-noise (S/N) ratio in analog systems and by the bit error rate (BER) in digital links. High-quality analog video links may require S/N ratios on the order of a hundred thousand (50 dB) or more. Good digital systems operate at error rates of 10^{-9} or better.

In a thermal noise-limited system the probability of error, P_e (which is the same as the bit error rate) is

$$P_e = 0.5 - 0.5 \operatorname{erf}(0.354\sqrt{S/N}) \quad (140.9)$$

where erf is the *error function*, tabulated in many references and available electronically as part of several math packages. An error rate of 10^{-9} requires a signal-to-noise ratio of nearly 22 dB ($S/N = 158.5$).

Defining Terms

Avalanche photodiode — Semiconductor photodetector having internal gain.

Bit error rate — Probability of error.

Dispersion — Wavelength-dependent pulse group velocity caused by the material and the fiber structure.

Results in pulse spreading due to the nonzero spectral emission widths of the light source.

Laser — Source producing highly coherent light.

Laser diode — Semiconductor laser. Spectral emission widths typically in the range of 1 to 5 nm. Special devices are available with spectral widths of 0.1 nm or less.

Light emitting diode — Semiconductor emitter having spectral emission widths much larger than those of the laser diode. Typical emission widths are in the range of 20 to 100 nm.

Optical frequency-division multiplexing (OFDM) — Transmission of closely spaced carrier wavelengths (a few tenths of a nanometer, or less) along a single fiber. Demultiplexing usually requires an optical coherent receiver.

PIN photodiodes — Semiconductor photodetector.

Signal-to-noise ratio — Ratio of signal power to noise power.

Single-mode fiber — Fiber that allows only one mode to propagate; has larger bandwidth which allows greater data rate than multimode fibers.

Wavelength-division multiplexing (WDM) — Simultaneous transmission of numerous carrier wavelengths to increase the capacity of a single fiber [Agrawal, 2002]. The individual carriers are spaced from a fraction of a nanometer to several hundred nm, permitting the number of independent channels to range from just a few to over 100.

141.9 Conclusion

Digital image processing is one of the most important areas of information processing and communications. It forms the basis of image and video processing, computer vision, and multimedia with a long list of applications in media arts and communications, preservation of cultural heritage, virtual digital museums, film-making, medical decision support, e-health care, distance education, e-commerce, telepresence, security/surveillance, training of athletes, and many more.

A digital image is an array of numbers, each representing a color or gray level. Each entry in the array is termed a *picture element* (pel) or *pixel*. The array consists of an organization or structure that when viewed by a human observer may exhibit some meaning greater than just an array of numbers.

The information revolution of the past two decades has relied mainly on digital processing techniques. Computer calculations rely on digital representations (numbers, concepts, and memory are represented by combinations of 1's and 0's, and communication channels rely largely on digital transmission), and they relay streams of 0's and 1's or bits. In addition, with the reduced cost and high availability of digital scanners, most image and document archives are currently being converted to digital format.

Most digital images are captured on charge-coupled devices (CCDs), which are used in digital cameras, scanners, photocopiers, electron microscopes, bar code readers, and so on. The CCD can either capture the image directly as with a digital camera, or can be used in converting images from analog to digital form, as with image scanners. A CCD consists of two fundamental elements: (1) a solid-state array, which captures the energy (energy is directly related to wavelength) of the incident light and translates it into a voltage; and (2) an analog-to-digital converter that converts the voltage into a digital signal.

141.1 Color and Gray Level

Digital images can be color or black and white. Black-and-white images are referred to as gray-level images, as they are not really black and white, but rather are made up of different shades of gray. In digital image processing, the gray levels are commonly represented by 8-bit values. Thus, there are 256

FIGURE 141.1 The gray square on the *left* appears “darker” to the human eye than the gray square on the *right*, even though both squares possess equivalent gray-level values.

different gray levels. The human eye can adapt to a large range of gray levels, but can only distinguish a very limited range of intensity levels simultaneously. In Figure 141.1, we note that the right square appears brighter than the left square, even though both squares are of exactly the same intensity.

Color is represented by a three-dimensional space, usually the primary colors red, green, and blue termed the *RGB* color space, but other combinations such as cyan, yellow, and magenta can be used. Each value is given by an 8-bit binary number, resulting in 24 bits for most color representations and 16,777,216 different colors! Another common representation is the *YIQ* color space. The *Y* value represents the luminance and the *I* (in phase) and *Q* (quadrature) values give the color information or chrominance. This representation was introduced for color television, since it sets up compatibility between color television and so-called “black and white” television. While the color television receives all three values, the black and white television will only receive the luminance value. This color space also has the advantage that the eye is more sensitive to luminance; thus the *I* and *Q* values are often down-sampled at a rate of 2:1 in each direction with little effect on the overall quality of the video. The *RGB* to *YIQ* conversion is given by the following equation:

$$\begin{bmatrix} Y \\ I \\ Q \end{bmatrix} = \begin{bmatrix} 0.299 & 0.587 & 0.114 \\ 0.596 & -0.275 & -0.321 \\ 0.212 & -0.523 & 0.311 \end{bmatrix} \begin{bmatrix} R \\ G \\ B \end{bmatrix} \quad (141.1)$$

The last color models worth mentioning are the *HSV* and *HSI*. The *HSV* and *HSI* (hue, saturation, value/intensity) are closely related to the way in which colors are perceived by human beings, and are thus widely used in computer vision applications. The hue gives the actual color, such as orange, red, blue, and so on. The saturation gives the purity of the color, such as how orange something is. The intensity or value gives the brightness of the color, such as dark orange as opposed to light orange.

141.2 Point Operations

Point operations are those procedures that modify a point or entry in the digital array, including *contrast stretching*, *brightening*, and *thresholding*. Contrast stretching and brightening are used to enhance the appearance of an image. Thresholding is used to obtain important aspects of image structure.

Contrast stretching is achieved with histogram equalization. The grayscale histogram measures the frequency of gray levels in an image. The histogram for an image with N gray levels is a discrete function $f(j) = n_j$, such that n_j is the number of pixels in the image with gray level j , $j = 0, 1, \dots, N$. This involves transforming the histogram of the image, which defines the probability distribution of the gray levels in the image to a uniform probability distribution, which can be achieved by considering the cumulative distribution of the image gray levels. The procedure is shown below, and transforms all pixels having gray level k to pixels with gray level b_k .

FIGURE 141.2 The histogram of Lena (darkened), and the histogram after equalization.

FIGURE 141.3 The darkened image Lena, and the image Lena after histogram equalization.

1. Calculate the image histogram. For an 8-bit image we will have values defined in the range $[0, 255]$. Define the “new” histogram value as

$$b_k = 255 * \sum_{j=0}^k \frac{n_j}{n}$$

where n is the total number of pixels in the image and n_j is the number of pixels with value j , $j = 0, 1, 2, \dots, 255$ and $k = 0, 1, 2, \dots, 255$.

Figure 141.2 shows the histogram of the original image (left) and after equalization (right). The corresponding images are illustrated in Figure 141.3.

141.3 Image Filtering

Image filtering is most commonly performed by using a 3×3 window and modifying the central pixel in the 3×3 window according to the filter coefficients, $a_1 - a_9$. A 3×3 filter is shown in the Equation (141.2).

$$\begin{bmatrix} a_1 & a_3 & a_3 \\ a_4 & a_5 & a_6 \\ a_7 & a_8 & a_9 \end{bmatrix} \tag{141.2}$$

FIGURE 141.4 Original image Lena, Lena with salt-and-pepper noise, after median filtering, after average filtering. The median filtered image is sharpened.

The operation is achieved by sliding the filter over the digital image, and the modified pixel is at the point in the image corresponding to a_5 when the filter is passed over this point. Thus,

$$x'_5 = \sum_{i=1}^9 a_i x_i \quad (141.3)$$

where x'_5 represents the modified image pixel.

If all the coefficients are positive and sum to 1, the filter is a low-pass filter. If the center coefficient is positive and all other coefficients are less than or equal to zero, then the filter is a high-pass filter, and if all coefficients sum to zero, the filter is an edge detector. Low-pass filtering is used for smoothing and noise reduction, while high-pass filtering is used for sharpening image features. Low-pass operations also include *median filtering*. The median is defined as the value for which half the pixels are less than and half the pixels are greater than. A median filter sets the new center pixel equal to the median of the 9 pixels in the window. This works better than averaging when the goal is to eliminate impulse noise. Impulse noise usually consists of pixels with values at one of the two extremes; for an 8-bit image the “noise” pixels will be close to 0 and 255. The effect of one of the “noise” pixels will be to raise or lower the average.

A common method for image sharpening is employment of a high-boost filter. A high-boost filter adds a high-pass filtered image to the original image to produce much sharper image details. Image sharpening can be used to reduce the blurring effects of a median filter. Figure 141.4 shows an image after undergoing different low-pass and high-pass filtering operations. Note that although the sharpened image is numerically different from the original one, it is visually much closer than the others.

Filters of other sizes, such as 7×7 or 25×25 , may be used; the only requirement is that filter dimensions are odd numbers that will result in a well-defined central point.

141.4 Edge Detection

An edge is given as the boundary between two regions of differing gray levels. At an edge the gradient of the gray level will be maximal; thus, an edge can be detected with a first-derivative filter. Second-derivative filters may also be used. The second-derivative will experience a zero crossing at a maximum point in the first derivative.

One of the simplest and most popular edge detectors is the Sobel filter, which detects the gradient of the image in the x and y directions. The structure of the Sobel filter is shown in Equation (141.4). The image is filtered with each of the filters. The absolute values of the two images obtained from the two filters are then added. An example of edge detection by the Sobel filter is shown in Figure 141.5.

FIGURE 141.5 Sobel image.

FIGURE 141.6 Canny image with small Gaussian blur and large Gaussian blur.

$$\begin{bmatrix} -1 & 0 & 1 \\ -2 & 0 & 2 \\ -1 & 0 & 1 \end{bmatrix} \quad (141.4)$$

A more sophisticated edge detector is the Canny edge detector. This detector starts with a Gaussian smoothing filter, which helps in the detection of global edges, and then incorporates hysteresis to locate secondary edge points that are connected to primary edge points. Figure 141.6 illustrates the Canny detector with different Gaussian blurs. Other edge detectors include the Prewitt operator, Roberts operator, and the Gaussian Laplacian.

141.5 Digital Image Restoration

Image restoration techniques rely on modeling the degradation function and then trying to reconstruct the image through an inverse process. Some common degradation types that are easily restored include constant motion relative to the camera lens, lens out of focus, and atmospheric turbulence. The degradation model is described by the following equation:

$$g(x, y) = (h \bullet f)(x, y) + \eta(x, y) \quad (141.5)$$

where $g(x, y)$ is the degraded image, $f(x, y)$ is the original image, $h(x, y)$ is the degradation system, $\eta(x, y)$ represents the additive noise, and \bullet represents the convolution operator.

In the following, we discuss two common types of restoration: inverse filtering and the Wiener filter.

Inverse filtering

Taking the Fourier transform of Equation (141.5), we obtain

$$G(u, v) = H(u, v)F(u, v) + N(u, v) \quad (141.6)$$

Rearranging this we obtain

$$F(u, v) = \frac{G(u, v)}{H(u, v)} - \frac{N(u, v)}{H(u, v)} \quad (141.7)$$

Assuming that the noise is small — the degradation being caused by the system $h(x, y)$ — we can neglect the noise term. The zeros of $H(u, v)$ will be few enough to ignore, but we must be careful because $H(u, v)$ will tend to decay faster than $N(u, v)$ as we move away from the origin in the uv plane. Reasonable results can be obtained by limiting the values of u and v close to the origin.

Obtaining $H(u, v)$ can be done by testing the system response to an impulse or point light source, that is, setting $f(x, y)$ to $\delta(x, y)$, where $\delta(x, y)$ is the Dirac delta function, as defined in Equation (141.8) and shown in Figure 141.7. An example of a test image is given in the figure. For motion relative to camera lens, lens out of focus, and atmospheric turbulence, the form of $H(u, v)$ is well known:

FIGURE 141.7 The impulse.

$$\delta(x, y) = \begin{cases} 1, & \text{if } x=0 \text{ and } y=0 \\ 0, & \text{otherwise} \end{cases} \quad (141.8)$$

Suppose an object traveling at a constant speed V in the x -direction is photographed with the shutter speed set so that the shutter is open for time T . Then the Fourier transform of the degradation is given by [2]

$$H(u, v) = \frac{\sin(\pi VTu)}{\pi Vu} \quad (141.9)$$

For a thin lens out of focus, the degradation is given by [2]

$$H(u, v) = \frac{J_1(a(u^2 + v^2))}{a(u^2 + v^2)} \quad (141.10)$$

where J_1 is a Bessel function of the first order, and a is the displacement.

Atmospheric turbulence mostly arises in remote sensing applications, such as taking terrestrial photographs from a satellite positioned thousands of miles above the earth. This is due to heat effects in the atmosphere. The refractive index of the medium will vary with temperature. When driving along a road on a really hot dry day, one sometimes notices the illusion of water on the road ahead. This is actually the sky. Because the sun heats the road, the air closer to the surface of the road is much warmer; thus the path of light from the sky to your eye bends toward the road. These refraction effects will alter the path of the light from the terrestrial surface to the satellite. This phenomenon is known as atmospheric turbulence and is modeled by the following equation [2]:

$$H(u, v) = e^{-c(u^2 + v^2)^{5/6}} \quad (141.11)$$

where c is a constant that can be determined experimentally.

Wiener filter

The Wiener filter minimizes the mean square error, e^2 , between the estimated image, \hat{f} , and the original image f . The error takes the following form:

$$e^2 = \left\{ \left[f - \hat{f} \right]^2 \right\} \quad (141.12)$$

The Fourier transform of the Wiener filter is given as

$$W(u, v) = \frac{1}{H(u, v)} \frac{|H(u, v)|^2}{|H(u, v)|^2 + [S_\eta(u, v) / S_g(u, v)]} \quad (141.13)$$

FIGURE 141.8 The image on the left is Lena corrupted by Gaussian noise, and the image on the right is Lena restored with the Wiener filter.

FIGURE 141.9 Lena after histogram thresholding.

where $S_g(u, v)$ and $S_n(u, v)$ are the power spectrums of the degraded image and noise components, respectively. These are often unknown, and it is often useful to approximate the Wiener filter as

$$W(u, v) = \frac{1}{H(u, v)} \frac{|H(u, v)|^2}{|H(u, v)|^2 + K} \quad (141.14)$$

where K is a real constant. Figure 141.8 demonstrates restoration of a noise-corrupted image by the Wiener filter.

141.6 Digital Image Segmentation

Image segmentation refers to grouping image regions. This can be done based on color, texture, or image structure. The simplest form of image segmentation is image thresholding as described in Section 141.2. Thresholding converts a gray-level image into a binary image, thus dividing the image into regions of black and regions of white. Thresholding is performed on a gray-level histogram, where object points are described as those above or those below a certain gray level or threshold, T . The output image $g(x, y)$ is defined as follows:

$$g(x, y) = \begin{cases} 255 & \text{if } f(x, y) > T \\ 0 & \text{otherwise} \end{cases} \quad (141.15)$$

An optimal threshold can be found by modeling the histogram as a mixture of two Gaussians and taking the threshold as the point of intersection of the Gaussians. This method may fail in the case of overlapping histograms between the object and the background. Figure 141.9 shows segmentation of an image by histogram thresholding.

Other methods of segmentation include *region growing by pixel aggregation* and *quad-tree split and merge*. Region growing by pixel aggregation starts with a scattered subset of pixels or “seeds,” and combines them with neighboring pixels based on some property such as color or texture. One of the problems that this method presents is seed selection. We would like to select seeds that lie within regions of interest, which requires some kind of knowledge of the application. For example, if we wish to segment only bananas we may select pixels corresponding to the color yellow.

Quad-tree split and merge works as follows:

1. Split the image into four equal parts.
2. Test each region to see if it satisfies some criterion, such as having a small gray-level variance, that is,

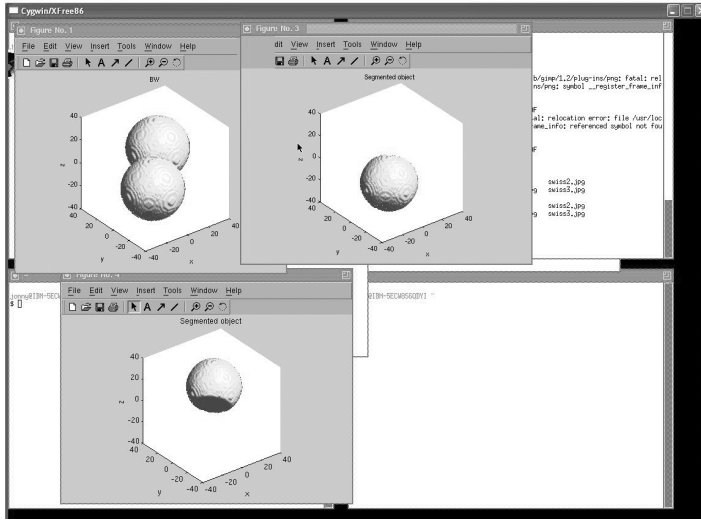

FIGURE 141.10 Watershed is used to split the two three-dimensional binary globes. The color in this example is used to capture the three-dimensional nature of the image, but the image is actually binary.

$$\frac{1}{N} \sum_{i=1}^N |x_i - \mu|^2 < T$$

If the criterion is satisfied, then no more splitting is required. If the region combined with one of its neighbors satisfies the criterion, then merge the two regions.

3. Start from Step 1 for regions that do not satisfy the criterion of Step 2.

Watershed

Watershed segmentation operates on two- and three-dimensional binary images, and is used for separating convex objects that slightly overlap. The algorithm starts with a distance map to find the fattest parts of the object (the peaks), and dilates (mathematical morphology) them until it reaches the edge of an object, or until it reaches the edge of another object. Significantly overlapping features may not be detected. An example of watershed segmentation is given in Figure 141.10.

141.7 Digital Image Compression

With most digital cameras today offering resolution in about the 2048×2048 range or 4 megapixels, for a color image at 24 bits per pixel (or 3 bytes per pixel) a single image will occupy 12 Mb of data space. The average computer screen has a resolution of about 1 Mpixel, so why do we need digital cameras with such high resolution? If we want to make $7'' \times 7''$ photo-quality prints at 300 dpi (dots per inch), then a 1 Mpixel resolution will require four dots per pixel, which will give us a blocky effect. In this raw format, 40 photographs of our last holiday will take up half a gigabyte of memory, and 5 minutes of video at 30 frames per second will occupy over 100 Gb of memory, which presents problems for both transmission and storage.

Image compression may be *lossless*, meaning that the decompressed image is exactly the same as the compressed image, or it may be *lossy*, meaning that some information is lost in the decompressed image. Lossless methods deliver, at best, compression ratios of about 3:1, while lossy methods may typically result in compression ratios of more than 10:1. Images usually contain large amounts of redundancy. Types of redundancy are coding redundancy, which occurs when more bits are used to code the pixel

FIGURE 141.11 The original image Lena (233 gray levels), and Lena with 64 gray levels.

values than absolutely necessary, psychovisual redundancy, which applies to information that may be removed without significantly degrading the performance of the image as perceived by the human observer, and interpixel redundancy, which occurs when pixels can be easily predicted from the values of their neighbors. For video images, interpixel redundancy can be extended to interframe redundancy. Coding redundancy occurs when more bits are used to code the pixel values than absolutely necessary.

Lossless compression takes advantage of both coding and interpixel redundancies. Coding redundancy is usually based on variable length coding (VLC). The most well-known example of VLC is the Morse code. The length of the codeword for each letter is based on the frequency with which that letter appears in the English language. For example the most common letter, the letter “e,” is given by a dot, while a letter less likely to appear, the letter “q,” is given by two dashes, a dot, and a dash. A pause is implemented between two letters so that one may recognize the finish of one letter and the start of the next one. This is not feasible for coding of digital images; thus, the VLC must be uniquely decidable (UD). A code is UD if and only if no codeword is a concatenation of two other codewords. Assume that we decide to assign the codeword 0 to the letter “e,” and the codeword 1 to the letter “t.” Then if the letter “q” is given by 1101, we will not be able to tell the difference between ttet and q. The best-known VLC for a zero memory source is the Huffman code.

Interpixel redundancies can be implemented in lossless coding in the following manner. Assume we have some kind of reasonable predictor to calculate the value of a pixel based on the value of the previous pixel. If the predictor is designed well, for a large proportion of the image pixels the error will be close to zero or zero. For an image with 256 gray levels, we only need to code the error, which will have a high probability of being close to zero. Thus, applying a Huffman code to the error will result in much higher compression than it would if applied to the original image. Lossless compression results in, at best, compression ratios of 3:1. We can achieve much higher compression ratios if we use lossy compression.

Lossy compression takes advantage of psychovisual redundancy, as well as coding and interpixel redundancies; thus, information “lost” due to compression should not infringe too heavily on image quality. The common methods of achieving this are scalar or vector quantizations. As discussed above, the amount of gray levels the human eye can distinguish at once is limited. Thus, we may reduce the number of bits used to encode the image without significantly degrading the quality as seen by the human observer. A look-up table is used to decode the image. In Figure 141.11, the image on the left contains 233 gray levels and the image on the right contains 64 gray levels.

Another common type of lossy compression is based on transform coding. This involves using a reversible transformation, such as the Fourier transform, and then coding the coefficients. For most natural images, most of the important information will be contained in only a few coefficients; thus, coefficients that make a smaller contribution to the image may be coded with fewer bits than those that make a significant contribution to the image. The most common lossy code is the JPEG (Joint Photographic Expert Group) standard, which relies on a discrete cosine transform (DCT). However, the most recent version of JPEG Standard, JPEG-2000, uses the discrete wavelet transform (DWT) to achieve higher compression ratios.

141.8 Image Description and Analysis

Used to describe and analyze images for applications, such as image object recognition, three-dimensional reconstruction, and automatic navigation, this process often relies on higher-level features, such as edge

FIGURE 141.12 Image Lena after morphological operations.

alignment, edge continuity, the shape of a given region, and region convexity. Methods include mathematical morphology, graph methods, and gestalt psychology.

Mathematical morphology can be used to *dilate* and *erode* image regions. Morphology consists of transforming the image based on its set relation to a structuring element. Basic morphological operations include *dilation*, *erosion*, *opening*, and *closing*. Figure 141.12 shows a thresholded image after the closing operation.

A graph is a data structure in which image elements are described by nodes, and relationships between the nodes are described by arcs, or connections. One of the simplest forms of such a data structure is the *region adjacency graph*. In such a graph, each region is represented by the node, and connections are formed with adjacent regions. The value of the connection may be given by some property such as the length of the common boundary, or a description of the smoothness of the boundary. Gestalt psychology derives such features as smoothness, continuity, and parallelism, all of which may be used to describe graphs.

141.9 Conclusion

This chapter presented a brief introduction to digital image processing. For readers interested in learning more about digital image processing, numerous references are available. Gonzalez and Woods [1] and Sonka et al. [2] are two of the best. Gonzalez and Woods [1] provide a thorough mathematical and theoretical outline of the subject, while Sonka et al. [2] are geared toward a more practical treatment of digital image processing.

142.1 Introduction

What is a general representation for bandpass digital and analog communication signals? How do we represent a **modulated signal**? How do we evaluate the spectrum and the power of these signals? These are some of the questions that are answered in this chapter.

A *baseband* waveform has a spectral magnitude that is nonzero for frequencies in the vicinity of the origin (i.e., $f = 0$) and negligible elsewhere. A *bandpass* waveform has a spectral magnitude that is nonzero for frequencies in some band concentrated about a frequency $f = \pm f_c$ (where $f_c \gg 0$), and the spectral magnitude is negligible elsewhere. f_c is called the *carrier frequency*. The value of f_c may be arbitrarily assigned for mathematical convenience in some problems. In others, namely, **modulation** problems, f_c is the frequency of an oscillatory signal in the transmitter circuit and is the assigned frequency of the transmitter, such as 850 kHz for an AM broadcasting station.

In communication problems, the information source signal is usually a baseband signal, for example, a transistor–transistor logic (TTL) waveform from a digital circuit or an audio (analog) signal from a microphone. The communication engineer has the job of building a system that will transfer the information from this source signal to the desired destination. As shown in [Figure 142.1](#), this usually requires the use of a bandpass signal, $s(t)$, which has a bandpass spectrum that is concentrated at $\pm f_c$, where f_c is selected so that $s(t)$ will propagate across the communication channel (either a wire or a wireless channel).

Modulation is the process of imparting the source information onto a bandpass signal with a carrier frequency f_c by the introduction of amplitude and/or phase perturbations. This bandpass signal is called

the *modulated* signal $s(t)$, and the baseband source signal is called the *modulating* signal $m(t)$. Examples of exactly how modulation is accomplished are given later in this chapter. This definition indicates that modulation may be visualized as a mapping operation that maps the source information onto the bandpass signal $s(t)$ that will be transmitted over the channel.

As the modulated signal passes through the channel, noise corrupts it. The result is a bandpass signal-plus-noise waveform that is available at the receiver input, $r(t)$, as illustrated in Fig. 1.1. The receiver has the job of trying to recover the information that was sent from the source; \tilde{m} denotes the corrupted version of m .

142.2 Complex Envelope Representation

All bandpass waveforms, whether they arise from a modulated signal, interfering signals, or noise, may be represented in a convenient form given by the following theorem. $v(t)$ will be used to denote the **bandpass waveform** canonically. That is, $v(t)$ can represent the signal when $s(t) \equiv v(t)$, the noise when $n(t) \equiv v(t)$, the filtered signal plus noise at the channel output when $r(t) \equiv v(t)$, or any other type of bandpass waveform.*

Theorem 142.1 Any physical bandpass waveform can be represented by

$$v(t) = \text{Re}\{g(t)e^{j\omega_c t}\} \quad (142.1a)$$

$\text{Re}\{\cdot\}$ denotes the real part of $\{\cdot\}$. $g(t)$ is called the *complex envelope* of $v(t)$, and f_c is the associated carrier frequency (hertz) where $\omega_c = 2\pi f_c$. Furthermore, two other equivalent representations are

$$v(t) = R(t)\cos[\omega_c t + \theta(t)] \quad (142.1b)$$

and

$$v(t) = x(t)\cos\omega_c t - y(t)\sin\omega_c t \quad (142.1c)$$

where

$$g(t) = x(t) + jy(t) = |g(t)|e^{j\angle g(t)} \equiv R(t)e^{j\theta(t)} \quad (142.2)$$

$$x(t) = \text{Re}\{g(t)\} \equiv R(t)\cos\theta(t) \quad (142.3a)$$

$$y(t) = \text{Im}\{g(t)\} \equiv R(t)\sin\theta(t) \quad (142.3b)$$

$$R(t) \triangleq |g(t)| \equiv \sqrt{x^2(t) + y^2(t)} \quad (142.4a)$$

*The symbol \equiv denotes an equivalence and the symbol \triangleq denotes a definition.

$$\theta(t) \triangleq \angle g(t) = \tan^{-1} \left(\frac{y(t)}{x(t)} \right) \quad (142.4b)$$

The waveforms $g(t)$, $x(t)$, $y(t)$, $R(t)$, and $\theta(t)$ are all **baseband waveforms**, and, except for $g(t)$, they are all real waveforms. $R(t)$ is a nonnegative real waveform. Equation (142.1) is a low-pass-to-bandpass transformation. The $e^{j\omega_c t}$ factor in Equation (142.1a) shifts (i.e., translates) the spectrum of the baseband signal $g(t)$ from baseband up to the carrier frequency f_c . In communications terminology, the frequencies in the baseband signal $g(t)$ are said to be *heterodyned* up to f_c . The **complex envelope**, $g(t)$, is usually a complex function of time and it is the generalization of the phasor concept. That is, if $g(t)$ happens to be a complex constant, then $v(t)$ is a pure sine wave of frequency f_c and this complex constant is the phasor representing the sine wave. If $g(t)$ is not a constant, then $v(t)$ is not a pure sine wave because the amplitude and phase of $v(t)$ varies with time, caused by the variations of $g(t)$.

Representing the complex envelope in terms of two real functions in Cartesian coordinates, we have

$$g(x) \equiv x(t) + jy(t) \quad (142.5)$$

where $x(t) = \text{Re}\{g(t)\}$ and $y(t) = \text{Im}\{g(t)\}$. $x(t)$ is said to be the *in-phase modulation* associated with $v(t)$, and $y(t)$ is said to be the *quadrature modulation* associated with $v(t)$. Alternatively, the polar form of $g(t)$, represented by $R(t)$ and $\theta(t)$, is given by Equation (142.2), where the identities between Cartesian and polar coordinates are given by Equation (142.3) and Equation (142.4). $R(t)$ and $\theta(t)$ are real waveforms, and, in addition, $R(t)$ is always nonnegative. $R(t)$ is said to be the *amplitude modulation* (AM) on $v(t)$, and $\theta(t)$ is said to be the *phase modulation* (PM) on $v(t)$.

The usefulness of the complex envelope representation for bandpass waveforms cannot be overemphasized. In modern communication systems, the bandpass signal is often partitioned into two channels, one for $x(t)$ called the I (in-phase) channel and one for $y(t)$ called the Q (quadrature-phase) channel. In digital computer simulations of bandpass signals, the sampling rate used in the simulation can be minimized by working with the complex envelope, $g(t)$, instead of with the bandpass signal, $v(t)$, because $g(t)$ is the baseband equivalent of the bandpass signal [1].

142.3 Representation of Modulated Signals

Modulation is the process of encoding the source information $m(t)$ (modulating signal) into a bandpass signal $s(t)$ (modulated signal). Consequently, the modulated signal is just a special application of the bandpass representation. The *modulated signal* is given by

$$s(t) = \text{Re}\{g(t)e^{j\omega_c t}\} \quad (142.6)$$

where $\omega_c = 2\pi f_c$. f_c is the carrier frequency. The complex envelope $g(t)$ is a function of the modulating signal $m(t)$. That is,

$$g(t) = g[m(t)] \quad (142.7)$$

Thus $g[\cdot]$ performs a mapping operation on $m(t)$. This was shown in [Figure 142.1](#).

[Table 142.1](#) gives an overview of the *big picture* for the modulation problem. Examples of the mapping function $g[m]$ are given for amplitude modulation (AM), double-sideband suppressed carrier (DSB-SC), phase modulation (PM), frequency modulation (FM), single-sideband AM suppressed carrier (SSB-AM-SC), single-sideband PM (SSB-PM), single-sideband FM (SSB-FM), single-sideband envelope detectable (SSB-EV), single-sideband square-law detectable (SSB-SQ), and quadrature modulation (QM). For each $g[m]$, [Table 142.1](#) also shows the corresponding $x(t)$ and $y(t)$ quadrature modulation components and

TABLE 142.1 Complex Envelope Functions for Various Types of Modulation^a

| Type of Modulation | Mapping Function $g(m)$ | Corresponding Quadrature Modulation | |
|------------------------|--|--|--|
| | | $x(t)$ | $y(t)$ |
| AM | $A_c[1 + m(t)]$ | $A_c[1 + m(t)]$ | 0 |
| DSB-SC | $A_c m(t)$ | $A_c m(t)$ | 0 |
| PM | $A_c e^{jD_p m(t)}$ | $A_c \cos[D_p m(t)]$ | $A_c \sin[D_p m(t)]$ |
| FM | $A_c e^{jD_f \int_{-\infty}^t m(\sigma) d\sigma}$ | $A_c \cos\left[D_f \int_{-\infty}^t m(\sigma) d\sigma\right]$ | $A_c \sin\left[D_f \int_{-\infty}^t m(\sigma) d\sigma\right]$ |
| SSB-AM-SC ^b | $A_c[m(t) \pm j\hat{m}(t)]$ | $A_c m(t)$ | $\pm A_c \hat{m}(t)$ |
| SSB-PM ^b | $A_c e^{jD_p[m(t) \pm j\hat{m}(t)]}$ | $A_c e^{\mp D_p \hat{m}(t)} \cos[D_p m(t)]$ | $A_c e^{\mp D_p \hat{m}(t)} \sin[D_p m(t)]$ |
| SSB-FM ^b | $A_c e^{jD_f \int_{-\infty}^t [m(\sigma) \pm j\hat{m}(\sigma)] d\sigma}$ | $A_c e^{\mp D_f \int_{-\infty}^t \hat{m}(\sigma) d\sigma} \cos\left[D_f \int_{-\infty}^t m(\sigma) d\sigma\right]$ | $A_c e^{\mp D_f \int_{-\infty}^t \hat{m}(\sigma) d\sigma} \sin\left[D_f \int_{-\infty}^t m(\sigma) d\sigma\right]$ |
| SSB-EV ^b | $A_c e^{j[\ln(1+m(t)) \pm j\hat{m}(t) + m(t)]}$ | $A_c [1 + m(t)] \cos\{\hat{\ln}[1 + m(t)]\}$ | $\pm A_c [1 + m(t)] \sin\{\hat{\ln}[1 + m(t)]\}$ |
| SSB-SQ ^b | $A_c e^{(1/2)[\ln(1+m(t)) \pm j\hat{m}(t) + m(t)]}$ | $A_c \sqrt{1 + m(t)} \cos\left\{\frac{1}{2} \hat{\ln}[1 + m(t)]\right\}$ | $\pm A_c \sqrt{1 + m(t)} \sin\left\{\frac{1}{2} \hat{\ln}[1 + m(t)]\right\}$ |
| QM | $A_c[m_1(t) + jm_2(t)]$ | $A_c m_1(t)$ | $A_c m_2(t)$ |

| Type of Modulation | Corresponding Amplitude and Phase Modulation | | Linearity | Remarks |
|------------------------|--|--|----------------|---|
| | $R(t)$ | $\theta(t)$ | | |
| AM | $A_c 1 + m(t) $ | $\begin{cases} 0, & m(t) > -1 \\ 180^\circ, & m(t) < -1 \end{cases}$ | L ^c | $m(t) > -1$ required for envelope detection |
| DSB-SC | $A_c m(t) $ | $\begin{cases} 0, & m(t) > 0 \\ 180^\circ, & m(t) < 0 \end{cases}$ | L | Coherent detection required |
| PM | A_c | $D_p m(t)$ | NL | D_p is the phase deviation constant (rad/volt) |
| FM | A_c | $D_f \int_{-\infty}^t m(\sigma) d\sigma$ | NL | D_f is the frequency deviation constant (rad/volt-sec) |
| SSB-AM-SC ^b | $A_c \sqrt{[m(t)]^2 + [\hat{m}(t)]^2}$ | $\tan^{-1}[\hat{m}(t) / m(t)]$ | L | Coherent detection required |
| SSB-PM ^b | $A_c e^{\mp D_p \hat{m}(t)}$ | $D_p m(t)$ | NL | |
| SSB-FM ^b | $A_c e^{\mp D_f \int_{-\infty}^t \hat{m}(\sigma) d\sigma}$ | $D_f \int_{-\infty}^t m(\sigma) d\sigma$ | NL | |
| SSB-EV ^b | $A_c 1 + m(t) $ | $\pm \hat{\ln}[1 + m(t)]$ | NL | $m(t) > -1$ is required so that the $\ln(\cdot)$ will have a real value |
| SSB-SQ ^b | $A_c \sqrt{1 + m(t)}$ | $\pm \frac{1}{2} \hat{\ln}[1 + m(t)]$ | NL | $m(t) > -1$ is required so that the $\ln(\cdot)$ will have a real value |
| QM | $A_c \sqrt{m_1^2(t) + m_2^2(t)}$ | $\tan^{-1}[m_2(t) / m_1(t)]$ | L | Used in NTSC color television; requires coherent detection |

^a $A_c > 0$ is a constant that sets the power level of the signal as evaluated by use of Eq. (1.11); L, linear; NL, nonlinear; and $[\hat{\cdot}]$ is the Hilbert transform (a -90° phase-shifted version of $[\cdot]$). For example, $m(t) = m(t) * \frac{1}{\pi t} = \frac{1}{\pi} \int_{-\infty}^{\infty} \frac{m(\lambda)}{t - \lambda} d\lambda$.

^b Use upper signs for upper sideband signals and lower signals for lower sideband signals.

^c In the strict sense, AM signals are not linear because the carrier term does not satisfy the linearity (superposition) condition.

the corresponding $R(t)$ and $\theta(t)$ amplitude and phase modulation components. Digitally modulated bandpass signals are obtained when $m(t)$ is a digital baseband signal, for example, the output of a transistor transistor logic (TTL) circuit.

Obviously, it is possible to use other $g[m]$ functions that are not listed in Table 142.1. The question is: are they useful? $g[m]$ functions are desired that are easy to implement and that will give desirable spectral properties. Furthermore, in the receiver, the inverse function $m[g]$ is required. The inverse should be single valued over the range used and should be easily implemented. The inverse mapping should suppress as much noise as possible so that $m(t)$ can be recovered with little corruption.

142.4 Generalized Transmitters and Receivers

A more detailed description of transmitters and receivers, as first shown in Figure 142.1, will now be illustrated.

There are two canonical forms for the generalized transmitter, as indicated by Equation (142.1b) and Equation (142.1c). Equation (142.1b) describes an AM-PM type circuit, as shown in Figure 142.2. The baseband signal processing circuit generates $R(t)$ and $\theta(t)$ from $m(t)$. The R and θ are functions of the modulating signal $m(t)$, as given in Table 142.1, for the particular modulation type desired. The signal processing may be implemented either by using nonlinear analog circuits or a digital computer that incorporates the R and θ algorithms under software program control. In the implementation using a digital computer, one analog-to-digital converter (ADC) will be needed at the input of the baseband signal processor, and two digital-to-analog converters (DACs) will be needed at the output. The remainder of the AM-PM canonical form requires radio frequency (RF) circuits, as indicated in the figure.

Figure 142.3 illustrates the second canonical form for the generalized transmitter. This uses in-phase and quadrature-phase (IQ) processing. Similarly, the formulas relating $x(t)$ and $y(t)$ to $m(t)$ are shown in Table 142.1, and the baseband signal processing may be implemented by using either analog hardware or digital hardware with software. The remainder of the canonical form uses RF circuits as indicated. Modern transmitters and receivers, such as those used in cellular telephones, often use IQ processing.

Analogous to the transmitter realizations, there are two canonical forms of receiver. Each one consists of RF carrier circuits followed by baseband signal processing, as illustrated in Figure 142.1. Typically, the carrier circuits are of the superheterodyne-receiver type which consist of an RF amplifier, a down converter (mixer plus local oscillator) to some intermediate frequency (IF), an IF amplifier, and then detector circuits [1]. In the first canonical form of the receiver, the carrier circuits have amplitude and phase detectors that output $\tilde{R}(t)$ and $\tilde{\theta}(t)$, respectively. This pair, $\tilde{R}(t)$ and $\tilde{\theta}(t)$, describe the polar form of the received complex envelope, $\tilde{g}(t)$. $\tilde{R}(t)$ and $\tilde{\theta}(t)$ are then fed into the signal processor, which uses the inverse functions of Table 142.1 to generate the recovered modulation, $\tilde{m}(t)$. The second canonical

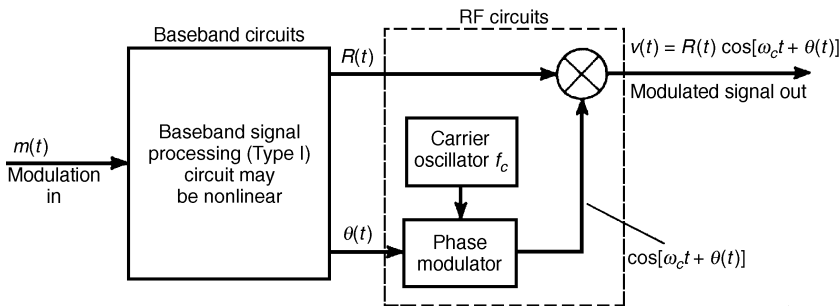

FIGURE 142.2 Generalized transmitter using the AM-PM generation technique. *Source:* Couch, L. W., II. *Digital and Analog Communication Systems*, 6th ed., ©2001, Prentice Hall, reprinted by permission of Pearson Education, Inc., Upper Saddle River, NJ, p. 282.

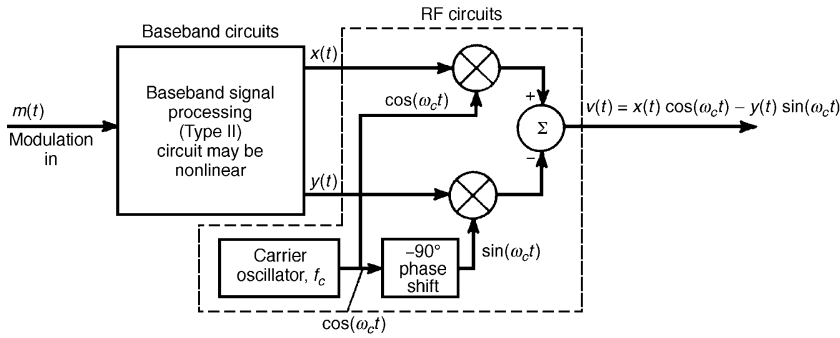

FIGURE 142.3 Generalized transmitter using the quadrature generation technique. *Source:* Couch, L. W., II. *Digital and Analog Communication Systems*, 6th ed., ©2001, Prentice Hall, reprinted by permission of Pearson Education, Inc., Upper Saddle River, NJ, p. 283.

form of the receiver uses quadrature product detectors in the carrier circuits to produce the Cartesian form (IQ processing) of the received complex envelope, $\tilde{x}(t)$ and $\tilde{y}(t)$. $\tilde{x}(t)$ and $\tilde{y}(t)$ are then inputted to the signal processor, which generates $\tilde{m}(t)$ at its output.

Once again, it is stressed that any type of signal modulation (see [Table 142.1](#)) may be generated (transmitted) or detected (received) by using either of these two canonical forms. Both of these forms conveniently separate baseband processing from RF processing. Digital signal processing (DSP) techniques are especially useful to realize the baseband processing portion. Furthermore, if DSP circuits are used, any desired modulation type can be realized by selecting the appropriate software algorithm. This is the basis for software radios [1].

142.5 Spectrum and Power of Bandpass Signals

The spectrum of the bandpass signal is the translation of the spectrum of its complex envelope. Taking the **Fourier transform** of Equation (142.1a), the spectrum of the bandpass waveform is [1]

$$V(f) = \frac{1}{2}[G(f - f_c) + G^*(-f - f_c)] \quad (142.8)$$

where $G(f)$ is the Fourier transform of $g(t)$,

$$G(f) = \int_{-\infty}^{\infty} g(t)e^{-j2\pi ft} dt$$

and the asterisk superscript denotes the complex conjugate operation. The *power spectra density* (PSD) of the bandpass waveform is [1]

$$P_v(f) = \frac{1}{4}[P_g(f - f_c) + P_g(-f - f_c)] \quad (142.9)$$

where $P_g(f)$ is the PSD of $g(t)$.

The average power dissipated in a resistive load is V_{rms}^2 / R_L or $I_{\text{rms}}^2 R_L$, where V_{rms} is the rms value of the voltage waveform across the load and I_{rms} is the rms value of the current through the load. For bandpass waveforms, Equation (142.1) may represent either the voltage or the current. Furthermore, the rms values of $v(t)$ and $g(t)$ are related by [1]

$$v_{\text{rms}}^2 = \langle v^2(t) \rangle = \frac{1}{2} \langle |g(t)|^2 \rangle = \frac{1}{2} g_{\text{rms}}^2 \quad (142.10)$$

where $\langle \cdot \rangle$ denotes the time average and is given by

$$\left\langle \left[\begin{array}{c} \\ \end{array} \right] \right\rangle = \lim_{T \rightarrow \infty} \frac{1}{T} \int_{-T/2}^{T/2} \left[\begin{array}{c} \\ \end{array} \right] dt$$

Thus, if $v(t)$ of Equation (142.1) represents the bandpass voltage waveform across a resistive load, the average power dissipated in the load is

$$P_L = \frac{v_{\text{rms}}^2}{R_L} = \frac{\langle v^2(t) \rangle}{R_L} = \frac{\langle |g(t)|^2 \rangle}{2R_L} = \frac{g_{\text{rms}}^2}{2R_L} \quad (142.11)$$

where g_{rms} is the rms value of the complex envelope, and R_L is the resistance of the load.

142.6 Amplitude Modulation

Amplitude modulation (AM) will now be examined in more detail. From [Table 142.1](#), the complex envelope of an AM signal is

$$g(t) = A_c [1 + m(t)] \quad (142.12)$$

so that the spectrum of the complex envelope is

$$G(f) = A_c \delta(f) + A_c M(f) \quad (142.13)$$

Using Equation (142.6), we obtain the AM signal waveform

$$s(t) = A_c [1 + m(t)] \cos \omega_c t \quad (142.14)$$

and, using Equation (142.8), the AM spectrum

$$S(f) = \frac{1}{2} A_c [\delta(f - f_c) + M(f - f_c) + \delta(f + f_c) + M(f + f_c)] \quad (142.15)$$

where $\delta(f) = \delta(-f)$ and, because $m(t)$ is real, $M^*(f) = M(-f)$. Suppose that the magnitude spectrum of the modulation happens to be a triangular function, as shown in [Figure 142.4\(a\)](#). This spectrum might arise from an analog audio source where the bass frequencies are emphasized. The resulting AM spectrum, using Equation (142.15), is shown in [Figure 142.4\(b\)](#). Note that because $G(f - f_c)$ and $G^*(-f - f_c)$ do not overlap, the magnitude spectrum is

$$|S(f)| = \begin{cases} \frac{1}{2} A_c \delta(f - f_c) + \frac{1}{2} A_c |M(f - f_c)|, & f > 0 \\ \frac{1}{2} A_c \delta(f + f_c) + \frac{1}{2} A_c |M(-f - f_c)|, & f < 0 \end{cases} \quad (142.16)$$

The 1 in

$$g(t) = A_c [1 + m(t)]$$

FIGURE 14.2.4 Spectrum of an AM signal. *Source:* Couch, L. W., II. *Digital and Analog Communication Systems*, 6th ed., ©2001, Prentice Hall, reprinted by permission of Pearson Education, Inc., Upper Saddle River, NJ, p. 239.

causes delta functions to occur in the spectrum at $f = \pm f_c$, where f_c is the assigned carrier frequency. Also, from Figure 14.2.4 and Equation (142.16), it is realized that the bandwidth of the AM signal is $2B$. That is, the bandwidth of the AM signal is twice the bandwidth of the baseband modulating signal.

The average power dissipated into a resistive load is found by using Equation (142.11).

$$P_L = \frac{A_c^2}{2R_L} \langle |1+m(t)|^2 \rangle = \frac{A_c^2}{2R_L} [1 + 2\langle m(t) \rangle + \langle m^2(t) \rangle]$$

If we assume that the *dc* value of the modulation is zero, $\langle m(t) \rangle = 0$, then the average power dissipated into the load is

$$P_L = \frac{A_c^2}{2R_L} \langle 1 + m_{\text{rms}}^2 \rangle \quad (142.17)$$

where m_{rms} is the rms value of the modulation, $m(t)$. Thus, the average power of an AM signal changes if the rms value of the modulating signal changes. For example, if $m(t)$ is a sine wave test tone with a peak value of 1.0 for 100% modulation,

$$m_{\text{rms}} = 1/\sqrt{2}$$

Assume that $A_c = 1000$ volts and $R_L = 50$ ohms, which are typical values used in AM broadcasting. Then, the average power dissipated into the 50Ω load for this AM signal is

$$P_L = \frac{(1000)^2}{2(50)} \left[1 + \frac{1}{2} \right] = 15,000 \text{ watts} \quad (142.18)$$

The Federal Communications Commission (FCC) rated carrier power is obtained when $m(t) = 0$. In this case, Equation (142.17) becomes $P_L = (1000)^2/100 = 10,000$ watts, and the FCC would rate this as a 10,000 watt AM station. The sideband power for 100% sine wave modulation is 5000 watts.

Now let the modulation on the AM signal be a binary digital signal such that $m(t) = \pm 1$ where +1 is used for a binary one and -1 is used for a binary 0. Referring to Equation (142.14), this AM signal becomes an *on-off keyed* (OOK) digital signal where the signal is on when a binary one is transmitted and off when a binary zero is transmitted. For $A_c = 1000$ and $R_L = 50 \Omega$, the average power dissipated would be 20,000 watts since $m_{\text{rms}} = 1$ for $m(t) = \pm 1$.

142.7 Phase and Frequency Modulation

Phase modulation (PM) and *frequency modulation* (FM) are special cases of angle-modulated signalling. In angle-modulated signalling, the complex envelope is

$$g(t) = A_c e^{j\theta(t)} \quad (142.19)$$

Using Equation (142.6), the resulting *angle-modulated* signal is

$$s(t) = A_c \cos[\omega_c t + \theta(t)] \quad (142.20)$$

For PM, the phase is directly proportional to the modulating signal:

$$\theta(t) = D_p m(t) \quad (142.21)$$

where the proportionality constant D_p is the phase sensitivity of the phase modulator, having units of radians per volt [assuming that $m(t)$ is a voltage waveform]. For FM, the phase is proportional to the integral of $m(t)$:

$$\theta(t) = D_f \int_{-\infty}^t m(\sigma) d\sigma \quad (142.22)$$

where the frequency deviation constant D_f has units of radians/volt-second. These concepts are summarized by the PM and FM entries in [Table 142.1](#).

By comparing the last two equations, it is seen that if we have a PM signal modulated by $m_p(t)$, there is *also* FM on the signal corresponding to a *different* modulating waveshape that is given by

$$m_f(t) = \frac{D_p}{D_f} \left[\frac{dm_p(t)}{dt} \right] \quad (142.23)$$

where the subscripts f and p denote frequency and phase, respectively. Similarly, if we have an FM signal modulated by $m_f(t)$, the corresponding phase modulation on this signal is

$$m_p(t) = \frac{D_f}{D_p} \int_{-\infty}^t m_f(\sigma) d\sigma \quad (142.24)$$

By using Equation (142.24), a PM circuit may be used to synthesize an FM circuit by inserting an integrator in cascade with the phase modulator input.

Other properties of PM and FM are that the **real envelope**, $R(t) = |g(t)| = A_c$, is a constant, as seen from Equation (142.19). Also, $g(t)$ is a *nonlinear* function of the modulation. However, from Equation (142.21) and Equation (142.22), $\theta(t)$ is a linear function of the modulation $m(t)$. Using Equation (142.11), the average power dissipated by a PM or FM signal is the constant

$$P_L = \frac{A_c^2}{2R_L} \quad (142.25)$$

That is, the average power of a PM or FM signal does not depend on the modulating waveform $m(t)$.

The *instantaneous frequency deviation* for an FM signal from its carrier frequency is given by the derivative of its phase $\theta(t)$. Taking the derivative of Equation (142.22), the *peak frequency deviation* is

$$\Delta F = \frac{1}{2\pi} D_f M_p \text{ Hz} \quad (142.26)$$

where $M_p = \max[m(t)]$ is the peak value of the modulation waveform and the derivative has been divided by 2π to convert from radians/sec to Hz units.

For FM and PM signals, Carson's rule estimates the transmission bandwidth containing approximately 98% of the total power. This FM or PM signal bandwidth is

$$B_T = 2(\beta + 1)B \quad (142.27)$$

where B is bandwidth (highest frequency) of the modulation. The modulation index β , is $\beta = \Delta F/B$ for FM and $\beta = \max[D_p m(t)] = D_p M_p$ for PM.

The AMPS (Advanced Mobile Phone System) analog cellular phones use FM signalling. A peak deviation of 12 kHz is specified with a modulation bandwidth of 3 kHz. From Equation (142.27), this gives a bandwidth of 30 kHz for the AMPS signal and allows a channel spacing of 30 kHz to be used. To accommodate more users, narrow-band AMPS (NAMPS) with a 5 kHz peak deviation is used in some areas. This allows 10 kHz channel spacing if the carrier frequencies are carefully selected to minimize interference to used adjacent channels. A maximum FM signal power of 3 watts is allowed for the AMPS phones. However, hand-held AMPS phones usually produce no more than 600 mW, which is equivalent to 5.5 volts rms across the 50 Ω antenna terminals.

The GSM (Group Special Mobile) digital cellular phones use FM with *minimum frequency-shift-keying* (MSK) where the peak frequency deviation is selected to produce orthogonal waveforms for binary one and binary zero data. (Digital phones use a speech codec to convert the analog voice source to a digital data source for transmission over the system.) Orthogonality occurs when $\Delta F = 1/4R$ where R is the bit rate (bits/sec)[1]. Actually, GSM uses Gaussian shaped MSK (GMSK). That is, the digital data waveform (with rectangular binary one and binary zero pulses) is first filtered by a low-pass filter having a Gaussian shaped frequency response (to attenuate the higher frequencies). This Gaussian filtered data waveform is then fed into the frequency modulator to generate the GMSK signal. This produces a digitally modulated FM signal with a relatively small bandwidth.

Other digital cellular standards use QPSK signalling, as discussed in the next section.

142.8 QPSK, $\pi/4$ QPSK, QAM, and OOK Signalling

Quadrature phase-shift-keying (QPSK) is a special case of quadrature modulation, as shown in [Table 142.1](#), where $m_1(t) = \pm 1$ and $m_2(t) = \pm 1$ are two binary bit streams. The complex envelope for QPSK is

$$g(t) = x(t) + jy(t) = A_c [m_1(t) + jm_2(t)]$$

where $x(t) = \pm A_c$ and $y(t) = \pm A_c$. The permitted values for the complex envelope are illustrated by the QPSK **signal constellation** shown in [Figure 142.5a](#). The *signal constellation* is a plot of the permitted values for the complex envelope $g(t)$. QPSK may be generated by using the quadrature generation technique of [Figure 142.3](#), where the baseband signal processor is a serial-to-parallel converter that reads in two bits of data at a time from the serial binary input stream, $m(t)$, and outputs the first of the two

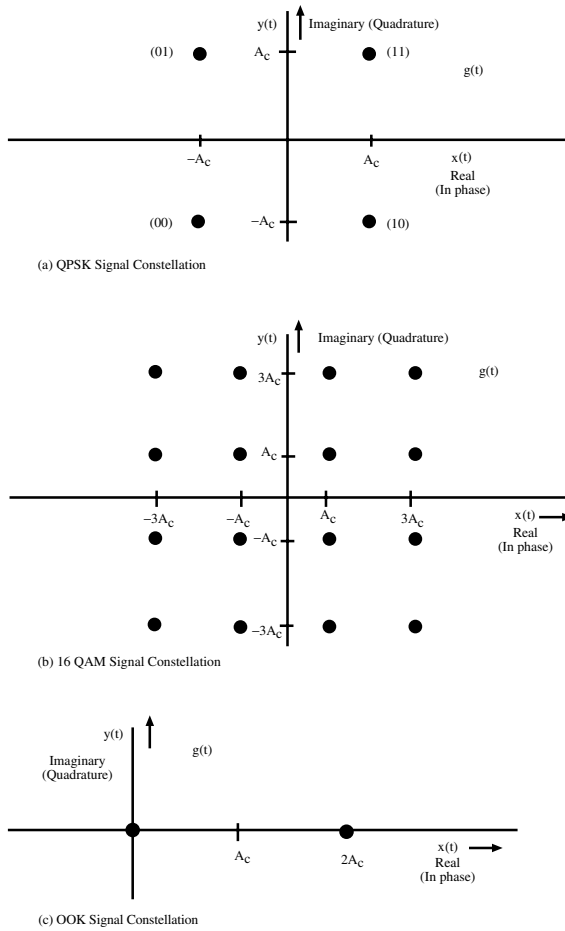

FIGURE 142.5 Signal constellations (permitted values of the complex envelope).

bits to $x(t)$ and the second bit to $y(t)$. If the two input bits are both binary ones, (11), then $m_1(t) = +A_c$ and $m_2(t) = +A_c$. This is represented by the top right-hand dot for $g(t)$ in the signal constellation for QPSK signalling in Figure 142.5a. Likewise, the three other possible two-bit words, (10), (01), and (00), are also shown. The QPSK signal is also equivalent to a four-phase phase-shift-keyed signal (4PSK) since all the points in the signal constellation fall on a circle where the permitted phases are $\theta(t) = 45^\circ, 135^\circ, 225^\circ,$ and 315° . There is no amplitude modulation on the QPSK signal since the distances from the origin to all the signal points on the signal constellation are equal.

For QPSK, the spectrum of $g(t)$ is of the $\sin x/x$ type since $x(t)$ and $y(t)$ consist of rectangular data pulses of value $\pm A_c$. Moreover, it can be shown that for equally likely independent binary one and binary zero data, the power spectral density of $g(t)$ for digitally modulated signals with M point signal constellations is [1]

$$P_g(f) = K \left(\frac{\sin \pi f \ell T_b}{\pi f \ell T_b} \right)^2 \quad (142.28)$$

where K is a constant, $R = 1/T_b$ is the data rate (bits/sec) of $m(t)$, and $M = 2^\ell$. M is the number of points in the signal constellation. For QPSK, $M = 4$ and $\ell = 2$. This PSD for the complex envelope, $P_g(f)$, is plotted in Figure 142.6. The PSD for the QPSK signal ($\ell = 2$) is given by translating $P_g(f)$ up to the carrier frequency as indicated by Equation (142.9).

FIGURE 14.2.6 PSD for the complex envelope of MPSK and QAM where $M = 2^\ell$ and R is bit rate (positive frequencies shown). *Source:* Couch, L. W., II. *Digital and Analog Communication Systems*, 6th ed., ©2001, Prentice Hall, reprinted by permission of Pearson Education, Inc., Upper Saddle River, NJ, p. 358.

Referring to Figure 14.2.6 or using Equation (142.28), the first-null bandwidth of $g(t)$ is R/ℓ Hz. Consequently, the null-to-null bandwidth of the modulated RF signal is

$$B_{\text{null}} = \frac{2R}{\ell} \text{ Hz} \quad (142.29)$$

For example, if the data rate of the baseband information source is 9600 bits/sec, then the null-to-null bandwidth of the QPSK signal would be 9.6 kHz since $\ell = 2$.

Referring to Figure 14.2.6, it is seen that the sidelobes of the spectrum are relatively large, so, in practice, the sidelobes of the spectrum are filtered off to prevent interference to the adjacent channels. This filtering rounds off the edges of the rectangular data pulses and this causes some amplitude modulation on the QPSK signal. That is, the points in the signal constellation for the filtered QPSK signal would be fuzzy since the transition from one constellation point to another point is not instantaneous because the filtered data pulses are not rectangular. QPSK is the modulation used for digital cellular phones with the IS-95 Code Division Multiple Access (CDMA) standard.

$\pi/4$ QPSK is generated by alternating symbols between a signal constellation shown by Figure 14.2.5a and a signal constellation (of Figure 14.2.5a) rotated by 45° . $\pi/4$ QPSK has the same spectrum as QPSK. However, the peak-to-average power ratio of filtered $\pi/4$ QPSK is much lower than that for filtered QPSK because there are no 180° phase transitions (from symbol to symbol) in the $\pi/4$ QPSK signal. $\pi/4$ QPSK is the modulation technique used for IS-136 TDMA digital cellular phones.

Equation (142.28) and Figure 14.2.6 also represent the spectrum for *quadrature modulation amplitude modulation* (QAM) signalling. QAM signalling allows more than two values for $x(t)$ and $y(t)$. For example, QAM where $M = 16$ has 16 points in the signal constellation with 4 values for $x(t)$ and 4 values for $y(t)$ such as, for example, $x(t) = +A_c, -A_c, +3A_c, -3A_c$ and $y(t) = +A_c, -A_c, +3A_c, -3A_c$. This is shown in Figure 14.2.5b. Each point in the $M = 16$ QAM signal constellation would represent a unique four-bit data word, as compared with the $M = 4$ QPSK signal constellation shown in Figure 14.2.5a, where each point represents a unique two-bit data word. For an $R = 9600$ bits/sec information source data rate, an $M = 16$ QAM signal would have a null-to-null bandwidth of 4.8 kHz since $\ell = 4$.

For OOK signalling, as described at the end of Section 142.6, the signal constellation would consist of $M = 2$ points along the x axis where $x = 0, 2A_c$ and $y = 0$. This is illustrated in Figure 142.5c. For an $R = 9600$ bit/sec information source data rate, an OOK signal would have a null-to-null bandwidth of 19.2 kHz since $\ell = 1$.

Defining Terms

Bandpass waveform: The spectrum of the waveform is nonzero for frequencies in some band concentrated about a frequency $f_c \gg 0$; f_c is called the carrier frequency.

Baseband waveform: The spectrum of the waveform is nonzero for frequencies near $f = 0$.

Complex envelope: The function $g(t)$ of a bandpass waveform $v(t)$ where the bandpass waveform is described by

$$v(t) = \text{Re}\{g(t)e^{j\omega_c t}\}$$

Fourier transform: If $w(t)$ is a waveform, then the Fourier transform of $w(t)$ is

$$W(f) = \mathfrak{F}[w(t)] = \int_{-\infty}^{\infty} w(t)e^{-j2\pi ft} dt$$

where f has units of hertz.

Modulated signal: The bandpass signal

$$s(t) = \text{Re}\{g(t)e^{j\omega_c t}\}$$

where fluctuations of $g(t)$ are caused by the information source such as audio, video, or data.

Modulation: The information source, $m(t)$, that causes fluctuations in a bandpass signal.

Real envelope: The function $R(t) = |g(t)|$ of a bandpass waveform $v(t)$ where the bandpass waveform is described by

$$v(t) = \text{Re}\{g(t)e^{j\omega_c t}\}$$

Signal constellation: The permitted values of the complex envelope for a digital modulating source.

143.2 RISC Architecture

Vojin G. Oklobdzija

University of California, Davis

On 7 April 1964, the term **computer architecture** was first defined by Amdahl, Blaauw, and Brooks [1964] of IBM Corporation in the paper announcing the IBM System/360 computer family. On that day IBM Corporation introduced, in the words of an IBM spokesman, “the most important product announcement that this corporation has made in its history.” There were six models introduced originally, ranging in performance from 25 to 1. Six years later this performance range was increased to about 200 to 1. This was the key feature that prompted IBM’s effort to design an architecture for a new line of computers that were to be code compatible with each other. The recognition that architecture and **computer implementation** could be separated and that one need not imply the other led to establishment of a common System/360 machine architecture implemented in the range of models.

In their milestone paper Amdahl, Blaauw, and Brooks identified three interfaces: architecture, implementation, and realization. They defined computer *architecture* as the attributes of a computer seen by the machine language programmer, as described in the **principles of operation**. IBM referred to the principles of operation as a definition of the machine that enables the machine language programmer to write functionally correct, time-independent programs that run across a number of implementations of that particular architecture. Therefore, the architecture specification covers all functions of the machine that are observable by the program [Siewiorek et al. 1982]. On the other hand, the principles of operation are used to define the functions that the implementation should provide. In order to be functionally correct, the implementation must conform to the principles of operation. Accordingly, for the first time in the history of computer development, IBM has separated *machine definition* from *machine implementation*, thus enabling the company to develop several machine implementations in a wide price and performance range that has reached — 22 years after the introduction of System/360 — 2000 to 1.

The principles of operation define computer architecture, which includes the following components:

- Instruction set
 - Instruction format
 - Operation codes
 - Addressing modes
-

common architecture requires unusual attention to details and some new procedures, which are described in the architecture control procedure. The design and control of system architecture is an ongoing process whose objective is to remove ambiguities in the definition of the architecture and, in some cases, to adjust the functions provided.

Definition of an architecture facilitated future development and introduction of not only new models but new **upwardly compatible architectures**. The architecture is upwardly compatible if the user's programs written for the old architecture run efficiently on the new models without modifications to the program. The limitations to upward compatibility are (1) that new systems have the same or equivalent facilities, and (2) that the programs have no time dependence, use only model-independent functions defined in the principles of operation, and do not use unassigned formats and operation codes [Case and Pedegs, 1978]. An example of upward compatibility is IBM System/360, introduced in June 1970.

143.1 Instruction Set

An instruction set defines a basic set of operations, as specified by the architecture, that a particular implementation of that architecture is required to perform. An *instruction* of the instruction set defines an atomic operation that may alter data or the machine state or may perform an I/O operation. In terms of the operation performed, instructions of the instruction set are broadly classified in one of the four general categories:

1. Instructions performing transformation of data
2. Instructions altering the program flow
3. Instructions performing data movement
4. System instructions

The first category includes instructions performing arithmetic and logical operations. The operations can be arithmetic, string, logical, or floating point. They are performed in the appropriate functional units of the particular implementation of the architecture.

Instructions affecting the flow of the program and/or machine state are branches, calls, and returns as well as loop control instructions.

The third category of instructions performs data movement across various functional units of the machine. Examples of such instructions are the load instruction, which loads a content of a memory location to a particular register in the general purpose register file (GPR), and the store instruction, which does the opposite. The move instruction moves a block of data from one memory location to another, or to and from the stack or GPR.

The system instructions change the system's mode and are not generally visible by the programmer who programs in the *problem state*. The problem state is the domain of the machine visible to a programmer executing a general-purpose program, as opposed to the *system state*, which is visible to the operating system. An example of the instruction set specified in the IBM System/360 architecture is given in [Figure 143.2](#).

We can further classify instructions in terms of the number of *explicit operands*, *operand locations*, and *type and size* of the operands. Instructions architecture that specifies no explicit operands is better known as *stack architecture*. In stack architecture all operations are performed on the data that are on the top of the stack. Examples of stack architecture are HP 3000/70 by Hewlett-Packard and B5500 by Burroughs. In the **accumulator architecture**, all operations are performed between the operand specified in the instruction and the *accumulator*, which is a special register. An example of accumulator architecture is the PRISC processor shown in [Figure 143.1](#). One of the well-known accumulator-based architectures is PDP-8, by Digital Equipment Corporation. Almost all modern machines have a repertoire of available general-purpose registers whose numbers range from 16 to 32 and in some cases even more than 32 (SPARC). The number of operands explicitly specified in the instructions of a modern architecture today can be two or three. In the case of three operands, an instruction explicitly specifies the location of both operands and the location where the result is to be stored. In some architectures (e.g., IBM System/360),

FIGURE 143.2 Continued.

only two operands are *explicitly specified* in order to save the bits in the instruction. As a consequence, one of the operands is always replaced by the result and its content is destroyed. This type of instruction is sometimes referred to as *diadic instruction*.

In terms of the operand locations, instructions can be classified as (1) register-to-register (R-R) instructions; memory-to-register (R-M) instructions; and memory-to-memory (M-M) instructions. The addresses of the operands are specified within the instruction. From the information contained in the particular operand field of the instruction, the address of the particular operand can be formed in various ways, described in the next section.

Addressing Modes

The way in which the address of the operand is formed depends on the location of the operand as well as choices given in the instruction architecture. It is obvious that in the case of stack or accumulator architecture, the address of the operand is implied and there is no need to specify the address of the operand. If the operand is in one of the GPRs, the operand field in the instruction contains the number (address) of that particular register. This addressing mode is known as *register direct addressing*, and is one of the simplest ways of pointing to the location of the operand. The addressing of an operand can be even simpler, as in the case where the operand is contained within the instruction. This mode is called the *immediate addressing mode*. The location pointed to by the address formed from the information contained in the operand field of an instruction can contain the operand itself or an address of the operand. The latter case is referred to as *indirect addressing*. Examples of several ways of forming an address of the operand are presented in [Figure 143.3](#).

Data Representation Formats

Another important issue in computer architecture is the determination of data formats. Data formats, along with instruction formats, were formerly of much influence in determining **word size**. Today it is commonly assumed that most of the machines use a 32-bit word size (which is gradually shifting toward 64 bits). This standard was not common in the past, and there was not a common word size used by the majority of the machines. A 36-bit word size was quite common (e.g., IBM's 701 and 704 series), and word sizes of 12, 18, and 60 bits were represented as well (PDP-8, CDC 6600). In the early days of computer development, interaction with the operator was done mainly via the teletype machine, which used 6 bits to represent each character. Therefore, the word sizes of the machines of that period were determined with the objective of being able to pack several characters in the machine word. The size of I/O interfaces was commonly 12 bits (two characters). Anticipation of the new standard for the representation of digits (USASCII-8) prompted IBM to introduce an 8-bit character (EBCDIC) in their introduction of System/360 architecture, which was also its reason for switching from the 36-bit to a new 32-bit word size. Since then (and until today), 32-bit word size and the multiples of the 8-bit quantity (**byte**) have been the most common data formats among various computer architectures. The new standard for representation of digits, USASCII-8, however, did not materialize. Instead, a 7-bit standard for data representation, ASCII, has been commonly used almost everywhere, except by IBM, which could not diverge from the 8-bit character representation defined in its architecture.

Every architecture must specify its representation of characters, integers, floating-point numbers, and logical operands. This representation must specify the number of bits used for every particular field, their order in the computer word, meaning of special bits, interpretation, and total length of data. Data types and data formats as defined in the Digital Equipment Corporation VAC 11/780 architecture are shown in [Figure 143.4](#).

Fixed-Point Data Formats

Fixed-point data forms are used to represent integers. Full-word (32-bit), half-word (16-bit), or double-word (64-bit) quantities are used for representation of integers. They can be signed or unsigned positive

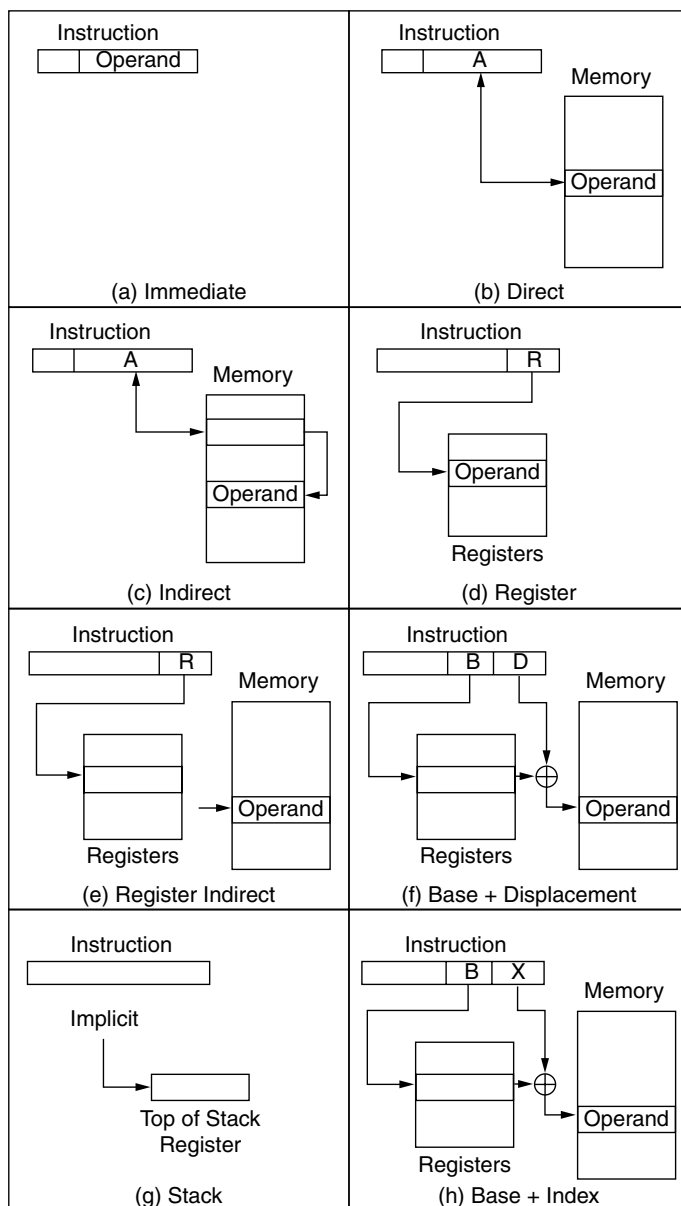

FIGURE 143.3 Example of addressing modes. (Adapted from Stallings, W. 1993. *Computer Organization and Architecture*. Macmillan, New York.)

integers. In the case of signed integers, one bit is used for representation of the sign to represent a range of positive and negative integers. The most common representation of integers is 2s complement format. Another not-so-common representation of integers is binary-coded decimal representation (BCD), used to represent integers as decimal numbers. Each digit position is represented by 4 bits. The coding is straightforward for the numbers from 0 to 9, and the unused bit combinations are used to represent the sign.

For the *logical operand*, a word is treated as a collection of individual bits, where each bit is assigned a Boolean value. A *variable bit field* can also be defined in cases where the field can be treated as a signed or unsigned field of bits.

| DATA TYPE | SIZE | RANGE (decimal) | |
|---------------------------|---------------------------|--|---------------------|
| Integer | | Signed | |
| Byte | 8 bits | -128 to +127 | 0 to 255 |
| Word | 16 bits | -32768 to +32767 | 0 to 65535 |
| Longword | 32 bits | -2^{31} to $+2^{31} - 1$ | 0 to $2^{32} - 1$ |
| Quadword | 64 bits | -2^{63} to $+2^{63} - 1$ | 0 to $2^{64} - 1$ |
| Octaword | 128 bits | -2^{127} to $+2^{127} - 1$ | 0 to $+2^{128} - 1$ |
| Floating Point | | | |
| F floating | 32 bits | approximately seven decimal digits precision | |
| D floating | 64 bits | approximately sixteen decimal digits precision | |
| G floating | 64 bits | approximately fifteen decimal digits precision | |
| H floating | 128 bits | approximately thirty-three decimal digits precision | |
| Packed Decimal String | 0 to 16 bytes (31 digits) | numeric, two digits per byte sign in low half of last byte | |
| Character String | 0 to 65535 bytes | one character per byte | |
| Variable-length Bit Field | 0 to 32 bits | dependent on interpretation | |
| Numeric String | 0 to 31 bytes (DIGITS) | $-10^{31}-1$ to $+10^{31}-1$ | |
| Queue | > 2 longwords/queue entry | 0 through 2 billion entries | |

Floating-Point Data Formats

For scientific computation, the dynamic range achievable using integers is not sufficient, and **floating-point** data representation is therefore defined. Each number is represented with the *exponent* and *fraction* (or mantissa). For the representation of a single number, one or more words could be used if required by the desired precision. Floating-point data formats specified in IBM System/360 architecture are shown in [Figure 143.5\(a\)](#).

A floating-point standard known as IEEE 754 has recently been introduced. The standard specifies the way that data are to be represented, as well as the way computation should be performed. The purpose of this standard is to ensure that floating-point computation always produces exactly the same results, regardless of the machine or machine architecture being used. This result can be achieved only if the architecture complies with the IEEE 754 standard for floating-point computation. Data formats prescribed by IEEE 754 are shown in [Figure 143.5\(b\)](#).

143.2 RISC Architecture

A special place in computer architecture has been given to RISC. RISC architecture was developed as a result of the 801 project, which started in 1975 at the IBM T. J. Watson Research Center and was completed by the early 1980s [Rading, 1982]. This project was not widely known to the world outside of IBM and people involved in two other projects with similar objectives started in the early 1980s at the University of California, Berkeley, and Stanford University [Patterson and Sequin, 1982; Hennessy, 1984]. The term **RISC** (reduced instruction set architecture), used for the Berkeley research project, is the term under which this architecture became widely known and recognized today.

(b)

FIGURE 143.4 Continued.

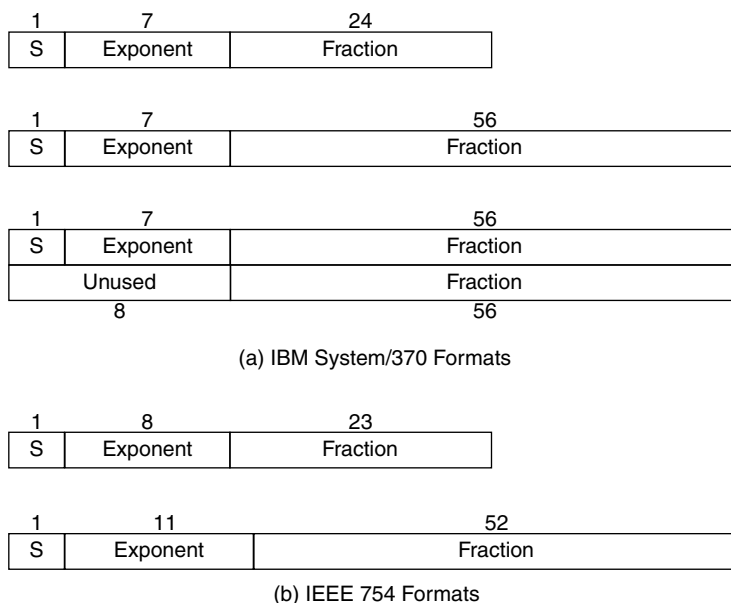

FIGURE 143.5 Floating-point data representation formats.

Development of RISC architecture started as a “fresh look at existing ideas” [Hopkins, 1987], after first revealing evidence that surfaced as a result of examination of how the instructions are actually used in the real programs. This evidence came from the analysis of the *trace tapes*, a collection of millions of the instructions that were executed in a machine running a collection of representative programs. This evidence showed that only about ten instructions from the instruction repertoire were actually used 90% of the time. Then the obvious question was asked: “Why not favor implementation of those selected instructions so that they execute in a short cycle, and emulate the rest of instructions.” The following reasoning was used: “If the presence of a more complex set adds just one logic level to a 10 level basic machine cycle, the CPU has been slowed down by 10%. The frequency and performance improvement of the complex functions must first overcome this 10% degradation, and then justify the additional cost” [Radin, 1982]. Therefore, RISC architecture starts with a small set of the most frequently used instructions that determines the pipeline structure of the machine, enabling fast execution of those instructions in one cycle. One cycle per instruction is achieved by exploitation of parallelism through the use of **pipelining**. It turns out that *parallelism through pipelining* is the single most important characteristic of RISC architecture, from which all the rest of the RISC features could be derived. We can characterize RISC basically as a performance-oriented architecture based on exploitation of parallelism through pipelining. A list of the remaining features of RISC architecture is given in [Table 143.1](#).

RISC architecture has proven itself; several *mainstream architectures* today are of the RISC type. These include SPARC (used by Sun Microsystems workstations, an outgrowth of Berkeley RISC); MIPS (an outgrowth of the Stanford MIPS project, used by Silicon Graphics); and a *superscalar* implementation of RISC architecture, IBM RS/6000 (also known as PowerPC architecture).

Defining Terms

Accumulator — A special register always containing one operand and possibly also receiving the result.

Architectural compatibility — Ability to run programs on separate machines and expect them to produce the same results.

Byte — An 8-bit quantity being treated as a unit.

TABLE 143.1 Features of RISC Architecture

| Feature | Characteristic |
|---|---|
| Load/store architecture | All operations are register to register. In this way, <i>operation</i> is decoupled from the <i>access to memory</i> . |
| Carefully selected subset of instructions | Control is implemented in hardware. There is no microcoding in RISC. In addition, this set of instructions is not necessarily small. ^a |
| Simple addressing modes | Only the most frequently used addressing modes are used. It is also important that they fit into the existing pipeline. |
| Fixed-size and fixed-field instructions | This is necessary to be able to decode instruction and access operands in one cycle (although there are architectures using two sizes for the instruction format, IBM PC-RT). |
| Delayed branch instruction (known also as <i>branch and execute</i>) | The most important performance improvement through instruction architecture. |
| One instruction per cycle execution rate, CPI = 1.0 | Possible only through the use of pipelining. |
| Optimizing compiler | Close coupling between the architecture and the compiler. Compiler “knows” about the pipeline. |
| Harvard architecture | Separation of instruction and data cache, resulting in increased memory bandwidth. |

^a IBM PC-RT instruction architecture contains 118 instructions, whereas IBM RS/6000 (PowerPC) contains 184 instructions. This should be contrasted to the IBM System/360, containing 143 instructions, and IBM System/370, containing 208. The first two are representative of RISC architecture, whereas the latter two are not.

Computer architecture — The attributes of a computer, as seen by the machine language programmer that enable this programmer to write functionally correct, time-independent programs.

Computer implementation — System organization and hardware structure.

Computer organization — Hardware structure encompassing the major functional units, data paths, and control.

Fixed point — Positive or negative integer.

Floating point — A number format, containing a fraction and an exponent, used for representation of numbers covering a wide range of values. Used for scientific computation where the range is important.

Pipelining — The technique used to initiate one operation in every cycle without waiting for the final result to be produced or completion of previously initiated operations.

Principles of operation — A definition of the machine. Term used for computer architecture by IBM.

RISC — Reduced instruction set computer.

Superscalar — Implementation of an architecture capable of executing more than one instruction in the same cycle.

Upwardly compatible architectures — Ability to efficiently run user programs written for the old architecture on the new models without modifications to the program; however, the capacity to do the reverse does not exist.

Word size — A quantity defined as the number of bits being operated on as a unit.

An operating system is a type of system software that manages and controls the resources and computing capability of a computer or a computer network, and provides users a logical interface for accessing the physical computer to execute applications. This chapter describes typical architectures and generic functions of operating systems. First, the basic concepts and brief history of operating system technologies are introduced. Next is a description of the conceptual and typical commercial architectures of operating systems. Common functions of operating systems, such as process and thread management, memory management, file system management, I/O system management, and network/communication management are then presented. Finally, real-time operating systems are described, with illustrations of the RTOS+ operating system.

144.1 Introduction

Operating system technologies have evolved from rather simple notions of managing the hardware on behalf of a single user or sequentially scheduled users to multiuser time-sharing systems and then to networked and distributed systems. Most modern operating systems are based on multiprogrammed timesharing technologies [Brinch-Hansen, 1971; Peterson and Silberschatz, 1985; Silberschatz et al., 2003; Tanenbaum, 2001].

An *operating system* is a type of system software that manages and controls the resources and computing capability of a computer or a computer network, and provides users a logical interface for accessing the physical computer to execute applications. Almost all general-purpose computers need an operating system before any specific application may be installed and executed by users. The role of an operating system as a conceptual model of a physical computer is shown in [Figure 144.1](#).

Operating systems have evolved from being one-of-a-kind programs useful for only one type of hardware configuration to being portable programs that can be made to operate in a homogeneous family

FIGURE 144.1 Role of an operating system in a general-purpose computer.

of hardware configurations and even in heterogeneous hardware platforms. The first operating system that operated on several different kinds of hardware configurations supporting many different kinds of devices was called OS/360. OS/360 was developed by IBM in the early 1960s as a computing platform for commercial applications. OS/360 enabled, for the first time, the support of different generations of hardware devices in a continuous manner, without having to modify the software that ran in the systems and avoiding the creation of completely new operating systems to accommodate new devices. The layered structure of operating systems was first proposed by Dijkstra in his THE multiprogramming system [Dijkstra, 1968].

The first commercial operating system, IBM VM/370, was developed in 1968. The first operating system to operate in a wide variety of hardware platforms was Unix, introduced by AT&T Bell Laboratories in the mid-1970s as a computing platform for research and development of engineering applications [Earhart, 1986]. Unix adopted the multitasking operating system technology, by which users may have several different kinds of concurrent activities to make better use of time and resources while getting work done. The size of Unix was small, and thus it could operate in inexpensive computers used for small groups of people. The first operating system to be used massively was MS-DOS, introduced by Microsoft in the early 1980s as a computing platform for personal or individual use [Microsoft, 1986].

The general-purpose operating systems can be classified into four types: the batch systems, time-sharing systems, real-time systems, and distributed systems. A *batch system* is an early type of operating systems that runs similar jobs sorted by an operator as a batch through an operation console. A *time-sharing system* is a type of multitasking operating systems that executes multiple jobs by automatically switching among them with predefined time slice. A *real-time operating system* is a type of special-purpose operating systems that is designed for dealing with highly time-constraint events of I/Os and processes for control systems. A *distributed operating system* is a type of operating systems that supports networking, communication, and file sharing among multiple computers via a network protocol [Sloane, 1993; Tanenbaum, 1994].

144.2 Architectures of Operating Systems

The architectures of operating systems have evolved over the years from being a monolithic set of system services whose boundaries were difficult to establish to being a structured set of system services. Today, for example, some of these services, like the file system in charge of administering the file data stored by users, have boundaries, or software interfaces, that are standards regulated by organizations that are not related to any computer vendor. This modularization of operating systems into well-understood components provides the possibility to “mix and match” components from different vendors in one system. This trend toward pluggable system parts is accelerating with the formation of various consortia whose charters are to specify common, appropriate, and widely accepted interfaces for various system services.

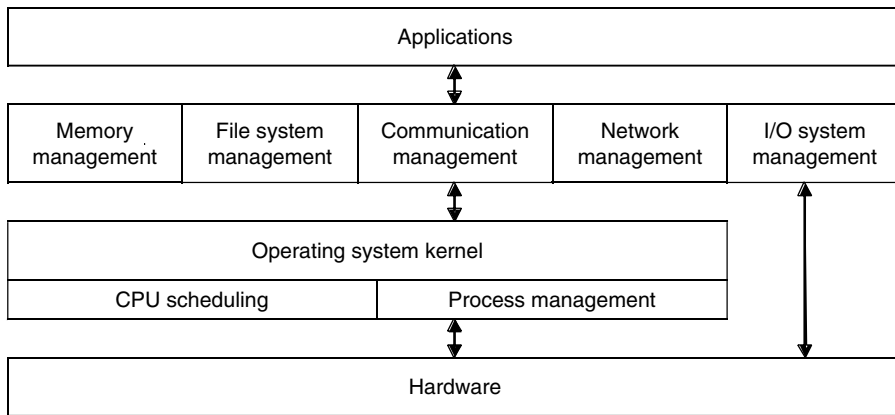

FIGURE 144.2 Generic architecture of operating systems.

Current operating systems are all based on the idea of building higher-level hardware abstraction from lower-level hardware-oriented functions. In other words, current operating systems build higher-level abstractions from lower-level functions that are closer to the raw hardware. Thus, all kinds of hard disks, for example, are made to look and operate in the same manner by their low-level device drivers. Then, in turn, the operating system presents, with all other services in the system (such as the file system), a uniform, common view of a hard disk. This process of successive layers of abstraction is also followed within other services [Dijkstra, 1968]. In file systems, for example, a layer providing the abstraction of continuous storage that does not have device boundaries is built from the abstraction provided by the individual storage in several disks.

Generic Architecture of Operating Systems

An operating system may be perceived as an agent between the hardware and computing resources of a computer or a computer network and the applications and users as shown in Figure 144.2. A generic operating system may be divided into two parts: the kernel and the resource management subsystems [Peterson and Silberschatz, 1985; Silberschatz et al., 2003; Tanenbaum and Tanenbaum, 2001]. The former is a set of central components for computing, including CPU scheduling and process management. The latter is a set of individual supporting software for various system resources and user interfaces.

The kernel is the most basic set of computing functions needed for an operating system. The kernel contains the interrupt handler, the task manager, and the interprocess communication manager. It may also contain the virtual memory manager and the network subsystem manager. With these services, the system can operate all the hardware present in the system and also coordinate the activities between tasks. The services provided by an operating system can be organized in categories. Four possible categories are task control, file manipulation, device control, and information maintenance.

Unix and Linux Operating Systems

The history of Unix goes back to 1969 based on Ken Thompson, Dennis Ritchie, and others' work [Thomas et al., 1986]. The name "Unix" was intended as a pun on Multics (UNiplexed Information and Computing System). The development of Unix was essentially confined to Bell Labs for DEC's PDP-11 (16 bits) and later VAXen (32 bits) [Earhart, 1986]. But much happened to Unix outside AT&T, especially at Berkeley [CSRG, 1986]. Major vendors of workstations, such as SUN's NFS, also contributed to its development.

The architecture of Unix is shown in Figure 144.3, which can be divided into the kernel and the system programs. The Unix kernel consists of system resource management, interfaces, and device drivers, such as the CPU scheduling, file system, memory management, and I/O management.

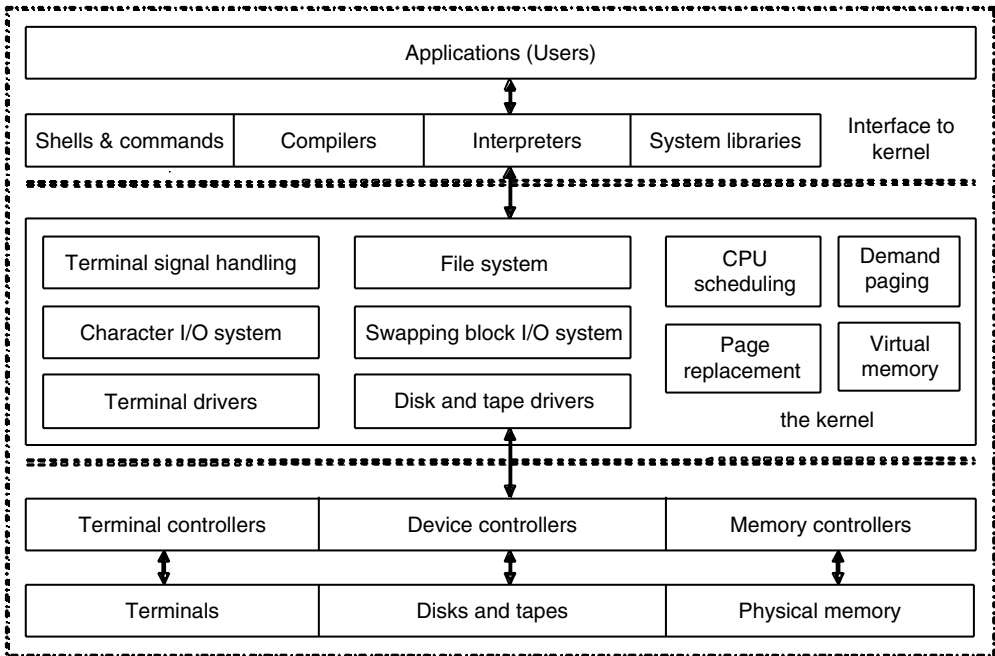

FIGURE 144.3 Architecture of Unix.

Linux is a complete Unix clone for Intel 386/486/Pentium machines [Siever et al., 2003]. Linux is an operating system, which acts as a communication service between the hardware and the software of a computer system. The Linux kernel contains all of the features that one would expect in any operating system. Some of these features are:

- Multitasking (a technique for sharing a single processor between several independent jobs)
- Virtual memory (allows repetitive, extended use of the computer's RAM for performance enhancement)
- Fast transmission control protocol (TCP)/Internet protocol (IP) drivers (for speedy communication)
- Shared libraries (enable applications to share common code)
- Multiuser capability (this means hundreds of people can use the computer at the same time, either over a network, the Internet, or on laptops/computers or terminals connected to the serial ports of those computers)
- Protected mode (allows programs to access physical memory, and protects stability of the system)

Windows XP Operating System

Windows XP is a multitasking operating system built on enhanced technologies that integrate the strengths of Windows 2000, such as standard-based security, manageability, and reliability, with the best features of Windows 98 and Windows Me, such as plug and play, and easy-to-use user interfaces.

The architecture of Windows XP is shown in Figure 144.4. Windows XP adopts a layered structure that consists of the hardware abstraction layer, the kernel layer, the executive layer, the user mode layer, and applications.

Each kernel entity of Windows XP is treated as an object that is managed by an object manager in the executive. The kernel objects can be called by the user-mode applications via an object handle in a process. The use of kernel objects to provide basic services, and the support of client-server computing, enable Windows XP to support a wide variety of applications. Windows XP also provides virtual memory, integrated caching, preemptive scheduling, stronger security mode, and internationalization features.

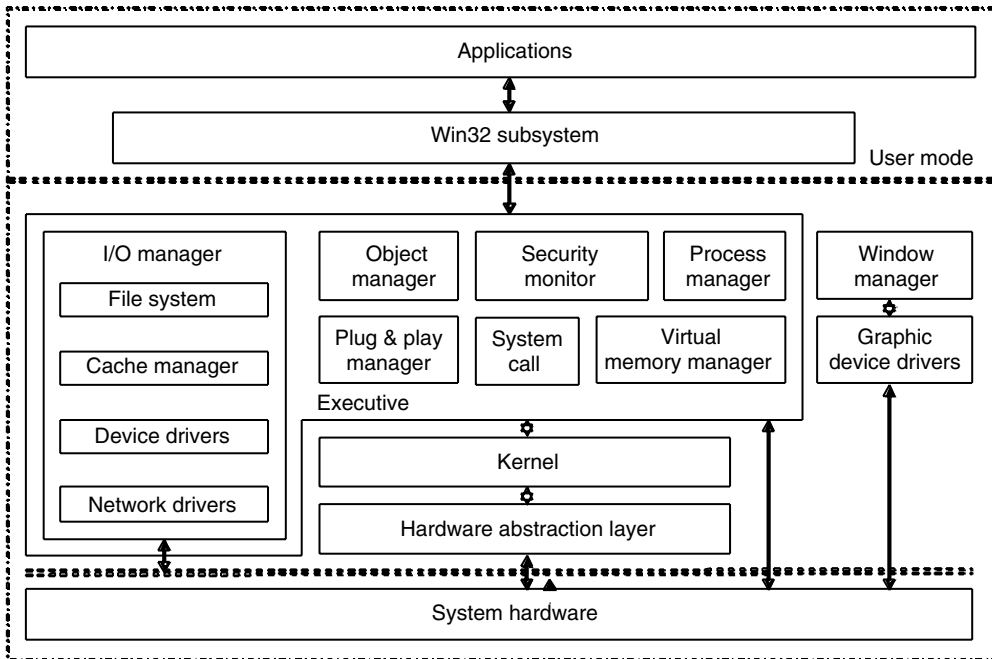

FIGURE 144.4 Architecture of Windows XP.

144.3 Functions of Operating Systems

The basic functions of operating systems can be classified as process and thread management, memory management, file system management, I/O system management, and network/communication management. This section describes the fundamental technologies of main operating system functions in modern operating systems.

Process Management

A *process* is an execution of a program on a computer under the support of an operating system. A process can be a system process or user process. The former executes system code, and the latter runs a user's application. Processes may be executed sequentially or concurrently depending on the type of operating systems.

The operating system carries out process management by the following activities:

- Detection of process requests
- Creation of processes by individual process control blocks (PCBs)
- Allocation of system resources to processes, such as CPU time, memory, files, and I/O devices
- Scheduling of processes based on a predefined process state transition diagram
- Termination of processes

A typical process state transition diagram of a real-time operating system, RTOS+ [Wang and Ngolah, 2003], is shown in [Figure 144.7](#).

Threads are an important concept of process management in operating systems [Anderson et al., 1989; Lewis and Berg, 1998]. A *thread* is a basic unit of CPU utilization, or a flow of control within a process, supported by a thread control block (TCB) with a thread ID, a program counter, a set of registers, and a stack. Conventional operating systems are single-thread systems. Multithreaded systems enable a process to control a number of execution threads. The benefits of multithreaded operating system and multi-

threaded programming are responsiveness, resource sharing, implementation efficiency, and utilization of multiprocessor architectures of modern computers.

CPU Scheduling

CPU scheduling is a fundamental operating system function to maximize CPU utilization. The techniques of multiprogram and multithread are introduced to keep the CPU running different processes or threads on a time-sharing basis. CPU scheduling is the basis of multiprogrammed and multithreaded operating systems [Brinch-Hansen, 1971].

- *CPU scheduler*. The CPU scheduler is a kernel function of operating systems that selects which process in the ready queue should be run next based on a predefined scheduling algorithm or strategy.
- *CPU dispatcher*. The CPU dispatcher is a kernel function of operating systems that switches control of the CPU to the process selected by the scheduler.

The typical CPU scheduling algorithms are described as follows:

- *First-come-first-served (FCFS) scheduling*. This algorithm schedules the first process in the ready queue to the CPU based on the assumption that all processes in the queue have an equal priority. FCFS is the simplest scheduling algorithm for CPU scheduling. The disadvantage of the FCFS algorithm is that if there are long processes in front of the queue, short processes may have to wait for a very long time.
- *Shortest-job-first (SJF) scheduling*. This algorithm gives priority to the short processes, which results in the optimal average waiting time. But the prediction of process length seems to be difficult when using the SJF strategy .
- *Priority (PR) scheduling*. This algorithm assigns different priorities to individual processes. Based on this, CPU scheduling will be carried out by selecting the process with the highest priority. The drawback of the priority algorithm is *starvation*, a term that denotes the indefinite blocking of low-priority processes under high CPU load. To deal with starvation, the *ageing* technique may be adopted that increases the priority levels of low-priority processes periodically, so that the executing priorities of those processes will be increased automatically while waiting in the ready queue.
- *Round-robin (RR) scheduling*. This algorithm allocates the CPU to the first process in the FIFO ready queue for only a predefined time slice, and then it is put back at the tail of the ready queue if it has not yet completed.
- *Multiprocessor scheduling*. This algorithm schedules each processor individually in a multiprocessor operating system on the basis of a common queue of processes. In a multiprocessor operating system, processes that need to use a specific device have to be switched to the right processor that is physically connected to the device.

Memory Management

Memory management is one of the key functions of operating systems because memory is both the working space and storage of data or files. Common memory management technologies of operating systems are contiguous allocation, paging, segmentation, and combinations of these methods [Silberschatz et al., 2003].

- *Contiguous memory allocation*. This method is used primarily in a batch system where memory is divided into a number of fixed-sized partitions. The contiguous allocation of memory may be carried out by searching a set of holes (free partitions) that best fit the memory requirement of a process. A number of algorithms and strategies were developed for contiguous memory allocation such as the first-fit, best-fit, and worst-fit algorithms [Tanenbaum and Tanenbaum, 2001].
- *Paging*. Paging is a dynamic memory allocation method that divides the logical memory into equal blocks known as pages corresponding to physical memory frames. In a paging system, each logical

address contains a page number and a page offset. The physical address is generated via a page table where the base address of an available page is provided. Paging technology is used widely in modern operating systems to avoid the fragmentation problem as found in the early contiguous memory allocation techniques.

- *Segmentation*. This is a memory management technique that uses a set of segments (logical address spaces) to represent a user's logical view of memory independent of the physical allocation of system memory. Segments can be accessed by providing their names (numbers) and offsets.
- *Virtual memory*. When the memory requirement of a process is larger than physical memory, an advanced technique needs to be adopted known as the virtual memory, which enables the execution of processes that may not be completely in memory. The main approach to implement virtual memory is to separate the logical view of system memory from its physical allocation and limitations. Various technologies have been developed to support virtual memory, such as the demand paging and demand segmentation algorithms [Silberschatz et al., 2003].

In memory-sharing systems, the sender and receiver use a common area of memory to place the data that is to be exchanged. To guarantee appropriate concurrent manipulation of these shared areas, the operating system has to provide synchronization services for mutual exclusion. A common synchronization primitive is the *semaphore*, which provides mutual exclusion for two tasks using a common area of memory. In a shared memory system the virtual memory subsystem must also collaborate to provide the shared areas of work.

File System Management

The file system is the most used function of operating systems for nonprogramming users. A file is a logical storage unit of data or code separated from its physical implementation and location. Types of files can be text, source code, executable code, object code, word processor formatted, or system library code. The attributes of files can be identified by name, type, location (path of directory), size, date/time, user ID, and access control information. Logical file structures can be classified as sequential and random files. The former are files that organize information as a list of ordered records; while the latter are files with fixed-length logical records accessible by block number.

Typical file operations are reading, writing, and appending. Common file management operations are creating, deleting, opening, closing, copying, and renaming.

The file system of an operating system consists of a set of files and a directory structure that organizes all files and provides detailed information about them. The major function of a file management system is to map logical files onto physical storage devices such as disks or tapes. Most file systems organize files by a tree-structured directory. A file in the file system can be identified by its name and detailed attributes provided by the file directory. The most frequently used method for directory management is the *hash table*. Although it is fast and efficient, backup is always required to recover a hash table from unpredicted damage.

A physical file system can be implemented by contiguous, linked, and indexed allocation. Contiguous allocation can suffer from external fragmentation. Direct access is inefficient with linked allocation. Indexed allocation may require substantial overheads for its index block.

I/O System Management

I/O devices of a computer system encompass a variety of generic and special hardware and interfaces. Typical I/O devices that an operating system deals with are shown in Table 144.1.

I/O devices are connected to the computer through buses with specific ports or I/O addresses. Usually, between an I/O device and the bus, there is a device controller and an associated device driver program. The I/O management system of an operating system is designed to enable users to use and access system I/O devices seamlessly, harmoniously, and efficiently.

I/O management techniques of operating systems can be described as follows:

TABLE 144.1 Types of I/O Devices

| Types of I/O devices | Examples |
|-------------------------|---|
| System devices | System clock, timer, interrupt controller |
| Storage devices | Disks, CD drivers, tapes |
| Human interface devices | Keyboard, monitor, mouse |
| Communication devices | Serial/parallel buses, network cards, DMA controllers, modems |
| Special devices | Application-specific control devices |

- *Polling*. Polling is a simple I/O control technique by which the operating system periodically checks the status of the device until it is ready before any I/O operation is carried out.
- *Interrupt*. Interrupt is an advanced I/O control technique that lets the I/O device or control equipment notifies the CPU or system interrupt controller whenever an I/O request occurs or a waiting event is ready. When an interrupt is detected, the operating system saves the current execution environment, dispatches a corresponding interrupt handler to process the required interrupt, and then returns to the interrupted program. Interrupts can be divided into different priorities on the basis of processor structures in order to handle complicated and concurrent interrupt requests.
- *DMA*. Direct memory access (DMA) is used to transfer a batch of large amount of data between the CPU and I/O devices, such as disks or communication ports. A DMA controller is handled by the operating system to carry out a DMA data transfer between an I/O device and the CPU.
- *Network sockets*. Most operating systems use a socket interface to control network communications. When requested in networking, the operating system creates a local socket and asks the target machine to be connected to establish a remote socket. Then, the pair of computers may communicate by a given communication protocol.

Communication Management

A fundamental characteristic that may vary from system to system is the manner of communication between tasks. The two manners in which this is done are via messages sent between tasks or via the sharing of memory where the communicating tasks can both access the data. Operating systems can support either. In fact, both manners can coexist in a system. In message-passing systems, the sender task builds a message in an area that it owns and then contacts the operating system to send the message to the recipient. There must be a location mechanism in the system so that the sender can identify the receiver. The operating system is then put in charge of delivering the message to the recipient. To minimize the overhead of the message delivery process, some systems try to avoid copying the message from the sender to the kernel and then to the receiver, but to provide means by which the receiver can read the message directly from where the sender wrote it. This mechanism requires the operating system intervene if the sender wants to modify the contents of a message before the recipient has gone through its content.

In memory-sharing systems, the sender and receiver use a common area of memory to place the data that is to be exchanged. To guarantee appropriate concurrent manipulation of these shared areas, the operating system has to provide synchronization services for mutual exclusion. A common synchronization primitive is the *semaphore*, which provides mutual exclusion for two tasks using a common area of memory. In a shared memory system, the virtual memory subsystem must also collaborate to provide the shared areas of work.

There are systems in which the amount of data that can be shared or sent between tasks is minimal. In the original Unix, for example, different tasks would not have shared memory, and only a very limited form of message passing was provided. The messages were constrained to be event notification. In this environment, data shared by processes have to be written into a common file. To support file sharing, some systems provide a locking service that is used to synchronize accesses to files by different tasks.

The ISO open systems interconnection (OSI) reference model was developed in 1983 [Day and Zimmermann, 1983] for standardizing data communication protocols between different computer sys-

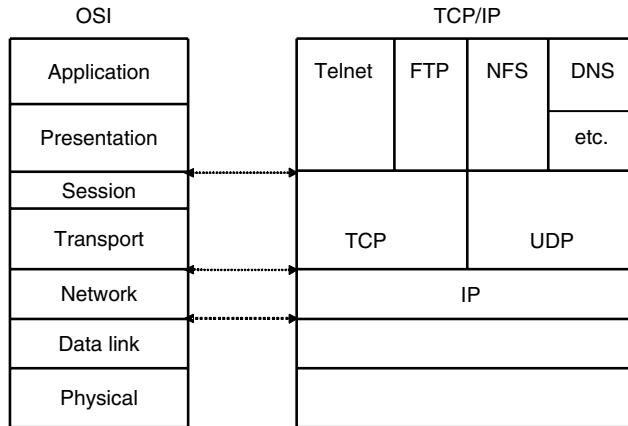

FIGURE 144.5 OSI reference model and TCP/IP.

tems and networks. The OSI reference model is an important protocol framework for regulating multi-vendor multi-OS computers interconnection in local area network (LAN) and wide area network (WAN) environments [Stallings, 2000]. From the bottom up, the seven layers are physical, data link, network, transport, session, presentation, and application, as shown in Figure 144.5.

- *Physical layer.* This layer provides a real communication channel for transmitting bit stream data. Mechanical, electrical, and procedural interfaces for different physical transmission media are specified on this layer.
- *Data link layer.* This layer implements data frames in the sender end and acknowledges frames in the receiver end, and provides retransmission mechanisms when a frame is not successfully transmitted. The data link layer converts a raw transmission line on the physical layer into a line that is free of transmission errors to the network layer.
- *Network layer.* This layer controls the operation of a subnet by determining how message packets are routed from source to destination. It also provides congestion control, information flow counting, and packet size conversion between different networks.
- *Transport layer.* This layer accepts data from the session layer, splits it up into smaller units for adapting to the network layer, and provides an interface between the session layer and the different implementations of the lower-layer protocol and hardware.
- *Session layer.* This layer provides transport session establishment, synchronization, and data flow control between different machines modeled by the transport layer.
- *Presentation layer.* This layer converts the original data represented in vendor-dependent format into an abstract data structure at the sender end and vice versa at the receiver end. The presentation layer enables data to be compressed or encoded for transmitting on the lower layers.
- *Application layer.* This layer adapts a variety of terminals into a unified network virtual terminal interface for transferring different files between various file systems.

Figure 144.5 also contrasts the functional equivalency between the OSI model and TCP/IP [Day and Zimmermann, 1983]. The TCP/IP design philosophy [Comer and Stevens, 1996; Comer, 2000] was intended to provide universal connectivity with connection-independent protocols at the network layer. Thus, TCP/IP does not address the data link and physical layers that determine the communication channels. There are no separate application, presentation, and session layers in TCP/IP; instead, a combined application layer is provided in TCP/IP, which has the functions of those layers.

The IP protocol is approximately equivalent to the OSI network layer. In a WAN, IP is presented on every node in the network. The role of IP is to segment messages into packets (up to 64 Kbytes) and then route and pass the packets from one node to another until they reach their destinations. IP uses packet switching as its fundamental transmission algorithm. A message is transmitted from gateway to

gateway by dynamic routed packets. IP routes packets to their destination network, but final delivery is left to TCP.

The TCP protocol fulfils the role of the OSI transport layer, plus some of the functionality of the session layer. TCP is designed to provide end-to-end connectivity. TCP is not required for packet routing, so it is not included on gateways. TCP provides an acknowledgment mechanism to enable messages to be sent from destination(s) back to the sender to verify receipt of each packet that makes up a message.

Network Management

A network operating system implements protocols that are required for network communication and provides a variety of additional services to users and application programs. Network operating systems may provide support for several different protocols known as stacks, such as a TCP/IP stack and an IPX/SPX stack. A modern network operating system provides a socket facility to help users to plug-in utilities that provide additional services. Common services that a modern network operating system can provide include the following:

- *File services.* File services transfer programs and data files from one computer on the network to another.
- *Message services.* Message services allow users and applications to pass messages from one computer to another on the network. The most familiar application of message services consists of email and intercomputer talk facilities.
- *Security and network management services.* These services provide security across the network and allow users to manage and control the network.
- *Printer services.* Printer services enable sharing of expensive printer resources in a network. Print requests from applications are redirected by the operating system to a network workstation that manages the requested printer.
- *Remote procedure calls (RPCs).* RPCs provide application program interface services to allow a program to access local or remote network operating system functions.
- *Remote processing services.* These services allow users or applications to remotely log in to another system on the network and use its facilities for program execution. The most familiar service of this type is Telnet, which is included in the TCP/IP protocol suite [Comer and Stevens, 1996; Comer, 2000] and many other modern network operating systems.

144.4 Real-Time Operating Systems

A real-time operating system (RTOS) is essential to implement embedded and/or real-time control systems. An RTOS is an operating system that guarantees timely processing of external and internal events of real-time systems. Problems often faced by RTOSs are CPU and tasks scheduling, timing/event management, and resource management. An RTOS requires multitasking, process threads, and explicit interrupt levels to deal with real-time events and interrupts.

Various RTOS models were developed [Labrosse, 1999; Laplante, 1977; Liu, 2000]. Existing RTOSs are target machine specific, implementation dependent, and not formally described. Therefore, they are usually not portable as a generic RTOS to be seamlessly incorporated into real-time or embedded system solutions.

An extended RTOS, RTOS+, is described in this section to address the above issues [Wang and Ngolah, 2003]. RTOS+ is a portable and multitask/multithread operating system capable of handling event-, time-, and interrupt-driven processes in a real-time environment. RTOS+ is also specified by real-time process algebra (RTPA), a formal specification language for real-time architecture and behavior description, particularly for the explicit description of the dynamic behaviors of real-time software systems [Wang, 2002/2003].

RTOS+ Architecture

The architecture of RTOS+ is described as shown in [Figure 144.6](#), where interactions between system resources, components, and internal control models are illustrated. There are four subsystems in RTOS+:

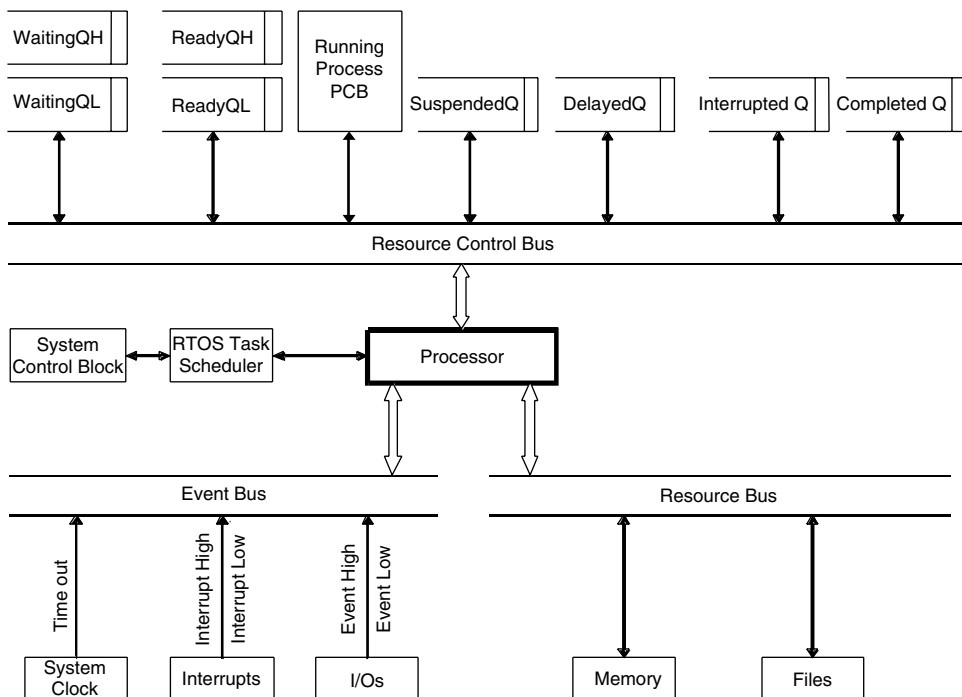

FIGURE 144.6 Architecture of RTOS+.

processor and task scheduler, resource controller, event handler, and system resources. The task scheduler is the innermost operating system kernel that directly controls the CPU and all other system resources by system control blocks. The resources of RTOS+, supplement to the CPU, are mainly the memory, system clock, I/O ports, interrupt facilities, files, and internal control models such as queues and task/resource control blocks as shown in Figure 144.6.

The task scheduling of RTOS+ is priority based. We use a fixed-priority scheduling algorithm where the priority of a task is assigned based on its importance when it is created. Tasks are categorized into four priority types: high- and low-priority interrupts, as well as base and high-priority processes. A process, when created, is placed in a proper queue corresponding to its predefined priority levels.

RTOS+ Task Scheduler

The *Task Scheduler* is the kernel of RTOS+. Its behaviors can be modeled by a state transition diagram as shown in Figure 144.7. The task scheduler of RTOS+ is designed for handling event-, time-, and interrupt-driven processes, in which the CPU is allocated by a fixed time slice for executing a given process.

Process requests are handled by the task scheduler for creating a process. When a new process is generated, it is first put into the *waiting state* with a process control block (PCB) and a unique task ID (Figure 144.7). The system uses a resource control block (RCB) (Figure 144.6) to manage system resources. Each task in the waiting state must be checked to see if there are enough resources for its execution. If resources are available, it is transferred into the *ready state*; otherwise, it has to be re-queued at the tail of the waiting queue until resources are available.

The task scheduler continuously checks the ready queue for any ready tasks. If there are ready tasks, it executes the first task in the queue until it is completed (State 4) or is suspended. There are three conditions that may cause a running task to be suspended during execution: interrupted by a task or event with higher priority, time-out for a scheduled time-slice of CPU, and waiting for a specific event. The scheduler may remove the CPU from a running task if a higher priority interrupt request occurs. Such interruption will cause the running task to go into the *interrupted queue* and later return to the

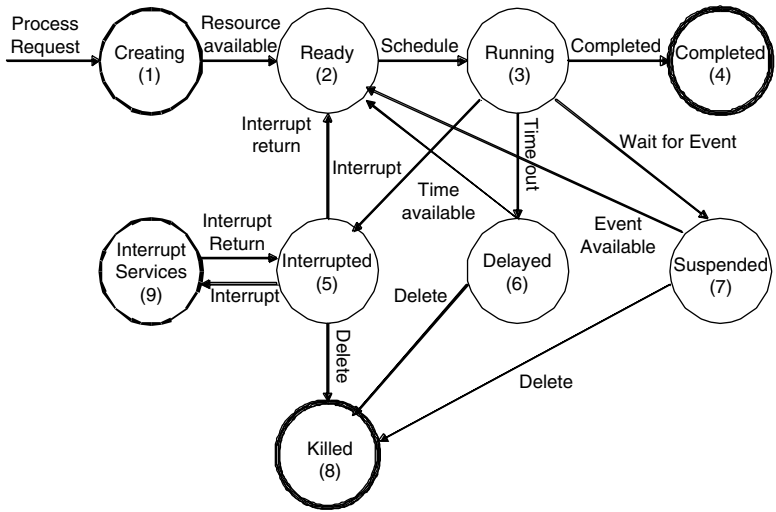

FIGURE 144.7 Process state-transition diagram of RTOS+.

appropriate ready queue when the interrupt service is over. A task that has exhausted its assigned time slice must go to the *delayed queue*. When a new CPU time-slice is available, it is rescheduled into the appropriate ready queue. A task that can no longer be executed due to waiting for an event goes into the *suspended queue*, and returns to the appropriate ready queue once the event has occurred. In any of these suspended cases, the task is put into a corresponding queue in States 5, 6, or 7, respectively. The task will be rescheduled into ready state when the cause of the suspension is no longer true.

A task suspended may be cancelled (State 8) by the scheduler from the queues of States 5, 6, or 7 in case there is a lack of resources or under the request of users.

Formal Description of RTOS+

In the previous subsection, the conceptual model of RTOS+ was established. To further refine the design of RTOS+, real-time process algebra (RTPA) is adopted as a formal specification means [Wang, 2002/2003]. RTPA is a mathematical notation capable of specifying and describing both architectures and behaviors of real-time systems.

The dynamic behaviors of RTOS+ can be described by the interactions of parallel processes between *TaskScheduling*, *TimeManagement*, *ResourceManagement*, and *SystemControlUpdate* as shown in Figure 144.8. RTOS+ runs the *TaskManagement* routine continuously by updating and dispatching various processes in different queues. If an interrupt occurs during run-time, the interrupt handling process (*SysClock100msInst*) saves the current executing environment, switches control to the interrupting process, and then automatically returns to the interrupted process following completion of a higher-priority operation. *SysClock100msInt* handles low-level interrupt events, such as system *ResourceManagement* at 100 ms intervals.

Corresponding to the state transition diagram as shown in Figure 144.7, the task scheduler of RTOS+ is specified by RTPA in Figure 144.9. RTPA describes a finite state machine as an event-driven process dispatching system, where a specific event is used to trigger a predefined process. *Process dispatch* in RTPA models dynamic process relations behaving at run-time. The process dispatching mechanism of RTPA is used to formally describe the RTOS+ dynamic behaviors by a set of event-driven relationships between system events and functional processes of the operating system kernel.

The core operations of RTOS+, such as task scheduling, and time, event, and resource management are rigorously described for better real-time performance and improved resource utilization. On the basis of the formal specification of RTOS+ by RTPA, architectural and behavioral consistency and correctness

of RTOS+ can be improved. RTOS+ has been found useful in a wide range of applications in real-time and embedded system design.

144.5 Conclusions

An operating system has been perceived as the agent between the hardware and computing resources of a computer or a computer network and the applications and users that manages and controls the resources and computing capability, and provides users a logical interface for accessing the physical computer in executing computing applications. This chapter has described typical architectures and generic functions of operating systems. The basic concepts and brief history of operating system technologies have been reviewed. The conceptual and typical commercial architectures of operating systems have been illustrated. The common functions of operating systems, such as process and thread management, memory management, file system management, I/O system management, and network/communication management have been described. A real-time operating system, RTOS+, has been presented with a formal description by using real-time process algebra (RTPA).

Acknowledgment

The author would like to thank L.F. Cabrera and C.F. Ngolah for their work and comments on this chapter.

145.1 Introduction

The goal of a programming language is to make it easier to build software. A programming language can help make software flexible, correct, and efficient. How good are today's languages and what hope is there for better languages in the future?

Many programming languages are in use today, and new languages are designed every year; however, the quest for a language that fits all software projects has so far come up short. Each language has its strengths and weaknesses, and offers ways of dealing with some of the issues that confront software development today. The purpose of this chapter is to highlight and discuss some of those issues, to give examples from languages in which the issues are addressed well, and to point to ongoing research that may improve the state of the art. It is *not* our intention to give a history of programming languages [42, 10].

We will focus on flexibility, correctness, and efficiency. While these issues are not completely orthogonal or comprehensive, they will serve as a way of structuring the discussion. We will view a programming language as more than just the programs one can write; it will also include the implementation, the programming environment, various programming tools, and any software libraries. It is the combination of all these things that makes a programming language a powerful means for building software.

Two particular ideas are used for many purposes in programming languages: compilers and type systems. Traditionally, the purpose of a compiler is to translate a program to executable machine code, and the purpose of a type system is to check that all values in a program are used correctly. Today, compilers and type systems serve more needs than ever, as we will discuss along the way.

145.2 Flexibility

We say that software is flexible when it can run on a variety of platforms and is easy to understand, modify, and extend. Software flexibility is to a large extent achieved by good program structure. A

programming language can help with the structuring of programs by offering language constructs for making the program structure explicit. Many such language constructs have been designed, and some of them will be highlighted in the following discussion of several aspects of software flexibility.

Platform Independence

Goal: Write once, run everywhere.

The C programming language [27] was invented in the 1970s. Over the years, it became the “gold standard” for platform independence: most general-purpose processors, supercomputers, etc. have their own C compiler, which, in principle, enables any C program to run on any such computer. This is much more flexible than rewriting every program from scratch, perhaps in machine code, for each new computer architecture.

In practice, most C programs will have some aspects that tie them closely to a particular architecture. Programmers are well aware of this and tend to design their programs such that porting software from one computer to the next entails minimal changes to the C source code. The main challenges to porting software lie partly in finding out the places in the C program where changes have to be made, and partly in understanding the differences between the two architectures in question.

In the 1990s, the Java programming language [23] popularized the use of virtual machines. Virtual machines increase platform independence by being an intermediate layer between high-level languages such as Java, and low-level languages such as machine code. A Java compiler will translate a Java program to virtual machine code, which the virtual machine executes. Each kind of computer will have its own implementation of the virtual machine, much like it will have its own C compiler. The virtual machine offers capabilities such as event handling in a platform-independent way, which in C would be platform dependent. This is a step towards the ultimate goal of “write once, run everywhere.” Intuitively, we have a spectrum

Virtual machines such as those for Java and the .NET Common Language Runtime [30] are slowly replacing C as “portable assembly code,” that is, the preferred target for compiling languages such as Java and C# [29]. Some virtual machines work in part by translating virtual machine code to C.

Platform independence is particularly important for mobile code that can move from one computer to another while it is executing. If the computers all run the same kind of virtual machine, then such movement is greatly simplified.

Platform independence via virtual machines comes with a price: it is more difficult to execute virtual machine code efficiently than it is to execute C code efficiently. Efficient implementation of virtual machines remains an active research area [2].

Abstraction

Goal: Never duplicate code.

When a programmer faces a programming task, it is tempting to program the needed functionality from scratch. It gives complete control over the code and minimizes the amount of attention that needs to be paid to other code. But it also runs the risk of duplicating work already done by another programmer.

A better scenario for the programmer would be to come across some portion of an already written program that does almost exactly the same as what needs to be programmed. The programmer can now copy and paste the code and perhaps customize it to fit the particular situation. This increases the amount of reading of code by the programmer, but greatly decreases the amount of writing of code. Thus, the programmer is likely to finish the job in less time. However, the copied code may have a problem or

defect, and if the original code gets fixed some day, the copy will stay the same. In other words, improvements cannot be done once and for all. The problem is that the code “lives” in several duplicates.

A vastly superior technique is to use abstraction to isolate and harness a piece of code that is useful in many scenarios. A popular abstraction mechanism is that of procedures which allow a code sequence to be called from many places. For example, suppose we have written code for sorting a list of data. In a language like C, we can abstract it into a procedure

```
void sort(int a[ ], int n) { ... }
```

which sorts the argument array *a* from positions 1 to *n*, whenever it is called. The devices of passing arguments and possibly returning results increase the usefulness of procedures as an abstraction mechanism.

An additional advantage of a procedure is that it creates a natural interface between the user and the implementer of the procedure. The implementer is free to change the implementation of the procedure as long as the new implementation has the same behavior. Thus, if the current implementation has a problem, then it can be fixed once and for all, to the benefit of all call sites.

Another abstraction mechanism is that of data abstraction, for example in the form of classes and objects. The idea is to let the programmer define a new data type with a well-defined set of operations and a hidden representation. Such a data type can be used in many places without duplication of code. Similar to the case of procedures, one can change the representation of a data type without affecting the clients.

Constructs for procedural and data abstraction are an integral part of object-oriented languages such as Java and C++. The highly successful and widely-used libraries that come with these languages were to a large extent enabled by these abstraction mechanisms.

The use of abstractions, particularly in libraries, switches some of the work of a programmer from writing to reading code. If a good abstraction can be located, perhaps the programmer needs to do little more than use it. The better the documentation, the more likely the programmer is to find something useful in a library.

Programmers continue to develop useful abstractions that cannot be easily expressed with the abstraction mechanisms of today’s programming languages. Instead they are expressed and documented more informally, for example, in the form of design patterns [21]. As a result, the code for a design pattern is often duplicated to each place it is used. Developing new abstraction mechanisms that can capture some of the growing list of design patterns remains an active research area [8, 13].

Code Management

Goal: Separation of concerns.

A large program tends to have other big features than many lines of code. It may have a large state space, represented by many variables, and it may have several rather independent subtasks that are handled by quite separate parts of the code. A programmer will manage the code complexity by trying to keep separate things separate. For example, a classical system design is to have three layers: a user interface, the business logic, and a database. If the code for each of the layers is kept separate and has minimal and well-defined interaction with the other layers, then the overall system will be easier to build, understand, and maintain.

A programming language can help enforce separation of concerns by offering ways of creating separate name spaces. For that purpose, Java has packages, ML [32] has modules, and C++ has so-called namespaces. In each case, the idea is, for example, to enable the name space of the user interface to be separate from that of the database. The advantage is that the programmer of the user interface will not accidentally or purposefully manipulate the internals of the database. Furthermore, the programmer of the database can choose names of variables, procedures, etc. without worrying about clashes with names used in the user interface code.

Good constructs for code management greatly enhance software engineering by teams of programmers where each programmer is responsible for a module. As long as the interfaces between the modules are well defined, each programmer can work independently.

Java packages are a simple mechanism for separation of concerns. Each package has a name and a separate name space, and it can access names from other packages only by explicitly importing them. For example, in Java, if we write

```
import java.util.*;
```

then we get access to all classes and interfaces defined in the package `java.util`.

The import statements make explicit the relationships with other modules and therefore avoid name clashes. The collection of Java classes is flat and unstructured; a Java package cannot be nested in another package. Moreover, a Java package is not a value; it cannot be stored in a variable, passed as an argument, or returned as a result.

In ML, a module is a first-class entity which can be stored and passed around in much the same way as a basic value such as an integer. There is a layering, though: functions that take modules as arguments are functors, not functions. So, functors are functions from modules to modules, while normal functions are functions from normal values to values.

ML modules and functors blend mechanisms for abstraction and for separation of concerns. Further blending of modules with mechanisms of object-oriented programming remains an active research area [20].

Concurrency Control

Goal: Control access to shared resources.

At the hardware level, synchronization of concurrent processes can be supported in a variety of ways. For example, there can be an atomic test-and-set operation that allows a shared register to be simultaneously read and written. Another example is an atomic operation for swapping the contents of two registers. Such operations enable a register to be a *lock* for a shared resource. With either of the two mentioned operations, one can ask for the lock, and possibly get it, in one computation step. If it had happened in two computation steps, then it is possible that two different concurrent processes simultaneously would ask for the lock, both find that the lock is not currently held, and then both processes take the lock. This would be a programming error.

Representing and operating on locks with atomic operations is fairly cumbersome and highly machine dependent. Programming languages tend to provide more convenient constructs for concurrency control. Those constructs can often be easily implemented using test-and-set, etc. A classical example is that of a semaphore [19], which is a data structure with just two operations: wait and signal. We can think of a semaphore as an abstraction of a lock. When a process wants access to a shared resource, it issues a wait to the semaphore that guards the resource. If no other process is currently accessing the resource, then the process is granted access right away and is now holding the lock. When the process is done with the access, it issues a signal to the semaphore, thereby releasing the lock. If the wait is issued while another process holds the lock, then the process will wait until the lock is released. In general, the semaphore may have a queue of processes waiting to access the shared resource.

A different construct for concurrency control is that of monitors [24]. A monitor is a data structure where we can think of all the operators as being guarded by a single semaphore. Whenever an operator is called, a wait to the semaphore is automatically issued, and when an operation is about to return, a signal is issued. The effect is that the data structure is accessed by at most one concurrent process at a time.

In Java, any variable can be used as a lock, and any block of code can be guarded by a lock. For example, we can write

```
synchronized(lock){ balance = balance + x; }.
```

Here we can think of `lock` as a semaphore on which a wait is automatically issued on entry to the guarded block of code, and on which a signal is automatically issued on exit. If every method of a class is guarded by *synchronized* on the same lock, then each object of that class is effectively a monitor.

Much research has gone into finding efficient implementations of the various constructs for concurrency control [5]. A radical idea is to let a compiler prove that a certain lock can be held by at most one process at a time. In such a case, the lock is unnecessary and the calls to be operations on it can be eliminated [1].

145.3 Correctness

We say that software is correct when it does what it is supposed to do. Most software has complex behavior and one can rarely get a waterproof guarantee that software is fully correct. However, a programming language can help establish partial correctness by offering ways of specifying and checking key properties. A variety of approaches to software verification and validation have been devised, and some of them will be highlighted in the following discussion of several aspects of software correctness.

Memory Safety

Goal: Avoid jumps to data addresses and data manipulation of code addresses.

One of the most dreaded software errors is reported at run time as something like “illegal address—core dump.” Such errors preclude graceful recovery and continuation of the computation, and they can be difficult to troubleshoot. They typically arise from careless manipulation of memory addresses which can look innocent in a machine code program. For example, a program may by mistake jump to a data address, or it may add a number to a code address and thereby get an illegal jump target. The idea of memory safety is to avoid all such errors.

For a given machine code program, it can be difficult to determine whether it is memory safe. Extensive software testing can increase confidence in memory safety, but, as always, testing can only show the presence of bugs, not prove the absence of bugs.

In high-level languages, such as Java, ML, and Scheme [15], memory safety is guaranteed via a type system. In these languages, data and code addresses are not manipulated directly; rather, the programmer works with convenient abstractions such as objects and functions. The type system enforces that those abstractions are used correctly. From the programmer’s point of view, data and code manipulation errors no longer manifest themselves as core dumps at the hardware level; instead they show up as type errors that are reported in a more intelligible way by the run-time system of the language. For example, in Scheme, each data value is tagged with information about its type. The tag can be “integer,” “procedure,” “heap address,” etc. Whenever a value is used, the run-time system checks whether the value is of the appropriate type. The run-time system will allow a number to be added to another number, but will disallow a number to be added to a procedure. A type error in Scheme will terminate the execution, but in a graceful way. An alternative is that the run-time system throws a type exception which can then, perhaps, be caught by an exception handler and thereby allow the computation to continue.

The Scheme style of type checking is known as dynamic type checking because it takes place at run time. It comes with an overhead in time and space because each value must be tagged and because the tags must be checked each time values are used. In contrast, ML has entirely static type checking. The idea is that before the program is run, a type checker will determine whether all data manipulation and procedure calls will operate on values of the correct types. If not, then the program is not executed at all. While this may seem restrictive, it has the benefit of saving time and space at run time, and of enforcing the program abstractions in a static way, that is, reporting problems early — even before running the program. Static type checking takes time itself, but is typically done along with compilation of the program and tends to take less time than the rest of the compilation process. Static type checking is a win-win technology: (1) problems are caught early, making it possible to complete software testing faster, and (2) it comes with no overhead for the running program.

In an object-oriented language such as Java, a data type can be a subtype of another type. For example, Plane and Helicopter can be two subtypes of Aircraft. The idea is that every Plane is an Aircraft, but not

vice versa. If we have a variable of type Aircraft, the actual object residing in the variable may be a Plane or a Helicopter. Since the type system does not know which one, it would be a type error to do a Plane-specific operation on the variable. This is where type casts come in: we can cast the variable to be a Plane before operating on it. If the variable actually contains a Plane object, then all is well; otherwise a type cast exception is thrown. If the exception is not caught, then the effect is the same as a dynamic type error in Scheme.

The quest of type systems research is to strike a balance between expressiveness, that is, the number of programs that can be type checked, and efficiency, that is, the time it takes to do the type checking. One of the current active research areas is to combine static type systems for object-oriented languages with a notion of generic types [11].

Proof

Goal: A guarantee that the program meets the specification.

Mathematical proofs of program properties are based on a formal description of program behavior. A description of program behavior is also known as the semantics of a programming language. There are several approaches to formal semantics. Operational semantics [40] models a computation as a step-by-step process in which commands are executed one after the other. The execution process is modeled on a mathematical, high-level representation of the bits and bytes in an actual computer. Denotational semantics [34] formalizes a program as simply its input-output behavior, that is, in the simplest case, how it maps an initial state to a final state. Axiomatic semantics [25] specifies relationships between program states, such as if a predicate is true of a state, then after executing a command, a somewhat different predicate is true of the next state. Once a formal semantics is in place, we have a foundation for mathematical reasoning about programs. The properties we want to prove must also be stated formally.

In general, proving that a program has a property can be difficult. The ultimate goal of proving that a program meets its entire specification remains elusive and is getting increasingly problematic as software grows in size and complexity. One kind of program has received particular attention when it comes to proving correctness: compilers. The motivation is that compilers are an important part of today's computational infrastructure; if the compiler is not working correctly, then all bets are off. Moreover, many aspects of compilers are well understood which increases the chance that good proof techniques can be found [17]. One aspect of compiler correctness can be stated as follows:

If a program p is compiled to code c , and evaluating p gives result r ,
then evaluating c gives a result which is a machine representation of r .

Notice that the semantics of both the source language and the target language play a crucial role in the statement of compiler correctness.

One of the goals of modern programming language design is to ensure that *all* programs in the language have a certain correctness property. One example is type soundness [31], which states:

Well-typed programs cannot go wrong.

Here, “well-typed” simply means that the program type checks, and “go wrong” is, intuitively, an abstraction of the error “illegal address — core dump” that one can encounter at the hardware level. The standard way of proving type soundness is to first prove two lemmas [37, 43]:

Preservation: If a well-typed program state takes a step, then the new program state is also well typed.

Progress: A well-typed program state is either done with its computation, or it can take a step.

The Preservation lemma says that if we have type checked a program, then during the computation, all reachable program states will also type check. The Progress lemma says that if we have reached a program

state that type checks, then we cannot go wrong in the next step of computation. Together, the two lemmas are sufficient to prove type soundness: when we have type checked a program, Preservation ensures that we will only reach typable program states, and Progress ensures that in those states, the computation cannot go wrong.

The field of program synthesis [7] is concerned with generating programs from specifications. This obviates the need for proofs altogether; if we can prove the correctness of the program generator, of course!

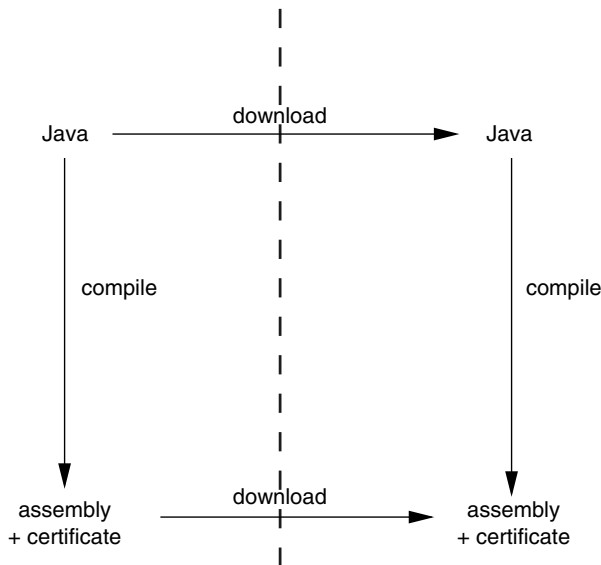

An active research area is that of proving the correctness of optimizing compilers [28]. Some optimizations radically change the code and remain a challenge to prove correct.

Certification

Goal: Verify a certificate before executing the program.

Clicking on a link may lead to the downloading and execution of Java bytecode. In addition, the bytecodes will be verified before execution, giving the same kind of guarantee as we get from type checking source code. This can be done easily because Java bytecode contains type information that guides the verifier. We can view this extra type information as a certificate which is checked by the bytecode verifier. If the raw bytecode does not match the certificate, then the bytecode will not be executed. The combination of code and certificate achieves a level of tamperproofing: one can try to tamper with either the code, the certificate, or both, but if the end result does not verify, then it will not be executed. In Java, bytecode verification first and foremost guarantees memory safety. Even if an attacker manages to change the code and the certificate in such a way that the result verifies, the code will be memory safe. It may no longer compute factorial, but will not crash your computer!

A weakness of the Java bytecode verification model is that after the verification is done, it may be necessary to compile the bytecode in order to achieve efficient execution. This entails that the compiler is part of the trusted computing base: if the compiler is faulty, then the guarantees obtained at the bytecode level are worthless. This raises the challenge of whether we can avoid trusting the compiler and have a certificate for machine code. The idea is that, instead of downloading Java bytecodes, we would like to download machine code plus a certificate which can be verified before execution. The certificate will be issued by the code producer, and there will be nothing to compile on the receiving end, thus obviating the need for a compiler in the trusted computing base.

The obvious place to put the burden of producing the certificate is with the compiler. This leads to the concept of a certifying compiler, which not only produces memory-safe code, but also a certificate that the code is memory safe.

One approach to low-level certified code is typed assembly language [33]. The idea is the same as for Java bytecode: extra type annotations in the code guide the type checker, and type checking guarantees memory safety. One of the main challenges in designing a typed assembly language is that high-level constructs and values, such as procedures and objects, at the assembly level are represented by a multitude of individual entities and instructions. For example, there may be one type rule for a Java method call, but at the machine level, the method call is represented by several instructions, each of which must type check. Another challenge is to design a type system that will be a convenient target for the compilation of a wide variety of source languages. The ultimate typed assembly language would enable easy compilation of all source languages. This goal seems elusive, and it may be that in the future there will be several competing type systems for the same assembly language.

While certified assembly code does eliminate the compiler from the trusted computing base, it does introduce the need for having a verifier in the trusted computing base. The good news is that a verifier tends to be much simpler than a compiler.

If we allow certificates to be written as proofs in a full-blown logic, then the certified code is known as proof-carrying code [36]. This is vastly more powerful and flexible than typed assembly language, but it is also more difficult to produce the proofs. It remains an active research area to develop industrial-strength certifying compilers that produce proof-carrying code. Another active research area concerns producing better certified bytecode representations of high-level programs [3].

Bug Finding

Goal: Find bugs faster than via software testing.

In most software engineering efforts, more time is spent on testing software than on writing software. The goal of software testing is to find as many bugs as possible. It is widely believed that no large piece of software can be bug free, even after extensive testing. Part of the testing process can be automated, but testing remains labor intensive and therefore costly. It is particularly time consuming to invent test cases and to figure out what the correct output should be.

Modern programming languages help with bug finding, even without running the program. Structured programming, variables instead of registers, static type checking, automatic memory management, and certifying compilers all contribute to lowering the number of bugs. Still, a program can contain errors in the program logic that will not be caught by, say, the Java type system.

The idea of model checking [14] is to try to find bugs in a model, that is, an abstraction of the program. If the model faithfully preserves some aspects of the program and eliminates others, then it will preserve some bugs and eliminate others. Thus, if we can find bugs in the model, then those bugs will likely correspond to bugs in the program. Creating good models is difficult. On one hand, we want small models that will make powerful bug finding algorithms feasible, and on the other hand, we want models that are large enough to contain at least some of the bugs.

For example, suppose we have a program and want to check whether all read operations on a file only happen after the file has been opened. We can create a model which eliminates all operations on data other than files, and which for every conditional statement embodies the abstraction that both branches are executable. This abstraction may well eliminate some bugs in the part of the code that is not concerned with files. However, if we find a read on a file without a preceding open operation, then chances are that we have identified a bug in the original program.

A model checking problem has two components: the model and the property we want to check. To enable flexible bug finding, we want to have a property language in which we can express a variety of properties to be checked. Otherwise, we would need a separate model checking algorithm for every property. One of the popular approaches to designing a property language is to base it on regular expressions. For example, we might choose the alphabet {open, read, write, close}, and check the property:

open · read*

We can understand the property as stating that a file must be opened exactly once, and only after that can it be read any number of times. A somewhat different property could be:

open · (read | write)* · close

The same general model checking algorithm would handle both properties and possibly report bugs.

While it is easiest to build the model independently of the desired property, it can lead to faster model checking if the model is property driven. For example, the first property above has no need for a model with write and close operations.

Model checking has been immensely successful at bug finding for hardware. Software model checking has turned out to be more difficult and remains an active research area [16, 6].

145.4 Efficiency

We say that software is efficient when it can do its job using the available resources. A variety of resources can be available to software, including time, space, power, databases, and networks. When resources are constrained, a programming language can help with using them judiciously by offering resource-aware language constructs and compilers. A variety of approaches to resource awareness have been devised, and some of them will be highlighted in the following discussion of several aspects of efficiency.

Execution Time

Goal: Complete the task faster.

For desktop computing, users want spreadsheets that update the fields quickly after changes, they want internet searches to complete quickly, they want games with fancy graphics and computer players that move quickly, and so on. High speed is in practice achieved by a combination of good algorithms, careful coding, good compilers, etc.

A good programming language can contribute to fast execution time in at least two ways. First, the language can make it easier to express efficient algorithms. For example, a recursive algorithm such as quicksort is easier to express in a language such as C than in assembly language because recursion is supported in C. Second, the compiler can have a major impact by doing good instruction selection, register allocation, etc. The difference between a simple compiler and a highly optimizing compiler can be several factors when measuring execution speed.

The traditional role of a compiler is to do its job “way ahead of time” (WAOT), that is, before the compiled code is run. A WAOT compiler can take as long time as it likes, as long as it generates efficient code. Usually, a highly-optimizing compiler has the following structure:

Each optimization step may use a static analysis that determines useful facts about the program. For example, a static analysis in a Java compiler may determine that certain call sites can be inlined, and the

optimizer may then go ahead and inline the calls. In more detail, consider a Java call site `x.m()` where `x` is variable and `m` is a method name. From the syntax alone, we cannot determine which method will be called. However, a static analysis might determine that only objects of class `C` will be assigned to `x`, so only the `m` method in `C` can be called, and therefore we can inline it [22].

In Java, classes can be loaded and used while a program is running. If we want newly loaded code to execute fast, then we need to compile “just in time” (JIT), that is, after the code is loaded but before it is executed. A JIT compiler is executed at run time, so the compilation time directly impacts the run time. This creates a trade off between compilation time and run time. For example, an inlining optimization for Java may take 4 seconds to execute on a large program and make the program execute 3 seconds faster. This is fine for a WAOT compiler. In a JIT compiler, we would prefer a simpler inlining optimization that takes just 1 second to execute and makes the program execute 2 seconds faster. Each optimization needs to “pay for itself” by creating a larger speed up than the time it takes to do the optimization.

Some program analyses and optimizations work on a per-procedure basis. That property make them good candidates for JIT compilers. Other program analyses are inherently whole-program analyses. Those analyses do not work so well for languages such as Java because the program can change after the analysis is done, due to dynamic class loading.

Some program analyses take advantage of being applied to programs that have already been type checked. Such analyses are called type-base analyses [38] and are the topic of much current research. Another active research area is to find fast and effective program analyses for use in JIT compilers [18, 41].

Memory Management

Goal: Use less space.

Many efficient algorithms require the use of pointers and dynamically allocated data structures. In languages such as C, programs manage a memory space known as the “heap” for dynamically allocated data. A program can allocate and deallocate heap space, and it can access and update heap objects. The “do-it-yourself” style of heap management can lead to efficient programs but also to nasty bugs. For example, a program may reference a memory area after it has been deallocated, a bug known as the “dangling pointer” error. A program might also keep allocating heap space indefinitely, a bug known as a “memory leak.” Some of these problems can be avoided by dealing with the heap at a higher level of abstraction and leaving the details to a memory management system. The memory manager is a part of the run-time system which is present during the execution of a program.

For example, in Java all dynamic memory allocation is done with expressions of the form

```
new C()
```

or something similar, where `C` is a class name. The memory manager will allocate space for a `C` object, that is, sufficient heap space for representing the fields and methods of a `C` object. When the program can no longer reach the object, then the memory manager will automatically deallocate it. The automatic deallocation, also known as garbage collection, ensures that dangling-pointer errors cannot occur.

A type system can help the compiler when it computes how much space is needed for the fields of an object. In Java, a field of type `int` takes four bytes, while a field of type `long` takes eight bytes. For a language without a static type system, it may not be easy to determine ahead of time what will be stored in a field. The usual solution is to “box” the data in the field, that is, instead of storing the data itself in the field, the program will store a pointer to the data. Given that all pointers have the same size, it is easy to determine the size of each field.

A compiler can help save data space by doing a data-flow analysis to determine, for example, whether the values stored in a field of type `long` really go beyond what could be stored in a field of type `int`. If not, then the compiler can treat the field as if it is of type `int`, and thereby save four bytes. Such an optimization is particularly important in embedded systems where memory may be limited [4].

The use of dynamic memory allocation can make it difficult to determine an upper bound on the need for heap space. As a consequence, some embedded software refrains entirely from dynamic memory allocation and instead allocates all data in a global area or on a stack. Even without dynamic memory allocation, it can be difficult to determine an upper bound on the need for stack space [12]. In particular, recursion makes it difficult to find such upper bounds. So, some embedded software also refrains from using recursion.

A compiler can help save stack space by inlining procedure calls. If a procedure is called more than once, such inlining may in turn increase the code size, creating a trade off between stack size and code size.

Current research includes developing memory managers that can allocate and deallocate data more efficiently and with smaller overhead [9]. Another active area is the development of methods for statically determining the need for heap space in recursive programs with dynamic memory allocation [26]. Yet another active area is resource-aware compilation [35, 39], where the compiler is told up front about resource constraints, such as memory limits, and the compiler then generates code that meets the requirements, or tells the programmer that it cannot be done.

145.5 Concluding Remarks

As the need for software grows, so does the need for better programming languages. New directions include power-aware compilers that can help save energy in embedded systems, and XML processing languages for programming of web services.

Acknowledgments

Thanks to Mayur Naik, Vidyut Samanta, and Thomas VanDrunen for helpful comments of a draft of the chapter.

Defining Terms

Flexibility — Software is flexible when it can run on a variety of platforms and is easy to understand, modify, and extend.

Correctness — Software is correct when it does what it is supposed to do.

Efficiency — Software is efficient when it can do its job using the available resources.

Compiler — The purpose of a compiler is to translate a program to executable machine code.

Type system — The purpose of a type system is to check that all values in a program are used correctly.

146.3 I/O Channel

[Cables](#) • [Channel Specification](#)

Input/output (I/O) devices are the elements that allow digital processing units to interact with the environment. The connection that transfers data between the central processor and the I/O devices is the I/O port. Through the I/O ports, a user can program a processor, access information, and store information. The I/O port is a connection that may comprise segments of physical connections with different signal environment and protocols. Dedicated processors that translate between the protocols bridge the segments or channels.

Performance measurement for an I/O device or I/O port is generically determined by the impact on the overall throughput of a processor. System throughput is often not a viable metric since it depends on many additional factors. More isolated metrics are commonly used for I/O channels such as (1) bandwidth, the amount of information that can be communicated per second (bits-per-second or baud-per-second); (2) latency, the delay of a response to a query; and (3) reliability, the number of erroneous data transfers (bit error rate). In this increasingly portable and environmentally aware world, some secondary metrics are the size/area and power associated with the I/O channel and I/O device.

As an example, [Figure 146.1](#) illustrates the common I/O connections of a central processor (CPU). As data rates of digital processors increase, the system throughput for many applications is increasingly dependent on the performance of the I/O. Particularly in storage, memory access, and network interface, I/O performance is designed to scale with the processor clock rate. This chapter first describes various I/O devices, followed by how a CPU interfaces with an I/O subsystem. The chapter ends with a discussion of selected I/O channel specifications. As the system demands higher performance, specifications has become more numerous and more difficult.

146.1 I/O Devices

I/O devices can be classified based on the type of agent, human or machine. Further differentiation can be based on whether the device is input only, output only, or both. The grouping can also be based on the application: memory access, storage, networking, video, audio, pointer, and so on. The following section briefly discusses a sampling of the common I/O devices.

FIGURE 146.1 I/O connections of a central processor.

Human-Oriented Interface

Our increasing reliance on computers spawns a diversity of human-machine interfaces. A short list of categories would include video displays, printers, keyboards, pointing devices, scanners, and digital cameras. Each category includes many implementations. For instance, displays include cathode ray tubes (CRTs), light-emitting diodes (LED), liquid crystal displays (LCDs, passive or active), and plasma displays. Output devices have predominantly involved only two of our senses, vision and hearing, in the form of displays and speakers. The input device that can be most easily interpreted by the computer is still the alphanumeric keyboard aided by a pointing device. Recent advances in pen-based entry on touch screens have enabled a growing set of small portable computers. Enabling accurate electronic interpretation of pictorial and audio inputs is an area of very active research that may eventually make scanners and voice recognition the norms of human-machine interface. Until then, this discussion is limited to the more common set of devices: displays, printer, keyboard, and mouse.

Displays

Video displays based on CRTs have existed for over a hundred years. The displays require large voltages in order to bend an electron beam so that it scans horizontally across the screen one line at a time. Physical depth is needed for a good control of the scan. A memory or frame buffer, contains a byte or word for the intensity of each color of each point in the picture (pixel). Computer displays have standardized resolution of 640×480 , 800×600 , 1280×1024 , or 1600×1200 (pixels). As one would expect, the higher resolution results in a larger frame buffer. The digital values in the frame buffer control the intensity of the electron beam as it scans. With a sufficiently fast scan rate, a picture is painted on the screen. The entire picture is refreshed 50 to 80 times per second. A display controller interfaces with the graphics processor to load the contents of the frame buffer.

The LCD is rapidly replacing the CRT; its primary advantages are smaller space requirements and lower power. The LCD consists of two thin sheets of glass that are transparent to opposite polarization and contain transparent electrodes and (for *active* displays) switches. Light (either backlit or reflected) illuminates the glass. The sheets sandwich a semisolid gel that is transparent and rotates the light polarization. The rotation changes with an applied voltage, which would cause the gel to be opaque. The opacity depends on the applied voltage. Each pixel has two electrodes and appears as a capacitance. For high density, one glass sheet contains horizontal conducting traces connecting rows of electrodes and the second sheet contains vertical traces connecting columns. Each of the three primary colors are connected separately. The minimum pitch (0.25 mm) of each dot (all three primary colors) limits the screen resolution and varies between manufacturers. The pixels are addressed via the rows and columns. Similar to a CRT, each pixel is activated serially by first converting the byte/word in the frame buffer for

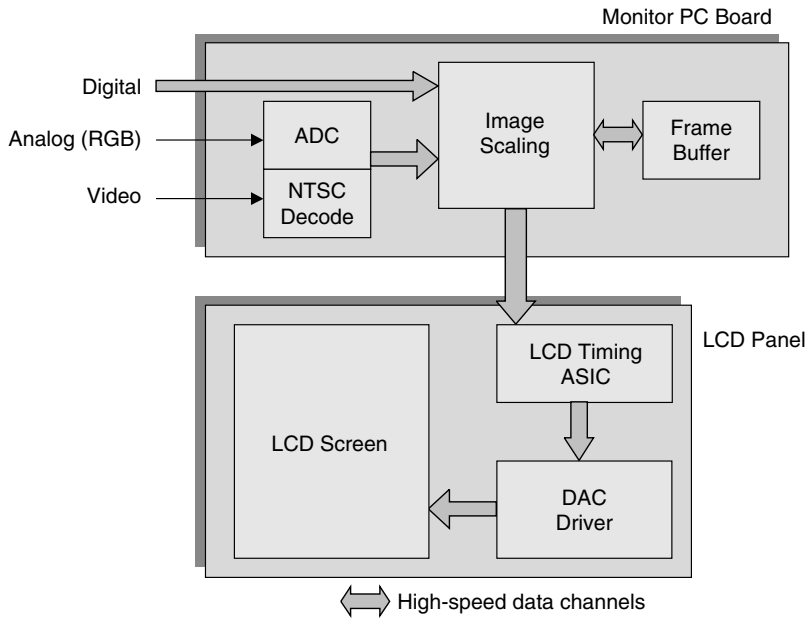

FIGURE 146.2 Liquid crystal display subsystem.

each color into an analog voltage and then driven onto the desired column. An LCD system is shown in Figure 146.2. Because of the capacitance of each pixel, driving a conductor loaded with pixels can be slow. This manifests as a shadow trailing behind a moving object on the screen. To improve the speed, manufacturers include a small transistor (thin-film transistor) for each color of a pixel. The transistor has little capacitance and can be switched quickly. The displays with the active switching are known as active-pixel LCD. Particularly for larger screens, LCDs are more costly than CRTs. Large LCDs have a low manufacturing yield because any processing defects result in dead pixels.

The connection between a display and a computer is a high-speed connection. A raw calculation of the data rate needed to load the frame buffer every refresh cycle would require several gigabits per second of transfer rate. Fortunately, not every pixel needs updating. The display controller substantially reduces the data bandwidth. However, the data rate still scales with screen size for a given resolution. I/O channels of multiple gigabits per second are used in display connections to support sufficient data bandwidth.

Printers

Another common output device is the printer. Printer technology can be classified into two main categories: impact and nonimpact. Impact printers are similar to a typewriter where small pins strike the paper through an ink ribbon. The resolution is limited by the size of the pins. Instead of using a pin, character printers limit the symbol set to predefined characters. Very fast and high-resolution character images can be produced but the application is limited. Impact technology has been, for the most part, replaced by nonimpact technology where the printer does not touch the paper. The dominant nonimpact printers are the inkjet printer and the laser printer.

Because of its low price, the inkjet printer is the most popular. Cartridges contain liquid black or multicolored ink and are attached to a print head. Very small droplets (50 to 60 nm) are dropped onto the paper, achieving resolution of up to 4800 × 1200 dots per inch (dpi). A droplet that has a well-controlled size is formed on a nozzle by various patented techniques such as vibration or heating. Each print head contains hundreds of nozzles. The printer head is scanned across the page and the paper is advanced. Both the scanning and paper feeding use accurate stepper motors. For color, several print heads are aligned and applied simultaneously. Because of mechanical scanning, the print speed is less than 20 pages per minute (ppm).

Laser printers are used for faster output. The printing operation is based on static charge. A rolling drum is first positively charged using a corona wire. A laser scans across the drum discharging portions of the drum. This process creates a negatively charged electrostatic pattern that is determined by the image to be printed. Positively charged toner, fine-colored plastic powder, is attracted to the pattern on the drum via electrostatic force. Then the powder is transferred to the paper via a stronger electric field using another corona wire. Finally, the paper is heated to melt the powder onto the paper. The drum is fully discharged before repeating. The typical resolution of a laser jet is 1200×1200 dpi, but can print at speeds up to 60 ppm because the laser scanning is considerably faster than mechanical scanning.

Printing resolution is considerably higher than display resolution. A large print buffer holds the print data. The high resolution and size of the document determines the size of the print job. For high-speed printing, the data bandwidth of the I/O channel between the computer and the printer can be very large. Instead of directly printing the transferred data, many printers contain a processor that can decode various compact data formats and compressed graphic formats. The I/O channel often limits the throughput for printing high-resolution graphics. Similar to displays, printer connections are moving toward multigigabit-per-second I/O channels.

Keyboards and Pointing Devices

One of the primary input devices is the keyboard. Key orientation varies slightly among manufacturers. Most abide by the QWERTY key arrangement. Similar to most peripheral I/O devices, the keyboard embeds a local processor. A matrix of conductors resides beneath the keys. As a user depresses each key, either the capacitance increases for that conductor, or a physical connection is made between two conductors beneath the key. The processor senses the change and interprets the meaning. The processor must handle multiple simultaneous depressions. Since key press may bounce, the processor must also filter the input and distinguish a bounce from a rapid series of presses. The keyboard processor transfers an encoded, 8-bit value of the keystroke to the computer.

Accompanying the keyboard is typically a mechanism for pointing to a location on a screen. A touch screen directly translates the pen location to the screen. The mechanism is very similar to that of a keyboard. By using additional layers of transparent conductors on the screen, the tap on a screen can be sensed as a change in the electrical resistance of the conductors. The resistance drops at the x and y location of the touch. Capacitive sensing is also possible through either using a mesh or charging a glass plate. When a user touches the screen, sensors measure a change in charge at the edges of the screen and estimate the location by comparing the differences between the sensors.

The most common pointing tool for computers is still the mouse. The introduction of the mouse dates back to 1960s and has become ubiquitous in the 1980s. The pointer on the screen, the cursor, has a reference origin chosen by the software. The mouse movements introduce Δx and Δy that adjust the current cursor position. The mouse contains a small processor that transfers the position adjustment periodically to the computer. A typical transfer rate is 40 reports per second or 1200 bits per second. The mouse consists of a rubber ball that drives an x shaft and a y shaft. Each shaft connects to a wheel that has slots on the surface. For each direction, an LED and optical sensor detects the amount of rotation with the number of pulses and the speed of rotation with the rate of the pulses. The mouse processor interprets the pulses into a binary adjustment to the registers that store the position.

In 1999, Agilent introduced an improved mouse based on optical sensing. Older models of optical mice require a special pad with a reflecting surface and a grid for the optics to determine the cursor position. The new optical mice rely on sophisticated digital signal processing (DSP) with an LED and a sensor array. The mouse can detect an image of the area beneath the mouse at 1500 images per second. Since processing chips are inexpensive, a DSP detects changes in the image pattern to determine Δx , Δy , and rate of motion. With no moveable parts that may fail or collect dust, the optical mouse is rapidly replacing the wheeled mice.

For portability, laptops use touch pads and strain gauges. Touch pads are very similar to touch screens without needing the absolute position. Strain gauges are small knobs situated within the keyboard. The cursor direction and speed are based on the amplitude of strain in both the x- and y-axes.

TABLE 146.1 Human-to-Machine Data Rates

| Human | Data Rate | Machine |
|--------------------|---------------|-------------------------------|
| Reading text | 30 to 375 B/s | Alphanumeric display |
| Typing at 100 wpm | 10 to 20 B/s | Keyboard |
| Pointing/selecting | 1 kB/s | Mouse; TrackPoint II™; tablet |
| Hearing | 8 to 60 kB/s | Speakers |
| Voice | 3 to 15 B/s | Microphone |

Human-oriented input devices typically do not limit a CPU's throughput because they require little data bandwidth. Table 146.1 summarizes the data rate for various human-machine interfaces.

Nonhuman Interface

Many I/O devices do not have a human interface. Some are machines that are slave devices to a CPU and responds to queries from the CPU such as memories and storage. Other I/O devices serve as communication between peers such as modems and multiprocessor interconnections. In fact, many human-oriented I/O devices have internal processors that run built-in operating systems and communicate with the CPU. This section briefly discusses these devices.

Main Memory

The memory storage for CPU is organized hierarchically with the low-latency but small-capacity level residing on chip as the first and second levels. The bulk of the memory for CPUs is off-chip dynamic RAMs (DRAMs) configured as a multidrop bus module. Although memory modules are often not considered to be a computer I/O, it is an important I/O port for the CPU. Each module contains up to eight ICs and can currently provide 1 Gb of storage capacity. The DRAM IC utilizes a dense capacitor arrays. Each capacitor dynamically stores charge and the amount of charge corresponds to a binary bits. Specialized processing of the capacitor is needed to achieve extremely high density while maintaining roughly 40 fF of capacitance. The minimum capacitance guarantees reliable charge storage that can withstand leakage, noise, and radiation. The module is connected to the CPU through a memory controller. The interface has a significant impact on system throughput and has very high data bandwidths and low latencies. A high-speed memory channel has bandwidth of 1.6 Gb/s with a latency of 40 ns.

Storage

Disks provide even larger storage capacity at low cost. Disks vary depending on their storage mechanism. The most common are magnetic disks (hard drives, tapes) and optical disks (CDs and DVDs). Data are stored on a platter or tape. Access times are significantly slower than DRAMs and depend on the physical mechanism of moving a sensing head to the appropriate location on the platter. Many architectures use multiple heads to speed along the search. Sequential access rate is considerably faster but are still slower than a DRAM due to the signal processing needed to recover the bit.

Magnetic disks are based on a magnetic recording medium in which the direction of the magnetic field over a small domain can be programmed. Writing data onto the platter involves moving a magnetic coil over the surface. With a sufficient magnetic field, the magnetic domain retains the direction. Reading involves using a sensitive magnetoresistive material on a moving head that senses the magnetic field from the domain. Hard disks comprised of multiple platters accessed in parallel with multiple heads. The platter spins under the head at speeds of 7200 to 10,000 rotations per minute. Data can be continuously read while the platter spins. The head moves along the radius to read different areas of the platter.

Optical disks operate in a similar manner except the storage mechanism is different. Instead of a magnetic domain, the platter is marked with very small bumps (1.6 μm in pitch between bumps for CDs and 0.74 μm for DVDs). A laser scans over the bumps to detect a difference in the reflection. A light sensor outputs pulses to indicate the data bits. To maintain constant bump density and constant sampling

rate across the disk, the rotation slows as the head moves radially outward. Because of the extraordinary density of CDs and DVDs, magnetic tapes have become much less common mediums.

The data rate for hard drives or CDs depends not only on platter size and rotation speed but also on the number of storage drives. Due to parallel access, the data rate for disks is not limited by the access latency of a single platter or disk.

Flash Memory

Recent advancements in electrically erasable and programmable ROMs have enabled dense, solid state nonvolatile memories known as flash ROMs or flash memories (with brand names such as Memory Stick, SmartMedia, etc.). Each IC can store several gigabits and several can be combined to form a very small memory card ranging from 32 to 512 Mb of capacity. Flash memories use specially processed transistors that behave as programmable switches. Each switch can be programmed to conduct or not conduct by using a large voltage (10 V). The initial write can take up to 7 μ s but subsequent serial writes can achieve rates near that of DRAMs of 50 ns. With considerably faster access times, the form factor of a quarter and no moving parts, flash memory cards serve as the ultimate portable electronic file. The technology is more costly than disks and is limited in the number of write/erase cycles.

Networking

Another type of I/O device enables peer-to-peer communication between computers, also known as computer networking. The physical distance between computers may range from a few meters to hundreds of kilometers. The data are not directly transmitted from one computer to the next. Depending on distance, the data may travel over many segments with differing mediums and protocols. The mediums may be optical fiber, shielded cables, unshielded cables, or wireless. The protocols may include transmission by packets (inserting headers and addresses), flow control, error correction, data encoding, data modulation, and so on. For a better understanding of networking layers and protocols, see the excellent texts appearing in the Bibliography section.

For a computer, the I/O device is a modem or network interface card (NIC). The NIC is an intelligent adapter that converts the data from the CPU into a format that can be transmitted over long distances. The transmitted signals are often analog in nature and modulated/encoded to ensure reliable transmission. Data flows back and forth so that erroneous data can be detected and resent. The transmitted signals have long latencies due to distance, so latency within the modem is typically not a concern.

Common interface standards are Ethernet (data rates of 10, 100, and 1000 Mbps), dial-up modems (300 to 56 Kbps), and xDSL (256 Kb to 20 Mbps). Although Ethernet has the highest transmission rates, it requires a high-quality connection with a shielded twisted-pair cable (CAT-5) for each segment. Cables from each computer are concentrated at a switch that redirects the data between the inputs. Each computer is assigned an address (unique name) and the information is transmitted in packets. The switching depends on the target computer's address associated with the data packet. Because homes are typically wired with high-performance cables, as an alternative, computers communicate from homes using the existing telephone cables. Computers can *dial up* a network provider and transmit data over the frequency bandwidth allotted for voice communication. Advances in the technology have reach data rates of 56 Kbps which very near the theoretical limit of data transmission in the medium. For further increase in bandwidth, telephone companies must relax the frequency bandwidth requirement with an explicit modem at the local switchbox. xDSL (digital subscriber line) are standards that can extend the home connection upward to 20 Mbps.

Table 146.2 and Table 146.3 list some of the performance and characteristics of the nonhuman interfaces.

146.2 I/O Subsystem

Most I/O events are not synchronous to the operation of the CPU. The data format to/from the I/O is not compatible with the CPU and hence an I/O cannot directly connect to the processor. In order to

TABLE 146.2 Storage I/O

| Device | Storage | Transfer Rate | Latency | Seek Time |
|--------------|----------------|----------------|--------------------|-------------------------|
| Floppy disk | 1.44 Mb | 0.125–1 Mb/s | 50–150 ms | 100–200 ms ^a |
| Disk drive | — ^b | — | 2–16 ms | 8–10 ms |
| CD ROM | 0.6–1.8 Gb | 0.15–6 Mb/s | 80 ms | 70–160 ms ^c |
| DVD ROM | 7 Gb | 1.35–21.6 Mb/s | 95 ms | 80–240 ms |
| Flash memory | 32–512 Mb | — | 40 ns ^d | — |

^a 500 ms spin-up time.

^b Disk arrays can have hundreds of gigabytes and a transfer rate that depends on ATAPI.

^c 6 s spin up time.

^d 7 μ s initial access.

TABLE 146.3 Networking I/O

| Medium | Bandwidth | Mode |
|-----------------|------------------|------|
| Telephone modem | 56 kb/s | C |
| xDSL | 256 kb/s–10 Mb/s | C |
| Wireless LAN | 200 kb/s | P |
| Ethernet | 10–1000 Mb/s | P |

Note: C, connection; P, packet.

TABLE 146.4 Processor Buses

| Bus | Data Width | Transfer Data Rate |
|-------------|------------|--------------------|
| ISA | 8, 16 | 8.33 Mb/s |
| EISA | 32 | 33 |
| PCI | 32, 64 | 133 |
| PCI express | 1, 4, 12 | 625–7500 |

Note: ISA, industry standard architecture; PCI, peripheral component interconnect; EISA, extended ISA; PCI express, a point-to-point PCI.

query a CPU or respond to a query, the data must pass through an I/O adapter that accompanies the device to “translate.” Once connected, there are several modes by which an I/O device can request the attention of a CPU with differing levels of intrusion and inefficiency. A device driver, or software that is part of the operating system specific to the I/O device, regulates the interface. In its entirety, the I/O subsystem appears to a computer user as a combination of both software and hardware. This section provides an overview of this subsystem.

I/O Adapters

As shown in the previous section, each I/O device connects to the computer with differing connectors and protocols. In order for each device to interface uniformly with the CPU, an *I/O adapter* must be used. Unlike cable adapters which only change the form factor of the connector, an I/O adapter converts the electrical signals and the signaling protocol into one that a CPU and memory can understand. Interestingly, this is similar to a network. Because of the short distances and latency concerns, the I/O adapter performs much less signal processing and error correction than typical communication networks.

CPU interfaces have evolved over time. Table 146.4 shows the transfer rates for various processor buses starting from the early ISA bus to the newly specified PCI Express. The most common interface for current personal computers is the peripheral component interconnect (PCI) bus. As illustrated in [Figure 146.3](#), PCI is a multidrop bus that allows connections to I/O devices, a memory controller, a storage controller (ATA), a graphics port (AGP), and bridges to older interfaces such as ISA. Because PCI is a shared bus, the I/O adapter is responsible for placing the data onto the bus with the appropriate timing. In addition to behaving as a bridge between the I/O device and the CPU, the I/O adapter can be designed to have significant processing and storage capability. It can often serve to detect errors in the data transmission, collect status information, and buffer data. A graphics card is one such example. Many personal computer motherboards use a single “super I/O processor” to handle most of the standard I/O interfaces such as keyboard, mouse, audio, and even simple networking.

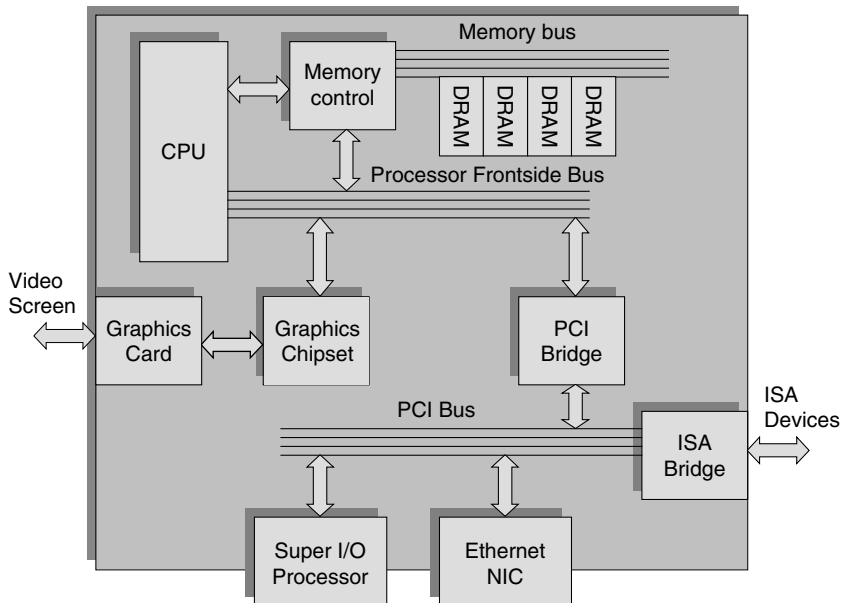

FIGURE 146.3 CPU I/O bus.

CPU Interface Modes

Once the physical connection has been established, depending on the design, different I/O devices require varying degrees of attention from the CPU. These interface modes can be classified into three main categories: programmed I/O, interrupt-driven I/O, and direct memory access. Typically, the CPU supports all three modes and each is needed by a particular I/O device and adapter.

In programmed I/O, the software code directly controls the CPU with specific I/O access commands. The CPU is directly programmed to read and write data, control, and status information to and from the I/O device. There is very little processing done in the I/O adapter. Since an I/O's bandwidth requirement varies, in a simple implementation the CPU periodically checks for an I/O event. This is known as *polling*. If the I/O device responds positively, the CPU acts to grab the new information. Because of the continuous attention from the CPU, the mode sacrifices throughput.

With a more intelligent I/O adapter, the CPU can offload the task of the continuously polling. However, the I/O adapter would interrupt the CPU upon new information or a hardware event. An interrupt handler determines the appropriate sequence of operations. The CPU must halt its execution, save the state of the execution, and service the interrupt. The original operation resumes after the interrupt is serviced. Interrupt handling must deal with the importance of an interrupt and simultaneous interrupt requests. When the CPU is running an important operation, the handler may need to disable the interrupt system. Otherwise, interrupts can be prioritized based on a priority mask that accompanies the interrupt. A particular interrupt can be disarmed or masked to ignore or postpone its service depending on the priority. Important interrupts, such as impending system failure, would be flagged as unmaskable. Interrupt handlers are increasingly complex because current CPUs are deeply pipelined (requiring more than ten clock cycles for a single operation), and can handle multiple streams of execution. Both software and hardware scheduling can help determine if the interrupt requires the CPU to fully halt its execution or to simply treat it as another stream.

An interrupt-driven I/O typically informs the CPU of an I/O event, and then the CPU proceeds to load or store the I/O data. If the data block is large, the transfer occupies the CPU and the system throughput decreases. To minimize the impact of large data transfers, some I/O adapters are given *direct memory access* (DMA). A specific location and size in either the physical memory or the virtual memory

is allotted to the I/O. A DMA controller writes the block of data from the I/O sequentially into the memory. Traditionally, a count is decremented starting from the desired block size. The transfer stops when the count decreases to zero. For some data transfers, the block size can be varied and even dynamically adjusting during data transfer. Once the desired block size is reached, the controller flags an interrupt to the CPU. Depending on the I/O device, the DMA controller can reside either in the I/O adapter (first-party DMA transfer) or externally in the memory controller (third-party DMA transfer). Whereas an interrupt-driven I/O mode would work well for the low data rate 56 K modem, DMA transfers are commonly used for storage devices or high-bandwidth network connections.

Device Drivers

The final part of the I/O subsystem links the software application with the I/O adapter and interrupt handler. The computer's operating system must recognize the I/O device; thus, an additional piece of software known as the *device driver* is installed into the operating system along with the installation of a new device. The driver provides a device name and memory location that the software can address. Instead of burdening a software programmer with knowing the specifics of an I/O device, the driver manages the I/O events and provides some degree of user programmability. The driver deals with resetting and arming interrupts, initializing the DMA controller, starting the I/O adapter, accessing status bits, handling errors, and so on.

146.3 I/O Channel

As seen in the previous section, the I/O connection between the I/O device and the CPU is not direct. It consists of the communication between three different processors: the processor resident on the device, the I/O adapter or I/O processor, and the CPU. The arrangement is not unlike a small network. As is typical of a network, different segments have different interface standards and bridges (I/O processors) convert between the standards. This section focuses on the segments and looks at some of the common physical mediums and specifications of the I/O channel.

Cables

The quality of a transmission medium is determined by signal loss. A signal propagating along a conductor establishes electric and magnetic fields with a nearby conductor (or conductors). Although the nearby conductor(s) may be grounded and do not carry a signal, they provide a path for the signal's return current that results from the terminating fields. The signal propagation depends on both conductors. Series resistance of the conductors appears as signal loss. Due to a phenomenon called *skin effect*, the series resistance increases with signal frequency. Nonuniform physical arrangements of the conductors from manufacturing imperfections result in varying fields, which also cause additional signal loss at higher frequencies. Therefore, transmission mediums such as cables or traces on a printed circuit board (PCB) appear as low-pass filters. The attenuation is proportional to the length of the transmission medium. High-quality cables use a metal layer around the signaling conductors to shield the signals and provide a uniform return path. Unshielded cables may use several conductors in parallel to provide the signal's return path. Pairs of wires are often twisted together (twisted pairs) to and driven differentially to guarantee their physical and electrical relationship.

A channel that connects between two IC can be described in many ways. Signals may be single ended or differential (where two signals with opposing polarity carry the data). The connection may be a point-to-point link or multidrop bus (where multiple ICs hang from each PCB trace). The channel may be parallel (where many single-ended or differential signals propagate the data) or serial (where only one or few signals are used). The connection may be simplex (only one direction of signal propagation); half-duplex (both directions of signal propagation are possible at different times); full duplex (both directions

TABLE 146.5 RS-232 Pin Assignments

| D-type-25 Pin no. | D-type-9 Pin no. | Abbreviation | Full Name |
|-------------------|------------------|--------------|---------------------|
| Pin 2 | Pin 3 | TD | Transmit data |
| Pin 3 | Pin 2 | RD | Receive data |
| Pin 4 | Pin 7 | RTS | Request to send |
| Pin 5 | Pin 8 | CTS | Clear to send |
| Pin 6 | Pin 6 | DSR | Data set ready |
| Pin 7 | Pin 5 | SG | Signal ground |
| Pin 8 | Pin 1 | CD | Carrier detect |
| Pin 20 | Pin 4 | DTR | Data terminal ready |
| Pin 22 | Pin 9 | RI | Ring indicator |

of signal propagation on different wires), or simultaneous bidirectional (both directions on the same physical wire).

There is a myriad of different cables and connectors in a computer system. Over short distances, the connection is through the PCB. For instance, the motherboard of a computer provides the connection between the CPU and I/O adapters through the PCI bus. The board is made with multiple insulating layers sandwiching patterned metal traces. Internal layers are often used as the controlled return path for the traces above it. To connect between PCBs within a machine's chassis, many use ribbon cables, a broad linear array of wires in parallel. The ribbon cable's poor frequency characteristic is not an issue over such short distances. Also the weak mechanical integrity of the cable and connector are protected within a computer's casing.

Many connections to the computer chassis use shielded cables and D-type connectors. A standard connection is the 25-pin or 9-pin connector for the RS-232 serial port. Table 146.5 shows the pin specifications for an RS-232 port. The protocol transmits data with two wires: one to transmit, and one to receive. The connection is named serial in contrast to using many wires in parallel to carry the data. The simple connection at 20 Kbps can be used over several tens of meters. The RS-232 protocol has been widely used for printers, scanners, and even single peer-to-peer computer connection. The 50-pin D connector is often used for the small computer systems interface (SCSI), a parallel connection for higher bandwidth. Similar to the D-type connector is the VGA connector with three rows of pins for a high-speed display connection. Small and round Deutsche Industrie Norm (DIN) connectors are the standard keyboard connectors. Telephone cables are unshielded twisted pair with the small rectangular, RJ-11, connector jack. Similar but slightly larger in shape is the commonly used thin Ethernet connector, RJ-45. To support a high data rate, the Ethernet cable, CAT-5, consists of four shielded, twisted pairs.

New standards are slowly replacing many of the I/O channels. As systems require higher data bandwidths, faster connections are needed. For example, the PCI bus has evolved from 33-MHz data frequency using 84 pins/traces (32 bits in parallel) to 133-MHz data frequency across 150 pins/traces (64 bits in parallel). Even at its fastest, the aggregate data bandwidth is approximately 1 Gb/s. Instead of continuing this trend of wider multidrop data buses, computer system manufacturers are moving toward an even faster connection with much fewer pins in parallel and point-to-point connections called PCI express. Using as few as 90 pins, the CPU connects to each I/O adapter with up to 12 parallel full-duplex connections. Each point-to-point connects at 2.5 Gbps, hence providing for an aggregate data rate of 60 Gbps for future system generations. In another example, the hard-drive interface known as ATAPI (AT attachment packet interface) had evolved to a 40-pin ribbon cable that has a total 133-Mbps transfer rate. Serial ATA is a new serial standard that will allow a 600 Mbps transfer rate over a single differential line. Finally, universal serial bus (USB) is a generic point-to-point serial connection with a pair of differential full-duplex signals that can operate up to 480 Mbps. It is rapidly replacing the connection to most peripheral devices such as keyboard, mouse, printers, scanners, flash cards, cameras, and so on. For each of these serial interfaces, an I/O adapter would serve as a bridge or hub that translates between data rates and signaling protocols.

Channel Specification

The specifications of a high-performance I/O channel contain the information needed to implement an I/O device that can directly plug in to the computer. The example that follows is based on Infiniband (part of the PCI express) specification.

Each pin of the interface is defined with the appropriate signal. The channel consists of 4 to 48 data signaling pins (1, 4, or 12 differential duplex channels). For the motherboard, an additional 24 pins are allotted for the return path for the shield of the cable. The 13 pins provide the power and power control signals. Five more pins manage the link. Only the 48 data pins operate at 2.5 Gbps. Management signals operate at kilohertz data rates. Each pair of data pins (a lane) transmits differentially in a single direction.

Each lane serially transmits a byte. Bytes are sequentially transmitted across 1, 4, or 12 lanes. Each byte is encoded using 8 bits/10 bits (encoding 8 bits using 10 bits). The encoding removes the DC component in the signal and also allows special control bytes that do not represent valid data. The data or control blocks are broken into packets that use special bytes as headers and trailers. Errors are checked per packet using a cyclic redundancy checker (CRC).

The binary 2.5-Gbps signals are carefully defined, including not only the voltage levels but also the signal transition times. There is a maximum tolerable skew between lanes. Also defined are the noise requirements for both voltage and timing. For instance, the receiver must be able to receive minimum signal amplitude of 175 mV, hence limiting the maximum internal noise of the receiver. Figure 146.4 illustrates the *mask* for the received data eye. The eye is the result of folding and overlapping a long data waveform over the time of one bit. The mask indicates where the signal voltage may transition. The opening indicates the location where the data can be reliably sampled with little error.

As data processing speeds increase, higher performance I/O channels will be developed to improve system throughput. As optical cables and attachments become more affordable, more optical I/O channels can be expected. At the same time, as we increasingly depend on computing, new I/O devices will allow more seamless interaction with machines. For instance, instead of being bound to the computer with cables, wireless protocols for input devices will be forthcoming. Ultra-wideband (UWB) is a developing

FIGURE 146.4 Infiniband (PCI express) receives eye mask.

standard that can provide low-data-rate, short-distance connectivity. The recently available 60-GHz wireless frequencies may even provide high data rate wireless.

Peter J. Varman

Rice University

Memory and storage devices are ubiquitous components of digital electronic systems ranging from PDAs and MP3 players, to high-end supercomputers driving businesses and scientific research. At a fundamental level such devices simply remember encoded information stored in them for recall at a later time. For instance, digitally encoded video written onto the surface of a video disk by the manufacturer can be repeatedly read using a DVD player that retrieves the stored information. Cassette tapes, audio CDs, smart cards, memory sticks, memory cards, hard disks, and random access memory (RAM) are some of the many storage devices found in everyday applications.

147.1 Storage Basics

Digital storage devices store information encoded as strings of binary digits or bits. A bit is stored by changing some distinguishing physical property of the storage medium to represent its two values. Solid-state DRAM chips for instance, alter the electrical charge on a capacitor to represent a bit, hard disks flip the polarization state of tiny magnetic particles on its surface, optical WORM devices create tiny pits on the medium to store a bit, and future biologically inspired memory devices may use different molecular sequences to encode information.

In a write-once memory (also referred to as a read-only memory) like a WORM device or a ROM, the change of state is irreversible. Once the information has been written it cannot be changed. In contrast, read/write memory devices, such as DRAM and SRAM chips or magnetic disks, can be rewritten at will, with the new information replacing the previous contents. A read returns the last written information. In between these extremes are erasable memories such as flash memory, which can be rewritten several times up to some limit.

A nonvolatile memory maintains the stored state even when power is removed. Write-once devices are typically nonvolatile, as are some read/write memory like magnetic disks and tapes, and erasable devices such as flash. Nonvolatile storage is also referred to as persistent storage. In contrast, volatile memory devices revert to a neutral state when power is removed, effectively erasing any stored informa-

tion. DRAM and SRAM chips are volatile. Persistence in systems built from volatile devices can be obtained by using redundant uninterruptible power supplies.

Two fundamental characteristics of memory systems are speed and cost. Speed reflects how long it takes the device to read or to write information. The access time or read latency of a device is the time required for it to respond to a read request. The throughput or bandwidth of the device is the rate at which it transfers information. The relation between these terms can be illustrated by analogy with a photocopy machine making multiple copies of a single page. The time required for the first copy to be output is the latency, which includes the time required to scan the page and for internal processing. Subsequent copies of the page are output faster by the machine, because it can avoid the initial scan and can overlap processing steps required for successive copies. The throughput reflects the rate at which successive copies are produced. Device speeds vary greatly. Solid-state SRAMs and DRAMs have latencies of a few to tens of nanoseconds, respectively, while mechanically driven devices like magnetic tapes can have latencies on the order of seconds. A magnetic disk has a latency of tens of milliseconds, but can transfer data at the rate of several million bits per second. In a computer system, the term memory usually refers to fast devices that are directly accessed by the processor, while the term storage refers to slower devices further from the processor that are accessed using specialized hardware controllers under the supervision of operating system software.

Sequential memory devices can be read only in a fixed order, and consequently incur a high latency when accessing arbitrary sections of storage. Random access devices, in contrast, permit efficient access to any portion of the stored information. Audio CDs and audiocassette tapes are easily recognizable examples of random access and sequential memory devices respectively.

The cost of a memory or storage device is often expressed in cents per bit. The capacity of a device is the number of bits it can store. Speed, capacity, and cost are related; not surprisingly, slow high-capacity devices have a lower cost than low-capacity, high-speed devices. Computer systems are built with a combination of devices organized in a hierarchy to optimize cost and performance characteristics: the goal is to achieve performance close to the fastest devices in the hierarchy at a cost approaching that of the cheapest. A typical memory hierarchy ordered from fastest to slowest consists of processor registers, primary or L1 cache, L2 and L3 caches, main memory, magnetic disks, and magnetic tape. Computer system designers have engineered ingenious schemes using caching and virtual memory techniques, to give programs the illusion of having access to unlimited amounts of fast memory. The program image is stored in its entirety on slow disks; active portions of a program are automatically moved to fast memory on demand. By multiplexing the fast memory among the currently active segments of a program, these techniques achieve favorable cost/performance characteristics.

The reliability of a storage device is usually expressed in terms of the mean time to failure (MTTF). This figure of merit informally refers to the length of the continuous up-time of the device. Transient disturbances can result in the corruption of data stored on a device. To protect against random bit flips that destroy data integrity, error detection or error correcting codes (ECCs) are often employed. By adding a few extra bits to each fixed-length sequence of bits, it is possible to detect whether one or more bits have been corrupted and to reconstruct the original data from the corrupted bit sequence.

147.2 Memory Systems

This section introduces some of the major types of memory and discusses their operation in more detail. We begin with a description of RAM-based memory system organization, followed by discussions of RAM and DRAM architectures, associative memory, and nonvolatile memory devices.

Random Access Memory

Random access memory (RAM) refers to read/write memory whose contents can be accessed in arbitrary order. Logically, a random access memory system can be viewed as a table of uniquely addressed words. Each word is made up of a fixed number of cells; a cell stores a single bit of information. The number of bits (cells) in a word is the memory width. The memory is accessed using an n -bit address, which can

uniquely address any of 2^n words. To perform a read the processor provides the n -bit address to the memory system on a set of signal lines known as the address bus; following the read latency, the bits in the word are available to the processor on the data bus. To perform a write, the processor provides the memory system with the address and the bits to be stored on the address and data buses, respectively; the memory system stores the bits present on the data bus in the cells at the addressed word.

A RAM system is implemented using memory devices such as SRAM (static RAM) and DRAM (dynamic RAM). Early systems used individual SRAM- or DRAM-integrated circuit chips in dual inline packages (DIP) directly in implementing the memory system. Nowadays, memory devices are packaged as industry-standard modules such as SIMMs (single inline memory modules) and DIMMs (dual inline memory modules). Memory modules consist of several memory chips assembled on a single standardized small circuit board, thereby easing implementation and increasing reliability.

From the viewpoint of the processor, a DRAM chip appears as a scaled-down version of the memory system. Logically a DRAM chip may be viewed as having 2^m , B -bit-wide memory locations. The memory system is built by arranging the appropriate number of memory chips in a two-dimensional matrix; each row will implement a word of the memory. Early DRAM chips had a width of 1 bit ($B = 1$) to minimize the number of data pins on the chip. For instance, using individual $4K \times 1$ DRAM chips ($m = 12$, $B = 1$), a 1M-word, 32-bit-wide memory system would be constructed as a 256×32 matrix. The 20-bit word address is decoded as follows: 8 bits of the address are used to select one of the 256 rows of the matrix. Each chip in the selected row is activated, and the 12 remaining bits of the address are used to access a location in each chip in this row. The 32 individual bits, 1 bit per chip in the selected row, make up the desired word. Writing a word of memory is similar; one bit of the 32-bit word is stored in each chip of the activated row, at the same location in each chip.

Memory packaging like SIMM and DIMM incorporate several chips into the same module. It would take just 256 modules, each made up of $32 \times 4K \times 1$ DRAM chips, to implement the memory system described above, with each module providing an entire 32-bit word. Later generations of DRAM and SRAM chips were able to devote more pins for data, and memory widths of 4, 8, or 16 bits are common. With wider memory chips, fewer of them are needed to build a module of a given width, thereby improving power consumption and reliability, while reducing system complexity. Some SIMMs and DIMMs may also provide parity and error-correction bits for fault tolerance. Single-bit error detection is accomplished by having one extra bit beyond the required width of the module; error-correcting modules such as a 32/36-DIMM module have a 32-bit data width and 4 additional bits for error correction.

SRAM and DRAM Organization

Internally, a RAM chip is organized as a two-dimensional grid with a memory cell at each of the grid points. A memory cell stores 1 bit. The geometry of the grid is governed by physical constraints, and is usually different from the logical view of the system designer. A $1-K \times 1$ RAM chip for instance may be physically organized as a 32×32 grid, rather than a single column of 1024 cells. The 10-bit address in this case is split into two halves, referred to as the row address and column address, respectively: the five high-order bits are used to address the rows of the grid, and the five low-order bits selects one of the columns of the grid. The cell at the intersection of the activated row and selected column is the one that is accessed.

The differences between a DRAM and SRAM stem fundamentally from different implementations of the memory cell. In an SRAM, the cell consists of a cross-coupled logic circuit built from four to six transistors; a SRAM memory cell will indefinitely remember the bit written to it as long as it is powered. In contrast, a DRAM cell is made from a single transistor and capacitor, and its memory is transient. The DRAM cell is written by charging its capacitor. This charge slowly leaks out of the device in the form of an electrical current so that without special intervention the information stored in the cell is irrevocably lost. As a consequence, DRAM cells need to be periodically refreshed every few milliseconds or so. To refresh a cell, its contents are read and then written back again, thereby replenishing the charge on the capacitor as needed. The need for refresh circuitry complicates the design and operation of the DRAM interface, and impacts its operating speed since some portion of the time is used by the chip for refresh.

However, because of the small size of each cell, DRAM chips are much denser than SRAM and have four to six times the capacity. SRAM, by contrast, is much faster and consumes less power than the DRAM, but holds fewer bits per chip and is considerably more expensive than DRAM.

In order to conserve pins on the chip, the row and column addresses on a DRAM chip are multiplexed on the same set of pins on consecutive cycles. The DRAM controller first presents the row address to the chip, which stores it in an internal register abbreviated as RAS (row address select), and uses it to activate the addressed row. Next the column address is sent on the same pins; the chip stores the address in the internal CAS (column access select) register, and uses it to select the cell in the addressed column of the previously activated row. SRAM chips being less dense typically have separate pins for both row and column addresses and do not require the two-cycle addressing strategy of a DRAM.

During a read, the entire row of the DRAM addressed by the RAS register is read internally, and then written back again, thereby refreshing all the cells in that row. The DRAM controller performs refresh cycles in a periodic pattern; each refresh cycle refreshes one row. The controller cycles through the row addresses in order using either a distributed or block refresh mode. In the former, the refresh cycles are evenly spaced, with normal memory accesses occurring between consecutive row refresh operations. In block refresh, all refresh cycles are performed together without any intervening memory accesses. The smaller the number of rows the fewer the number of refresh cycles needed, favoring organizations with more columns than rows.

High-Performance DRAM

With modern processors operating at gigahertz clock rates, DRAM access latencies of tens of nanoseconds is a significant performance bottleneck. Consequently, a number of techniques spanning the device, architecture, compiler, and application levels have been developed to mitigate this problem. At the device level, evolution of the basic DRAM technology and architecture have resulted in current industry-standard DRAMs such as fast page mode (FPM) DRAM; extended data out (EDO) DRAM; synchronous DRAM (SDRAM); double data rate (DDR) SDRAM; and direct RAMBUS DRAM (DRDRAM).

Current DRAM designs have been optimized for burst modes of access, in which a number of adjacent memory words are read in succession. A FPM DRAM is organized so that whenever a cell is read, adjacent cells in the same row (or page) may be read quickly. Since these locations all have the same row address, accessing them only requires the column address to be incremented, decreasing their access latency. An EDO DRAM also allows FPM capability; in addition, it pipelines internal operations so that the period of time that data remain available on the data bus is increased, providing greater flexibility to the memory controller.

SDRAM, the current-volume industry-standard DRAM has several advantages over FPM/EDO. First, SDRAM operates synchronously with the system clock increasing performance, and provides flexible programmable block access modes to control burst length and column access order. In addition, the internal architecture of SDRAM supports a multiple bank organization. The separate banks can be controlled so that while one bank is being read, another can be primed by activating its RAS, an operation known as precharging. Consequently, different rows can also be accessed in burst mode as long as they reside in different banks, resulting in high memory bandwidth. DDR SDRAM is similar to SDRAM, but doubles the memory bandwidth by transferring data twice per clock cycle, at both the rising and falling edges of the clock.

Rambus memory is a proprietary memory technology invented by Rambus Inc. to provide high memory bandwidth. Rambus memory chips are called RDRAMs (Rambus DRAMs), and the memory modules are called RIMM. RDRAM is considered to be a revolutionary rather than evolutionary memory technology and necessitates a totally new memory architecture.

Content Addressable Memory

Unlike memory devices in which information is accessed by specifying the address or location of the desired information, content-addressable memories (CAMs) or associative memories access information

by value. Each block of memory contains additional logic in the form of a comparator that compares an input search value against a stored tag in the block. If the tag matches the input, the information associated with the selected block is retrieved.

Associative memories are used as main memory caches within a computer system. A cache is a small high-speed memory (usually SRAM) that stores a copy of frequently accessed main memory (DRAM) locations. Since many possible main memory locations may map to the same cache block, there must be some way of distinguishing the actual memory words that are currently stored in a cache block. The cache is organized as an associative memory whose search key is the main memory address of a word, and the data are the actual contents of the word. When the processor presents the address of a main memory location, the cache is associatively searched. If the desired address is found in the cache, the associated data can be immediately returned without the need to access the much slower DRAM memory.

Processor-in-memory architectures, which attempt to migrate processing logic closer to the memory, generalize the concept underlying associative memories and are an area of current research.

Nonvolatile Memory

Nonvolatile memory devices retain stored information even when power is removed. The basic solid-state nonvolatile memory is the read only memory (ROM) chip. ROM has evolved to include several variants, such as programmable ROM (PROM), erasable PROM (EPROM), electrically erasable PROM (EEPROM), and the ubiquitous flash memory. Unlike RAM, which can be read and written with equal ease, ROM devices are either unchangeable or require special operations to change the stored information.

Like RAM chips, the family of ROM devices also consists of an orthogonal grid of wires, with a bit stored at each grid point. Members of the family differ according to the type of circuit element at each grid point. In a ROM, the presence or absence of a diode between the row and column wires fixes the bit value stored at a grid point. A diode permits current flow between the column and row when energized, while the two wires are isolated if there is no diode at the grid point. A PROM allows the user to program the pattern of 0's and 1's at the grid points, rather than building it in at the time of manufacture. Equipment known as a PROM programmer is used to selectively blow out fuses between the column and rows at each grid point. Once programmed, the PROM cannot be altered. An EPROM permits the stored information to be altered, by first erasing the information using ultraviolet light, and then reprogramming the grid. Each grid point contains a two-transistor device that exploits quantum tunneling to coerce electrons to cross an insulating barrier in the presence of an applied voltage. When the voltage is removed, the electrons are trapped. Erasure using ultraviolet light causes the entire memory to be reset. An EEPROM permits selective erasure of the device by the application of a suitable electrical voltage. This allows the EEPROM to be altered in place without removing the chip, and without the need for specialized equipment. However, EEPROMs are too slow for applications that must make rapid changes to the stored data.

Flash memory is the latest generation of nonvolatile solid-state memory. Flash is used in the BIOS chip of PCs, digital cameras, memory sticks, PCMCIA Type I and Type II memory cards used as solid-state disks in laptop computers, and memory cards for video game consoles. Flash memory is similar to the EEPROM described above, but can be erased in units known as blocks, by the application of a high voltage using in-circuit wiring. Flash memory has a maximum number of erase cycles depending on the process, which can be a limitation in some applications. As the price of flash memory drops, it offers an alternative to hard disk technology in environments where reliability, speed, and power consumption are the dominant considerations.

A number of nonvolatile memory technologies are currently under research and development. Polymer memory uses the polarization state of a polymer chain instead of a transistor to record a bit of information. The advantages of the technology are low power, high capacity, and low cost. Its disadvantages are its slower speed compared to electronic memory, and destructive reads that necessitate rewriting circuitry for refresh. Polymer memory is thought to be a good candidate for portable devices such as MP3 players, digital cameras, PDAs, and other hand-held devices.

Magnetoresistive RAM (MRAM) technology is based on altering the magnetic polarity and consequent change of resistance in response to an electrical current. Its promise is density, speed, and nonvolatility, and is considered an alternative to flash memory. Another nascent technology, OUM, uses a thin film of chalcogenide alloy used in rewritable CDs and DVDs between electrodes, and electronically switches the material from crystalline to amorphous. Potential advantages include high density, low power and cost, ease of integration with existing technology, a nondestructive read cycle, and a lifetime of an estimated trillion writes.

147.3 Storage Systems

In this section, we focus on mass storage systems built from hard disks and magnetic tapes. The most common mass storage devices are hard disks, while magnetic tapes are used primarily for backup and archival storage. The current trend in storage systems is toward decentralized, networked storage decoupled from the server.

Magnetic Disks

Magnetic disks are the most common devices used in online mass-storage systems. Magnetic disks record information in the form of magnetic polarization of particles on its surface. A disk system consists of a number of platters mounted on a common spindle, with coupled read/write heads for each platter. A platter is made up of a number of concentric tracks, divided into smaller units known as sectors. A common sector size is 512 bytes, and is the smallest unit of access. The tracks in different platters line up to form a cylinder. Disk systems have shown remarkable improvements in capacity and performance over the past decade, resulting in dramatically decreasing costs. Innovations in technology have resulted in higher recording densities, smaller form factors, increased spindle speeds, and optimized transfer rates by the use of multizoned disks.

Reading and writing a disk is slow since it requires moving the head till it is positioned on the correct track, and then waiting for the correct sector to rotate under the head. The mechanical and rotational delay result in long access latencies. Reading or writing several consecutive sectors together in a block can amortize the positioning overheads. Software and hardware optimizers therefore chain together accesses to consecutive sectors to improve performance. For the same reason, I/O intensive applications like database systems place data so that it can be accessed in units of a track or cylinder. Low level hardware enhancements like track buffering store the contents of the entire track in an internal buffer as the disk rotates, avoiding rotational latency for accesses to different sectors on the same cylinder.

RAID Systems

RAID (redundant arrays of independent disks) systems provide increased storage capacity and higher bandwidth by incorporating several multiple disk drives within a single storage unit. Fault tolerance techniques are employed to cope with the increased probability of system failure arising from the use of multiple devices. RAID organizations, referred to as RAID level 0 through RAID 5, use different redundancy techniques for fault tolerance, similar to the use of parity and ECC codes in DRAM memory. RAID 1 uses data mirroring whereby the entire disk contents are replicated on a second disk. RAID 4 and RAID 5 employ the concept of a parity block for fault tolerance. The multiple disk system is viewed as a collection of stripes, composed of a block from each disk. One block of each stripe is designated as the parity block, and stores the bit wise exclusive or of the corresponding bits of the remaining blocks in that stripe. In the event of a single-disk failure, the blocks on the failed disk can be reconstructed from the blocks in the same stripe on the working disk. The storage overhead is much less than the 100% redundancy of RAID 1 systems. The penalty is an increase in write time since a write to a block requires a read-modify-write operation on the parity block as well. A RAID 4 system uses a single designated disk as the parity disk for all stripes. In RAID 5, the use of roving parity that associates different parity disks for different stripes, alleviates the parity-disk bottlenecking of a RAID 4 design. Other RAID organizations have since been proposed. RAID 6 permits the failure of up to two disks without data loss, by employing

either two parity blocks with differently computed parities, or employing a two-dimensional arrangement of disks with associated row and column parities. RAID 0 does not provide fault tolerance, but allows data to be striped across the disks, thereby facilitating high-bandwidth data transfers. Hybrid combinations such as RAID 10 and RAID53 attempt to combine the advantages of different RAID levels.

Networked Storage

Storage architecture and the interconnection of storage devices is one of the rapidly changing characteristics of modern computing systems. Traditional server-centric storage architectures use bus-based interconnects such as IDE (interface data exchange) or SCSI. These direct-attached architectures are finding it difficult to meet the growing demand for flexible, high-performance storage. To achieve desired scalability, decentralized storage architectures networked together to create a virtual storage pool have gained popularity.

A SAN or storage area network is a dedicated network connecting servers and storage devices. Storage subsystems such as disk arrays or magnetic tape backup units are accessed over this backend network without loading of the LAN. SANs facilitate sharing stored data among multiple servers by avoiding the three-step process (read I/O, network transfer, write I/O) required in transferring data on traditional server-hosted I/O architectures. Furthermore, they permit autonomous data transfer between devices simplifying backup and data replication for performance or reliability, and encourage the spatial distribution of devices on the network, while maintaining the capability for centralized management.

In a typical SAN, dedicated protocols such as fiber channel protocol (FCP) are used to transport SCSI commands from a host bus adapter (HBA) in the server, over the fiber channel optical (or copper) interconnection fabric, to storage units connected to the SAN. The high costs of fiber channel switch hardware, training, and support have spurred interest in an alternative SAN technology known as iSCSI. The iSCSI protocol uses TCP/IP (running over Gigabit Ethernet for instance) as the transport for SCSI commands, reducing costs by leveraging the networking infrastructure already developed for Ethernet-based systems. Furthermore, the solution naturally scales to wide area networks due to the use of Internet protocols like TCP/IP as the transport mechanism.

A network-attached storage (NAS) device allows many of the server functions to be offloaded directly to the device. Once a request is authenticated by the server and forwarded to the device, data transfer to the network proceeds independently without further involvement of the server. In principle, a NASD can be directly connected to the local area network or may serve as an independent module in a backend SAN.

As storage and memory systems get more complex with increased numbers of concurrent activities, automated management techniques for data allocation, replication, backup, compression, scheduling, and load balancing are becoming necessary for cost-effective deployment.

147.4 Summary

Memory and storage are fundamental components of all digital electronic devices. The range of technologies, devices, and system architectures employed is astounding. There will continue to be a push for innovative solutions to keep pace with ever-faster processor speeds, exponentially increasing data volumes, need for reliability for critical data, protection techniques for security, complexity, manageability, and performance. Research into new MEMS-based (micro electromechanical) storage, miniature devices based on nanotechnology, and biologically inspired memory hold the promise for revolutionary future developments.

List of Acronyms

| | |
|------|----------------------------|
| BIOS | Basic input/output system |
| CAM | Content addressable memory |
| CAS | Column address select |

| | |
|--------------|---|
| CD | Compact disk |
| DDR SDRAM | Double data rate SDRAM |
| DIP | Dual inline package |
| DIMM | Dual inline memory module |
| DRAM | Dynamic random access memory |
| DRDRAM | Direct RAM bus DRAM |
| DVD | Digital video disk |
| ECC | Error-correcting codes |
| EDO DRAM | Extended data out DRAM |
| EEPROM | Electrically erasable PROM |
| EPROM | Erasable PROM |
| FCP | Fiber channel protocol |
| FPM DRAM | Fast-page mode DRAM |
| HBA | Host bus adapter |
| IDE | Interface data exchange |
| ISCSI | SCSI over TCP/IP |
| L1 cache | Level 1 (or primary) cache |
| L2, L3 cache | Level 2 (level 3) or secondary cache |
| MEMS | Micro electromechanical systems |
| MP3 | A popular encoding and compression scheme for music |
| MTTF | Mean time to failure |
| NAS | Network attached storage |
| PDA | Personal digital assistant |
| PROM | Programmable read-only memory |
| RAID | Redundant array of independent disks |
| RAM | Random access memory |
| RAS | Row address select |
| ROM | Read-only memory |
| SAN | Storage area network |
| SCSI | Small computer system interface |
| SDRAM | Synchronous DRAM |
| SIMM | Single inline memory module |
| SRAM | Static random access memory |
| WORM | Write once/read many |

Further Information

In the United States, the most relevant professional organizations that sponsor publications and conferences related to memory and mass storage systems are the Institute of Electrical and Electronics Engineers (IEEE) and the Association for Computing Machinery (ACM). In particular, *IEEE Transactions on Computers*, *ACM Transactions on Computer Systems*, *IEEE Journal of Solid-State Circuits*, IEEE/NASA Symposia on Mass Storage Systems and Technologies, USENIX Conferences on File and Storage Technologies, IEEE/ACM International Symposia on Computer Architecture, ACM Symposium on Parallel Algorithms and Architectures, IEEE/ACM International Conferences on Architectural Support for Programming Languages and Operating Systems, and ACM Symposia on Operating Systems Principles are excellent sources for up-to-date technical information on designing, building, and using memory and mass storage systems.

This chapter discusses far-reaching developments in design, analysis, modeling, and synthesis of nanocomputers using nanotechnology. In particular, nanoICs can be applied to synthesize and design nanocomputers utilizing two- and three-dimensional architectures. The nanoarchitectronics paradigm allows one to develop high-performance nanoICs utilizing recently developed nanoelectronics components and devices, including nanoscale transistors, switches, capacitors, etc. Nanotechnology offers benchmarking opportunities to fabricate the components needed, and to date, different nanotechnologies are under developments. Though molecular-, single-electron, carbon-, silicon-, GaAs-, and organic-based electronics has been developed to fabricate nanodevices, and promising pioneering results have been reported, it is difficult to accurately predict and envision the most promising high-yield affordable technologies and processes. Correspondingly, while covering some nanotechnologies to fabricate nanodevices and nanoICs, this chapter focuses on the advanced concepts in fundamental and applied research in nanocomputers synthesis, design, and analysis. Mathematical models are developed using nanodevices and nanoICs behavior description. The models proposed are straightforwardly applied to perform analysis, design, simulation, and optimization of nanocomputers. Novel methods in design of nanocomputers and their components are documented. Fundamental and applied results documented expand the horizon of nanocomputer theory and practice. It is illustrated that high-performance nanocomputers can be devised and designed using nanoICs integrated within the *nanoarchitectronics* concept to synthesize two- and three-dimensional computer topologies with novel robust fault-tolerant organizations.

^{*}Parts of this chapter were published in: S. E. Lyshevski, Nanocomputer Architectronics and Nanotechnology, in *Handbook of Nanoscience, Engineering, and Technology*, W. A. Goddard, D. W. Brenner, S. E. Lyshevski, and G. J. Iafrate, Eds., CRC Press, Boca Raton, FL, 2003.

148.1 Introduction

Recently meaningful applied and experimental results in nanoelectronic have been reported [1–15]. Though fundamental research has been performed in analysis of nanodevices, limited number of feasible technologies has been developed to date to design applicable nanodevices operating at room temperature. However, the progress made in integrated carbon/silicon-based technology provides the confidence that nanoscale devices will be mass-produced in the nearest future. Unfortunately, no perfect nanodevices and large-scale nanodevice assemblies (matrices) can be fabricated. Correspondingly, novel adaptive and robust computing architectures, topologies, and organizations must be devised and developed. Our goal is to further expand and apply fundamental theory of nanocomputers, develop the basic research towards the sound nanocomputer theory and practice, as well as report the application of nanotechnology to fabricate nanocomputers and their components.

Several types of nanocomputers have been proposed. For last thousand years the synthesis and design of computers have been performed as a sequence of different paradigms and changes, e.g., from gears to relays, then to valves and to transistors, and recently (in 1980s) to integrated circuits [16]. Currently, the ICs technology progressed to the point that hundreds of millions of transistors are fabricated on 1 cm² silicon chip. The transistors are downsized to hundreds of nanometers using 50- and 70-nm fabrication technologies. However, the silicon-based technology reaching the limit, and scaling laws cannot be applied due to the fundamental limitations and basic physics. Nanotechnology allows to fabricate nanoscale transistors that operate based on the quantum mechanics paradigms. Furthermore, computing can be performed utilizing quantum principles. Digital computers use bits (charged is 1 and not charged is 0). A register of 3 bits is represented by eight numbers, e.g., 000, 001, 010, 100, 011, 101, 110, and 111. In the quantum state (quantum computing), an atom (one bit) can be in two places at once according to the laws of quantum physics. Therefore, two atoms (quantum bits or qubits) can represent eight numbers at any given time. For x number of qubits, 2^x numbers are stored. Parallel processing can take place on the 2^x input numbers, performing the same task that a classical computer would have to repeat 2^x times or use 2^x processors working in parallel. Therefore, quantum computer offers an enormous gain in the use of computational resources in terms of time and memory. Unfortunately, limited progress has been made to date in practical application of this concept. Though conventional computers require exponentially more time and memory to match the power of a quantum computer, it is unlikely that quantum computers become the reality in the near observable future. Correspondingly, experimental, applied, and fundamental research in nanocomputers has been performed to significantly increase the computational and processing speed, memory, and other performance characteristics utilizing novel nanodevices through application of nanotechnology (rather than solely rely on the quantum computing and possible quantum computers due to existing formidable challenges). Nanocomputer will allow one to compute and process information thousands times faster than advanced computers.

Bioelectrochemical nanocomputers store and process information utilizing complex electrochemical interactions and changes. Bioelectrochemical nanobiocircuits that store, process, and compute exist in nature in enormous variety and complexity evolving through thousands years of evolution. The development and prototyping of bioelectrochemical nanocomputer and three-dimensional circuits have been progressed through engineering bioinformatic and biomimetic paradigms. Mechanical nanocomputers can be designed using tiny moving components (nanogears) to encode information. These nanocomputers can be considered as evolved Babbage's computer (Charles Babbage in 1822 built 6-digit calculator that performed mathematical operations using gears). Complexity of mechanical nanocomputers is a major drawback, and this deficiency unlikely can be overcome.

First-, second-, third-, and fourth-generations of computers emerged, and tremendous progress has been achieved. The Intel® Pentium® 4 (3 GHz) processor was built using advanced Intel® NetBurst™ microarchitecture. This processor ensures high-performance processing, and is fabricated using 0.13 micron technology. The processor is integrated with high-performance memory systems, e.g., 8KB L1 data cache, 12 K μops L1 Execution Trace Cache, 256 KB L2 Advanced Transfer Cache and 512 KB Advance Transfer Cache. Currently, 70 and 50 nm technologies are emerged and applied to fabricate

FIGURE 148.1 Moore's laws and nanotechnologies.

high-yield high-performance ICs with billions of transistors on a single 1 cm^2 die. Further progress is needed, and novel developments are emerging. The fifth generation of computers will be built using emerging nanoICs. This chapter studies the application of nanotechnology to design nanocomputers with nanoICs. Synthesis, integration, and implementation of new affordable high-yield nanoICs are critical to meet Moore's first law. Figure 148.1 illustrates the first and second Moore laws (reported data and foreseen trends can be viewed as controversial and subject to adjustments, however, the major trends and tendencies are obvious, and most likely cannot be seriously argued and disputed) [10].

Nanotechnology and far-reaching fundamental progress eventually will lead to three-dimensional nanoICs. This will result in synthesis and design of nanocomputers with novel computer architectures, topologies, and organizations. These nanoICs and nanocomputers will guarantee superior level of overall performance. In particular, compared with the existing most advanced computers, in nanocomputers the execution time, switching frequency, bandwidth, and size will be decreased by the order of millions, while the memory capacity will be increased by the order of millions. However, significant challenges must be overcome particularly in synthesis and design of three-dimensional nanodevices, nanoelectronics, and nanoICs. Many problems (novel nanocomputer architectures, advanced organizations, robust adaptive topologies, high-fidelity modeling, data-intensive analysis, heterogeneous simulations, optimization, reconfiguration, self-organization, robustness, utilization, and other) must be addressed, researched, and solved. Many of the above-mentioned problems have not been even addressed yet. Due to tremendous challenges, much effort must be focused to solve these problems. This chapter formulates and solves some long-standing fundamental and applied problems in synthesis, design, analysis, and optimization of nanocomputers utilizing nanoICs. The fundamentals of nanocomputer *architectronics* are reported, and the basic organizations and topologies are examined progressing from the general system-level consideration to the nanocomputer subsystem/unit/device-level study.

148.2 Nanoelectronics and Nanocomputer Fundamentals

In general, reversible and irreversible nanocomputers can be designed. Now days, all existing computers are irreversible. The system is reversible if it is deterministic in the reverse and forward time directions. The reversibility implies that no physical state can be reached by more than one path (otherwise, reverse evolution would be nondeterministic). Current computers constantly irreversibly erase temporary results, and thus, the entropy changes. The average instruction execution speed (in millions of instructions executed per second I_{ps}) and cycles per instruction are related to the time required to execute instructions as given by $T_{inst} = 1/f_{clock}$. The clock frequency f_{clock} depends mainly on the ICs or nanoICs used as well as upon the fabrication technologies (for example, the switching frequency 3 GHz was achieved in the existing Intel Pentium processors). The quantum mechanics implies an upper limit on the frequency at

which the system can switch from one state to another. This limit is found as the difference between the total energy E of the system and ground state energy E_0 . We have the following explicit inequality to find

the maximum switching frequency $f_i \leq \frac{4}{h}(E - E_0)$. Here, h is the Planck constant, and $h = 6.626 \times 10^{-34}$

J-sec or J/Hz. An isolated nanodevice, consisting of a single electron at a potential of 1 V above its ground state, contains 1 eV of energy (1 eV = 1.602×10^{-19} J) and, therefore, cannot change its state faster than

$$f_i \leq \frac{4}{h}(E - E_0) = \frac{4}{6.626 \times 10^{-34}} 1.602 \times 10^{-19} \approx 0.97 \times 10^{15} \text{ Hz.}$$

For example, the switching frequency can be achieved in the range up to 1×10^{15} Hz. We conclude that the switching frequency of nanoICs can be significantly increased compared with the currently used CMOS-technology-based ICs.

In asymptotically reversible nanocomputers, the generated entropy is found as $S = b/t_p$, where b is the entropy coefficient that varies from 1×10^7 to 1×10^6 bits/GHz for ICs, and from 1 to 10 bits/GHz for quantum FETs; t_p is the length of time over which the operation is performed. Hence, the minimum entropy and processing (operation) rate for quantum nanodevices are $S = 1$ bit/operation and $r_e = 1 \times 10^{26}$ operation/sec-cm², while CMOS technology allows one to fabricate devices with $S = 1 \times 10^6$ bits/operation and $r_e = 3.5 \times 10^{16}$ operation/sec-cm².

The nanocomputer architecture integrates the functional, interconnected, and controlled hardware units and systems that perform propagation (flow), storage, execution, and processing of information (data). Nanocomputer accepts digital or analog input information, processes and manipulates it according to a list of internally stored machine instructions, stores the information, and produces the resulting output. The list of instructions is called a program, and internal storage is called memory.

In general, nanocomputer architecture can be synthesized utilizing the following major systems: (1) input – output, (2) memory, (3) arithmetic and logic, and (4) control units.

The input unit accepts information from electronic devices or other computers through the cards (electromechanical devices, such as keyboards, can be also interfaced). The information received can be stored in the memory, and then, manipulated and processed by the arithmetic and logic unit (ALU). The results are output using the output unit. Information flow, propagation, manipulation, processing and storage (memory) are coordinated by the control unit. The arithmetic and logic unit, integrated with control unit, is called the processor or central processing unit (CPU). Input and output systems are called the input-output unit (I/O unit). The memory unit integrates memory systems that stores programs and data. There are two main classes of memory called *primary* (main) and *secondary* memory. The primary memory is implemented using nanoICs that can consist of billions of nanoscale storage cells (each cell can store one bit of information). These cells are accessed in groups of fixed size called words. The main memory is organized such that the contents of one word can be stored or retrieved in one basic operation called a memory cycle. To provide a consistent direct access to any word in the main memory in the shortest time, a distinct address number is associated with each word location. A word is accessed by specifying its address and issuing a control command that starts the storage or retrieval process. The number of bits in a word is called the word length. Word lengths vary, for example from 16 to 64 bits. Personal computers and workstations usually have a few million words in the main memory, while nanocomputers can have hundreds of millions of words with the time required to access a word for reading or writing within psec range. Although the main memory is essential, it tends to be expensive and volatile. Therefore, nanoICs can be effectively used to implement the additional memory systems to store programs and data forming secondary memory.

Using the number of instructions executed (N), the number of cycles per instruction (C_{pi}) and the

clock frequency (f_{clock}), the program execution time is found to be $T_{ex} = \frac{N \times C_{pi}}{f_{clock}}$. In general, the hardware

defines the clock frequency f_{clock} , the software influences the number of instructions executed N , while the nanocomputer architecture defines the number of cycles per instruction C_{pi} .

One of the major performance characteristics is the time that takes to execute a program. Suppose N_{inst} is the number of the machine instructions needed to be executed. A program is written in high-

FIGURE 148.2 Processor and memory hierarchy in nanocomputer with cache (primary and secondary), primary (main) memory, and virtual memories.

level language, translated by compiler into machine language, and stored. An operating system software routine loads the machine language program into the main memory for execution. Assume that each machine language instruction requires N_{step} basic steps for execution. If basic steps are executed at the

constant rate of R_T [steps/sec], then, the time to execute the program is $T_{ex} = \frac{N_{inst} \times N_{step}}{R_T}$. The main

goal is to minimize T_{ex} . Optimal memory and processor design allows one to achieve this goal. The access to operands in processor registers is significantly faster than access to the main memory. Suppose that instructions and data are loaded into the processor. Then, they are stored in a small and fast cache memory (high-speed memory for temporary storage of copies of the sections of program and data from the main memory that are active during program execution) on the processor. Hence, instructions and data in cache are accessed repeatedly and correspondingly. The program execution will be much faster. The cache can hold small parts of the executing program. When the cache is full, its contents are replaced by new instructions and data as they are fetched from the main memory. A variety of cache replacement algorithms are used. The objective of these algorithms is to maximize the probability that the instructions and data needed for program execution can be found in the cache. This probability is known as the cache hit ratio. High hit ratio means that a large percentage of the instructions and data are found in the cache, and the requirement to access the slower main memory is reduced. This leads to decreasing in the memory access basic step time components of N_{step} , and this results in a smaller T_{ex} . The application of different memory systems results in a memory hierarchy concept as will be studied later. The nanocomputer memory hierarchy is shown in Figure 148.2. As was emphasized, to attain efficiency and high performance, the main memory should not store all programs and data. Specifically, caches are used. Furthermore, virtual memory, which has the largest capacity but the slowest access time, is used. Segments of a program are transferred from the virtual memory to the main memory for execution. As other segments are needed, they may replace the segments existing in the main memory when the main memory is full. The sequential controlled movement of large program and data between the cache, main, and virtual memories, as programs execute, is managed by a combination of operating system software and control hardware. This is called the memory management.

Using the memory hierarchy illustrated in Figure 148.2, the CPU communicates directly only with M_1 , and M_1 communicates with M_2 , and so on. Therefore, for the CPU to assess the information, stored in the memory M_j , requires the sequence of j data transfer as given by

$$M_{j-1} := M_j, M_{j-2} := M_{j-1}, \dots, M_1 := M_2, CPU := M_1.$$

However, the memory bypass can be implemented and effectively used.

To perform computing, specific programs consisting of a set of machine instructions are stored in the main memory. Individual instructions are fetched from the memory into the processor for execution. Data used as operands are also stored in the memory. The connection between the main memory and the processor that guarantees the transfer of instructions and operands is called the bus. A bus consists of a set of address, data, and control lines. The bus permit transfer program and data files from their long-term location (virtual memory) to the main memory. Communication with other computers is ensured by transferring the data through the bus. Normal execution of programs may be preempted if some IO device requires urgent control. To perform this, specific programs are executed, and the device sends an interrupt signal to the processor. The processor temporarily suspends the program that is being executed, and executes the special interrupt service routine instead. After providing the required interrupt service, the processor switches back to the interrupted program. During program loading and execution, the data should be transferred between the main memory and secondary memory. This is performed using the direct memory access.

Nanocomputers can be classified using different classification principles. For example, making use of the multiplicity of instruction and data streams, the following classification can be applied:

1. single instruction stream/single data stream – conventional word-sequential architecture including pipelined nanocomputers with parallel arithmetic logic unit (ALU)
2. single instruction stream/multiple data stream – multiple ALU architectures, e.g., parallel-array processor (ALU can be either bit-serial or bit-parallel)
3. multiple instruction stream/single data stream
4. multiple instruction stream/multiple data stream – the multiprocessor system with multiple control unit

The execution of most operations is performed by the ALU. In the ALU, the logic nanogates and nanoregisters used to perform the basic operations (addition, subtraction, multiplication, and division) of numeric operands, and the comparison, shifting, and alignment operations of general forms of numeric and nonnumeric data. The processors contain a number of high-speed registers, which are used for temporary storage of operands. Register, as a storage device for words, is a key sequential component, and registers are connected. Each register contains one word of data and its access time at least 10 times faster than the main memory access time. A register-level system consists of a set of registers connected by combinational data-processing and data-processing nanoICs. Each operation is implemented as given by the following statement

$$\text{cond: } X := f(x_1, x_2, \dots, x_{i-1}, x_i).$$

Thus, when the condition `cond` holds, compute the combinational function of f on $x_1, x_2, \dots, x_{i-1}, x_i$ and assign the resulting value to X . Here, `cond` is the control condition prefix which denotes the condition that must be satisfied; $X, x_1, x_2, \dots, x_{i-1}, x_i$ are the data words or the registers that store them; f is the function to be performed within a single clock cycle.

Suppose that two numbers located in the main memory should be multiplied, and the sum must be stored back into the memory. Using instructions, determined by the control unit, the operands are first fetched from the memory into the processor. They are then multiplied in the ALU, and the result is stored back in memory. Various nanoICs can be used to execute data-processing instructions. The complexity of ALU is determined by the arithmetic instruction implementation. For example, ALUs that perform fixed-point addition, subtraction, and word-based logics can be implemented as combinational nanoICs. The floating-point arithmetic requires complex implementation, and arithmetic coprocessors to perform complex numerical functions needed. The floating-point numerical value of a number X is (X_m, X_e) , where X_m is the mantissa and X_e is the fixed-point number. Using the base b (usually, $b = 2$), we have $X = X_m \times b^{X_e}$. Therefore, the general basic operations are quite complex and some problems (biasing, overflow, underflow, etc.) must be resolved.

Memory–processor interface — A memory unit that integrates different memory systems stores the information (data). The processor accesses (reads or loads) the data from the memory systems, performs

FIGURE 148.3 Memory–processor interface.

computations, and stores (writes) the data back to memory. The memory system is a collection of storage locations. Each storage location (memory word) has a numerical address. A collection of storage locations forms an address space. Figure 148.3 documents the data flow and its control, representing how a processor is connected to a memory system via address, control and data interfaces. High-performance memory systems should be capable to serve multiple requests simultaneously, particularly for vector nanoprocessors.

When a processor attempts to load or read the data from the memory location, the request is issued, and the processor stalls while the request returns. While nanocomputers can operate with overlapping memory requests, the data cannot be optimally manipulated if there are long memory delays. Therefore, a key performance parameter in the design of nanocomputer is the effective speed of its memory. The following limitations are imposed on any memory systems: the memory cannot be infinitely large, cannot contain an arbitrarily large amount of information, and cannot operate infinitely fast. Hence, the major characteristics are speed and capacity.

The memory system performance is characterized by the latency (τ_l) and bandwidth (B_w). The memory latency is the delay as the processor first requests a word from memory until that word arrives and is available for use by the processor. The bandwidth is the rate at which information can be transferred from the memory system. Taking note of the number of requests that the memory can service concurrently

$N_{request}$, we have $B_w = \frac{N_{request}}{\tau_l}$. Using nanoICs, it become feasible to design and build superior memory

systems with desired capacity, low latency, and high bandwidth approaching the physical limits. Using nanoICs, it will be possible to match the memory and processor performance characteristics.

Memory hierarchies provide decreased average latency and reduced bandwidth requirements, whereas parallel memories provide higher bandwidth. As was emphasized, nanocomputer architectures that utilize a small and fast memory located in front of a large but relatively slow memory, can tremendously enhance speed and memory capacity by making use of nanoICs. This results in application of registers in the CPU, and most commonly accessed variables should be allocated at registers. A variety of techniques, employing either hardware, software, or a combination of hardware and software, are employed to ensure that most references to memory are fed by the faster memory. The locality principle is based on the fact that some memory locations are referenced more often than others. The implementation of spatial locality, due to the sequential access, provides one with the property that an access to a given memory location increases the probability that neighboring locations will soon be accessed. Making use of the frequency of program looping behavior, temporal locality ensures the access to a given memory location increasing the probability that the same location will be accessed again soon. It is evident that if a variable was not referenced for a while, it is unlikely that this variable will be needed soon.

As illustrated in Figure 148.2, the top of the memory hierarchy level are the superior speed CPU registers. The next level in the hierarchy is a high-speed cache memory. The cache can be divided into multiple levels, and nanocomputers will likely have multiple caches that can be fabricated on the CPU nanochip. Below the cache memory is the slower but larger main memory, and then, the large virtual memory which is slower than the main memory. These level can be designed and fabricated utilizing

different nanoICs. Three performance characteristics (access time, bandwidth, and capacity) and many factors (affordability, robustness, adaptability, reconfigurability, etc.) support the application of multiple levels of cache memory and the memory hierarchy concept. The time needed to access the primary cache should match with the clock frequency of the CPU, and the corresponding nanoICs must be used. We place a smaller first-level (primary) cache above a larger second-level (secondary) cache. The primary cache is accessed quickly, and the secondary cache holds more data close to the CPU. The nanocomputer architecture, build using nanoelectronics integrated within nanoICs assemblies, depends on the technologies available. For example, primary cache can be fabricated on the CPU chip, while the secondary caches can be on- or out-of-chip solution.

Size, speed, latency, bandwidth, power consumption, robustness, affordability, and other performance characteristics are examined to guarantee the desired overall nanocomputer performance based upon the specifications imposed. The performance parameter, which can be used to quantitatively examine different memory systems, is the effective latency τ_{ef} . We have

$$\tau_{ef} = \tau_{hit} R_{hit} + \tau_{miss} (1 - R_{hit}),$$

where τ_{hit} and τ_{miss} are the hit and miss latencies; R_{hit} is the hit ratio, $R_{hit} < 1$.

If the needed word is found in a level of the hierarchy, it is called a hit. Correspondingly, if a request must be sent to the next lower level, the request is said to be a miss. The miss ratio is given as $R_{miss} = (1 - R_{hit})$. These R_{hit} and R_{miss} are strongly influenced by the program being executed and influenced by the high-/low-level memory capacity ratio. The access efficiency E_{ef} of multiple-level memory ($i - 1$ and i) is found using the access time, hit and miss ratios. In particular,

$$E_{ef} = \frac{1}{\frac{t_{access\ time\ i-1}}{t_{access\ time\ i}} R_{miss} + R_{hit}}$$

The hardware can dynamically allocate parts of the cache memory for addresses likely to be accessed soon. The cache contains only redundant copies of the address space. The cache memory can be associative or content-addressable. In an associative memory, the address of a memory location is stored along with its content. Rather than reading data directly from a memory location, the cache is given an address and responds by providing data which might or might not be the data requested. When a cache miss occurs, the memory access is then performed from main memory, and the cache is updated to include the new data. The cache should hold the most active portions of the memory, and the hardware dynamically selects portions of main memory to store in the cache. When the cache is full, some data must be transferred to the main memory or deleted. Therefore, a strategy for cache memory management is needed. Cache management strategies are based on the locality principle. In particular, spatial (selection of what is brought into the cache) and temporal (selection of what must be removed) localities are embedded. When a cache miss occurs, hardware copies a contiguous block of memory into the cache, which includes the word requested. This fixed-size memory block can be small (bit or word) or hundreds of bytes. Caches can require all fixed-size memory blocks to be aligned. When a fixed-size memory block is brought into the cache, it is likely that another fixed-size memory block must be removed. The selection of the removed fixed-size memory block is based on effort to capture temporal locality. In general, this is difficult to achieve. Correspondingly, viable methods are used to predict future memory accesses. A least-recently-used concept can be the preferred choice for nanocomputers.

The cache can integrate the data memory and the tag memory. The address of each cache line contained in the data memory is stored in the tag memory (the state can also track which cache lines is modified). Each line contained in the data memory is allocated by a corresponding entry in the tag memory to indicate the full address of the cache line. The requirement that the cache memory be associative (content-addressable) complicates the design because addressing data by content is more complex than by its address (all tags must be compared concurrently). The cache can be simplified by embedding a mapping

of memory locations to cache cells. This mapping limits the number of possible cells in which a particular line may reside. Each memory location can be mapped to a single location in the cache through direct mapping. Although there is no choice of where the line resides and which line must be replaced, however, poor utilization results. In contrast, a two-way set-associative cache maps each memory location into either of two locations in the cache. Hence, this mapping can be viewed as two identical directly-mapped caches. In fact, both caches must be searched at each memory access, and the appropriate data selected and multiplexed on a tag match — hit and on a miss. Then, a choice must be made between two possible cache lines as to which is to be replaced. A single least-recently-used bit can be saved for each such pair of lines to remember which line has been accessed more recently. This bit must be toggled to the current state each time. To this end, an M -way associative cache maps each memory location into M memory locations in the cache. Therefore, this cache map can be constructed from M identical direct-mapped caches. The problem of maintaining the least-recently-used ordering of M cache lines is primarily due to the fact that there are $M!$ possible orderings. In fact, it takes at least $\log_2 M!$ bits to store the ordering. It can be envisioned that two-, three- or four-way associative cache will be implemented in nanocomputers.

Consider the write operation. If the main memory copy is updated with each write operation, then, write-through or store-through technique is used. If the main memory copy is not updated with each write operation, write-back or copy-back or deferred writes algorithm is enforced. In general, the cache coherence or consistency problem must be examined due to implementation of different bypass techniques.

Parallel Memories — Main memories can comprise a series of memory nanochips or nanoICs on a single nanochip. These nanoICs form a *nanobank*. Multiple memory *nanobanks* can be integrated together to form a parallel main memory system. Since each *nanobank* can service a request, a parallel main memory system with N_{mb} *nanobanks* can service N_{mb} requests simultaneously, increasing the bandwidth of the memory system by N_{mb} times the bandwidth of a single *nanobank*. The number of *nanobank* is a power of two, that is, $N_{mb} = 2^p$. An n -bit memory word address is broken into two parts: a p -bit *nanobank* number and an m -bit address of a word within a *nanobank*. The p bits used to select a *nanobank* number could be any p bits of the n -bit word address. Let us use the low-order p address bits to select the *nanobank* number, and the higher order $m = n - p$ bits of the word address is used to access a word in the selected *nanobank*.

Multiple memory *nanobank* can be connected using *simple paralleling* and *complex paralleling*. Figure 148.4 shows the structure of a simple parallel memory system where m address bits are simultaneously supplied to all memory *nanobanks*. All *nanobanks* are connected to the same read/write control line. For a read operation, the *nanobanks* perform the read operation and deposit the data in the latches. Data can then be read from the latches one by one by setting the switch appropriately. The *nanobanks* can be accessed again to carry out another read or write operation. For a write operation, the latches are loaded one by one. When all latches have been written, their contents can be written into the memory *nanobanks*

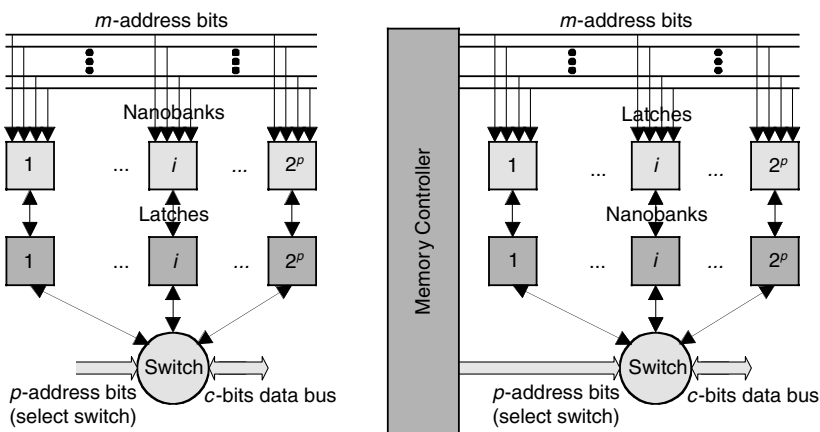

FIGURE 148.4 Simple and complex parallel main memory systems.

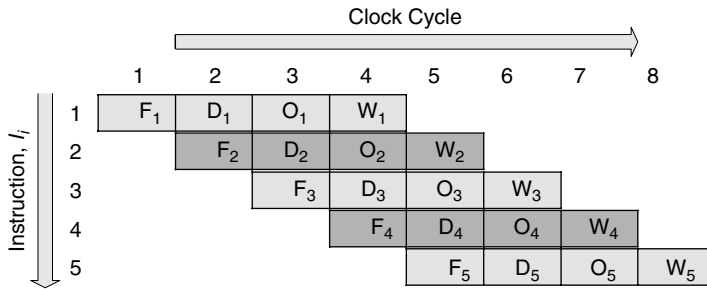

FIGURE 148.5 Pipelining of instruction execution.

by supplying m bits of address. In a simple parallel memory, all *nanobanks* are cycled at the same time. Each *nanobank* starts and completes its individual operations at the same time as every other *nanobank*, and a new memory cycle starts for all *nanobanks* once the previous cycle is complete.

A complex parallel memory system is documented in [Figure 148.4](#). Each *nanobank* is set to operate on its own independent of the operation of the other *nanobanks*. For example, i th *nanobank* performs a read operation on a particular memory address, while $(i + 1)$ th *nanobank* performs a write operation on a different and unrelated memory address. Complex paralleling is achieved using the address latch and a read/write command line for each *nanobank*. The *memory controller* handles the operation of the complex parallel memory. The processing unit submits the memory request to the memory controller, which determines which *nanobank* needs to be accessed. The controller then determines if the *nanobank* is busy by monitoring a busy line for each *nanobank*. The controller holds the request if the *nanobank* is busy, submitting it when the *nanobank* becomes available to accept the request. When the *nanobank* responds to a read request, the switch is set by the controller to accept the request from the *nanobank* and forward it to the processing unit. It can be foreseen that complex parallel main memory systems will be implemented in vector nanoprocessors. If consecutive elements of a vector are present in different memory *nanobank*, then the memory system can sustain a bandwidth of one element per clock cycle. Memory systems in nanocomputers can have hundreds of *nanobanks* with multiple memory controllers that allow multiple independent memory requests at every clock cycle.

Pipelining — Pipelining is a technique to increase the processor throughput with limited hardware in order to implement complex *datapath* (data processing) units (multipliers, floating-point adders, etc.). In general, a pipeline processor integrates a sequence of i data-processing nanoICs (nanostages) which cooperatively perform a single operation on a stream of data operands passing through them. Design of pipelining nanoICs involves deriving multistage balanced sequential algorithms to perform the given function. Fast buffer registers are placed between the nanostages to ensure the transfer of data between nanostages without interfering with one another. These buffers should be clocked at the maximum rate that guarantees the reliable data transfer between nanostages.

As illustrated in [Figure 148.5](#), the nanocomputers must be designed to guarantee the robust execution of overlapped instructions using pipelining. Four basic steps (fetch F_i – decode D_i – operate O_i – and – write W_i) with specific hardware units are needed to achieve these steps. As a result, the execution of instruction can be overlapped. When the execution of some instruction I_i depends on the results of a previous instruction I_{i-1} which is not yet completed, instruction I_i must be delayed. The pipeline is said to be stalled, waiting for the execution of instruction I_{i-1} to be completed. While it is not possible to eliminate such situations, it is important to minimize the probability of their occurrence. This is a key consideration in the design of the instruction set for nanocomputers and the design of the compilers that translate high-level language programs into machine language.

Multiprocessors — Multiple functional units can be applied to attain the nanocomputer operation when more than one instruction can be in the operating stage. The parallel execution capability, when added to pipelining of the individual instructions, means that more than one instruction can be executed per basic step. Thus, the execution rate can be increased. This enhanced processor performance is called

FIGURE 148.6 Multiprocessor architecture. The basic parallel organization for nanocomputers is represented in Figure 148.7.

superscalar processing. The rate R_T of performing basic steps in the processor depends on the processor clock rate. This rate is in the order of billions steps per second in current high-performance nanoICs. It was illustrated that physical limits prevent single processors from being speeded up indefinitely. Nanocomputers with multiprocessors will speed up the execution of large programs by executing subtasks in parallel. The main difficulty in achieving this is decomposition of given task into its parallel subtasks and ordering these subtasks to the individual processors in such a way that communication among the subtasks will be performed efficiently and robustly. Figure 148.6 documents a block diagram of a multiprocessor system with the interconnection network needed for data sharing among the processors P_i . Parallel paths are needed in this network in order to allow parallel activity to proceed in the processors as they access the global memory space represented by the multiple memory units M_i .

Nanocomputer Architectonics — The theory of computing, computer architecture, and networking are the study of efficient robust processing and communication, modeling, analysis, optimization, adaptive networks, architecture and organization synthesis, as well as other problems of hardware and software design. These studies have emerged as a synergetic fundamental discipline (computer engineering and science), and many problems have not been solved yet. Correspondingly, a large array of questions is still unanswered. Nanocomputer *architectonics* is the theory of nanocomputers devised and designed using fundamental theory and applying nanoICs. Our goal is to develop the nanocomputer *achitectronics* basics, e.g., fundamental methods in synthesis, design, analysis, modeling, computer-aided-design, etc. Nanocomputer *achitectronics*, which is a computer science and engineering frontier, will allow one to solve a wide spectrum of fundamental and applied problems. Applying the nanocomputer *achitectronics* paradigm, this chapter spans the theory of nanocomputers and related areas, e.g., information processing, communication paradigms, computational complexity theory, combinatorial optimization, architecture synthesis, optimal organization, and their applications. Making of the nanocomputer *achitectronics* paradigms, one can address and study fundamental problems in nanocomputer architecture synthesis, design and optimization applying three-dimensional organization, application of nanoICs, multithreading, error recovery, massively parallel computing organization, shared memory parallelism, message passing parallelism, etc. The nanocomputer fundamentals, operation, and functionality can be devised through neuroscience. The key to understand learning, adaptation, control, architecture, hierarchy, organization,

FIGURE 148.7 Parallel nanocomputer organization to maximize the computer concurrency.

FIGURE 148.8 Vertebrate neuron (soma, axon with synaptic terminals, dendrites, and synapses), three-dimensional nanoICs, aligned carbon nanotubes, and single C_{60} buckyballs on Si.

memory, intelligence, diagnostics, self-organization, computing and other system-level basics lies in the study of phenomena and effects in the central nervous system, its components (brain and spinal cord), and the fundamental building blocks, e.g., neurons. Neuronal cells have a large number of synapses. A typical nerve cell in the human brain has thousands of synapses which establish communication and information processing. The communication and processing are not fixed, and constantly change and adapt. Neurons function in the hierarchically distributed robust adaptive network manner. During information transfer, some synapses on a cell are selectively triggered to release specific neurotransmitters, while other synapses remain passive. Neurons consist of a cell body with a nucleus (soma), axon (which transmits information from the soma), and dendrites (which transmit information to the soma), see Figure 148.8. It becomes possible to implement three-dimensional nanoICs structures using biomimetic analogies as illustrated in Figure 148.8. For example, the complex inorganic dendrite-like trees can be implemented using the carbon nanotube-base technology (the Y-junction branching carbon nanotube networks ensure robust ballistic switching and amplification behavior desired in nanoICs. Other nanodevices are emerged. For example, single isolated C_{60} molecules and multi-layered C_{60} can form nanodevices (superconducting transitions), see Figure 148.8. Unfortunately, due to low temperature, the buckyball C_{60} solution in nanodevices is not feasible. However, the carbon-based technology is progressed to possible application in nanoICs within three-dimensional architectures.

Two- and three-dimensional topology aggregation — There is a critical need to study the topology aggregation in the hierarchical distributed nanocomputer that will utilize two- and three-dimensional nanoICs. One can examine how a hierarchical network with multiple paths and routing domain functions. Figure 148.9 shows the principle of topology aggregation of nanodevices in nanoICs for nanocomputers. For example, the documented network consists of four routers (buffers) numbered 1, 2, 3, and 4, and

FIGURE 148.9 Network topology aggregation.

interior (core) routers are illustrated. After the aggregation, a meshed network with four nodes represents the same topology. The difficulty in topology aggregation is to calculate the link metrics to attain the accuracy and to synthesize optimized network topologies. The aggregated link metrics can be computed using the methods used for multiplayer artificial networks. The bandwidth and delay are integrated to optimize the hierarchically distributed networks. We believe that the *distributed-memory* nanocomputers can be adaptively configured and reconfigured based upon *processing*, *communication*, and *control* (instruction) *parallelisms*.

148.3 Nanocomputer Architecture

System-level performance analysis is based on mathematical models used to examine nanocomputers and optimize their architectures, organization, topologies, and parameters, as well as to perform optimal hardware-software codesign. Computers process inputs, producing outputs accordingly. To examine the performance, one should develop and apply the mathematical model of a nanocomputer which comprises central processing, memory, input – output, control, and other units. However, one cannot develop the mathematical model without explicitly specifying the nanocomputer architecture, identifying the optimal organization, and synthesizing the topologies. There are different levels of abstraction for nanocomputer architectures, organizations, models, etc.

Advanced nanocomputer architectures (beyond Von Neumann computer architecture) can be devised to guarantee superior processing and communication speed. Novel nanodevices that utilize new effects and phenomena to perform computing and communication are sought. For example, through the quantum computing, the information can be stored in the phase of wavefunctions, and this concept leads to utilization of massive parallelism of these wavefunctions to achieve enormous processing speed.

The central processing unit (CPU) executes sequences of instructions and operands, which are fetched by the program control unit (PCU), executed by the data processing unit (DPU), and, then, placed in memory. In particular, caches (high speed memory where data is copied when it is retrieved from the random access memory improving the overall performance by reducing the average memory access time) are used. The instructions and data form instruction and data streams which flow to and from the processor. The CPU may have two or more processors and coprocessors with various execution units and multi-level instruction and data caches. These processors can share or have their own caches. The CPU *datapath* contains nanoICs to perform arithmetic and logical operations on words such as fixed- or floating-point numbers. The CPU design involves the trade-offs analysis between the hardware, speed, and affordability. The CPU is usually partitioned on the control and *datapath* units, and the control unit selects and sequence the data-processing operations. The core interface unit is a switch that can be implemented as autonomous cache controllers operating concurrently and feeding the specified number (32, 64, or 128) of bytes of data per cycle. This core interface unit connects all controllers to the data or instruction caches of processors. Additionally, the core interface unit accepts and sequences information from the processors. A control unit is responsible for controlling data flow between controllers that regulate the *in* and *out* information flows. There is the interface to input/output devices. On-chip debug, error detection, sequencing logic, self-test, monitoring, and other units must be integrated to control a pipelined nanocomputer. The computer performance depends on the architecture and hardware components (which are discussed in this Chapter). [Figure 148.10](#) illustrates the possible nanocomputer organization.

In general, nanodevices ensure high density, superior bandwidth, high switching frequency, low power, etc. It is envisioned that in the near future nanocomputers will allow one to increase the computing speed by a factor of millions compared with the existing CMOS ICs computers. Three-dimensional multiple-layered high-density nanoIC assemblies, shown in [Figure 148.11](#), are envisioned to be used. Unfortunately, the number of formidable fundamental, applied, experimental, and technological challenges arise, e.g., robust operation and characteristics of nanoICs are significantly affected by the “second-order” effects (gate oxide and bandgap tunneling, energy quantization, electron transport, etc., and, furthermore, the operating principles for nanodevices can be based on the quantum effects), noise vulnerability, complexity, etc. It is well-known that high-fidelity modeling, data-intensive analysis, het-

FIGURE 148.10 Nanocomputer organization.

erogeneous simulation, and other fundamental issues even for a single nanodevice are not completely solved yet. In addition, the currently existing fabrication processes and technologies do not allow one to fabricate ideal nanodevices and nanostructures. In fact, even molecular wires are not perfect. Different fabrication technologies, processes, and materials have been developed to attain self-assembly and self-ordered features in fabrication of nanoscale devices [7–9], see Figure 148.11. As example, the self-assembled and aligned carbon nanotubes array is illustrated in Figure 148.11.

One of the basic component of the current computers is CMOS transistors fabricated using different technologies and distinct device topologies. However, the CMOS technology and transistors fabricated by using even most advanced CMOS processes reach the physical limits. Therefore, the current research developments have been concentrated on the alternative solutions, and leading companies (IBM, Intel, Hewlett-Packard, etc.), academia, and government laboratories develop novel nanotechnologies. We study computer hardware. Nanodevices (switches, logics, memories, etc.) can be implemented using the illustrated in Figure 148.11 three-dimensional nanoelectronics arrays. It must be emphasized that the

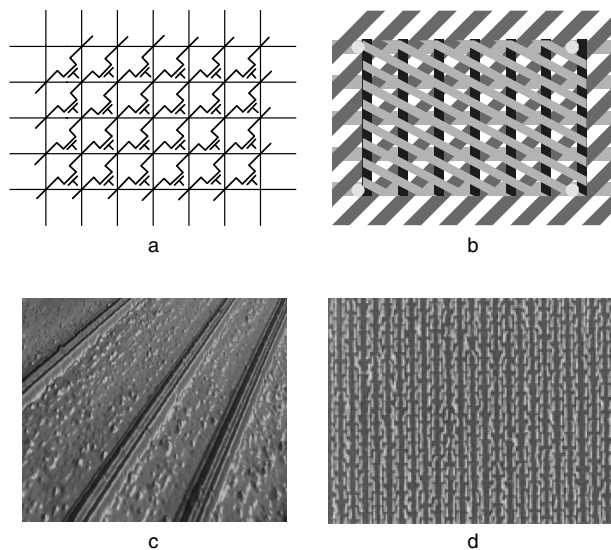

FIGURE 148.11 Three-dimensional multiple-layered high-density nanoIC assemblies (crossbar switching, logic, or memory arrays), 3 nm wide parallel (six-atom-wide) erbium disilicide (ErSi_2) nanowires (Hewlett-Packard), and carbon nanotube array.

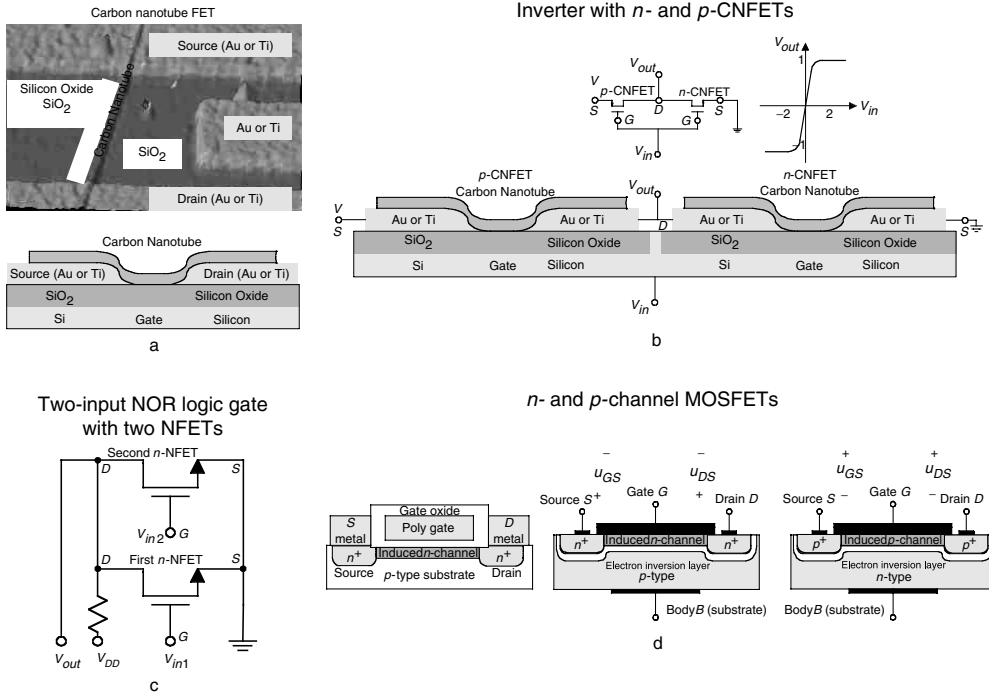

FIGURE 148.12 (a) Carbon nanotube FETs; (b) inverter with CNFETs; (c) NOR gate with NFETs; (d) *n*- and *p*-channel MOSFETs.

extremely high-frequency logic gates can be fabricated using carbon nanotubes, which are from 1 to 10 nm in diameter (100,000 times less than the diameter of human hair). *P*- and *n*-type carbon nanotube field-effect transistors (CNFETs) with single- and multi-wall carbon nanotubes as the channel were fabricated and tested [11]. The atomic force microscope image of a single-wall CNFET (50 nm total length) and CNFET are documented in Figure 148.12.a.

It should be emphasized that the two-dimensional carbon nanotube structure can be utilized to devise and build different transistors with distinct characteristics utilizing different phenomena [10, 11]. For example, twisted carbon nanotubes can be used. Carbon nanotubes can be grown on the surface using chemical vapor deposition, deposited on the surface from solvent, etc. Photolithography can be used to attain the device-level structural and functional integration connecting source, drain, gate, etc. One concludes that different transistors topologies and configurations are available, and these results are reported in [11–13]. Taking note of this fact, we use nanoscale field-effect transistors (NFET) to synthesize and analyze the nanoICs. The carbon nanotube inverter, formed using the series combination of *p*- and *n*-CNFETs, is illustrated in Figure 148.12.b. The gates and drains of two CNFETs are connected together to form the input and output. The voltage characteristics can be examined studying the various transistor bias regions. When the inverter input voltage V_{in} is either a logic 0 or a logic 1, the current in the circuit is zero because one of the CNFETs is cut off. When the input voltage varies in the region $V_{threshold} < V_{in} < V - |V_{threshold}|$, both CNFETs are conducting and a current exists in the inverter.

The current-control mechanism of the field-effect transistors is based on an electrostatic field established by the voltage applied to the control terminal. Figure 148.12.d shows an *n*- and *p*-channel enhancement-type MOSFETs with four terminals (the gate, source, drain, and base (substrate) terminals are denoted as G, S, D, and B). Consider the *n*-channel enhancement-type MOSFETs. A positive voltage u_{GS} , applied to the gate, causes the free positively charged holes in the *n*-channel region. These holes are pushed downward into the *p*-base (substrate). The applied voltage u_{GS} attracts electrons from the source and drain regions into the channel region. The voltage is applied between the drain and source, and the

TABLE 148.1 Two-input NOR Logic Circuit with Two NFETs

| 1 | 0 | 0 |
| 0 | 1 | 0 |
| 1 | 1 | 0 |

current flows through the induced n -channel region. The gate and body form a parallel-plate capacitor with the oxide layer. The positive gate voltage u_{GS} causes the positive charge at the top plate, and the negative charge at the bottom is formed by the electrons in the induced n -channel region. Hence, the electric field is formed in the vertical direction. The current is controlled by the electric field applied perpendicularly to both the semiconductor substrate and to the direction of current (the voltage between two terminals controls the current through the third terminal). The basic principle of the MOSFET operation is the metal-oxide-semiconductor capacitor, and high-conductivity polycrystalline silicon is deposited on the silicon oxide. As a positive voltage u_{DS} is applied, the drain current i_D flows in the induced n -channel region from source to drain, and the magnitude of i_D is proportional to the effective voltage $u_{GS} - u_{GSf}$. If u_{GS} is greater than the threshold value u_{GSf} , $u_{GS} > u_{GSf}$, the induced n -channel is enhanced. If one increases u_{DS} , the n -channel resistance is increased, and the drain current i_D saturates, and the saturation region occurs as one increases u_{DS} to the u_{DSsat} value. The sufficient number of mobile electrons accumulated in the channel region to form a conducting channel if the u_{GS} is greater than the threshold voltage u_{GSf} , which usually is 1 V, e.g., thousands of electrons are needed. It should be emphasized that in the saturation region, the MOSFET is operated as an amplifier, while in the triode region and in the cut off region, the MOSFET can be used as a switch. A p -channel enhancement-type MOSFETs are fabricated on the n -type substrate (body) with p^+ regions for the drain and source. Here, the voltages applied u_{GS} and u_{DS} , and the threshold voltage u_{GSf} are negative.

We use and demonstrate the application of nanoscale field-effect transistors (NFETs) to design the logic nanoICs. The NOR logic can be straightforwardly implemented when the first and second n -NFETs are connected in parallel, see Figure 148.12c. Different flip-flops usually are formed by cross-coupling NOR logic gates. If two input voltages are zero, both n -NFET are cut off, and the output voltage V_{out} is high. Specifically, $V_{out} = V_{DD}$, and if $V_{DD} = 1$ V, then $V_{out} = 1$ V. If $V_{in1} \neq 0$ (for example, $V_{in1} = 1$ V) and $V_{in2} = 0$, the first n -NFET turns on and the second n -NFET is still cut off. The first n -NFET is biased in the nonsaturation region, and V_{out} reaches the low value ($V_{out} = 0$). By changing the input voltages such as $V_{in1} = 0$ and $V_{in2} \neq 0$ ($V_{in2} = 1$ V), the first n -NFET becomes cut off, while the second n -NFET is biased in the nonsaturation region. Hence, V_{out} has the low value, $V_{out} = 0$. If $V_{in1} \neq 0$ and $V_{in2} \neq 0$ ($V_{in1} = 1$ V and $V_{in2} = 1$ V), both n -NFET become biased in the nonsaturation region, and V_{out} is low ($V_{out} = 0$). Table 148.1 summarizes the result and explains how the NFET can be straightforwardly used in nanocomputer units.

The series-parallel combination of the NFETs is used to synthesize complex logic gates. As an example, the resulting carbon nanotube circuitry using n -NFETs to implement the Boolean output function $V_{out} = f(A \cdot B + C)$ is illustrated in Figure 148.13. The n -NFETs executive OR logic gate $V_{out} = A \otimes B$ can be made, see Figure 148.13. If $A = B = \text{logic } 1$, the path exists from the output to ground through NFET

FIGURE 148.13 Static logic gates $V_{out} = f(A \cdot B + C)$ and $V_{out} = A \otimes B$ synthesized using n - and p -NFETs.

FIGURE 148.14 NanoICs pass network.

A and NFET B transistors, and the output goes low. If $A = B = \text{logic } 0$ ($\bar{A} = \bar{B} = \text{logic } 1$), the path exists from the output to ground through NFET A1 and NFET B1 transistors, and the output goes low. For all other input logic signal combinations, the output is isolated from ground, and, hence, the output goes high. Two logic gates $V_{out} = f(A \cdot B + C)$ and $V_{out} = A \otimes B$ synthesized are the static nanoICs (the output voltage is well-defined and is never left floating). The static nanoICs can be redesigned adding the clock.

The nanoICs pass networks can be easily implemented. Consider the nanoICs with two n -NFETs documented in Figure 148.14. The nanoICs output V_{out} is determined by the conditions listed in Table 2. In states 1 and 2, the transmission gate of NFET2 is biased in its conduction state (NFET2 is on), while NFET1 is off. For state 1, $\bar{A} = \text{logic } 1$ is transmitted to the output, and $V_{out} = 1$. For state 2, $\bar{A} = \text{logic } 0$, and though $A = \text{logic } 1$, due to the fact that NFET1 is off, $V_{out} = 0$. In states 3 and 4, the transmission gate of NFET1 is biased, and NFET2 is off. For state 3, $A = \text{logic } 0$, we have $V_{out} = 0$ because NFET2 is off ($\bar{A} = \text{logic } 1$). In contrast, in state 4, $A = \text{logic } 1$ is transmitted to the output, and $V_{out} = 1$. For other states the results are reported in Table 148.2. We conclude that the output V_{out} is a function of two variables, e.g., gate control and input (logic) signals.

The clocked nanoICs are dynamic circuits that in general precharge the output node to a particular level when the clock is at a logic 0. The generalized clocked nanoICs is illustrated in Figure 148.15,

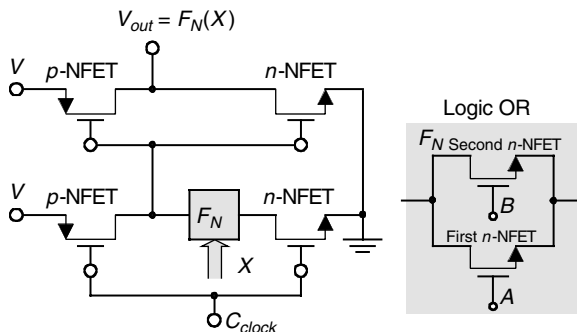

FIGURE 148.15 Dynamic generalized clocked nanoIC with logic function $F_N(X)$.

FIGURE 148.16 One n -NFET dynamic RAM with the storage capacitor.

where F_N is the NFETs network that performs the particular logic function $F_N(X)$ of i variables, here $X = (x_1, x_2, \dots, x_{i-1}, x_i)$. The set of X inputs to the logic nanoICs $F_N(X)$ is derived from the outputs of other static and dynamics nanoICs. When $C_{clock} = \text{logic } 0$, the outputs of all inverters are a logic 0 during the precharged cycle, and during the precharged cycle all x variables of $X = (x_1, x_2, \dots, x_{i-1}, x_i)$ are logic 0. During the precharge phase, all NFETs are cut off, and the transistor outputs are precharged to V . The transitions are possible only during the evaluation phase. The output of the nonoICs buffer change from 0 to 1. Specifically, the logic OR function is illustrated to demonstrate the generalized clocked nanoICs in [Figure 148.15](#).

Combination of logic gates is used to perform logic functions, addition, subtraction, multiplication, division, multiplexing, etc. To store the information, the memory cell nanoICs are used. A systematic arrangement of memory cells and peripheral nanoICs (to address and write the data into the cells as well as to delete data stored in the cells) constitute the memory. The NFETs can be used to build superior static and dynamic random access memory (RAM is the read-write memory in which each individual cell can be addressed at any time), programmable and alterable read-only memory (ROM is commonly used to store instructions of a system operating systems). The static RAM (implemented using six NFETs) consists a basic flip-flop nanoICs with two stable states (0 and 1), while dynamic RAM (implemented using one NFET and storage capacitor) stores one bit of information charging the capacitor. As an example, the dynamic RAM (DRAM) cell is documented in [Figure 148.16](#). In particular, the binary information is stored as the charge on the storage capacitor C_s (logic 0 or 1). The DRAM cell is addressed by turning on the pass n -NFET via the world line signal S_{w_i} and charge is transferred into and out of C_s on the data line (C_s is isolated from the rest of the nanoICs when the n -NFET is off, but the leakage current through the n -NFET requires the cell refreshment to restore the original signal).

Dynamic shift registers are implemented using transmission gates and inverters, flip-flops are synthesized by cross-coupling NOR gates, while delay flip-flops are built using transmission gates and feedback inverters.

Though for many nanoICs (we do not consider the optical, single-electron, and quantum nanoICs) synthesis and design can be performed using the basic approaches, methods and computer-aided design developed for conventional ICs (viable results exist for MOSFETs), the differences must be outlined. The major problems arise due to the fact that the developed technologies cannot guarantee the fabrication of high-yield perfect nanoICs and different operating principles. In general, the secondary effects must be integrated (for example, even for NFETs, which are comparable to MOSFETs, the switching and leakage phenomena are different). Correspondingly the simple scaling of ICs with MOSFETs to nanoICs cannot be performed.

The direct self-assembly, nanopatterning, nanoimprinting, nanoaligning, nanopositioning, overlayering, margining, and annealing were shown to be quite promising. However, it is unlikely that near-future nanotechnologies will guarantee the reasonable repeatable characteristics, high-quality, satisfactory geometry uniformity, suitable failure tolerance, and other important specifications and requirements imposed on nanodevices and nanostructures. Therefore, synthesis of robust defect-tolerant adaptive (reconfigurable) nanocomputer architectures (hardware) and software to accommodate failures, inconsistency, variations, nonuniformity, and defects is critical [10].

148.4 Hierarchical Finite-State Machines and Their Use in Hardware and Software Design

Simple register-level systems perform a single data-processing operations, e.g., summation $X:=x_1+x_2$, subtraction $X:=x_1-x_2$, etc. To do different complex data-processing operations, multifunctional register-level systems should be synthesized. These multifunctional register-level systems are partitioned as a data-processing unit (*datapath*) and a controlling unit (control unit). The control unit is responsible for collecting and controlling the data-processing operations (actions) of the *datapath*. To design the register-level systems, one studies a set of operations to be executed, and then, designs nanoICs using a set of register-level components that implement the desired functions satisfying the affordability and performance requirements. It is very difficult to impose meaningful mathematical structures on register-level behavior or structure using Boolean algebra and conventional gate-level design. Due to these difficulties, the heuristic synthesis is commonly accomplished as sequential steps listed below:

1. define the desired behavior as a set of sequences of register-transfer operations (each operation can be implemented using the available components) comprising the algorithm to be executed
2. examine the algorithm to determine the types of components and their number to attain the required *datapath*. Design a complete block diagram for the *datapath* using the components chosen
3. examine the algorithm and *datapath* in order to derive the control signals with ultimate goal to synthesize the control unit for the found *datapath* that meet the algorithm's requirements
4. analyze and verify performing modeling and detail simulation (VHDL, Verilog, ModelSim, and other environments are commonly used)

Let us perform the synthesis of virtual control units that ensures extensibility, flexibility, adaptability, robustness, and reusability. The synthesis will be performed using the hierarchic graphs (HG). A most important problem is to develop straightforward algorithms which ensure implementation (nonrecursive and recursive calls) and utilize hierarchical specifications. We will examine the behavior, perform logic synthesis, and implement reusable control units modeled as hierarchical finite-state machines with virtual states. The goal is to attain the top-down sequential well-defined decomposition in order to develop complex robust control algorithm step-by-step.

We consider *datapath* and control units. The *datapath* unit consists memory and combinational units. A control unit performs a set of instructions by generating the appropriate sequence of micro instructions that depend on intermediate logic conditions or on intermediate states of the *datapath* unit. To describe the evolution of a control unit, behavioral models were developed [27, 28]. We use the direct-connected HGs containing nodes. Each HG has an entry (*Begin*) and an output (*End*). Rectangular nodes contain micro instructions, macro instructions, or both.

A micro instruction U_i includes a subset of micro operations from the set $U = \{u_1, u_2, \dots, u_{u-1}, u_u\}$. Micro operations $\{u_1, u_2, \dots, u_{u-1}, u_u\}$ force the specific actions in the *datapath* (see [Figure 148.17](#) and [Figure 148.19](#)). For example, one can specify that u_1 pushes the data in the local stack, u_2 pushes the data in the output stack, u_3 forms the address, u_4 calculates the address, u_5 pops the data from the local stack, u_6 stores the data from the local stack in the register, u_7 pops the data from the output stack to external output, etc.

A micro operation is the output causing an action in the *datapath*. Any macro instruction incorporates macro operations from the set $M = \{m_1, m_2, \dots, m_{m-1}, m_m\}$. Each macro operation is described by another lower level HG. Assume that each macro instruction includes one macro operation. Each rhomboidal node contains one element from the set $L \cup G$. Here, $L = \{l_1, l_2, \dots, l_{l-1}, l_l\}$ is the set of logic conditions, while $G = \{g_1, g_2, \dots, g_{g-1}, g_g\}$ is the set of logic functions. Using logic conditions as inputs, logic functions are calculated examining predefined set of sequential steps that are described by a lower level HG. Directed lines connect the inputs and outputs of the nodes.

Consider a set $E = M \cup G$, $E = \{e_1, e_2, \dots, e_{e-1}, e_e\}$. All elements $e_i \in E$ have HGs, and e_i has the corresponding HG Q_i which specifies either an algorithm for performing e_i (if $e_i \in M$) or an algorithm

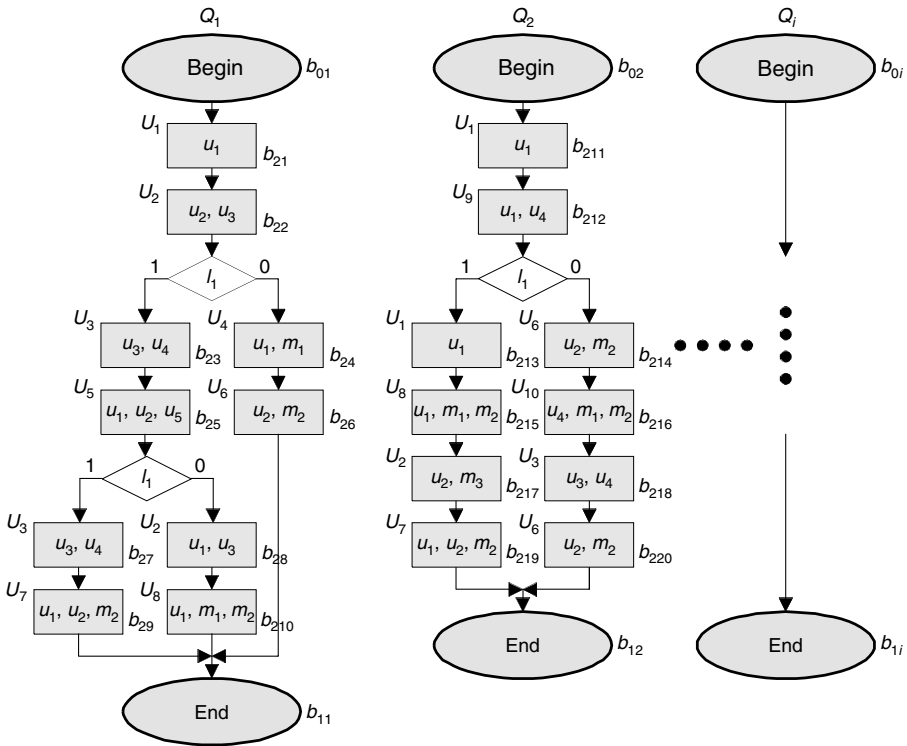

FIGURE 148.17 Control algorithm represented by HGs Q_1, Q_2, \dots, Q_i .

for calculating e_i (if $e_i \in G$). Assume that $M(Q_i)$ is the subset of macro operations and $G(Q_i)$ is the subset of logic functions that belong to the HG Q_i . If $M(Q_i) \cup G(Q_i) = \emptyset$, the well-known scheme results [10, 27, 28]. The application of HGs enables one to gradually and sequentially synthesize complex control algorithm concentrating the efforts at each stage on a specified level of abstraction because specific elements of the set E are used. Each component of the set E is simple and can be checked and debugged independently. Figure 148.17 reports HGs Q_1, Q_2, \dots, Q_i which describe the control algorithm.

The execution of HGs is examined studying complex operations $e_i = m_j \in M$ and $e_i = g_j \in G$. Each complex operation e_i that is described by a HG Q_i must be replaced with a new subsequence of operators that produces the result executing Q_i . In the illustrative example, shown in Figure 148.18, Q_1 is the first HG at the first level Q^1 , the second level Q^2 is formed by Q_2, Q_3 , and Q_4 , etc. We consider the following hierarchical sequence of HGs $Q^1_{(level\ 1)} \Rightarrow Q^2_{(level\ 2)} \Rightarrow \dots \Rightarrow Q^{i-1}_{(level\ i-1)} \Rightarrow Q^i_{(level\ i)}$. All $Q^i_{(level\ i)}$ have the corresponding HGs. For example, Q^2 is a subset of the HGs that are used to describe elements from the set $M(Q_1) \cup G(Q_1) = \emptyset$, while Q^3 is a subset of the HGs that are used to map elements from the sets $\cup_{q \in Q^2} M(q)$ and $\cup_{q \in Q^2} G(q)$. In Figure 148.18, $Q^1 = \{Q_1\}$, $Q^2 = \{Q_2, Q_3, Q_4\}$, $Q^3 = \{Q_2, Q_4, Q_5\}$, etc.

Micro operations u^+ and u^- are used to increment and to decrement the stack pointer (SP). The problem of switching to various levels can be solved using a stack memory, see Figure 148.18. Consider an algorithm for $e_i \in M(Q_1) \cup G(Q_1) = \emptyset$. The SP is incremented by the micro operation u^+ , and a new register of the stack memory is set as the current register. The previous register stores the state when it was interrupted. New Q_i becomes responsible for the control until terminated. After termination of Q_i , the micro operation u^- is generated to return to the interrupted state. As a result, control is passed to the state in which Q_j is called.

The synthesis problem can be formulated as: for a given control algorithm A , described by the set of HGs, construct the FSM that implements A .

In general, the synthesis includes the following steps:

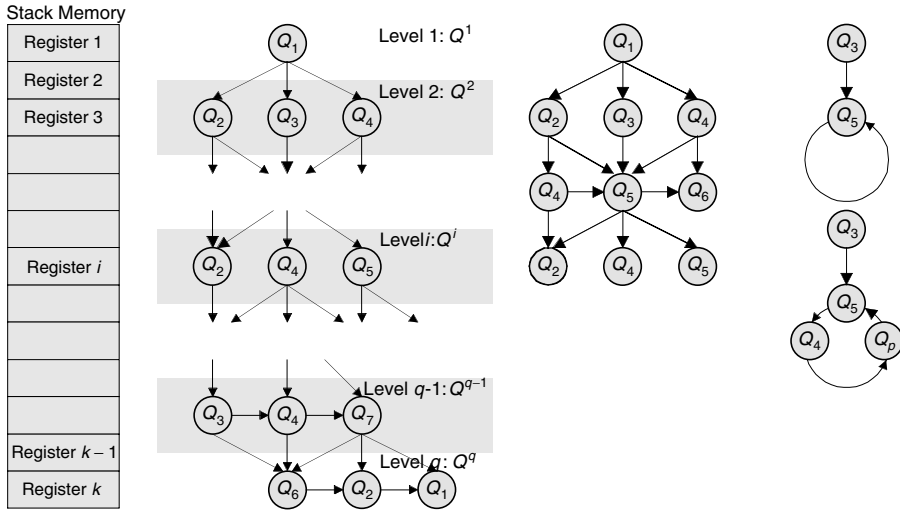

FIGURE 148.18 Stack memory with multilevel sequential HGs with illustration of recursive call.

- transforming the HGs to the state transition table
- state encoding
- combinational logic optimization
- final structure design

The first step is divided into substeps as: (1) marking the HGs with labels b , see Figure 148.18; (2) recording all transitions between the labels in the extended state transition table; and (3) convert the extended table to ordinary form.

The labels b_{01} and b_{11} are assigned to the nodes *Begin* and *End* of the Q_1 . The label b_{02}, \dots, b_{0i} and b_{12}, \dots, b_{1i} are assigned to nodes *Begin* and *End* of Q_2, \dots, Q_i , respectively. The labels $b_{21}, b_{22}, \dots, b_{2j}$ are assigned to other nodes of HGs, inputs and outputs of nodes with logic conditions, etc. Repeating labels are not allowed. The labels are considered as the states. The extended state transition table is designed using the state evolutions due to inputs (logic conditions) and logic functions which cause the transitions from $x(t)$ to $x(t + 1)$. All evolutions of the state vector $x(t)$ are recorded, and the state $x_k(t)$ has the label k . It should be emphasized that the table can be converted from the extended to the ordinary form. To program the Code Converter, one records the transition from the state x_1 assigned to the *Begin* node of the HG Q_1 , e.g., $x_{01} \Rightarrow x_{21}(Q_1)$. The transitions between different HGs are recorded as $x_{ij} \Rightarrow x_{nm}(Q_j)$. For all transitions, the data-transfer instructions are synthesized. The hardware implementation is illustrated in Figure 148.19.

Robust algorithms are synthesized and implemented using the HGs utilizing the hierarchical behavior specifications and top-down decomposition. The reported method guarantees exceptional adaptation and reusability features through reconfigurable hardware and reprogrammable software.

148.5 Reconfigurable Nanocomputers

To design nanocomputers, specific hardware and software solutions must be developed and implemented. For example, ICs are designed by making use of hardware description languages, e.g., Very High Speed Integrated Circuit Hardware Description Language (VHDL) and Verilog. Making the parallel to the conventional ICs, the programmable gate arrays (PGAs) developed by Xilinx, Altera, Actel, and other companies, can serve as the meaningful inroad in design of reconfigurable nanocomputers. These PGAs lead one to the on-chip reconfigurable logic concept. The reconfigurable logic can be utilized as a functional unit in the *datapath* of the processor, having access to the processor register file and to on-

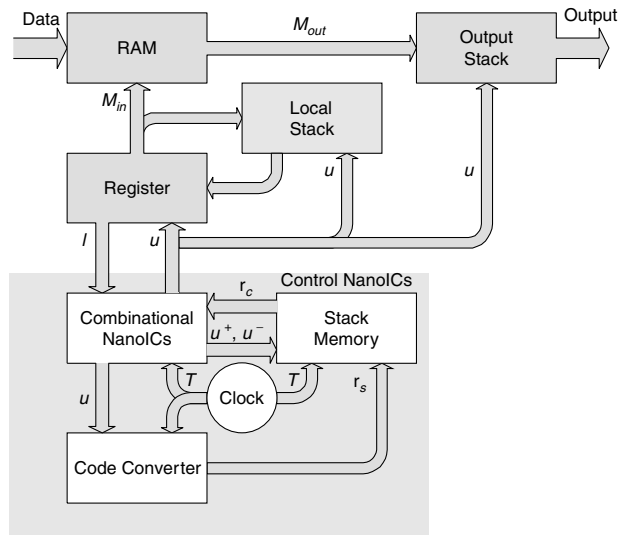

FIGURE 148.19 Hardware implementation.

chip memory ports. Another approach is to integrate the reconfigurable part of the processor as a coprocessor. For this solution, the reconfigurable logic operates concurrently with the processor. Optimal design and memory port assignments can guarantee the coprocessor reconfigurability and concurrency.

In general, the reconfigurable nanocomputer architecture synthesis emphasizes a high-level design, rapid prototyping and reconfigurability in order to reduce time and cost improving performance and reliability. The goal is to device, design, and fabricate affordable high-performance high-yield nanoICs arrays and application-specific nanoICs (ASNICs). These ASNICs should be testable to detect the defects and faults. The design of ASNICs involves mapping application requirements into specifications implemented by nanoICs. The specifications are represented at every level of abstraction including the system, behavior, structure, physical, and process domains. The designer should be able to differently utilize the existing nanoICs to meet the application requirements. User-specified nanoICs and ASNICs must be developed to attain affordability and superior performance.

The PGAs can be used to implement logic functions utilizing millions of gates. The design starts by interpreting the application requirements into architectural specifications. As the application requirements are examined, the designer translates the architectural specifications into behavior and structure domains. Behavior representation means the functionality required as well as the ordering of operations and completion of tasks in specified times. A structural description consists of a set of nanodevices and their interconnection. Behavior and structure can be specified and studied using hardware description languages. This nanoICs Hardware Description Language (NHDL) should manage efficiently very complex hierarchies which can include millions of logic gates. Furthermore, NHDLs should be translated into net-lists of library components using synthesis software. The NHDLs software, which is needed to describe hardware and must permit concurrent operations, should perform the following major functions:

- translate text to a Boolean mathematical representation,
- optimize the representation based specified criteria (size, delays, optimality, reliability, testability, etc.),
- map the optimized mathematical representation to a technology-specific library of nanodevices.

Reconfigurable nanocomputers should use reprogrammable logic units (e.g., PGAs) to implement a specialized instruction set and arithmetic units to optimize the performance. Ideally, reconfigurable nanocomputers can be reconfigured at real-time (runtime), enabling the existing hardware to be reused

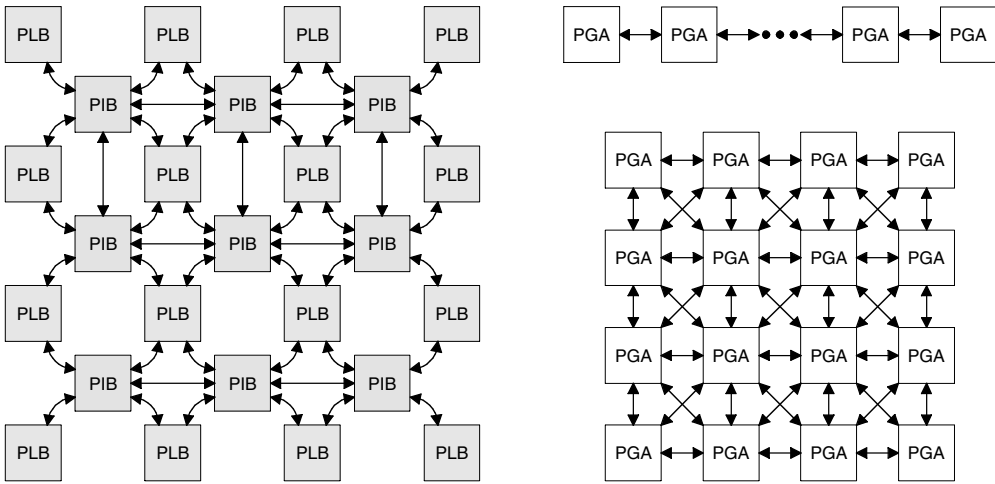

FIGURE 148.20 Programmable gate arrays and multiple PGAs architectures.

depending on its interaction with external units, data dependencies, algorithm requirements, faults, etc. The basic PGAs architecture is built using the programmable logic blocks (PLBs) and programmable interconnect blocks (PIBs), see Figure 148.20. The PLBs and PIBs will hold the current configuration setting until adaptation will be accomplished. The PGA is programmed by downloading the information in the file through a serial or parallel logic connection. The time required to configure a PGA is called the configuration time (PGAs could be configured in series or in parallel). Figure 148.20 illustrates the basic architectures from which most of multiple PGAs architectures can be derived (pipelined architecture with the PGAs interfaced one to other is well fit for functions that have streaming data at specific intervals, while arrayed PGAs architecture is appropriate for functions that require a systolic array). A hierarchy of configurability is different for the different PGAs architectures.

The goal is to design reconfigurable nanocomputer architectures with corresponding software to cope with less-than-perfect, entirely or partially defective and faulty nanoscale devices, structures, and connects (e.g., nanoICs) encountered in arithmetic and logic, control, input-output, memory, and other units. To achieve our objectives, the redundant nanoICs units can be used (the redundancy level is determined by the nanoscale ICs quality and software capabilities). Hardware and software evolutionary learning, adaptability and reconfigurability can be achieved through decision-making, diagnostics, health-monitoring, analysis, and optimization of software, as well as pipelining, rerouting, switching, matching, and controlling of hardware. We concentrate our research on how to devise – design – optimize – build – test — configure nanocomputers. The overall objective can be achieved guaranteeing the evolution (behavior) matching between the ideal (C_I) and fabricated (C_F) nanocomputer, their units, systems, or components. The nanocompensator (C_{F1}) can be designed for the fabricated C_{F2} such that the response of the cf. will match the evolution of the C_p , see Figure 148.21. The C_I gives the reference ideal evolving model which analytically and/or experimentally maps the ideal (desired) input-output behavior, and the nanocompensator C_{F1} should modify the evolution of C_{F2} such that cf. described by $C_F = C_{F1} \circ C_{F2}$ (series architecture), matches the C_I behavior. Figure 148.21 illustrates the concept. The necessary and sufficient conditions for strong and weak evolution matching based on C_I and C_{F2} must be derived.

148.6 Mathematical Models for Nanocomputers

Six-Tuple Nanocomputer Model

To address analysis, control, diagnostics, optimization, and design problems, the explicit mathematical models of nanocomputers must be developed and applied. There are different levels of abstraction in

FIGURE 148.21 Nanocomputers and evolution matching.

nanocomputer modeling, simulation, and analysis [10]. High-level models can accept streams of instruction descriptions and memory references, while the low-level (device-level) logic gates or memory modeling can be performed by making use of streams of input and output signals and nonlinear transient behavior of devices. The system- and subsystem-level modeling (medium-level) also can be formulated and performed. It is evident that one subsystem can contain millions of nanodevices. For example, computer systems can be modeled as queuing networks. Different mathematical modeling frameworks exist and have been developed for each level. In this section we concentrate on the high-, medium-, and low-level systems modeling of nanocomputer systems using the finite state machine concept.

Computer accepts the input information, processes it according to the stored instructions, and produces the output. There exist numerous computer models, e.g., Boolean models, polynomial models, information-based, etc. However, all mathematical models are the mathematical idealization based upon the abstractions, simplifications and hypotheses made. In fact, it is virtually impossible to develop and apply the complete mathematical model due to complexity and numerous obstacles.

It is possible to concurrently model nanocomputers by the six-tuple

$$C = \{X, E, R, Y, F, X_0\},$$

where X is the finite set of states with initial and final states $x_0 \in X$ and $x_f \in X$; E is the finite set of events (concatenation of events forms a string of events); R and Y are the finite sets of the input and output symbols (alphabets); F are the transition functions mapping from $X \times E \times R \times Y$ to X (denoted as F_X), to E (denoted as F_E) or to Y (denoted as F_Y), $F \subseteq X \times E \times R \times Y$ (we assume that $F = F_X$, e.g., the transition function defines a new state to each quadruple of states, events, references, and outputs, and F can be represented by a table listing the transitions or by a state diagram).

The nanocomputer evolution is due to inputs, events, state evolutions, and parameter variations (as explained in the end of this subsection), etc.

We formulate two useful definitions.

Definition 1. A vocabulary (or an alphabet) A is a finite nonempty set of symbols (elements). A world (or sentence) over A is a string of finite length of elements of A . The empty (null) string is the string which does not contain symbols. The set of all words over A is denoted as A_w . A language over A is a subset of A_w .

Definition 2. A finite-state machine with output $C_{FS} = \{X, A_R, A_Y, F_R, F_Y, X_0\}$ consists of a finite set of states S , a finite input alphabet A_R , a finite output alphabet A_Y , a transition function F_Y that assigns a new state to each state and input pair, an output function F_Y that assigns an output to each state and input pair, and initial state X_0 .

Using the input-output map, the evolution of C can be expressed as

$$E_C \subseteq \mathbf{R} \times \mathbf{Y}.$$

That is, if the computer in state $\mathbf{x} \in \mathbf{X}$ receives an input $\mathbf{r} \in \mathbf{R}$, it moves to the next state $f(\mathbf{x}, \mathbf{r})$, and produces the output $\mathbf{y}(\mathbf{x}, \mathbf{r})$. Nanocomputers can be represented as the state tables which describe the state and output functions. In addition, the state transition diagram (direct graph whose vertices correspond to the states and edges correspond to the state transitions, and each edge is labeled with the input and output associated with the transition) is frequently used.

Nanocomputer Modeling With Parameters Set

Nanocomputers can be modeled using the parameters set \mathbf{P} . Designing reconfigurable fault-tolerant nanocomputer architectures, sets \mathbf{P} and \mathbf{P}_0 should be integrated, and we have

$$\mathbf{C} = \{\mathbf{X}, \mathbf{E}, \mathbf{R}, \mathbf{Y}, \mathbf{P}, \mathbf{F}, \mathbf{X}_0, \mathbf{P}_0\}.$$

It is evident that the nanocomputer evolution depends upon \mathbf{P} and \mathbf{P}_0 . The optimal performance can be achieved through adaptive synthesis, reconfiguration and diagnostics. For example, one can vary \mathbf{F} and variable parameters \mathbf{P}_v to attain the best possible performance.

The nanocomputer evolution, considering states, events, outputs, and parameters, can be expressed as

$$(x_0, e_0, y_0, p_0) \xRightarrow{\text{evolution 1}} (x_1, e_1, y_1, p_1) \xRightarrow{\text{evolution 2}} \cdots \xRightarrow{\text{evolution } j-1} (x_{j-1}, e_{j-1}, y_{j-1}, p_{j-1}) \xRightarrow{\text{evolution } j} (x_j, e_j, y_j, p_j).$$

The input, states, outputs, events, and parameter sequences are aggregated within the model $\mathbf{C} = \{\mathbf{X}, \mathbf{E}, \mathbf{R}, \mathbf{Y}, \mathbf{P}, \mathbf{F}, \mathbf{X}_0, \mathbf{P}_0\}$. The concept reported allows us to find and apply the minimal — but — complete functional description of nanocomputers. The minimal subset of state, event, output, and parameter evolutions (transitions) can be used. That is, the partial description $\mathbf{C}_{\text{partial}} \subset \mathbf{C}$ results, and every essential nanocomputer quadruple (x_i, e_i, y_i, p_i) can be mapped by $(x_i, e_i, y_i, p_i)_{\text{partial}}$. This significantly reduces the complexity modeling, simulation, analysis, and design problems.

Let the transition function F maps from $\mathbf{X} \times \mathbf{E} \times \mathbf{R} \times \mathbf{Y} \times \mathbf{P}$ to \mathbf{X} , e.g., $\mathbf{F}: \mathbf{X} \times \mathbf{E} \times \mathbf{R} \times \mathbf{Y} \times \mathbf{P} \rightarrow \mathbf{X}$, $\mathbf{F} \subseteq \mathbf{X} \times \mathbf{E} \times \mathbf{R} \times \mathbf{Y} \times \mathbf{P}$. Thus, the transfer function F defines a next state $\mathbf{x}(t+1) \in \mathbf{X}$ based upon the current state $\mathbf{x}(t) \in \mathbf{X}$, event $e(t) \in \mathbf{E}$, reference $\mathbf{r}(t) \in \mathbf{R}$, output $\mathbf{y}(t) \in \mathbf{Y}$ and parameter $\mathbf{p}(t) \in \mathbf{P}$. Hence,

$$\mathbf{x}(t+1) = F(\mathbf{x}(t), e(t), \mathbf{r}(t), \mathbf{y}(t), \mathbf{p}(t)) \text{ for } \mathbf{x}_0(t) \in \mathbf{X}_0 \text{ and } \mathbf{p}_0(t) \in \mathbf{P}_0.$$

The robust adaptive control algorithms must be developed. The control vector $\mathbf{u}(t) \in \mathbf{U}$ is integrated into the nanocomputer model. We have $\mathbf{C} = \{\mathbf{X}, \mathbf{E}, \mathbf{R}, \mathbf{Y}, \mathbf{P}, \mathbf{U}, \mathbf{F}, \mathbf{X}_0, \mathbf{P}_0\}$.

Nanocompensator synthesis procedure is reported in the following sections. This synthesis approach is directly applicable to design nanocomputers with two- and three-dimensional nanoICs.

148.7 Nanocompensator Synthesis and Design Aspects

In this section we will design the nanocompensator. Two useful Definitions which allow one to precisely formulate and solve the problem are formulated.

Definition 3. The strong evolutionary matching $C_F = C_{F1} \circ C_{F2} =_B C_I$ for given C_I and cf. is guaranteed if $E_{C_F} = E_{C_I}$. Here, $C_F =_B C_I$ means that the behaviors (evolution) of C_I and cf. are equivalent. ~

Definition 4. The weak evolutionary matching $C_F = C_{F1} \circ C_{F2} \subseteq_B C_I$ for given C_I and cf. is guaranteed if $E_{C_F} \subseteq E_{C_I}$. Here, $C_F \subseteq_B C_I$ means that the evolution of cf. is contained in the behavior C_I . ~

The problem is to derive a nanocompensator $C_{F_1} = \{X_{F_1}, E_{F_1}, R_{F_1}, Y_{F_1}, F_{F_1}, X_{F_1 0}\}$ such that for given $C_I = \{X_I, E_I, R_I, Y_I, F_I, X_{I 0}\}$ and $C_{F_2} = \{X_{F_2}, E_{F_2}, R_{F_2}, Y_{F_2}, F_{F_2}, X_{F_2 0}\}$ the following conditions

$$C_F = C_{F_1} \circ C_{F_2} =_B C_I \text{ (strong behavior matching)}$$

or

$$C_F = C_{F_1} \circ C_{F_2} \subseteq_B C_I \text{ (weak behavior matching)}$$

are satisfied.

Here we assume that the following conditions are satisfied:

- output sequences generated by C_I can be generated by C_{F_2} ;
- the C_I inputs match the C_{F_1} inputs.

It must be emphasized that the output sequences means the state, event, output, and/or parameters vectors, e.g., the triple (x, e, y, p) .

Lemma 1. If there exists the state-modeling representation $\gamma \subseteq X_I \times X_F$ such that $C_I^{-1} \times \gamma_B C_{F_2}^{-1}$ (if $C_I^{-1} \times \gamma_B C_{F_2}^{-1}$, then $C_I \times \gamma_B C_{F_2}$), then the evolution matching problem is solvable. The nanocompensator C_{F_1} solves the strong matching problem $C_F = C_{F_1} \circ C_{F_2} =_B C_I$ if there exist the state-modeling representations $\beta \subseteq X_I \times X_{F_2}$, $(X_{I 0}, X_{F_2 0}) \in \beta$ and $\alpha \subseteq X_{F_1} \times \beta$, $(X_{F_1 0}, (X_{I 0}, X_{F_2 0})) \in \alpha$ such that $C_{F_1} = \alpha_B C_I^\beta$ for $\beta \in \Gamma = \{\gamma [C_I^{-1} \times \gamma_B C_{F_2}^{-1}]\}$. Furthermore, the strong matching problem is tractable if there exist C_I^{-1} and $C_{F_2}^{-1}$.

The nanocomputer can be decomposed using algebraic decomposition theory which is based on the closed partition lattice. For example, consider the fabricated nanocomputer C_{F_2} represented as $C_{F_2} = \{X_{F_2}, E_{F_2}, R_{F_2}, Y_{F_2}, F_{F_2}, X_{F_2 0}\}$.

A partition on the state set for C_{F_2} is a set $\{C_{F_2 1}, C_{F_2 2}, \dots, C_{F_2 p}, \dots, C_{F_2 k-1}, C_{F_2 k}\}$ of disjoint subsets of the state set X_{F_2} whose union is X_{F_2} , e.g., $\bigcup_{i=1}^k C_{F_2 i} = X_{F_2}$ and $C_{F_2 i} \cap C_{F_2 j} = \emptyset$ for $i \neq j$. Hence, we can design and implement the nanocompensators (hardware) $C_{F_1 i}$ for given $C_{F_2 i}$.

Misconceptions about Software Engineering

Phillip A. Laplante

Penn State University

149.1 Classification of Software Qualities

Software can be characterized by any of a number of qualities. External qualities are visible to the user, such as usability and reliability, and are of concern to the end user. Internal qualities may not be necessarily visible to the user, but help developers to achieve improvement in external qualities. For example, good requirements and design documentation might not be seen by the typical user, but these are necessary to achieve improvement in most of the external qualities. A specific distinction between whether a particular quality is external or internal is not often made because they are so closely tied. Moreover, the distinction is largely a function of the software itself and the kind of user involved.

While it is helpful to describe these qualities, it is equally desirable to quantify them. Quantification of these characteristics of software is essential in enabling users and designers to talk succinctly about the product and for software process control and project management.

Reliability

Reliability is a measure of whether a user can depend on the software. This notion can be informally defined in a number of ways. For example, one definition might be “a system that a user can depend on.” Other loose characterizations of a reliable software system include:

- The system “stands the test of time.”
- There is an absence of known catastrophic errors, that is, errors that render the system useless.
- The system recovers “gracefully” from errors.
- The software is robust.

For mission critical systems, other informal characterizations of reliability might include:

- Downtime is below a certain threshold.
 - The accuracy of the system is within a certain tolerance.
 - Real-time performance requirements are met consistently.
-

While all of the above are desirable in any system, these informal characteristics are difficult to measure. Moreover, they are not truly measures of reliability, but of other attributes of the software.

Specialized literature on software reliability exists that defines this quality in terms of statistical behavior, that is, the probability that the software will operate as expected over a specified time interval. These characterizations generally take the following approach. Let S be a software system, and let T be the time of system failure. Then the reliability of S at time t , denoted $r(t)$, is the probability that T is greater than t ; that is,

$$r(t) = P(T > t) \tag{149.1}$$

this is the probability that a software system will operate without failure for a specified period of time.

Thus, a system with reliability function $r(t) = 1$ will never fail. However, it is unrealistic to have such expectations. Instead, some reasonable goal should be set, for example, in mission critical systems that the failure probability be no more than 10^{-9} per hour. This represents a reliability function of $r(t) = (0.99999999)^t$ with t in hours. Note that as $t \rightarrow \infty$, $r(t) \rightarrow 0$.

Another way to characterize software reliability is in terms of a real-valued failure function. One failure function uses an exponential distribution where the abscissa is time and the ordinate represents the expected failure intensity at that time (Equation 149.2).

$$f(t) = \lambda e^{-\lambda t} \quad t \geq 0 \tag{149.2}$$

Here the failure intensity is initially high, as would be expected in new software as faults are detected during testing. However, the number of failures would be expected to decrease with time, presumably as failures are uncovered and repaired (Figure 149.1). The factor λ is a system-dependent parameter.

A second failure model is given by the “bathtub curve” shown in Figure 149.2. Brooks notes that while this curve is often used to describe the failure function of hardware components, it might also be useful in describing the number of errors found in a certain release of a software product.¹

The interpretation of this failure function is clear for hardware — a certain number of product units will fail early due to manufacturing defects. Later, the failure intensity will increase as the hardware ages

FIGURE 149.1 An exponential model of failure represented by the failure function $f(t) = \lambda e^{-\lambda t}$, $t \geq 0$. λ is a system-dependent parameter.

FIGURE 149.2 A software failure function represented by the bathtub curve.

and wears out. But software does not wear out. If systems seem to fail according to the bathtub curve, then there has to be some plausible explanation.

It is clear that a large number of errors will be found in a particular software product early, just as in the exponential model of failure. But why would the failure intensity increase much later? There are at least three possible explanations. The first is that the errors are due to effects of patching the software for various reasons. The second reason is that late software failures are really due to failure of the underlying hardware. Finally, additional failures could appear because of the increased stress on the software by expert users. That is, as users master the software and begin to expose and strain advanced features, it is possible that certain poorly tested functionality of the software is beginning to be used.

Often the traditional quality measures of mean time to first failure (MTTF) or mean time between failures (MTBF) are used to stipulate reliability in the software requirements specification. This approach to failure definition places great importance on the effective elicitation (gathering) and specification of functional requirements, because requirements define software failure.

Correctness

Software correctness is closely related to reliability and the terms are often used interchangeably. The main difference is that minor deviation from the requirements is strictly considered a failure, and hence means that the software is incorrect. However, a system may still be deemed reliable if only minor deviations from the requirements are experienced. Correctness is measured in terms of number of failures detected over time.

Performance

Performance is a measure of some required behavior. For example, an imaging system might be required to display a filtered image at a rate of 30 frames per second. A photo reproduction system might be required to digitize, clean, and output color copies at a rate of 1 every 2 seconds.

Many software systems are real-time systems, that is, performance satisfaction is based on both the correctness of the outputs, as well as the timeliness of those outputs. Hard real-time systems are those in which missing even a single deadline will lead to total system failure. Firm real-time systems can

tolerate a few missed deadlines, while in soft real-time systems, missing deadlines generally leads only to performance degradation.

One method of measuring performance is based on mathematical or algorithmic complexity. Another approach involves directly timing the behavior of the completed system with logic analyzers and similar tools. Finally, a simulation of the finished system might be built with the specific purpose of estimating performance.

Usability

Often referred to as ease of use, or user friendliness, usability is a measure of how easy the software is for humans to use. This quantity is an elusive one. Properties that make an application user-friendly to novice users are often different from those desired by expert users or the software designers. Use of prototyping can increase the usability of a software system because, for example, interfaces can be built and tested by the user.

Usability is difficult to quantify. However, informal feedback can be used, as well as user feedback from surveys and problem reports in most cases.

Interoperability

This quality refers to the ability of the software system to coexist and cooperate with other systems. For example, in certain systems the software must be able to communicate with various devices using standard bus structures and protocols.

A concept related to interoperability is that of an open system. An open system is an extensible collection of independently written applications that cooperate to function as an integrated system. Open systems differ from open source code, which is source code that is made available to the user community for moderate improvement and correction.

An open system allows the addition of new functionality by independent organizations through the use of interfaces whose characteristics are published. Any applications developer can then take advantage of these interfaces, and thereby create software that can communicate using the interface. Open systems allow different applications written by different organizations to interoperate.

Interoperability can be measured in terms of compliance with open system standards.

Maintainability

Anticipation of change is a general principle that should guide the software engineer. A software system in which changes are relatively easy to make has a high level of maintainability. In the long run, design for change will significantly lower software life-cycle costs and lead to an enhanced reputation for the software engineer, the software product, and the company.

Maintainability can be decomposed into two contributing properties: evolvability and repairability. Evolvability is a measure of how easily the system can be changed to accommodate new features or modification of existing features. Software is repairable if it allows for fixing defects.

Measuring these qualities of software is not always easy, and is often based on anecdotal observation only. This means that changes and the cost of making them are tracked over time. Collecting these data has a twofold purpose. First, the costs of maintenance can be compared to other similar systems for benchmarking and project management purposes. Second, the information can provide experiential learning that will help to improve the overall software production process and skills of the software engineers.

Portability

Software is portable if it can easily run in different environments. The term *environment* refers to the hardware on which the system runs, operating system, or other software with which the system is expected

TABLE 149.1 Selected Software Properties and Measurement Approaches

| Software Quality | Possible Measurement Approach |
|------------------|---|
| Correctness | Probabilistic measures, MTBF, MTFF |
| Interoperability | Compliance with open standards |
| Maintainability | Anecdotal observation of resources spent |
| Performance | Algorithmic complexity analysis, direct measurement, simulation |
| Portability | Anecdotal observation |
| Reliability | Probabilistic measures, MTBF, MTFF, heuristic measures |
| Usability | User feedback from surveys and problem reports |
| Verifiability | Software monitors |

Note: MTBF, mean time between failures; MTTF, mean time to first failure.

to interact. Because of the specialized hardware with which they interact, special care must be taken in making imaging systems portable.

Portability is achieved through a deliberate design strategy in which hardware-dependent code is confined to the fewest code units as possible. This strategy can be achieved using either object-oriented or procedural programming languages and through object-oriented or structured approaches. Both of these will be discussed below.

Portability is difficult to measure, other than through anecdotal observation. Person months required to perform the port are the standard measure of this property.

Verifiability

A software system is verifiable if its properties, including all of those previously introduced, can be verified easily. One common technique for increasing verifiability is through the insertion of software code that is intended to monitor various qualities such as performance or correctness. Modular design, rigorous software engineering practices, and the effective use of an appropriate programming language can also contribute to verifiability.

Summary of Software Properties and Associated Metrics

Thus far, it has been emphasized that measurement of software properties is essential throughout the software life cycle. A summary of the software qualities just discussed and possible ways to measure them is shown in Table 149.1.

149.2 Basic Software Engineering Principles

Software engineering has been criticized for not having the same kind of underlying rigor as other engineering disciplines. And while it may be true that there are few formulaic principles, there are many fundamental rules that form the basis of sound software engineering practice. The following sections describe the most general and prevalent of these.

Rigor and Formality

Because software development is a creative activity, there is an inherent tendency toward informal ad hoc techniques in software specification, design, and coding. But the informal approach is contrary to good software engineering practice.

Rigor in software engineering requires the use of mathematical techniques. Formality is a higher form of rigor in which precise engineering approaches are used.

For example, imaging systems require the use of rigorous mathematical specification in the description of image acquisition, filtering, enhancement, and so on. But the existence of mathematical equations in the requirements or design does not imply an overall formal software engineering approach. In the case

of imaging systems, formality further requires that there be an underlying algorithmic approach to the specification, design, coding, and documentation of the software.

Separation of Concerns

Separation of concerns is a kind of divide-and-conquer strategy that software engineers use. There are various ways in which separation of concerns can be achieved. In terms of software design and coding, it is found in modularization of code and in object-oriented design. There may be separation in time, such as developing a schedule for a collection of periodic computing tasks with different periods.

Yet another way of separating concerns is in dealing with qualities. For example, it may be helpful to address the fault tolerance of a system while ignoring other qualities. However, it must be remembered that many of the qualities of software are interrelated, and it is generally impossible to affect one without affecting the other, possibly adversely.

Modularity

Some separation of concerns can be achieved in software through modular design. Modular design involves the decomposition of software behavior in encapsulated software units, and can be achieved in either object-oriented or procedurally oriented programming languages.

Modularity is achieved by grouping together logically related elements, such as statements, procedures, variable declarations, object attributes, and so on in increasingly fine-grained levels of detail (Figure 149.3).

The main objectives in seeking modularity is to foster high cohesion and low coupling. With respect to the code units, cohesion represents intramodule connectivity and coupling represents intermodule connectivity. Coupling and cohesion can be illustrated informally as in Figure 149.4, which shows software

FIGURE 149.3 Modular decomposition of code units. *Arrows* represent inputs and outputs in the procedural paradigm. In the object-oriented paradigm, *arrows* represent associations or messages. The *boxes* represent encapsulated data and procedures in the procedural paradigm. In the object-oriented paradigm they represent classes.

FIGURE 149.4 Software structures with high cohesion and low coupling (a) and low cohesion and high coupling (b). The inside *squares* represent statements or data, and *arcs* indicate functional dependency.

structures with high cohesion and low coupling, and low cohesion and high coupling. The inside squares represent statements or data, and arcs indicate functional dependency.

Cohesion relates to the relationship of the elements of a module. High cohesion implies that each module represents a single part of the problem solution. Therefore, if the system ever needs modification, then that part that needs to be modified exists in a single place, making it easier to change.

Constantine and Yourdon identified seven levels of cohesion in order of strength:⁴

- *Coincidental*. Parts of a module are not related, but simply bundled into a single module.
- *Logical*. Parts that perform similar tasks are put together in a module.
- *Temporal*. Tasks that execute within the same time span are brought together.
- *Procedural*. The elements of a module make up a single control sequence.
- *Communicational*. All elements of a module act on the same area of a data structure.
- *Sequential*. The output of one part in a module serves as input for some other part.
- *Functional*. Each part of the module is necessary for the execution of a single function.

Coupling relates to relationships between the modules themselves. There is great benefit in reducing coupling so that changes made to one code unit do not propagate to others (i.e., they are hidden). This principle of “information hiding,” also known as Parnas partitioning, is the cornerstone of all software design.³ Low coupling limits the effects of errors in a module (lower “ripple effect”), and reduces the likelihood of data integrity problems. In some cases, however, high coupling due to control structures may be necessary. For example, in most graphical user interfaces, control coupling is unavoidable, and indeed desirable.

Coupling has also been characterized in increasing levels as follows:

1. *No direct coupling*. All modules are completely unrelated.
2. *Data*. When all arguments are homogeneous data items, that is, every argument is either a simple argument or data structure in which all elements are used by the called module.
3. *Stamp*. When a data structure is passed from one module to another, but that module operates on only some of the data elements of the structure.
4. *Control*. One module passes an element of control to another, that is, one module explicitly controls the logic of the other.
5. *Common*. When two modules both have access to the same global data.
6. *Content*. One module directly references the contents of another.

Anticipation of Change

It has been mentioned that software products are subject to frequent change either to support new hardware or software requirements or to repair defects. A high maintainability level of the software product is one of the hallmarks of outstanding commercial software.

Software engineers know that their systems are frequently subject to changes in hardware, algorithms, and even application. Therefore, these systems must be designed in such a way so as to facilitate changes without degrading other desirable properties of the software.

Anticipation of change can be achieved in the software design through appropriate techniques, adoption of an appropriate software life-cycle model and associated methodologies, and appropriate management practices.

Generality

In solving a problem, the principle of generality can be stated as the intent to look for the more general problem that may be hidden behind it. For instance, designing the visual inspection system for a specific application is less general than designing it to be adaptable to a wide range of applications.

Generality can be achieved through a number of approaches associated with procedural and object-oriented paradigms. For example, in procedural languages, Parnas’s information hiding can be used. In object orientation, the Liskov substitution principle can be used.

Although generalized solutions may be more costly in terms of the problem at hand, in the long run, the costs of a generalized solution may be worthwhile.

Incrementality

Incrementality involves a software approach in which progressively larger increments of the desired product are developed. Each increment provides additional functionality, which brings the product closer to the final one. Each increment also offers an opportunity for demonstration of the product to the customer for the purposes of gathering requirements and refining the look and feel of the product.

Traceability

Traceability is concerned with the relationships among requirements, their sources, and system design. Regardless of the process model, documentation and code traceability are paramount. A high level of traceability ensures that the software requirements flow down through the design and code and then can be traced back up at every stage of the process. This would ensure, for example, that a coding decision could be traced back to a design decision to satisfy a corresponding requirement.

Traceability is particularly important in embedded systems because often design and coding decisions are made to satisfy hardware constraints that may not be easily associated with a requirement. Failure to provide a traceable path from such decisions through the requirements can lead to difficulties in extending and maintaining the system.

Generally, traceability can be obtained by providing links between all documentation and the software code. In particular, the following links should be in place:

- From requirements to stakeholders who proposed these requirements
- Between dependent requirements
- From the requirements to the design
- From the design to the relevant code segments
- From requirements to the test plan
- From the test plan to test cases

One way to achieve these links is through the use of an appropriate numbering system throughout the documentation. For example, a requirement numbered 3.2.2.1 would be linked to a design element with a similar number (the numbers do not have to be the same so long as the annotation in the document provides traceability). These linkages are depicted in [Figure 149.5](#). Although the documents shown in [Figure 149.5](#) have not been introduced yet, the point to be made is that the documents are all connected through appropriate referencing and notation.

[Figure 149.5](#) is simply a graphical representation of traceable links. In practice, a traceability matrix is constructed to help cross-reference documentation and code elements ([Table 149.2](#)). The matrix is constructed by listing the relevant software documents and the code unit as columns, and then each software requirement in the rows. Constructing the matrix in a spreadsheet software package allows for providing multiple matrices sorted and cross referenced by each column as needed. For example, a traceability matrix sorted by test case number would be an appropriate appendix to the test plan.

The traceability matrices are updated at each step in the software life cycle. For example, the column for the code unit names (e.g., procedure names, object class) would not be added until after the code is developed.

Finally, a way to foster traceability between code units is through the use of data dictionaries.

149.3 Role of Software Engineer

Software production is a problem-solving activity that is accomplished by modeling. As a problem-solving, modeling discipline, software engineering is a human activity that is biased by previous experience and subject to human error.

Modeling is a translation activity. The software product concept is translated into requirements specification. The requirements are converted into a design. The design is then converted into code, which

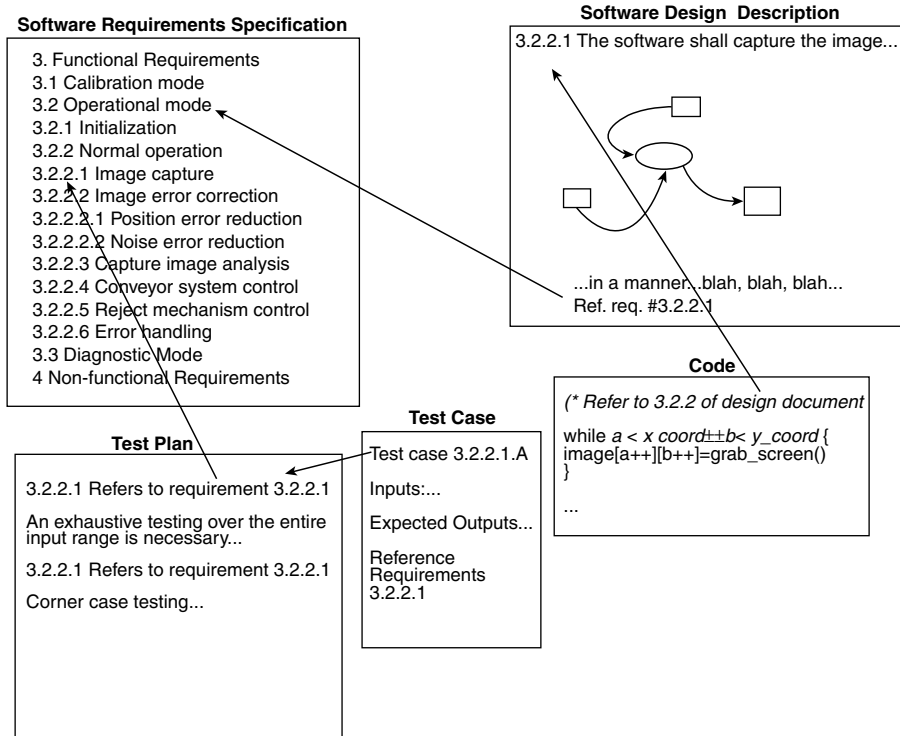

FIGURE 149.5 Linkages between software documentation and code. In this case, the links are achieved through both similarity in numbering and through specific reference to the related item in the appropriate document.

TABLE 149.2 Traceability Matrix Corresponding to Figure 149.5 Sorted by Requirement Number

| Requirement Number | Software Design | | Code Unit Name(s) | Test Case Number(s) |
|--------------------|------------------------------|-------------------------------|-------------------|---------------------------|
| | Document Reference Number(s) | Test Plan Reference Number(s) | | |
| 3.1.1.1 | 3.1.1.1, 3.2.4 | 3.1.1.1, 3.2.4.1, 3.2.4.3 | Simple_fun | 3.1.1.A, 3.1.1.B |
| 3.1.1.2 | 3.1.1.2, | 3.1.1.2 | Kalman_filter | 3.1.1.A, 3.1.1.B |
| 3.1.1.3 | 3.1.1.3 | 3.1.1.3 | Under_bar | 3.1.1.A, 3.1.1.B, 3.1.1.C |

is automatically translated by compilers and assemblers, which produce machine executable code. In each of these translation steps, however, errors are likely to be introduced either by the humans involved or the tools they use. Thus, software engineer must strive to identify these likely errors and avoid or fix them.

Software engineers should also strive to develop code that is built to be tested, designed for reuse, and ready for inevitable change. Anticipation of problems can only come from experience and from drawing on a body of software practice experience from the past 50-plus year.

Software engineers probably spend less than 10% of their time writing code. The other 90% of the time is involved other activities that are generally more important than writing the code. These activities include:

1. Eliciting requirements.
2. Analyzing requirements.
3. Writing software requirements documents.
4. Building and analyzing prototypes.
5. Developing software designs.
6. Writing software design documents

7. Researching software engineering techniques or obtaining information about the application domain.
8. Developing test strategies and test cases.
9. Testing the software and recording the results.
10. Isolating problems and solving them.
11. Learning to use or installing and configuring new software and hardware tools.
12. Writing documentation such as user manuals.
13. Attending meetings with colleagues, customers, and supervisors.
14. Archiving software or preparing it for distribution.

This only provides a partial list of software engineering activities. These activities are not necessarily sequential and not all encompassing. Finally, most of these activities can recur throughout the software life cycle and in each new minor or major software version. Many software engineers specialize in a small subset of these activities, for example, software testing.

Misconceptions about Software Engineering

There are many misconceptions about what software engineering is and what it is intended to do. Often practitioners of “hard” engineering disciplines such as mechanical or electrical engineering view software engineering dimly or not as an engineering discipline at all. This perception could exist partly because there are no fundamental physical laws governing the practice of software engineering, as there are in mechanical, electrical, civil, and other types of engineering. More likely, however, the reason that software engineering does not always get the respect it deserves is that it is often not practiced as an engineering discipline and the barriers to “practicing” it are considered to be too low. Anyone can call herself or himself a software engineer if she or he writes code, but these individuals are not usually practicing software engineering. (As of this writing, one notable exception involves the requirement of professional licensure for individuals practicing software engineering in New York State.)

Some misconceptions about software engineering and brief rebuttals follow:

1. Software system development is primarily concerned with programming.

As mentioned before, 10% or less of the software engineer’s time is spent writing code. Someone who spends the majority of his or her time generating code is more aptly called a “programmer.” Just as wiring a circuit designed by an electrical engineer is not engineering, writing code designed by a software engineer is not an engineering activity.

2. Software tools and development methods can solve most or all of the problems pertaining to software engineering.

This is a dangerous misconception. Tools, software or otherwise, are only as good as the user. Bad habits and flawed reasoning can just as easily be amplified by tools as corrected. While software engineering tools are essential and provide significant advantages, to rely on them to remedy process or engineering deficiencies is naive.

3. Software productivity is a function of system complexity.

While it is certainly the case that system complexity can degrade productivity, there are many other factors that affect productivity. Requirements stability, engineering skill, quality of management, and availability of resources are just a few of the factors that affect productivity. Once software is delivered, the job is finished.

4. Of course, this is not true. At the very least, some form of documentation of the end product as well as the process used needs to be written. More likely, the software product will now enter a maintenance mode after delivery in which it will experience many recurring life cycles as errors are detected and corrected and features are added.

5. Errors are an unavoidable side effect of software development.

While it is unreasonable to expect that all errors can be avoided (as in every discipline involving humans), good software engineering techniques can minimize the number of errors that are delivered to a customer. The attitude that errors are inevitable can be used to excuse sloppiness or complacency, whereas an approach to software engineering that is intended to detect every possible error, no matter how unrealistic this goal may be, will lead to a culture that will encourage engineering rigor and high software quality.

Acknowledgments

This chapter is adapted from *Software Engineering for Image Processing*, by Phillip A. Laplante, CRC Press, Boca Raton, FL, 2003, and from *The Computer Science and Engineering Handbook*, edited by Alan Tucker, CRC Press, Boca Raton, FL, 1996.

Defining Terms

Software design — A phase of the software development life cycle that maps what the system is supposed to do into how the system will do it in a particular hardware/software configuration.

Software engineering — Systematic development, operation, maintenance, and retirement of software.

Software evolution — The process that adapts the software to changes of the environment in which it is used.

Software reengineering — The reverse analysis of an old application to conform to a new methodology.

Human–computer Interface (HCI) design is a new field of scientific inquiry. We now know that the idea of “slapping on an interface” after the software has been programmed could be costly and dangerous if the software is used in safety-critical systems. This chapter focuses on interface design and evaluation, mostly from the user perspective. We will describe the elements of the HCI first. Then, we will present the tools and techniques used to design and evaluate interfaces. Overall, we hope to show that HCI design is a necessary and critical component of any software development in the early design stages.

150.1 A Definition for HCI

HCI is the study of the human and the computer interacting through a medium called an interface. Computers and humans speak different languages, and in order to bridge the gap between them, a common language (or translator) is needed. Given the limitations of humans and the ever-expanding capabilities of computers, it is important to design for this cross-communication through an interface.

150.2 Why Is HCI Design Important?

Most users are familiar with common commercial interfaces using the windows, icons, menus, and pointers (WIMP) design from OpenWindows, KDE, Microsoft Windows, or the MacOS. They most likely can recall receiving a cryptic error message after performing an illegal action, such as a 404 error in Internet Explorer. While these messages convey to the user that there is something wrong, they do not

inform the user about the exact problem nor how to begin fixing the problem at hand. This results in a frustrated user with limited options to perform the next set of tasks. At some time during both the design of the HTTP status code and the design of a compiler, decisions were made on how user feedback was generated. In the HTTP case, error messages have at least a code number, and are usually accompanied by a text description. But it is frequently the case that the messages do not describe the exact problem, especially for those who are unfamiliar with HTTP status codes.

While the idea of providing intuitive feedback to the user seems simple, unfortunately a number of complex issues need to be addressed before the entire system can be rendered user-friendly. In many cases, an interface design that might support a novice user might not allow enough flexibility for more experienced users. For example, a person who programs HTTP code would certainly look at HTTP status codes differently from someone who only uses the web to read email. And anyone who has programmed even a few hundred lines of code knows that a long list of syntax errors could be the result of a single instruction error several lines away from the indicated location of the error. It is now believed that incorporating HCI principles and interface design guidelines have important ramifications on the product's success in today's information-intensive society. Moreover, in safety critical systems, well-designed interfaces could reduce the potential for death and destruction. For example, a fratricide incident in December 2001 in Afghanistan was caused when a soldier mistook his own position for the enemy's because of a poorly designed interface.

150.3 The Human

Computational power has increased by leaps and bounds since the first ENIAC computer was created at Penn State in 1946 [Weik, 1961]. Yet, our human capabilities, as the basis for understanding the computational universe, have remained unchanged over time. As a result, the need to “adapt” the computer to suit human end users has elevated the field of human factors to become an important component in software design. So, the premise here is to design software to fit and adapt to human capabilities by studying the human component of the system first.

Most computer systems require some form of user interaction. By considering the human as a component of system design, system developers are required to include users from the early stages of design. The interface can be viewed as the communication channel through which the human and computer provide each other inputs and outputs. The inputs and outputs need to be specified and protocols established that govern the interaction through the interface. The illustration in Figure 150.1 shows the

FIGURE 150.1 A graphical depiction of human-computer interface from the perspective of input/output communication channels.

human output information channels and the computer's input information channels in a closed system loop. The field of HCI attempts to optimize the compatibility among these input/output channels.

Human Physical Abilities

Human capabilities can be broken down into two major categories: physical and cognitive. There are five basic human senses that are used as input channels for humans: visual, auditory, haptic (or touch), olfactory (or smell), and taste. Human cognitive abilities are used to process and interpret these sensory inputs. Regardless of how technologically advanced our systems may be (e.g., how fast the processor processes, the software compiles, or the display shows rich colors), the range of physical and cognitive capabilities of human beings remains fairly constant across the general population. It seems that in terms of computer technologies, it is the human that is the limiting factor. It is also important to mention that human capabilities vary significantly among user populations, which makes HCI design a challenging multidisciplinary task.

Visual

Among the human senses, vision has been extensively studied and documented in the HCI literature. Vision is the ability to perceive size, colors, and movement of objects. For a visual display to consider these aspects of human perception, there are a number of guidelines, some of which are mentioned below.

Contrast and Color

Contrast is the distinction of light and dark between elements of the display. With proper contrast between the display elements, the user will be able to perceive the information presented on the screen with higher accuracy and lower eyestrain. "When contrast is low, objects must be larger to be equally discriminable" [Sanders and McCormick, 1993]. In addition to perceiving contrast, the human eye distinguishes three primary colors: red, green, and blue. All other colors are a resultant combination of these colors. Contrast is typically more important than color. In general, a dark background with light text is preferred for human perception. The dark background has an added benefit of decreasing the perception of screen flicker as the display is refreshed. However, color can attract attention to a particular area of an interface. When used correctly, color can add depth and aid in conveying importance for key elements of the display. An interface with highlighted text will attract the user's attention to that portion before any other aspect of the text. The application of color to an interface design can allow the designer to focus the user's attention to the areas of the designer's intent.

However, among the general population, 8% of males and 1% of females are colorblind, rendering color displays useless for these users. Color blindness is defined as the inability to perceive one of the three primary colors. Only rarely is a person totally color blind (monochromatic). So, if the interface is designed with contrast rather than color in mind, colorblind users will also be able to use the interface with high degree of accuracy. A quick test of the visibility of the design is to turn the monitor to black and white mode and to evaluate each of the elements of the display in grayscale. Any elements that are not easily detectable should be considered for presentation with higher contrast or a different color.

Movement, Size, and Depth

Humans view size, depth, dimensions, movement, and other distinguishing features of objects in a combinatorial fashion. Size, depth, and dimension are largely determined through the interpretation of the light or brightness of an object. Generally, objects that flash quickly indicate an emergency and attract the most immediate attention. In detecting and perceiving objects, our stored memory about an object also plays a large role. For example, if a person is looking at a pine tree that appears to be 6" tall, the human brain automatically interprets that the tree is far away from the viewer. This is because not only is the reflection of the light from the tree less intense than that of a nearby object, but also we have previous knowledge that pine trees are tens of feet tall. The combination of these two factors allows the perception that the tree might be hundreds of feet away. This principle holds true when viewing a display

as well. An object that is known to the user will be interpreted relative to the other objects in the display. Therefore, a tree in the foreground should be larger than a tree in the background.

Auditory

Human auditory receptors can perceive sounds within a wide range of frequency and intensity. Based on these abilities, there are some key concepts that help in designing auditory interfaces.

Pitch and Intensity

Generally, auditory perception is a result of interpreting pitch, intensity, and duration of sound. Like visual perception, sounds should convey information consistent with existing knowledge (e.g., smoke detector sounds indicate an emergency). They should also be detectable and distinguishable from surrounding noise and other auditory signals. Humans can perceive even minute pitch or tone differences. On the other hand, auditory displays should avoid excessive auditory signals because they can become distractions rather than providing useful information to the user. When designing for an interface in an area with excessive ambient noise, a signal's auditory pitch and intensity must be determined such that it is not masked by environmental noise. Another consideration is the possibility of perceptual adaptation when the user "filter's out" a signal because it fails to provide further useful information after first encountered. Interrupted or variable signals are less likely to encounter this problem and will have a longer-lasting capability of transferring the required information.

In order to best differentiate warning sounds and signals used in an interface, the following guidelines are recommended [Sanders and McCormick, 1993]:

- Use frequencies between 200 and 5000 Hz, preferably between 500 and 3000 Hz.
- Use a modulated signal (1 to 8 beeps per second, or warbling sounds varying 1 to 3 times per second), since it is different enough from normal sounds.
- Use frequencies different from those that dominate any background noise to minimize masking.

Loudness

Sound intensity is measured in decibels, a measure of the physical compression of air in a sinusoidal waveform. It is important to recognize that both pitch and intensity affect the overall sound effect. Loudness is the human perception of this effect. Obviously, the perceived relative loudness of a sound varies by individual. Another consideration is the relative loudness of an auditory signal as it is perceived in the environment where the auditory interface is being used. For example, if an interface is to be used in the cargo area of a container ship, an auditory signal will be perceived as less loud compared to the same signal in an executive office area.

Haptic

The fingers and thumbs contain the most sensitive receptors to external pressure. Haptic interfaces take advantage of these sensitive receptors. However, the methods for transmitting complicated information through haptic senses require significant training (e.g., Braille). In its simplest form, computer users have been using their haptic sense through a keyboard, mouse, touch pad, and so on.

Haptic receptors on human hands can detect such things as mechanical vibration, electrical impulses, and physical pressure. The fingers can generally sense pressures with a two-point threshold of 0.25 cm, the thumb a bit less at 0.3 cm. Therefore, if a haptic element is planned for an interface, it is important to recognize the need to provide the user with at least that level of resistance so that the user perceives the interaction. The user will not perceive any response that is lower than the measured resistance. Touch screens are a prime example of a situation when tactile feedback contributes to the user's overall ability to control the system. In these systems, a user will manipulate the interface faster and with greater accuracy if the system provided tactile feedback that the input was received by the interface. A tactile feedback coupled with auditory cues is the best solution. An example of this is a standard keyboard. The keys provide resistance when depressed and a light tapping sound is registered, signaling that the key has been successfully engaged to convey information to the computer.

Olfactory/Taste

While these two senses are very important human receptors, there is no evidence that olfactory or taste sensations have been used successfully in human computer interface design. There is potential use for these senses as virtual reality becomes more developed. For example, a new research endeavor is being organized in “affective” computing. Affective computing attempts to provide human–computer interactions that contain feelings and emotions. In this respect, the above senses might play an important role in the future.

Human Cognitive Capabilities

In HCI, the designer must be aware of how humans acquire and process information from the interface. Therefore, human memory, reasoning (problem solving), and learning play key roles in how humans interact with computing systems. Limitations in these human abilities and large variations among them must also be understood in order to design interfaces properly.

Memory

In general, three types of human memory systems interact to give us the ability to store information. The *sensory* memory acts as a buffer for stimuli received through the senses. These memories are constantly overwritten by new information coming in on a sensory channel. Information is passed from sensory memory into *short-term* memory by attention. Attention filters the stimuli, leaving those that are of interest at a given time. This is the memory that helps us listen to a conversation while attending to other information in the background. From an HCI design perspective, an example for the use of this memory is to provide “closure” when a specific task is complete. A dialog box indicating: “Are you sure you want to exit this module ...” brings closure to a subtask and allows the user to delete short-term memory storage and continue with other tasks required by the system. Lastly, a *long-term* memory is a permanent storage of factual information, experiential knowledge, procedural rules, and so on. Its characteristics are large amounts of storage, slow access and retrieval time, and a slow forgetting process. We store information in long-term memory through an elaborate network of identity connections (semantic, visual, procedural, etc.) and retrieve it by familiarity, structure, and concreteness. Two types of information retrieval have been extensively used in HCI design: recognition and recall. Information displays using memory recognition require knowledge that the information has been seen before. For example, a web page giving a choice of menus uses recognition memory. On the other hand, information displays using memory recall are based on the fact that the information is reproduced from memory. An example of this is a page that requires the user to enter a choice of airline in a data field for ticketing purposes.

Reasoning

Reasoning is the process by which we use the knowledge we have to draw conclusions or generate new inferences about the domain of interest. *Deductive* reasoning derives the logically necessary conclusions from the given set of premises. For example, the use of the word “Lassie” in a web page on dogs logically conjures up the image of the Lassie dog from a famous television serial. However, the same name in a different context might conclude a different entity. *Inductive* reasoning, on the other hand, is a generalization from the cases we have seen or experienced to infer information about cases that we have not seen or experienced. For example, the use of color red on a dial generally indicates the presence of a hazard. If we use the color red on an interface designed to show different levels of pressure, then, we should expect the users to make a similar inference. Of course, this inference may be unreliable in some other situations (e.g., the use of color red in a nuclear power control panel may denote safety rather than danger). The third type of reasoning is *abduction*, which derives a fact from the action or state that caused it. For example, in a word processor, closing a document assumes that the user has finished using or modifying the document. However, a proper design would include a dialog box asking the user if the system should save any unsaved portion.

Learning/Skill Acquisition

One of the distinguishing characteristics of human beings is the ability to learn. As such, interface designers can use this human potential to design adaptive systems. At the lowest common denominator, a designer must consider the “norm” behavior and abilities of the user population in allocating functions to any interface feature. In general, there are three basic levels of skills as users go through their learning process [Dix et al., 1998]: (1) the learner uses general-purpose rules, which interpret facts about a problem; (2) the learner develops rules specific to the task; and (3) the rules are tuned to speed up performance. From an interface design standpoint, a thorough investigation and understanding of the language and symbols of the user population can facilitate interface design because many of the rules to perform the tasks are already known as part of the user skill set. A prime example of learning gone wrong is the case of the QWERTY keyboard layout. The QWERTY keyboard layout is certainly not the optimal interface design for typing; however, through many years of learned behavior, this less-than-optimal design has become the standard for keyboard interface. Other keyboard layout designs that have proven to be faster and more accurate have not achieved market success because the relearning process would be cost prohibitive.

150.4 The Interaction

In an ideal human–computer interactive world, humans and computers would perfectly understand each other’s intentions. Current popular software systems in use are quite distant from such a perfect communicative state. HCI designers must anticipate the needs of the end user to create programs that are natural to use and easy to learn. While human limitations must be considered when designing any HCI, there are a number of usability issues that help to account for user abilities and intentions in a more natural interactive fashion.

Paradigm Shifts

Perceptions about the use of computers have shifted drastically over the years. When the first electronic computer was introduced during the mid-1940s, interaction consisted of flipping a series of switches. It required weeks to correctly reprogram by changing the status of these manual switches. During the early 1970s, Xerox PARC developed the direct manipulation concepts of the WIMP and graphical user interface (GUI) paradigms that have been used by most HCI designers since the late 1980s. Since the mid-1990s, much research has been conducted in three-dimensional visual interfaces, natural language interfaces, and even direct neural interfaces — a clear paradigm shift to a more natural human–computer interaction.

Despite these shifts, it is still unclear as to what exactly constitutes good interaction. With each new paradigm there is an associated set of advantages and disadvantages. For example, while WIMP and GUI have proven extremely successful over the past 20 years, they still have many problems. The user must still be able to successfully navigate through a program to perform different tasks. For this reason most Windows programs have a basic set of tasks such as Open File, Close File, Save, and so on that are always located in the same relative place in the interface. However, beyond these basic tasks, each program has its own tasks with which a user must slowly and fitfully learn and use. For example, a paint program might require users to manipulate filters in order to modify a graphics file, whereas a word processor might require format changes in how a text file is printed. These may be considered as basic tasks within their respective program environments. While there are no obvious methods to instruct users how to perform tasks within each program, there are principles that can be used to aid program designer to convey their intent to the user. These are discussed in the subsequent sections.

150.5 Usability Principles

Over the years there have been many attempts to produce guidelines to help designers develop better interfaces. From these attempts, usability heuristics seem to be the most widely used approach. Jakob

Nielsen's *Ten Usability Heuristics* is a simple set of guidelines for HCI design and redesign improvements [Nielsen, 1994]. These ten heuristics are listed below:

1. *Visibility of system status*
The system should always keep users informed about what is going on, through appropriate feedback within reasonable time.
2. *Match between system and the real world*
The system should speak the user's language with words, phrases, and concepts familiar to the user, rather than system-oriented terms. Follow real-world conventions, making information appear in a natural and logical order.
3. *User control and freedom*
Users often choose system functions by mistake and will need a clearly marked "emergency exit" to leave the unwanted state without having to go through an extended dialogue (e.g., support "undo" and "redo").
4. *Consistency and standards*
Users should not have to wonder whether different words, situations, or actions mean the same thing. Follow platform conventions.
5. *Error prevention*
Even better than good error messages is a careful design that prevents a problem from occurring in the first place.
6. *Recognition rather than recall*
Make objects, actions, and options visible. The user should not have to remember information from one part of the dialogue to another. Instructions for use of the system should be visible or easily retrievable whenever appropriate.
7. *Flexibility and efficiency of use*
Accelerators — unseen by the novice user — may often speed up the interaction for the expert user such that the system can cater to both inexperienced and experienced users. Allow users to tailor frequent actions.
8. *Aesthetic and minimalist design*
Dialogues should not contain information that is irrelevant or rarely needed. Every extra unit of information in a dialogue competes with relevant units of information and diminishes their relative visibility.
9. *Help users recognize, diagnose, and recover from errors*
Error messages should be expressed in plain language (not code numbers), precisely indicate the problem, and constructively suggest a solution.
10. *Help and documentation*
It is ideal if the system can be used without documentation. Nevertheless, in most systems it may be necessary to provide help and documentation. Any such information should be easy to search, focused on the user's task, list concrete steps to be carried out, and not be too lengthy.

One interesting feature of the above set of heuristics is that the ten points are mostly independent of each other and therefore can be applied separately to any interface design. And, these heuristics are general enough to be applied in various user interface domains and applications.

As an example, to increase the precision of using these heuristics, Rahimi [2002] has applied weighted scores to the heuristics to compare usability between a DOS and Windows version of a vehicle routing system. Each heuristic was used as an independent attribute and was assigned a score for each system. When the scores were summed, the DOS version received a higher overall usability score than the Windows version. This may have explained why users were consistently in favor of using the DOS routing system. This finding reinforces the notion of user preference for a simpler and more consistent interface over a sophisticated GUI innovation.

150.6 Models of Users in Design

From an HCI design perspective, there are two basic types of users: novice and expert. A basic premise is that the system must facilitate the transition from the novice level of use to expert level of use with minimum transition time and the least number of errors possible. One way of doing this is to allow the user to modify a program while minimizing the degree of task interference. Another approach is to let the system determine where the user is in the expertise spectrum and adapt itself to the user's dynamic performance, using intelligent support tools and interactive help systems.

An example for this transition is the use of "agents." The idea of agents is to create a simple, guided, and intelligent capability within the interface. Most current Microsoft products include subsidiary programs that help (novice) users perform any of a number of tasks. However, for many expert users, these agents tend to interfere with the more specialized tasks expert users typically perform. To counter this problem, expert users frequently decide to relax or remove agent-imposed constraints altogether. Microsoft Office's Paperclip is an example of a type of an agent that was designed to help users perform various tasks with Microsoft Office. However, it is considered unhelpful by many intermediate to expert users.

Modeling the User

There are several tools to analyze user interactions across an interface. One useful technique is the goal, operators, methods, selections (GOMS) model by Card et al. [1983] and its later derivatives. GOMS attempts to model and prescribe user interaction in a task domain. Typically, the focus is more on the physical interactions with the system than on a purely cognitive process. As a result, this technique has been used for analyzing how long a task should take for a group of users. For instance, a simple GOMS model of writing a letter on paper might be:

```
GOAL: WRITE-LETTER
      GOAL: LOCATE-PAPER
      GOAL: LOCATE-PEN
      GOAL: WRITE-WORDS-ON-PAPER
            WRITE-GREETING
            WRITE-THINGS-YOU-WANT-TO-SAY
            WRITE-ENDING
```

...

By assigning task times to each GOAL, one could estimate total performance time. There is an extensive literature on GOMS and other similar user modeling techniques [see Dix et al., 1998].

150.7 Task Analysis

One important tool for HCI design is *task analysis*. Dix et al. [1998] define task analysis as "the process of analyzing the way people perform their jobs: the things they do, the things they act on and the things they need to know." We use a brief example of checking for email using a computer web browser to illustrate this process:

In order to check email on a computer web browser:

```
find a usable computer and turn it on
start web browser
enter URL of web-based email program
enter username and password into program
check email
```

For each one of these tasks, one can create a more complex set of subtasks to explain the user performance in more detail. For example, we can expand "start web browser" into a series of steps such as:

find web browser icon on screen or menu
click web browser icon to start web browser program

There are various ways in which a task can be decomposed into its smaller components. We explain three classes of task analyses in this chapter:

1. Task decomposition examines the way in which a task can be broken down into subtasks and the order in which these can be performed.
2. Knowledge-based techniques examine what users need to know about the object and actions involved in performing a task and how that knowledge is organized.
3. Entity-relation-based analysis is an object-based approach that emphasizes identifying the actor and objects, the relationships between them, and the actions they perform.

Task Decomposition

As stated above, task decomposition requires breaking down a task into several subtasks and ordering them in such a way as to show how the subtasks are performed. One approach to performing task decomposition is *hierarchical task analysis* (HTA) [Shepherd, 1989]. HTA creates a listing of tasks and the order in which these tasks must be performed. We again use the email example above to illustrate how to make a simple HTA. We assume that there are no server-related problems while retrieving the e-mail. We also use a “plan” to denote the ordering of subtasks or any other special arrangements in regards to the tasks to be performed.

```
0. In order to check email on a computer web browser
  1. If computer does not function find functional computer
  2. If computer is off turn it on
  3. If monitor is off turn it on
  4. Start web browser
  5. Check email
5.1 Enter email program URL into web browser address bar
5.2 Login to retrieve email
5.2.1 When email portal appears enter username into username datafield
5.2.2 When email portal appears enter password into password datafield
5.2.3 Send username and password
5.3 Read email
Plan 0: do 1 before 2 - 3 - 4 - 5
do 2 - 3 in any order before 4 - 5
do 4 - 5 in that order
Plan 5: do 5.1 - 5.2 - 5.3 in that order
Plan 5.2: do 5.2.1 - 5.2.2 in any order before 5.2.3
continue to do 5.2 until successfully logged in
```

[Figure 150.2](#) converts the textual format outlined above into a graphical depiction.

A number of assumptions were made while performing this HTA. We assumed that the user knows how to operate a computer with enough proficiency to turn one on and to start a web browser program. Furthermore, we assumed that the user knows the URL of the email portal, and his or her username and password. Lastly, we assumed that the user knows how the web-based email program works. The key concept in designing any HTA is that tasks can be studied by breaking them down into smaller and often more manageable subcomponents. One of the key skills in creating an HTA, therefore, is developing an understanding about the degree of depth that meaningfully captures an actual user-task interaction. Keep in mind that any assumptions made by the modeler have significant ramifications on how a designer reflects these task interactions into the interface design requirements.

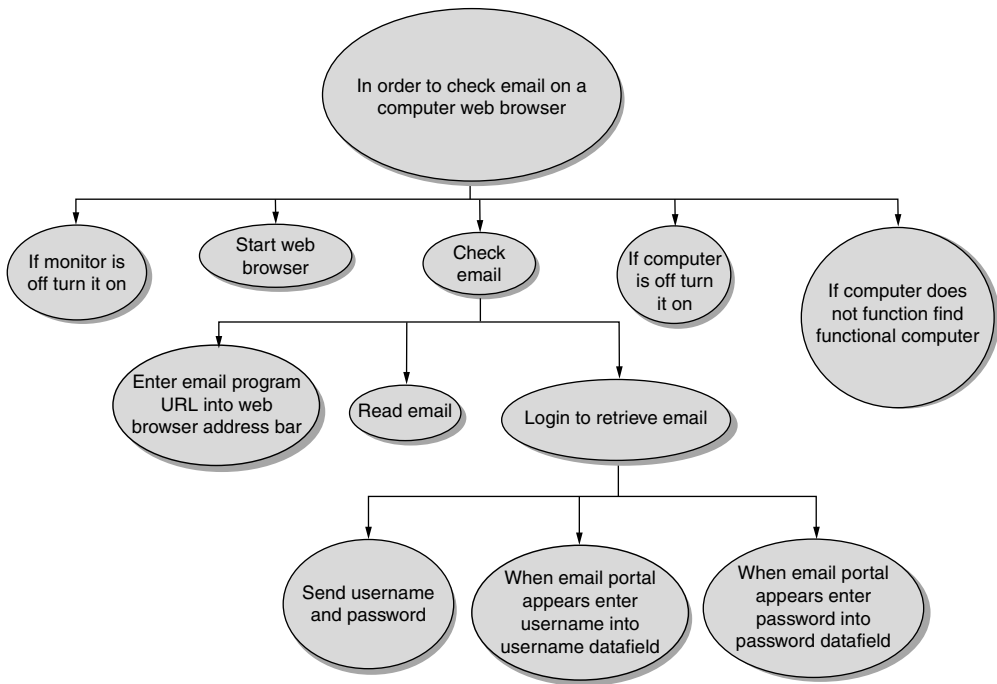

FIGURE 150.2 A graphical depiction of a Hierarchical Task Analysis for checking and reading an e-mail.

Knowledge-Based Analysis

Knowledge-based analysis is similar to task decomposition except that it creates a taxonomy or semantic-based relationship among objects and actions associated with a task. Instead of looking exclusively at how a task is performed, a knowledge-based analysis looks at how the multiple components of an interactive task fit together. One technique for performing knowledge-based analysis is task analysis for knowledge description (TAKD) [Diaper, 1989], which uses a special taxonomy called task description hierarchy (TDH).

TAKD uses a list of attributes needed to perform a task and logically relates them using TDH's three basic logical operators: AND, OR, and XOR. For instance, creating a knowledge-based analysis of the email example above, we have the following:

```

check email on computer AND
/___computer status AND
  /_____functional
  /_____turned on
/___monitor status AND
  /_____functional
  /_____turned on
/___web browser program AND
  /_____started
  /_____email URL entered
  /_____email username entered
  /_____email password entered
  
```

Note that unlike the task decomposition, there is no indication as to how the task is performed. Rather, the focus is on what actions and objects must be used to correctly check email on a computer. This

method provides a more abstract approach to analyzing a task, thereby allowing the modeler to understand the general components required to perform a task with logical interconnections.

Entity-Relationship-Based Techniques

Entity-relationship-based analysis is an object-oriented approach. It stresses understanding the relationship of the entities to a task, rather than on the components of the task alone. It is similar in design and function to object-oriented programming. This approach shares the need to catalog actions and objects with the knowledge-based approach. For example, using the email illustration again we have:

```
Object email user human actor
```

```
  Actions:
```

```
    U1: Check if X works
```

```
    U2: Start X
```

```
    U3: Use X
```

```
    U4: Type X
```

```
    U5: Read X
```

```
Object computer simple
```

```
  Attribute:
```

```
    functional
```

```
    on
```

```
Object monitor simple
```

```
  Attributes:
```

```
    functional
```

```
    on
```

```
Object web browser simple
```

```
  Attributes:
```

```
    functional
```

```
    on
```

```
  Event:
```

```
    URL found
```

```
Relations: action-event
```

```
  before (U1, U2)
```

```
-device must work before it can be turned on
```

```
  before (U2, U3)
```

```
-device or program must be started before they can be used
```

```
  before (U2, U3)
```

```
-user must type in correct username and password before they can read their email.
```

Unlike the previous example, the entity-relationship technique focuses on object interactions rather than on the task itself. Therefore, it is useful for creating models where less is known about a task and more is known about the objects performing a task.

150.8 Implementation Evaluation

Interface valuations are performed after a design is implemented. Therefore, these techniques center on examining how well users perform in a given environment. The evaluations could take one of several forms mentioned below.

Empirical methods frequently use statistical analysis to examine user performance. This requires gathering data indicating user performance attributes such as the time required for a user to finish a task

or how many errors occur in performing a task. In its simplest form, a Student's t -test is performed to show differences in performance between two interface designs.

Observational methods involve watching and recording how users perform the required tasks in an interactive manner. These methods are generally employed when the users need to perform their tasks in a natural setting. Therefore, the investigators must pay special attention to the observation tools used so as not to interfere with the actual user tasks. An example for this type of technique is called verbal protocol analysis.

Query techniques “debrief” users after they have performed a task in order to understand the user's point of view. While this technique is similar to the observation method above, query techniques tend to be more informal and limit external interference. A formal survey or question/answer tool would be an excellent complement to some of the more specific task-modeling approaches mentioned previously.

150.9 Concluding Remarks

HCI design is a broad and interdisciplinary field. While we have attempted to briefly summarize key areas in this field, a vast amount of literature exists on different aspects of HCI design not covered here. We intended to explain HCI design in the context of software design process. We believe that interface design is an effort that should be addressed at all stages of software design. A proper interface design should support the tasks that users actually want to do, and forgive those that they inadvertently initiate as mistakes. Therefore, it is a design process that should consider the users as intelligent entities with specific tasks in mind, who want to use the interface in a way that is seamless with respect to their everyday jobs. In this respect, the interface as a critical component of the software should be designed to:

- Match the tasks that the users want to perform
- Be easy to use and adaptable to user-level skills and knowledge
- Provide feedback on system status and users' upcoming task options
- Provide information on task completion

Finally, the basis of this chapter seems to be users and their tasks, rather than computers and their ability to generate objects on the interface. This emphasis forces us to consider HCI as an iterative design process, since we do not have a sufficiently strong theory about human task performance. In this respect, we are dealing with a field that is both science and art.

Defining Terms

GUI — Graphical user interface.

GOMS — Goal, operators, methods, selections.

Human senses — Five essential human senses used for interacting with computers.

Paradigm shift — Perceptions about computer use in society.

Portal — A website or service that offers a broad array of resources and services, such as e-mail, forums, search engines, and online shopping malls.

Task analysis — The process of decomposing a user task into its meaningful components.

TAKD — Task analysis for knowledge description.

TDH — Task description hierarchy.

Usability — The process of evaluating software usage.

WIMP — Windows, icons, menus, and pointers.

Rosemary L. Smith

University of California, Davis

Sensors are critical components in all measurement and control systems. Along with the always-present need for sensors in science and medicine, the demand for sensors in automated manufacturing and processing is rapidly growing. In addition, small, inexpensive sensors are finding their way into all sorts of consumer products, from children's toys to dishwashers to automobiles. Because of the vast variety of useful things to be sensed and sensor applications, sensor engineering is a multidisciplinary and interdisciplinary field or endeavor. This chapter introduces some basic definitions, concepts, and features of sensors and illustrates them with several examples. The reader is directed to the references and further information for more details and examples.

The terms *sensor*, *transducer*, *meter*, *detector*, and *gauge* are often used synonymously. Generally, a transducer is defined as a device that converts energy from one form to another. However, the most widely used definition for sensor is that which has been applied to electrical transducers by the Instrument Society of America [ANSI, 1975]: "Transducer — A device which provides a usable output in response to a specified measurand." The measurand can be any physical, chemical, or biological property or condition to be measured. A usable output refers to an optical, electronic, or mechanical signal. Following the advent of the microprocessor, a usable output has come to mean to many an electronic output signal. For example, consider the common thermometer. In response to a temperature increase, the volume of mercury inside increases via thermal expansion. The change in height of the mercury column inside the glass tube is a usable output, although it is not an electrical signal. The change in mercury height is detected by the human eye, which acts as a secondary transducing element. In order to produce an electrical signal as output, the height of the mercury has to be converted, for example, by using optical or capacitive effects. However, there are more direct temperature-sensing methods in which an electrical output is produced in response to a change in temperature. An example is given in the next section on physical sensors.

Many sensors employ more than one transduction mechanism to produce a usable output signal. Sometimes sensors are classified as direct or indirect according to how many transduction mechanisms are required to produce the desired output signal. A thermocouple, used to measure temperature, is a direct sensor because it produces an electrical voltage directly as output in response to a temperature gradient. However, most flow rate sensors are indirect sensors. Flow rate is usually inferred from a secondary measurement, such as the displacement of an object placed in the flow stream (e.g., rotome-

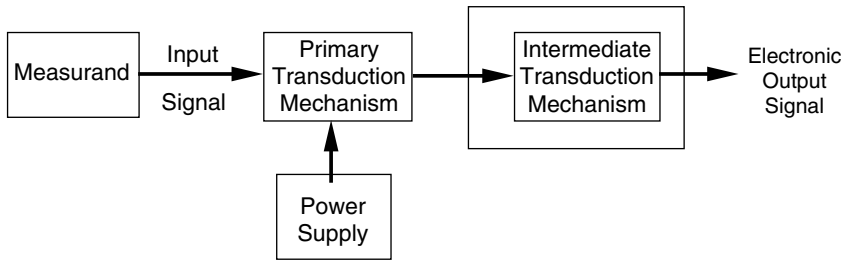

FIGURE 151.1 Sensor block diagram. Active sensors require input power to accomplish transduction. Many sensors employ multiple transduction mechanisms in order to produce an electronic output in response to the measurand.

ters), the temperature measured downstream from a hot element (anemometer), or the difference in pressure measured at two points along the flow path. Figure 151.1 depicts a typical sensor block diagram identifying the measurand and associated input signal, the primary and intermediate transduction mechanisms, and the electronic output signal. Indirect sensors typically require an electrical power source be applied in order to produce an electronic output signal. A piezoresistor, for example, is a resistor that changes value when strained. But in order to generate a corresponding electrical signal, a current is passed through the resistor to generate an output voltage signal, whose value is related to the resistance by Ohm’s law: $V = I \cdot R$. Table 151.1 is a 6×6 matrix of some of the more commonly employed physical and chemical transduction mechanisms. Detailed descriptions of these mechanisms can be found in college-level physics textbooks.

In choosing a particular sensor for a given application, many factors must be considered. These deciding factors, or specifications, can be divided into three major categories: environmental factors, economic factors, and sensor performance. The most commonly encountered factors are listed in Table 151.2, although not all of these may be pertinent to a particular application. Environmental factors determine the *packaging* of the sensor — which refers to its encapsulation or insulation that provides protection or isolation — and the input/output, leads, connections, and cabling. Economic factors determine the type of manufacturing and materials used in the sensor, and to some extent, the quality of the materials. For example, a very expensive sensor may be cost-effective if it is used repeatedly, operates reliably for very long periods of time, or has exceptionally high performance. On the other hand, a disposable sensor, such as is desired in many medical applications, should be inexpensive. The performance requirements of the sensor are usually the specifications of primary concern. The most important of these are *sensitivity*, *stability*, and *repeatability*. Normally, a sensor is only useful if all three of these parameters are tightly specified for a given range of measurand and time of operation. For example, a highly sensitive device is not very useful if its output signal drifts greatly during the measurement time, and the data obtained are not reliable if the measurement is not repeatable. Other output signal characteristics, such as selectivity and linearity, can often be compensated for by using additional independent sensors or with signal-conditioning circuits. In fact, most sensors have a response to temperature, since most transduction mechanisms are temperature dependent.

Sensors are most often classified by the type of measurand they are to measure — that is, physical, chemical, or biological. This is a much simpler means of classification than by transduction mechanism or type of output signal (e.g., digital or analog), since many sensors use multiple transduction mechanisms and the output signal can always be processed, conditioned, or converted by a circuit so as to cloud the definition of output. A description of each classification and examples are given in the following sections. In Section 151.4, *microsensors* are introduced with a few examples.

151.1 Physical Sensors

Physical measurands include temperature, strain, force, pressure, displacement, position, velocity, acceleration, optical radiation, sound, flow rate, viscosity, and electromagnetic fields. In Table 151.1, note that

TABLE 151.1 Physical and Chemical Transduction Principles

| Primary Signal | Secondary Signal | | | | | |
|----------------|--|---|--|--|---|--|
| | Mechanical | Thermal | Electrical | Magnetic | Radiant | Chemical |
| Mechanical | (Fluid) mechanical and acoustic effects (e.g., diaphragm, gravity balance, echo sounder) | Friction effects (e.g., friction calorimeter), cooling effects (e.g., thermal flowmeters) | Piezoelectricity; piezoresistivity; resistive, capacitive, and inductive effects | Magnetomechanical effects (e.g., piezomagnetic effect) | Photoelastic systems (stress-induced birefringence), interferometers, Sagnac effect, Doppler effect | |
| Thermal | Thermal expansion (bimetal strip, liquid in glass, and gas thermometers: resonant frequency), radiometer effect (light mill) | | Seebeck effect, thermoresistance, pyroelectricity, thermal (Johnson) noise | | Thermo-optical effects (e.g., in liquid crystals), radiant emission | Reaction activation (e.g., thermal dissociation) |
| Electrical | Electrokinetic and electromechanical effects (e.g., piezoelectricity, electrometer, Ampere's law) | Joule (resistive) heating, Peltier effect | Charge collectors, Langmuir probe | Biot–Savart's law | Electro-optical effects (e.g., Kerr effect, Pockels effect, electroluminescence) | Electrolysis, electromigration |
| Magnetic | Magnetomechanical effect (e.g., magnetostriction, magnetometer) | Thermomagnetic effects (e.g., Righi-Leduc effect), galvanomagnetic effects (e.g., Ettingshausen effect) | Thermomagnetic effects (e.g., Ettingshausen–Nernst effect), alvano-magnetic effects (e.g., Hall effect, magnetoresistance) | | Magneto-optical effects (e.g., Faraday effect, Cotton–Mouton effect) | |
| Radiant | Radiation pressure | Bolometer, thermopile | Photoelectric effects (e.g., photovoltaic effect, photoconductive effect) | | Photorefractive effects, optical bistability | Photosynthesis, dissociation |
| Chemical | Hygrometer, electrodeposition cell, photoacoustic effect | Calorimeter, thermal conductivity cell | Potentiometry, conductimetry, amperometry, flame ionization, Volta effect, gas sensitive field effect | Nuclear magnetic resonance | (Emission and absorption) spectroscopy, chemiluminescence | |

TABLE 151.2 Factors for Considerations in Sensor Selection

| Environmental Factors | Economic Factors | Sensor Performance |
|------------------------------------|------------------|--------------------|
| Temperature range | Cost | Sensitivity |
| Humidity effects | Availability | Range |
| Corrosion | Lifetime | Stability |
| Size | Performance | Repeatability |
| Over-range protection | | Linearity |
| Susceptibility to EM interferences | | Accuracy |
| Self-test capability | | Response time |
| Ruggedness | | Frequency response |
| Power consumption | | |

all but those transduction mechanisms listed in the chemical row are used in the design of physical sensors. Clearly, physical sensors compose a very large proportion of all sensors. It is impossible to illustrate all of them, but three measurands stand out in terms of their widespread application: temperature, displacement (or associated force), and optical radiation.

Temperature Sensors

Temperature is an important parameter in many control systems, most familiarly in environmental control systems. Several distinct transduction mechanisms have been employed. The mercury thermometer was mentioned earlier as a nonelectronic sensor. The most commonly used electronic temperature sensors are thermocouples, thermistors, and resistance thermometers. Thermocouples operate according to the Seebeck effect, which occurs at the junction of two dissimilar metal wires, such as copper and constantan. A voltage difference is generated at the hot junction due to the difference in the energy distribution of thermally energized electrons in each metal. A temperature gradient between the hot junction and the cooler ends produces the requisite, albeit minute, current that enables the measurement of the junction voltage between the ends of the two wires. The output voltage changes linearly with temperature over a given range, depending on the choice of metals. To minimize measurement error, the cool end of the couple must be kept at a constant temperature and the voltmeter must have a high input impedance. Connecting thermocouples in series creates a thermopile that produces an output voltage approximately equal to that produced from a single thermocouple voltage multiplied by the number of couples.

The resistance thermometer relies on the increase in resistance of a metal wire with increasing temperature. As the electrons in the metal gain thermal energy, they move about more rapidly and undergo more frequent collisions with each other and the atomic nuclei. These scattering events reduce the mobility of the electrons, and since resistance is inversely proportional to mobility, the resistance increases. Resistance thermometers usually consist of a coil of fine metal wire. Platinum wire gives the largest linear temperature range of operation. To determine the resistance, a constant current is supplied and the voltage is measured. A resistance measurement can be made by placing the resistor in the sensing arm of a Wheatstone bridge and adjusting the opposing resistor to “balance” the bridge, which produces a null output. A measure of the sensitivity of a resistance thermometer is its temperature coefficient of resistance: $TCR = (\Delta R/R)(1/\Delta T)$, in units of percent resistance per degree of temperature.

Thermistors are resistive elements made of semiconductive materials. Semiconductors have a negative coefficient of resistance that can be up to 100 times higher in value than the TCR of a metal, which is positive. The mechanism governing the resistance change of a thermistor is the increase in the number of charge carriers with increase in temperature due to thermal generation. Electrons that are tightly bound to the nucleus by coulombic attraction, called the valence electrons, gain sufficient thermal energy to break away from the nucleus and become influenced by external electric fields. Thermistors are measured in the same manner as resistance thermometers, but are much more sensitive.

FIGURE 151.2 Schematic diagram of a mechanical oscillator made up of a mass at the end of a spring. The displacement of the mass, $x(t)$, in response to an acceleration, $a(t)$, is given by $F = M \cdot a(t) = M \ddot{x} + D \dot{x} + Kx$, where K is the spring constant, D is viscous drag, M is the mass, and F is the net force exerted on the mass. For a constant acceleration due to gravity, g , the steady-state solution to this differential equation yields $x = Mg/K$. The displacement of a known mass, therefore, can be used to determine its acceleration.

Displacement and Force Sensors

Many types of forces are sensed by the displacements they create. For example, the force due to acceleration of a mass at the end of a spring will cause the spring to stretch and the mass to move. This phenomenon is illustrated in Figure 151.2. The displacement, x , of the mass, M , from its zero acceleration position, is governed by the force generated by acceleration ($F = M \cdot a$) and the restoring force of the spring ($F = -K \cdot x$). For a constant acceleration due to gravity, g , the steady state displacement, x , is equal to $M \cdot g/K$. Therefore, the force due to acceleration can be determined by measuring the displacement of a known mass on which the force is acting.

Another example of force sensed by displacement is the displacement of the center of a deformable membrane due to a difference in pressure across it. Both the pressure sensor and the accelerometer examples use multiple transduction mechanisms to produce an electronic output. The primary mechanism converts force to displacement (mechanical to mechanical). An intermediate mechanism is used to convert displacement to an electrical signal (mechanical to electrical). Displacement can be determined by measuring the capacitance between two plates that move with respect to each other. The gap between the two plates is the displacement, and the associated capacitance is given by $C = \text{area} \times \text{dielectric constant} / \text{gap length}$. The ratio of plate area to gap length must be greater than 100, since most dielectric constants are on the order of $1 \cdot 10^{-13}$ farads/cm and capacitance is readily resolvable to only about 10^{-11} farads. This is because measurement leads and contacts create parasitic capacitances of about 10^{-12} farads. If the capacitance is measured at the generated site by an integrated circuit (see discussion of microsensors), capacitances as small as 10^{-15} farads can be measured. Displacement is also commonly measured by the movement of a ferromagnetic core inside an inductor coil. The displacement produces a change in inductance that can be measured by placing the inductor in an oscillator circuit and measuring the change in frequency of oscillation.

The most commonly used force sensor is the strain gage. It consists of metal wires that are fixed to an immobile structure at one end and to a deformable element at the other. The resistance of the wire changes as it undergoes strain; that is, resistance changes in length, since the resistance of a wire is $R = \text{resistivity} \times \text{length} / \text{cross-sectional area}$. The wire's resistivity is a bulk property of the metal, which is a constant for constant temperature. For example, a strain gage can be used to measure force by attaching both ends of the wire to a cantilever beam, with one end of the wire at the attached beam end and the other at the free end. The cantilever-beam free end moves in response to an applied force that produces strain in the wire and a subsequent change in resistance. The sensitivity of a strain gage is described by the unitless gage factor, $G = (\Delta R/R) / (\Delta L/L)$. For metal wires, gage factors typically range from 2 to 3. Semiconductor materials are known to exhibit *piezoresistivity*, a change in resistance in response to strain that involves a large change in resistivity in addition to the change in linear dimension. Piezoresistors have gage factors as high as 130. Piezoresistive strain gages are frequently used in silicon microsensors because they can be fabricated inside the same semiconductor material as the micromechanical device.

Piezoelectric sensors use materials that produce electric charge, measured as a voltage, at their surface in response to mechanical deformation, for example by application of pressure. The charge is generated by the deformation of dipoles that are a consequence of the molecular structure of the material itself. The inverse effect is also true, that is, application of a voltage will produce deformation. Examples of

piezoelectric materials are polyvinylidene difluoride (PVDF), quartz, and ZnO. Piezoelectric sensors generally cannot measure a constant pressure or strain, because the materials employed are not perfectly insulating, such that the generated charge eventually leaks away. Hence, most often, piezoelectric materials are used to make mechanical oscillators, which in turn can be used to sense several different measurands, including changing mass, temperature, and viscosity. For example, a very common film thickness monitor for thin film evaporation systems is one that uses a quartz oscillator, onto which the film is deposited at the same time as the object one wishes to coat. The added film increases the mass of the oscillator, changing its oscillation frequency, which is measured by an accompanying electronic circuit.

Optical Radiation Sensors

The intensity and frequency of optical radiation are parameters of ever-growing interest and utility in consumer products, such as the video camera and home security systems, and in optical communications systems. The conversion of optical energy to electronic signals can be accomplished by several mechanisms; however, the most commonly used is the photogeneration of electrons in semiconductors. Band-to-band generation requires that the energy of the incident photons, $E = h\nu$, is greater than the semiconductor bandgap. The most often used device for this is the semiconductor PN junction photodiode. The construction of this device is very similar to that of diodes used in electronic circuits as rectifiers. The photodiode is operated in reverse bias, where very little current normally flows. When light is incident on the structure and is absorbed in the semiconductor, energetic electrons are produced. These electrons flow in response to the electric field sustained internally across the junction, producing an externally measurable current. The current magnitude is proportional to the light intensity and also depends on the frequency of the light according to the semiconductor material used.

Sensing infrared radiation (IR) by means of photogeneration requires very small bandgap semiconductors, such as HgCdTe. Since electrons in semiconductors are also generated by thermal energy (e.g., thermistors), these IR sensors require cryogenic cooling in order to achieve reasonable sensitivity. Another means of sensing IR is to first convert the optical energy to heat inside an absorbing material, and then measure the accompanying temperature change. Accurate and highly sensitive measurements require passive temperature sensors, such as a thermopile or a pyroelectric sensor, since active devices can themselves generate enough joule heating to effect a temperature change.

151.2 Chemical Sensors

Chemical measurands include ion concentration, chemical composition, rate of reactions, reduction-oxidation potentials, and gas concentration. The last row of [Table 151.1](#) lists some of the transduction mechanisms that have been, or could be, employed in chemical sensing. Two examples of chemical sensors are described here: the ion-selective electrode (ISE) and the gas chromatograph. These sensors were chosen because of their general use and availability and because they illustrate the use of a primary (ISE) versus a primary plus intermediate (gas chromatograph) transduction mechanism.

Ion-Selective Electrode

As the name implies, ISEs are used to measure the concentration of a specific ion concentration in a solution of many ions. To accomplish this, a membrane that selectively generates a potential dependent on the concentration of the ion of interest is used. The generated potential is an equilibrium potential, called the *Nernst potential*, which develops across the interface of the membrane and the solution under test. This potential is generated by the initial net flow of ions (charge) across the membrane in response to a concentration gradient. From that moment on, the diffusional force becomes balanced by an opposing electric force, and equilibrium is established. This potential is very similar to the built-in potential of a PN junction diode, except that ions are the charge carriers instead of electrons. The ion-selective membrane acts in such a way as to ensure that the generated potential is dependent mostly on a particular

FIGURE 151.3 An electrochemical cell comprising an ion-selective electrode (ISE) and reference electrode in an ionic solution. The ion exchange membrane of the ISE generates a potential, E , that is proportional to the log of the concentration of the ion of interest.

ion of interest and negligibly on any other ions in solution. This condition is achieved by enhancing the rate at which the ion of interest is transported across the membrane relative to all others, so that it is the ion that generates and maintains the potential.

The most familiar ISE is the pH electrode. In this device the membrane is a thin, sodium-rich glass that exhibits a high exchange rate for H^+ . The generated Nernst potential, E , is described by the expression: $E = E_0 + (RT/F)\ln[H^+]$, where E_0 is a constant for constant temperature, R is the gas constant, and F is the Faraday constant. The pH is defined as the negative of the $\log[H^+]$; therefore $pH = (E_0 - E)(2.3)F/RT$. One pH unit change corresponds to a ten-fold change in the molar concentration of H^+ and a 59 mV change in the Nernst potential at room temperature. Other ISEs exhibit the same form of voltage dependence with concentration, but the response is specific to a different ion, depending on the choice of membrane. Some ISEs employ ionophores trapped inside a polymeric membrane to generate selectivity. An ionophore is a molecule that selectively and reversibly binds with an ion. When placed inside a membrane, it provides a source (or sink), thereby creating a high exchange rate for that particular ion.

The typical ISE consists of a glass or plastic tube with the ion-selective membrane closing the end of the tube that is immersed into the test solution (see Figure 151.3). The Nernst potential is measured by making electrical contact to either side of the membrane. The solution side of the membrane is contacted by a reference electrode placed inside the same solution under test. The reference electrode is constructed in the same manner as the ISE, but it has a porous membrane or leaky plug that creates a liquid junction between its inner filling solution and the test solution. That junction is designed so that the potential across it is ideally invariant with changes in concentration of any ion in the test solution. The opposite side of the membrane is contacted by a fixed-concentration, conductive, filling solution and specially coated metal wire inside the tube. The reference electrode, the solution under test, and the ISE form an electrochemical cell. The reference electrode potential acts like the ground reference in electric circuits, and the ISE potential is measured between the two wires emerging from the respective electrodes. The details of the mechanisms of transduction in ISEs and conditions necessary to create a stable electrochemical cell are beyond the scope of this article. See Bard and Faulkner [1980] or Koryta [1975] for more details.

Gas Chromatograph

Molecules in gases have thermal conductivities that are dependent on their masses; therefore, a pure gas can be identified by its thermal conductivity. One way to determine the composition of a gas is to first separate it into its components and then measure the thermal conductivity of each. A gas chromatograph does exactly that. The gas mixture flows through a long narrow column, which is packed with an adsorbent solid (for gas-solid chromatography), wherein the gases are separated according to the retentive properties of the packing material for each gas. As the individual gases exit the end of the tube one at a time, they

flow over a heated wire. The amount of heat transferred to the gas depends on its thermal conductivity. The gas temperature is measured a short distance downstream and compared to a known gas flowing in a separate sensing tube. The temperature is related to the amount of heat transferred and can be used to derive the thermal conductivity according to thermodynamic theory and empirical data. This sensor requires two transductions: a chemical-to-thermal energy transduction, followed by a thermal-to-electrical transduction.

151.3 Biosensors

Biosensors respond to biologically produced substances, such as antibodies, glucose, hormones, and enzymes. A biosensor is not the same as a biomedical sensor, which can be any type of sensor that is used in biomedical applications, such as a blood pressure sensor or heart rate monitor. Many biosensors are biomedical sensors; however, biosensors are also used in industrial applications, such as the monitoring and control of fermentation reactions or in drug discovery. Table 151.1 does not include biological signals as primary signals because they can usually be classified as either chemical or physical in nature. Biosensors are of special interest because of the very high selectivity associated with biological reactions and binding. However, detection of that reaction or binding is often elusive. A very familiar commercial biosensor is the in-home pregnancy test sensor, which detects the presence of human growth factor in urine. That device is a nonelectronic sensor since the output is a color change that your eye senses. In fact, most biosensors require multiple transduction mechanisms to arrive at an electrical output signal. Two examples are given below: immunosensor and enzyme sensor.

Immunosensor

Most commercial techniques for detecting antibody-antigen binding use optical fluorescence detection. For example, an optically fluorescent molecule can be attached to the species of interest by selective chemical attachment via a linking molecule. The fluorescent tag is introduced into the test solution where it teams up with the target species, if it is present. The complementary binding species is chemically bound to a glass substrate, or onto glass beads that are packed into a column. The solution containing the tagged species of interest, say the antibody, is passed over the antigen-coated surface, where the two selectively bind. The nonbound fluorescent molecules are washed away, and the antibody concentration is determined by the intensity of fluorescence emitted when the antigen-coated surface is excited by a UV (typical) light source. These sensing techniques are quite costly and bulky, and therefore other biosensing mechanisms are rapidly being developed and commercialized. One technique uses the change in the permittivity or index of refraction of the bound antibody-antigen complex in comparison to an unbound surface layer of antigen. The technique utilizes surface plasmon resonance as the mechanism for detecting the change in permittivity. Surface plasmons are charge density oscillations that propagate along the interface between a dielectric and a thin metal film. They can be generated by the transfer of energy from an incident, transverse magnetic (TM) polarized light beam. Plasmon resonance, or maximum energy transfer, occurs when the light beam is incident at a specific angle that depends on, and is extremely sensitive to, the dielectric permittivity at the interface on either side of a given metal film. At resonance, the optical beam intensity reflected from the metal film drops to a minimum; therefore, the resonance angle can be determined by recording reflected intensity (e.g., with a photodiode), versus incident light beam angle. The binding of antibody to an antigen layer attached to the metal film will produce a change in this resonance angle because of the minute change in permittivity produced at the interface.

Enzyme Sensor

Enzymes selectively react with a chemical substance to modify it, usually as the first step in a chain of reactions to release energy (metabolism). A well-known example is the selective reaction of glucose oxidase (enzyme) with glucose to produce gluconic acid and peroxide, according to the following formula:

An enzymatic reaction can be sensed by measuring the rise in temperature associated with the heat of reaction or by the detection and measurement of the reaction by-products. In the glucose example, the reaction can be sensed by measuring the local dissolved peroxide concentration. This is done via an electrochemical analysis technique called *amperometry* [Bard and Faulkner, 1980]. In this method, a potential is placed across two inert metal wire electrodes immersed in the test solution, and the current that is generated by the reduction/oxidation (redox) reaction of the species of interest is measured. The current is proportional to the concentration of the reducing/oxidizing species. A selective response is obtained if no other species in the vicinity of the electrodes has a lower redox potential. Because the selectivity of peroxide over oxygen is poor, some glucose-sensing schemes employ a second enzyme called *catalase*, which converts the peroxide to oxygen and hydroxyl ions. This produces a change in the local pH. As described earlier, an ISE can then be used to convert the pH to a measurable voltage. In this example, glucose sensing involves two chemical-to-chemical transductions followed by a chemical-to-electrical transduction mechanism.

151.4 Microsensors

Microsensors are manufactured using integrated circuit fabrication techniques and/or micromachining technology. Integrated circuits are fabricated using a series of process steps that are done in batch fashion, meaning that thousands of circuits are processed together at the same time in the same way. The patterns that define the components of the circuit are photolithographically transferred from a master template to a semiconducting substrate using a photosensitive organic coating, called photoresist. The coating pattern is then transferred into the substrate, or into a thin film sitting on top of the substrate through an etching process. The photolithographic transfer process is illustrated in Figure 151.4. This process is repeated for each additional thin film that is deposited, building up the respective layers comprising the circuit elements. Each template, called a *photomask*, can contain thousands of identical sets of patterns, with each set representing a circuit. This “batch” method of manufacturing is what makes integrated circuits so reproducible and inexpensive. In addition, photoreduction enables one to make extremely small features, on the order of microns, which is why this collection of process steps is referred to as *microfabrication*. The resulting integrated circuit is contained in only the top few microns of the semiconductor substrate and the submicron thin films on its surface. Hence, integrated circuit technology is said to consist of a set of planar microfabrication processes.

Micromachining refers to the set of processes that produce three-dimensional microstructures using technology that is similar to integrated circuit manufacturing methods. The third dimension refers to the height above or the depth into the substrate. Micromachining produces objects with third dimension in the range of 1 to 500 microns. The use of microfabrication to manufacture sensors promises the same

FIGURE 151.4 An illustration of the photolithographic process used to transfer a pattern from a master template (photomask) to a thin solid film in integrated circuit manufacturing.

FIGURE 151.5 Schematic cross-section of a silicon piezoresistive pressure sensor. A differential pressure deforms the silicon diaphragm, producing strain in the integrated piezoresistor. The change in resistance is measured via a Wheatstone bridge.

benefits as it does for circuits: low cost per sensor, small size, and highly reproducible geometries. It also enables the integration of circuits, sensors, and actuators — that is, entire sensing and control systems — which provides a dramatic improvement in capability for very little increase in cost. For these reasons there is a great deal of research and development activity in microsensors and microsystems. The first microsensors were standard integrated circuit components, such as semiconductor resistors and PN junction diodes. The piezoresistivity of semiconductors and optical sensing by the photodiode were discussed earlier. Diodes can also be used as temperature-sensing devices. When forward biased with a constant diode current, the resulting diode voltage will increase approximately linearly with increasing temperature. The first micromachined microsensor to be commercially produced was the silicon pressure sensor. It was invented in the mid- to late 1950s at Bell Labs and commercialized in the 1960s by General Electric, Endevco, and Fairchild Control Division (now Foxboro/ICT, Inc.). This device contains a thin silicon diaphragm (≈ 10 microns) that deforms in response to a pressure difference across it (Figure 151.5). The deformation produces two effects: a position-dependent displacement, which is maximum at the diaphragm center, and position-dependent strain, which is maximum near the diaphragm edge. Both of these effects have been used to produce an electrical output that is proportional to differential pressure. Membrane center displacement is sensed capacitively, as previously described, in one type of pressure sensor. In another, the strain is sensed by placing a piezoresistor, fabricated in the same silicon substrate, along one edge of the diaphragm. The two leads of the piezoresistor are connected to a Wheatstone bridge. The latter type of sensor is called a *piezoresistive pressure sensor* and is the more common type of commercial pressure microsensor. Pressure microsensors constituted about 5% of the total U.S. consumption of pressure sensors in 1991. Most of them are used in the medical and automotive industry because of their low cost and small, rugged construction. Many other types of microsensors are available commercially, including accelerometers, flow rate sensors, gas sensors, and biosensors.

Defining Terms

Biosensor — A sensor that responds to biologically produced substances, such as enzymes, antibodies, viruses, RNA, and hormones.

Micromachining — The set of processes that produce three-dimensional microstructures using sequential photolithographic pattern transfer and etching or deposition in a batch-processing method.

Microsensor — A sensor that is fabricated using integrated circuit and micromachining technologies.

Repeatability — The ability of a sensor to reproduce output readings for the same value of measurand, when applied consecutively and under the same conditions.

Sensitivity — The ratio of the change in sensor output to a change in the value of the measurand.

Sensor — A device that produces a usable output in response to a specified measurand.

Stability — The ability of a sensor to retain its characteristics over a relatively long period of time.

Transducer — A device that converts one form of energy to another.

Example
- 152.6 Additional Considerations

Engineers are increasingly being asked to monitor or evaluate the efficiency of a process or the performance of a device. When a measurement result is as expected, there is the temptation to claim that the data are “accurate.” When unexpected results occur, often the claim is made that there must be major errors and engineers begin searching for them. What is needed is an objective method for assessing data quality or measurement uncertainty.

Results are often derived from the combination of values determined from a number of individual measurements. In the planning of an experiment, an attempt is usually made to minimize the error associated with the experimental measurements. Unfortunately, every measurement is subject to error, and the degree to which this error is minimized is a compromise between the (overall) accuracy desired and the expense required to reduce the error in the component measurements to an acceptable value.

Good engineering practice dictates that an indication of the error or uncertainty should be reported along with the derived results. Occasionally, the error in a derived result would be treated as the sum of the errors of the component measurements. Implicit in this assumption is that the worst-case errors will occur simultaneously in all the measurements and in the most detrimental fashion. This condition is unlikely, and therefore such an analysis usually results in an over prediction of the error in a derived result.

A realistic estimate of error cannot be achieved. Error cannot be known. It is possible only to estimate (with some confidence) the potential size of a particular error or combination of errors. This estimation process is called measurement uncertainty analysis. The estimation of these uncertainties and their combination process in a measurement process are detailed in two excellent sources. The first is *Guide to the Expression of Uncertainty in Measurement* [ISO, 1993]. It is especially suited to meteorologists. The second is the American Society of Mechanical Engineers’ PTC 19.1 publication on test uncertainty [ASME, 1998]. Its approach is better suited for engineers and scientists. The following discussion is meant to provide insight into measurement uncertainty rather than a rigorous treatment of its theoretical basis. Readers are encouraged to consult the references noted dealing with these issues if they consider it necessary.

152.1 Measurement Errors and Uncertainty

Measurement error may be defined as the difference between the true value and the measured value of the quantity:

$$E = M - T$$

where E is the error in x , M is a measured or observed value of some physical quantity, and T is the actual value.

The errors that occur in an experiment are usually categorized as mistakes or recording errors (blunders), systematic or fixed errors, and accidental or random errors.

- Mistakes or recording errors are usually the result of blunders (e.g., the observer reads 10.1 instead of 11.1 units on the scale of a meter). It is assumed that careful experimental practices will minimize the occurrence of these blunders. They are not a part of an objective uncertainty analysis.
- Systematic errors (formerly called bias errors) are errors that persist and cannot be considered due entirely to chance. Systematic errors may result from the residual errors in instrument calibration and relate to instrument performance (the ability of the instrument to indicate the true value). These errors do not change for the duration of a test or experiment.
- Random errors cause readings to take random values on either side of some mean value. They may be due to the observer or the instrument and are revealed by repeated observations. They are disordered in incidence and variable in magnitude.
- If an error source causes scatter in test data, it is a random source. If not, it is systematic.

In measurement systems, accuracy generally refers to the closeness of agreement of a measured value and the true value. All measurements are subject to both systematic and random errors to differing degrees, and consequently the true value can only be estimated. To illustrate the above concepts, consider the case shown in Figure 152.1, where measurements of a fixed value are taken over a period of time.

As illustrated, the measured values are scattered around some mean value, x_m . In effect, if many measurements of the quantity were taken, we could calculate a mean value of the fixed quantity. If we further grouped the data into ranges of values, it would be possible to plot the frequency of occurrence in each range as a histogram (Figure 152.2) If a large number, N , of measurements were recorded (i.e., as N goes to infinity), a plot of the frequency distribution of the measurements, $f(X)$, could be constructed (Figure 152.3). Figure 152.3 is often referred to as a plot of the probability density function, and the area under the curve represents the probability that a particular value of X (the measured quantity) will occur. The total area under the curve has a value of 1, and the probability that a particular measurement will fall within a specified range (e.g., between X_1 and X_2) is determined by the area under the curve bounded by these values. Figure 152.3 indicates that there is a likelihood of individual measurements being close to X_m , and that the likelihood of obtaining a particular value decreases for values farther away from the mean value, X_m .

FIGURE 152.1 Repeated measurements of a fixed value. FIGURE 152.2 Histogram of measured values.

FIGURE 152.3 Frequency distribution of repeated measurements.

The frequency distribution shown in Figure 152.3 corresponds to a Gaussian or normal distribution curve [Bolz and Tuve, 1987], the form generally assumed to represent random measurement uncertainty. There is no guarantee that this symmetrical distribution, indicating an equal probability of measurements falling above or below the mean value, X_m , will occur, but experience has shown that the normal distribution is generally suitable for most measurement applications. Other distributions could be determined based on taking large numbers of measurements and plotting the results [Bevington, 1969], but generally this information (large numbers of measurements) is unavailable.

In analyzing these results, we may apply standard statistical tools to express our confidence in the determined value based on the probability of obtaining a particular result. If experimental errors follow a normal distribution, then a widely reported value is the standard deviation, σ [Bevington, 1969]. There is a 68% (68.27%) probability that an observed value x will fall within $\pm\sigma$ of X_m (Figure 152.3). Other values are often reported for $\pm 2\sigma$ (probability 95.45%) or $\pm 3\sigma$ (probability 99.73%). Values of probabilities are tabulated [Bolz and Tuve, 1987] for ranges from X_{k1} to X_{k2} , or $X_m \pm k\sigma$, as illustrated in Figure 152.3. It should also be noted that these confidences, based on one, two, or three sigma, are also based on an infinite population or set of data. In experimental work, we usually only have a data sample. We then cannot use sigma, but rather the sample standard deviation. We will discuss more details on this later.

In reporting measurements, an indication of the probable error in the result is often stated based on an absolute error prediction (e.g., a temperature of 48.3 ± 0.1 , based on a 95% probability) or on a relative error basis (e.g., voltage of $9.0 \text{ V} \pm 2\%$ (based on a 95% probability)). The choice of probability value corresponding to the error limits is arbitrary, but a value of 95%, corresponding to $\pm 2\sigma$, appears to be widely used.

When considering the results in Figure 152.3, lacking other information, our best estimate of the true value of the measured quantity is the mean (or average) of the measured values. Based on the previous discussions we may characterize measurements and instrumentation as being of high or low random uncertainty. This is illustrated in Figure 152.4, where two probability distributions are plotted. As may be seen, the probability of obtaining values near the mean is greater for the low random uncertainty measurement (i.e., the measurements are highly repeatable or precise). The high random uncertainty measurements have a wider distribution and are characterized by a greater standard deviation, $\pm\sigma_H$ compared with the low random uncertainty measurements, $\pm\sigma_L$.

It is worth noting that while the high random uncertainty measurements are not highly repeatable, if the mean value of a large number of measurements is calculated, then the value x_m should be the same as that determined from the low random uncertainty measurement. Therefore, the more measurements that we average, the closer to the true mean our sample mean will be. What is needed usually is not an estimate of the standard deviation of our measurements, but the standard deviation of our average. This

FIGURE 152.4 Frequency distributions for instruments of varying precision.

is obtained by dividing the standard deviation of our measurements by the square root of the number of measurements in the average as follows:

$$S_{\bar{x}} = \frac{S_x}{\sqrt{N}}$$

where S_x = the standard deviation of our measurements. Note that this is our estimate of σ , $S_{\bar{x}}$ = the standard deviation of our average result. This is also called the “random standard uncertainty, and N = the number of measurements in our average result. Note that we have now made the transition from the population estimates of random uncertainty, σ , to that of our sample of measurements, S_x .

The previous discussion, which illustrated the concept of random measurement error, did not address the effects of systematic or fixed errors. In reality, even though a high probability exists that an individual measurement will be close to the mean value, there is the guarantee that the value of the mean of the large sample of measurements will not be the true value (Figure 152.5). In effect, a particular measurement and measurement instrument may be highly repeatable (low random errors and uncertainty), but possess significant error (i.e., not accurate). This additional error source beyond that of random is called systematic. Systematic errors may arise from either the observer or the instrument. They are constant for the duration of a measurement process. When an error source introduces variable errors into a measurement, this results in observable data scatter and that error source is classified as random. Systematic error sources displace all measurements of a process from the true value by a fixed amount.

The estimate of the limits of a systematic error begins with assuming a distribution for those errors (usually Gaussian) and assigning a confidence (usually 95%). The term often applied here is the “systematic standard uncertainty,” which we will define as: $B_{\bar{x}}$. $B_{\bar{x}}$ represents one standard deviation for the systematic errors affecting our average, \bar{X} .

FIGURE 152.5 Measurements with bias errors in addition to random errors.

Note that trends in data or errors may be predictable and may alter test results. These trends need to be quantified. Then the error in that quantification can be estimated with either systematic or random uncertainty. Systematic errors may be significant but, by their nature, should be identifiable and their effects accounted for through careful calibration and comparison with other instruments. This will reduce their effects but not eliminate them. Recently, methods for combining systematic and random uncertainty estimates into an overall uncertainty estimate have been presented [ANSI/ASME, 1998; Dieck, 2002].

152.2 Estimating Measurement Uncertainty

In the previous discussion, we considered multisample experiments of a single parameter. Multisample experiments are those in which, for a given set of the independent experimental variables, the readings are taken many times. If we could repeat our tests many times, with many observers and a variety of instruments, we could apply statistics to determine the reliability of the results as in the previously discussed methods.

In engineering we are often forced to conduct “single-sample” experiments, and therefore we cannot estimate uncertainty by observing repeated tries. Single-sample experiments are those in which, for a given set of experimental conditions, the readings are taken only once. These are typical in engineering, where financial or time constraints limit the number of repetitions of a particular test. In all cases the uncertainty in the measurements can only be estimated.

In estimating the random uncertainty in a measurement, there is usually data from which to calculate the sample standard deviation, S_x , and the standard deviation of the average, $S_{\bar{x}}$. When there are no data, an estimate of S_x must be made from judgment or previous experience. For the systematic uncertainty estimates, the experimenter often must rely on judgment based on experience.

152.3 Propagation of Measurement Uncertainty

As previously stated, results are often derived from the combination of values determined from a number of individual measurements. The propagation of uncertainty is defined as the way in which uncertainties in the variables affect the uncertainty in the calculated results. Both the abovementioned ISO and ASME documents have presented a technique for determining the propagation of uncertainties into a derived result. In this technique, a best estimate of the uncertainty in each variable is made by the researcher assuming an equivalent 1S value, or 68% confidence, that a measured value will fall within the uncertainty interval. Therefore, assuming that a desired result is derived from n independent variables or simultaneous measurements (e.g., $R = R[X_1, X_2, X_3, \dots, X_n]$) and letting U_1, U_2, \dots, U_n be the uncertainties in the independent variables, we can derive an expression for the uncertainty in the result, U_R . Note especially here that the “ U ” values are typical of the random and/or systematic components of an uncertainty analysis. They are either all random, that is, $S_{\bar{x}}$, or all systematic, that is, $B_{\bar{x}}$, in any one propagation equation. We cannot mix the random and systematic terms in one propagation equation, but must handle each separately. Later, the random and systematic uncertainties for a result will be combined for a result uncertainty.

If the same uncertainty estimate is used for all the component variables in the analysis (i.e., all the uncertainties must be standard uncertainties, systematic or random), the uncertainty in the result will be given by

$$u_R = \pm \left[\left(\frac{\partial R}{\partial X_1} u_1 \right)^2 + \left(\frac{\partial R}{\partial X_2} u_2 \right)^2 + \left(\frac{\partial R}{\partial X_3} u_3 \right)^2 + \dots + \left(\frac{\partial R}{\partial X_n} u_n \right)^2 \right]^{1/2}$$

This equation is in engineering units or absolute uncertainty.

For systematic terms, the previous equation becomes:

$$B_{\bar{R}} = \pm \left[\left(\frac{\partial R}{\partial X_1} B_{\bar{X}_1} \right)^2 + \left(\frac{\partial R}{\partial X_2} B_{\bar{X}_2} \right)^2 + \left(\frac{\partial R}{\partial X_3} B_{\bar{X}_3} \right)^2 + \cdots + \left(\frac{\partial R}{\partial X_n} B_{\bar{X}_n} \right)^2 \right]^{1/2}$$

For random terms, this equation becomes:

$$S_{\bar{X},R} = \pm \left[\left(\frac{\partial R}{\partial X_1} S_{\bar{X}_1} \right)^2 + \left(\frac{\partial R}{\partial X_2} S_{\bar{X}_2} \right)^2 + \left(\frac{\partial R}{\partial X_3} S_{\bar{X}_3} \right)^2 + \cdots + \left(\frac{\partial R}{\partial X_n} S_{\bar{X}_n} \right)^2 \right]^{1/2}$$

In certain instances (such as a product form of the equation, i.e., $R = X_1^a \cdot X_2^b \cdot X_3^c \cdots X_n^m$), the former equation can be reduced to

$$\frac{u_R}{R} = \pm \left[\left(a \cdot \frac{u_1}{X_1} \right)^2 + \left(b \cdot \frac{u_2}{X_2} \right)^2 + \left(c \cdot \frac{u_3}{X_3} \right)^2 + \cdots + \left(m \cdot \frac{u_n}{X_n} \right)^2 \right]^{1/2}$$

where U_R/R is the relative uncertainty in the result, R [Moffat, 1988]. For this equation as well, we can substitute the $B_{\bar{R}}$ and $S_{\bar{X}}$ terms for the systematic and random components of uncertainty.

152.4 Uncertainty of a Result

Once the systematic and random uncertainties have been obtained, it is necessary to combine them into the uncertainty of a result. This is done with the following equation:

$$U_R = \pm t_{95} \left[\left(B_{\bar{R}} \right)^2 + \left(S_{\bar{X},R} \right)^2 \right]^{1/2}$$

where U_R = the result uncertainty at 95% confidence, $B_{\bar{R}}$ = the systematic uncertainty of the average result. It is a standard uncertainty, $S_{\bar{X},R}$ = the random uncertainty of the average result. It is a standard uncertainty, and t_{95} = Student's t for 95% confidence level. This is the most common confidence level used in uncertainty analysis.

Note that the Student's t_{95} depends on the degrees of freedom for U_R . For this presentation, we will assume all degrees of freedom are 30 or higher and that Student's t_{95} , therefore, is 2.

152.5 Uncertainty Analysis in Experimental Design

Possible experimental errors should be examined before conducting an experiment to ensure the best results. The experimenter should estimate the uncertainties in each measurement. Uncertainty propagation in the result depends on the squares of the uncertainties in the independent variables; thus the squares of the large uncertainty values dominate the result. Consequently, in designing an experiment, very little is gained by reducing the small errors (uncertainties). A series of measurements with relatively large uncertainties could produce a result with an uncertainty not much larger than that of the most uncertain measurement. Thus, to improve the overall experimental result, the large uncertainties must be reduced [Moffat, 1985, 1988].

Example

Consider an experiment to measure the thermal efficiency, η , of a solar collector for heating water. During testing, the solar collector is connected in series with an electric reference heater, and cooling water is

circulated through both. Values of η are obtained by individual measurements of: the temperature rise across the solar collector, ΔT_c , and reference heater, ΔT_h ; the power input to the reference heater, P_h ; and the total solar energy incident on the collector surface, G_i . The thermal efficiency, η , is determined according to

$$\eta = \frac{P_h}{G_i} \cdot \left(\frac{\Delta T_c}{\Delta T_h} \right)$$

To estimate the relative uncertainty in the measured value of η , the uncertainties in the component measurements must be estimated. The electrical power input to the reference heater was measured with a power transducer with an estimated uncertainty of $\pm 1\%$ of reading random uncertainty and a $\pm 1\%$ of reading systematic uncertainty. The measurement of solar radiation introduced the largest uncertainty and was estimated at $\pm 5\%$ of reading random uncertainty and a $\pm 5\%$ of reading systematic uncertainty. Uncertainties in the measurement of temperature rise across the heater and collector were estimated at $\pm 0.1^\circ\text{C}$ for the random component and $\pm 0.1\%$ for the systematic component. These uncertainties are summarized below.

| Measurement | Systematic Uncertainty | Random Uncertainty |
|------------------------------|------------------------|--------------------|
| Power, P_h | 0.1%R | 0.1%R |
| Radiation, G_i | 5% | 5%R |
| Temperature rise, ΔT | 0.1°C | 0.1°C |

Therefore, the uncertainty values are

$$B_{\bar{P}_h} = S_{\bar{P}_h} = \pm 0.01 \times P_h$$

$$B_{\bar{G}_i} = S_{\bar{G}_i} = \pm 0.05 \times G_i$$

$$B_{\Delta T} = S_{\Delta T} = \pm 0.1^\circ\text{C}$$

These values are based on best estimates and represent the odds of 20 to 1 that measured values will fall within these limits.

Applying the analysis described above, the relative systematic uncertainty in determining η is

$$\frac{B_{\bar{\eta}}}{\eta} = \pm \left[\left(\frac{B_{\bar{P}_h}}{P_h} \right)^2 + \left(\frac{B_{\bar{G}_i}}{G_i} \right)^2 + \left(\frac{B_{\Delta T_h}}{\Delta T_h} \right)^2 + \left(\frac{B_{\Delta T_c}}{\Delta T_c} \right)^2 \right]^{1/2}$$

Substituting typical test conditions, that is, $\Delta T_c \approx 3.5^\circ\text{C}$ and $\Delta T_h \approx 6^\circ\text{C}$, then

$$\frac{B_{\bar{\eta}}}{\eta} = \pm [(0.01)^2 + (0.05)^2 + (0.1/6)^2 + (0.1/3.5)^2]^{0.5} = \pm 0.06$$

Thus, the relative uncertainty in the measured value of solar collector efficiency would be ± 0.06 , or $\pm 6\%$ (based on 20-to-1 odds). The same uncertainty would result from the random terms.

We now must calculate the uncertainty for the result. Here we will assume over 30 degrees of freedom so that $t_{95} = 2$. We then have

$$U_R = \pm t_{95} \left[(B_{\bar{R}})^2 + (S_{\bar{x},R})^2 \right]^{\frac{1}{2}} = \pm 2 \left[(0.06)^2 + (0.06)^2 \right]^{\frac{1}{2}} = \pm 0.17 \text{ or } \pm 17\%$$

It is apparent from this analysis that the uncertainty in the solar radiation measurement dominates the uncertainty in the result; that is, decreasing the uncertainty in the other measurements has little effect on the result. It is also worth noting that as ΔT_c becomes smaller, the overall uncertainty in the result increases. This effect could be minimized by reducing the uncertainty in the ΔT_c measurement.

152.6 Additional Considerations

All the above analysis has been based on several simplifying assumptions, summarized below.

1. Degrees of freedom are all 30 or higher (noted in the text above).
2. All uncertainties are symmetrical about the measured average.
3. There are no correlated error sources.

Assumption 3 is particularly troublesome when there is error correlation. Nonsymmetrical uncertainties also must be considered in many experimental results. For a treatment of all these effects, consider consulting Dieck [2002].

Defining Terms

Accuracy — The closeness of agreement of a measured value and the true value. As there are many confusing definitions for “accuracy,” its use is not recommended.

Bias error — The tendency of a deviation estimate in one direction from a true value. As there are many, conflicting definitions for the term “bias,” its use is not recommended.

Frequency distribution — A description of the frequency of occurrence of the values of a variable.

Gaussian or normal distribution curve — The theoretical distribution function for the conceptual infinite population of measured values. This distribution is characterized by a limiting mean and standard deviation. The interval of the limiting mean plus or minus two standard deviations will include approximately 95% of the total scatter of measurements.

Measurement error — The difference between true and observed values.

Multisample experiments — Experiments in which uncertainties are evaluated by many repetitions and many diverse instruments. Such experiments can be analyzed by classical statistical means.

Precision — The repeatability of measurements of the same quantity under the same conditions. As there are many definitions for this term, its use is not recommended.

Random errors — Errors that cause readings to take random values on either side of some mean value. They may be due to the observer or the instrument and are revealed by repeated observations.

Random uncertainty — The uncertainty estimate that applies to random error sources. It estimates the limits to which a random error may go with some confidence.

Standard deviation — A measure of dispersion of a population. It is calculated as the square root of the average of the squares of the deviations from the mean (root mean square) deviation.

Standard uncertainty — An uncertainty, systematic or random, that is the equivalent of one standard deviation of the average for a group of measurements.

Systematic errors — Errors that persist and cannot be considered due to chance. Systematic errors may be due to instrument manufacture or incorrect calibration and relate to instrument accuracy (the ability of the instrument to indicate the true value).

Systematic uncertainty — The uncertainty estimate that applies to systematic error sources. It estimates the limits to which a systematic error may go with some confidence.

Uncertainty — The estimated error limit for a measurement of a result for given odds.

Further Information

Extensive discussion of measurement instrumentation and an introduction to measurement errors and uncertainty analysis are presented in Beckwith et al. [1993] and J. P. Holman, 1994, *Experimental Methods for Engineers*, 6th ed., McGraw-Hill, New York.

Detailed discussions of the treatment of systematic and random errors for measurement systems are given in ASME Standard 19.1-1985 and the *ASHRAE Handbook of Fundamentals*, chapter 13, available from American Society of Heating, Refrigerating and Air-Conditioning Engineers, New York.

The use of uncertainty analysis in the planning of experiments is outlined with examples by Moffat [1985].

Signal Conditioning

153.1 Linear Operations

Amplitude Scaling • Impedance Transformation • Linear Filtering

153.2 Nonlinear Operations

153.3 Example

Stephen A. Dyer
Kansas State University

Kelvin's first rule of instrumentation states, in essence, that the measuring instrument must not alter the event being measured. For the present purposes, we can consider the instrument ([Figure 153.1](#)) to consist of an input transducer followed by a signal-conditioning section, which in turn drives the signal and data processing and communication sections (the remainder of the instrument). We are using the term *instrument* in the broad sense, with the understanding that it may actually be a measurement subsystem within virtually any type of system.

Certain requirements are imposed upon the transducer if it is to reproduce an event faithfully: it must exhibit amplitude linearity, phase linearity, and adequate frequency response. But it is the task of the signal conditioner to accept the output signal from the transducer and from it produce a signal in the form appropriate for introduction to the remainder of the instrument.

Analog signal conditioning can involve strictly *linear* operations, strictly *nonlinear* operations, or some combination of the two. In addition, the signal conditioner may be called on to provide auxiliary services, such as introducing electrical isolation, providing a reference of some sort for the transducer, or producing an excitation signal for the transducer.

Important examples of linear operations include *amplitude scaling*, *impedance transformation*, *linear filtering*, and *modulation*.

A few examples of nonlinear operations include obtaining the *root-mean-square (rms) value*, *square root*, *absolute value*, or *logarithm* of the input signal.

A wide variety of building blocks are available in either modular or integrated circuit (IC) form for accomplishing analog signal conditioning. Such building blocks include operational amplifiers, instrumentation amplifiers, isolation amplifiers, and a plethora of nonlinear processing circuits such as comparators, analog multiplier/dividers, log/antilog amplifiers, rms-to-DC converters, and trigonometric function generators.

Also available are complete signal-conditioning subsystems consisting of various plug-in input and output modules that can be interconnected via universal backplanes that can be either chassis or rack mounted.

153.1 Linear Operations

Three categories of linear operations important to signal conditioning are amplitude scaling, impedance transformation, and linear filtering.

FIGURE 153.1 Basic block diagram of an electronic instrument.

Amplitude Scaling

The amplitude of the signal output from a transducer must typically be scaled — either amplified or attenuated — before the signal can be processed.

Amplification

Amplification is generally accomplished by an *operational amplifier*, an *instrumentation amplifier*, or an *isolation amplifier*.

Operational Amplifiers

A conventional operational amplifier (op amp) has a differential input and a single-ended output. An *ideal* op amp, used often as a first approximation to model a real op amp, has infinite gain, infinite bandwidth, infinite differential input impedance, infinite slew rate, and infinite common-mode rejection ratio (CMRR). It also has zero output impedance, zero noise, zero bias currents, and zero input offset voltage. Real op amps, of course, fall short of the ideal in all regards.

Important parameters to consider when selecting an op amp include:

1. DC voltage gain K_o .
2. Small-signal gain-bandwidth product (GBWP) f_T , which for most op amps is $f_T \approx K_o f_b$, where f_b is the lower break frequency in the op amp's transfer function. The GBWP characterizes the closed-loop, high-frequency response of an op-amp circuit.
3. Slew rate, which governs the large-signal behavior of an op amp. Slew rates range from less than 1 v/ μ s to several thousand volts per microsecond.

Other parameters, such as input and output impedances, DC offset voltage, DC bias current, drift voltages and currents, noise characteristics, and so forth, must be considered when selecting an op amp for a particular application.

There are several categories of operational amplifiers. In addition to “garden-variety” op amps, there are many op amps whose characteristics are optimized for one or more classes of use. Some categories of op amps include:

- *Low-noise* op amps, which are useful in the portions of signal conditioners required to amplify very-low-level signals.
- *Chopper-stabilized* op amps, which are useful in applications requiring extreme DC stability.
- *Fast* op amps, which are useful when large slew rates and large GBWPs are required.
- *Power* op amps, which are useful when currents of greater than a few mA must be provided to the op amp's load.
- *Electrometer* op amps, which are used when very high ($>10^{13} \Omega$) input resistances and very low (<1 pA) input bias currents are required.

An introduction to op amps and basic circuit configurations can be found in essentially any modern text on circuit theory or electronics, and the reader can find detailed theoretical developments and many useful configurations and applications in Roberge (1975), Graeme et al. (1971), Graeme (1973, 1977), Horowitz and Hill (1989), and Stout and Kaufman (1976).

Instrumentation Amplifiers

Instrumentation amplifiers (IAs) are gain blocks optimized to provide high input impedance, low output impedance, stable gain, relatively high common-mode rejection (CMR), and relatively low offset and drift. They are well suited for amplification of outputs from various types of transducers such as strain gages, for amplification of low-level signals occurring in the presence of high-level common-mode voltages, and for situations in which some degree of isolation is needed between the transducer and the remainder of the instrument.

Although instrumentation amplifiers can be constructed from conventional op amps (a three-op-amp configuration is typically discussed; see, for example, Stout and Kaufman [1976]), they are readily available and relatively inexpensive in IC form. Some IAs have digitally programmable gains, whereas others are programmable by interconnecting resistors internal to the IA via external pins. More-basic IAs have their gains set by connecting external resistors.

Isolation Amplifiers

Isolation amplifiers are useful in applications in which a voltage or current occurring in the presence of a high common-mode voltage must be measured safely, accurately, and with a high CMR. They are also useful when safety from DC and line-frequency leakage currents must be ensured, such as in biomedical instrumentation.

The isolation amplifier can be thought of as consisting of three sections: an input stage, an output stage, and a power circuit. All isolation amplifiers have their input stages galvanically isolated from their output stages. Communication between the input and output stages is accomplished by modulation/demodulation.

An isolation amplifier is said to provide two-port isolation if there is a DC connection between its power circuit and its output stage. If its power circuit is isolated from its output stage as well as its input stage, then the amplifier is said to provide three-port isolation. Isolation impedances on the order of $10^{10} \Omega$ are not atypical.

Isolation amplifiers are available in modular form with either two-port or three-port isolation. Both single-channel and multichannel modules are offered.

Attenuation

Although the majority of transducers are low-level devices such as thermocouples, thermistors, resistance temperature detectors (RTDs), strain gages, and so forth, whose outputs require amplification, there are many measurement situations in which the input signal must be attenuated before introducing it to the remainder of the system.

Voltage Scaling

Most typically, the signals to be attenuated take the form of voltages. Broadly, the attenuation is accomplished by either a *voltage divider* or a *voltage transformer*.

Voltage Dividers — In many cases, a simple chain divider proves adequate. The transfer function of a two-element chain of impedances $Z_1(s)$ and $Z_2(s)$ is

$$\frac{V_o(s)}{V_{in}(s)} = \frac{Z_1(s)}{Z_1(s) + Z_2(s)}$$

where the output voltage $V_o(s)$ is the voltage across $Z_1(s)$, and the input voltage $V_{in}(s)$ is the voltage across the two-element combination.

Of course, the impedances of the source (transducer) and the load (the remainder of the system) must be taken into account when designing the divider network.

Resistive Dividers — If the elements in the chain are resistors, then the divider is useful from DC up through the frequencies for which the impedances of the resistors have no significant reactive components. For $Z_1(s) = R_1$ and $Z_2(s) = R_2$,

$$\frac{V_o(s)}{V_{in}(s)} = \frac{R_1}{R_1 + R_2}$$

Other configurations are available for resistive dividers. One example is the Kelvin–Varley divider, which has several advantages that make it useful in situations requiring high accuracy. For a detailed description, see Gregory (1973).

Capacitive Dividers — If the elements in the chain divider are capacitors, then the divider has as its transfer function

$$\frac{V_o(s)}{V_{in}(s)} = \frac{C_2}{C_1 + C_2}$$

This form of divider is useful from low frequencies up through frequencies of several megahertz. A common application is in the scaling of large voltages.

Inductive Dividers — If the elements in the chain divider are inductors, then an autotransformer results. Inductive dividers are useful over frequencies from a few hertz to several hundred kilohertz. Errors in the parts-per-billion range are achievable.

Voltage Transformers — Voltage transformers constitute one of the most common means of accomplishing voltage scaling at line frequencies. Standard double-wound configurations are useful unless voltages above about 200 kV are to be monitored. For very high voltages, alternative configurations such as the *capacitor voltage transformer* and the *cascade voltage transformer* are employed (Gregory, 1973).

Current Scaling

Current scaling is typically accomplished via either a current shunt or a current transformer.

A *current shunt* is essentially an accurately known resistance through which the current to be measured is passed. The voltage developed across the shunt as a result of the current is the quantity measured. Shunts are useful at DC and frequencies through the audio range. Two disadvantages are: (1) the shunt consumes power, and (2) the measurement circuitry must be operated at the same potential as the shunt.

The *current transformer* overcomes the mentioned disadvantages of the current shunt. Typically, the current transformer consists of a specially constructed toroidal core upon which the secondary (sense) winding is wrapped and through which the primary winding is passed. A single-turn primary is commonly used, although multiturn primaries are available.

Other Attenuators

In addition to the aforementioned means of voltage and current scaling, there are attenuator pads that provide, in addition to voltage or power reduction, the ability to be matched in impedance to the source and load circuits between which it is connected. The common pads include the T, L, and Π types, either balanced or unbalanced. Resistive attenuator pads are discussed in most textbooks on circuit design (e.g., Cuthbert, 1983). They are useful from DC through several hundred megahertz.

Impedance Transformation

Oftentimes the impedance of the transducer must be transformed to a value more acceptable to the remainder of the measurement system. In many cases, maximum power must be transferred from the transducer's output signal to the remaining circuitry. In other cases, it is sufficient to provide buffering that presents very high impedance to the transducer, a very low impedance to the rest of the system, and a voltage gain of unity.

Matching transformers, passive matching networks such as attenuator pads, and unity-gain buffers are standard means of accomplishing impedance transformation. Unity-gain buffers are available in IC form.

Linear Filtering

Although, in general, digital signal processing offers many advantages over analog techniques for filtering signals, there are many relatively simple applications for which *frequency-selective analog filtering* is well suited.

Filters are used within signal conditioners (1) to reduce the effects of noise that corrupts the input signal; (2) as part of a demodulator; (3) to limit signal bandwidth; or (4) if the signal is to be sampled, to limit its bandwidth in order to prevent aliasing. These filters can be built either entirely of passive components or based on active devices such as op amps.

There are many good references that discuss methods of characterizing, specifying, and implementing frequency-selective analog filters. See Van Valkenburg (1960) for design of passive filters; for the design of active-RC filters, see Sedra and Brackett (1978) and Stephenson (1985).

153.2 Nonlinear Operations

A wide variety of nonlinear operations are useful to signal-conditioning tasks. Listed below are some typical nonlinear blocks along with brief descriptions. Most of the blocks are available as ICs.

1. *Comparator*. A comparator is a two-input device whose output voltage, V_o , takes on one of two stable values, V_{o0} and V_{o1} , as follows:

$$V_o = \begin{cases} V_{o0}, & \text{if } V_2 < V_1 \\ V_{o1}, & \text{otherwise} \end{cases}$$

where V_1 and V_2 are the voltages at the two inputs.

2. *Schmitt trigger*. A Schmitt trigger is a comparator with hysteresis. It can be constructed from a comparator by applying positive feedback.
3. *Multiplier*. A two-input multiplier supplies an output voltage that is proportional to the product of its input voltages.
4. *Divider*. A two-input divider has as its output a voltage proportional to the ratio of its input voltages. The functions of multiplication and division are usually combined within a single device.
5. *Squarer*. A squarer has as its output a voltage proportional to the square of its input. Squarers can be constructed by a number of means: from multipliers, based on diode-resistor networks, based on FETs, and so forth.
6. *Square-rooter*. A square-rooter has as its output a voltage proportional to the square root of its input. A square-rooter can be built most easily from either a divider or a log/antilog amplifier.
7. *Logarithmic/antilogarithmic amplifier*. A log/antilog amplifier produces an output voltage proportional to the logarithm or the antilogarithm of its input voltage.
8. *True RMS-to-DC converter*. A true RMS-to-DC converter computes the square root of the average, over some interval of time, of the instantaneous square of the input signal. The averaging operation is generally accomplished via a simple low-pass filter whose capacitor is selected to give the desired interval.
9. *Trigonometric function generator*. Generators are available in IC form that produce as their outputs any of the standard trigonometric functions or their inverses, taken as functions of the differential voltage at the generator's inputs.
10. *Sample-and-hold and track-and-hold amplifiers*. A sample-and-hold amplifier (SHA) is a device that samples the signal at its input and holds the instantaneous value whenever commanded by a logic control signal. A track-and-hold amplifier is identical to an SHA but is used in applications

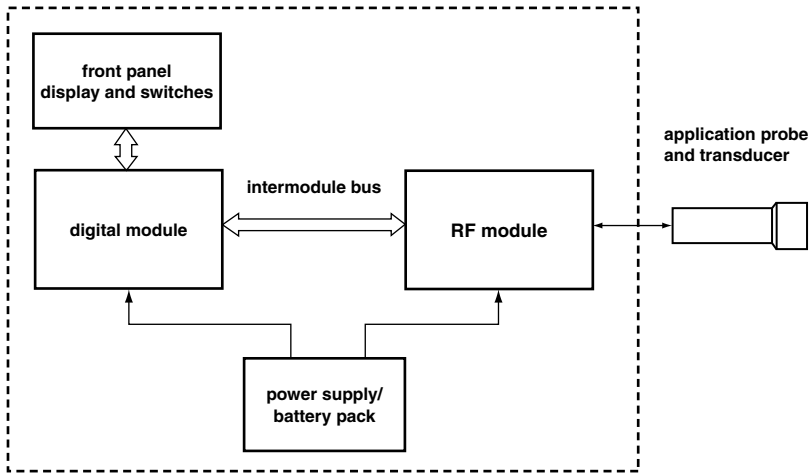

FIGURE 153.2 Basic block diagram of the therapeutic ultrasound unit discussed as an example.

where it spends most of its time tracking the input signal (i.e., in “sample” or “track” mode), in contrast to the SHA, which spends most of its time in “hold” mode.

11. *Precision diode-based circuits.* Circuits such as precision half-wave rectifiers, absolute-value circuits, precision peak detectors, and precision limiters are relatively easy to design and implement based on diodes and op amps. See Horowitz and Hill (1989), Stout and Kaufman (1976), and Graeme (1977).

A detailed description of these and other nonlinear circuit blocks can be found in Sheingold (1976).

153.3 Example

We provide briefly an example of a device that has embedded within it several signal-conditioning circuits. Figure 153.2 shows the basic block diagram of a therapeutic ultrasound unit, which finds widespread use in medicine.

The particular unit being discussed consists of five principal subsystems:

1. An application probe and ultrasound transducer, which imparts ultrasonic energy to the tissue being treated. *Note that this transducer is not an input transducer such as has been discussed in relation to signal conditioners.*
2. A radio-frequency (RF) module, which provides electrical excitation to the ultrasound transducer.
3. Front-panel display and switches, which allow communication between the unit and its operator.
4. A microprocessor-based digital module, which orchestrates the overall control of the ultrasound unit.
5. A power supply/battery pack, which provides operating power to the unit.

We focus now on the RF module, whose basic block diagram is shown in Figure 153.3. The module consists of a sine-wave oscillator that produces a signal at the resonant frequency of the transducer, a modulator that allows that signal to be pulse-modulated, and an amplifier with RF-voltage feedback. Incorporated in the amplifier are a power amplifier capable of driving the transducer and automatic-gain-control (AGC) circuitry required to adjust the output power to coincide with that selected by the operator. The AGC uses a standard feedback-control loop to maintain a constant-voltage envelope on the RF signal output from the power amplifier.

Some of the signal conditioners employed within the RF module include the following:

1. The RF-voltage pickoff at the output of the power amplifier. The pickoff employs a half-wave rectifier, followed by a simple capacitive chain divider for voltage scaling.

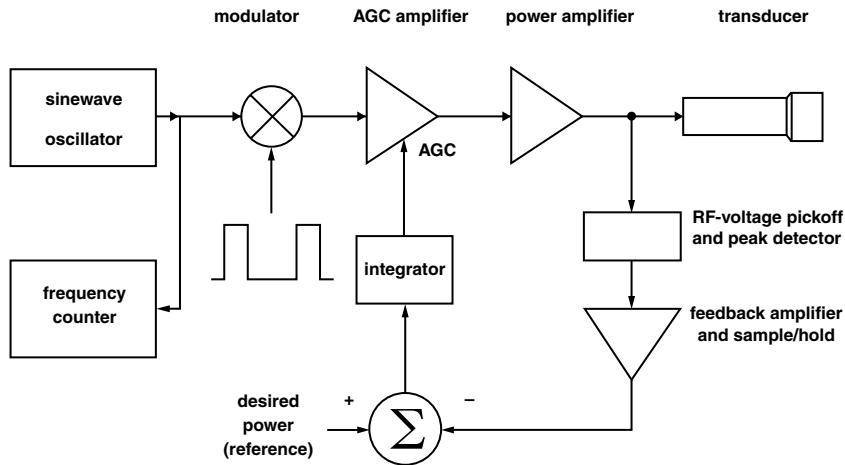

FIGURE 153.3 Simplified block diagram of the RF module used in the ultrasound unit of Figure 153.2.

2. A precision peak detector, which obtains the peak value of the output from the voltage divider during a modulation cycle and presents that value to the feedback loop.
3. An amplifier, having digitally selectable gain, which amplifies the output of the peak detector.
4. A sample-and-hold amplifier, used to hold the amplified output from the peak detector during the “off time” of the modulator. The SHA is needed since the time constant of the peak detector is not sufficient to prevent significant “droop” during the off-time of the modulator.
5. An integrator (an example of frequency-selective filtering), which develops the control voltage for the AGC loop from the output of the differencer.
6. A current shunt, not shown in Figure 153.3, which is used to monitor the DC current supplied to the power amplifier.

As can be seen from this simple example, several signal-conditioning functions may be employed within a single system, and the system itself might not even be an instrument!

Defining Terms

Common-mode rejection (CMR) — CMRR given in decibels. $CMR = 20 \log[CMRR]$. CMR is a non-linear function of common-mode voltage and depends on other factors such as temperature.

Common-mode rejection ratio (CMRR) — The ratio of the differential gain to the common-mode gain of an amplifier.

Gain bandwidth product (GBWP) — The product of an amplifier’s highest gain and its corresponding bandwidth. Used as a rough figure of merit for bandwidth.

Slew rate — The maximum attainable time rate of change of an amplifier’s output voltage in response to a large step change in input voltage.

Telemetry

Stephen Horan
New Mexico State University

- 154.1 Data Measurements
- 154.2 Telemetry Systems
- 153.3 Data Channels
- 153.4 Data Transmission Formats

Telemetry systems are found in a variety of applications, from automobiles, to hospitals, to interplanetary spacecraft. Although these examples represent a broad range of applications, they all have many characteristics in common: a natural parameter is measured by a sensor system, the measurement is converted to numbers or data, the data are transported to an analysis point, and an end user makes use of the data gathered. After all, the implication of telemetry is to “measure at a distance.”

154.1 Data Measurements

The general purpose of a telemetry system is to gather information about a subject of interest and present that measurement to a user. The physical quantity or property that is being measured is known as the *measurand*. Each measurand is sampled by a sensor at a rate appropriate for the bandwidth of the signal. The sampled analog signals are then frequently digitized by using an analog-to-digital converter. This produces a *pulse-coded modulation* (PCM) data stream. This process is illustrated in [Figure 154.1](#) where an analog signal is sampled as a function of time. The sampled signal is represented by a voltage at the sensor output. This voltage is converted to the PCM form in the analog-to-digital conversion process to produce one digital sample for each sample. The data user will reverse this process to estimate the measurand value as a function of time. To produce an accurate estimate of the measurand, the sensor and conversion process will need to be calibrated and the calibration coefficients incorporated in the inverse transformation.

The sampling rate for each sensor is determined by the signal’s *Nyquist sampling rate*. If W is the signal bandwidth in hertz, then the Nyquist sampling rate, f_N , in samples per second, is given by

$$f_N = 2W \tag{154.1}$$

In practice, a minimal sampling rate of five times the signal bandwidth is typically used to accurately reconstruct the measurand.

154.2 Telemetry Systems

Measurement systems requiring the sampling of more than a single sensor require more complicated support and coordination to allow sampling of several measurands. These measurement systems are typically located at a distance from the eventual data user, which can be a person or a machine. The measurements are transmitted over some type of data channel, such as a radio link, fiber optic cable, or

FIGURE 154.1 Sampling an analog voltage signal and converting it to a PCM digital signal.

FIGURE 154.2 Overall data flow in a telemetry and telecommand system composed of sensors (S) and actuators (A).

telecommunications network. This architecture produces a telemetry system having the following characteristics of the standard telecommunications definition of telemetry [1]:

1. The use of telecommunication for automatically indicating or recording measurements at a distance from the measuring instrument.
2. The transmission of nonvoice signals for the purpose of automatically indicating or recording measurements at a distance from the measuring instrument.

The control functions in a telemetry system are accomplished through *actuators*, which are devices that respond to transmitted control signals to affect the measurement system characteristics or interact with the measurement environment. The control is achieved through a *telecommand* link which is the “use of telecommunication for the transmission of signals to initiate, modify, or terminate functions of equipment at a distance” [1]. The data flow in a telemetry/telecommand system is illustrated in Figure 154.2. The telemetry measurements from the sensors flow back to the user over the data channel. The sampling and multiplexing components format and sequence order the data for transmission over the channel. The data processing returns the measurement values to estimates of the actual measurand values for presentation to the user. In the user interface, the PCM signal will either be converted back to an analog waveform or left as a series of discrete measurements for use and analysis. The user interface may be a display screen, a set of gages, or a chart recorder. The user interface often contains data-logging capabilities to provide a permanent record of the measurements.

The user also enters commands at the user interface to control the actuators. The data processing prepares the user input into telecommands for transmission over the data channel. The control functions then interpret these commands and cause the actuators to respond. The design of the telemetry and telecommand data structures is generally individualized for each system by the system designers. The overall structure of the data structures can be classified as either frames or packets as discussed later.

153.3 Data Channels

The configuration and quality of the data channel will influence the design of the data transmission structure. Telemetry systems have two general channel configurations: common channel mode or distributed channel mode, as illustrated in Figure 154.3. In common channel mode, all telemetry and

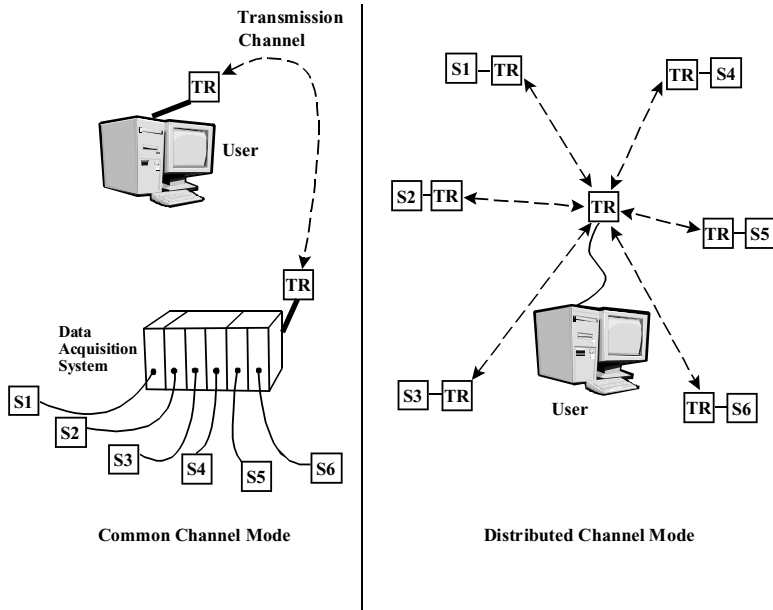

FIGURE 154.3 Common and distributed data channels for telemetry and telecommand systems. The data sources are the sensors (S) and the channel interface occurs at a transceiver (TR).

telecommand data traverse a single, logical link. This link may be either full duplex or parallel simplex links, depending on the nature of the physical channel and the access protocol. In this mode, all sensor data are combined at a common data acquisition system prior to transmission over the channel. Typical environments for this mode include rocket payloads, laboratory data acquisition systems, and remote vehicle telemetry systems. The common channel is frequently a radio link, a wire, or a local area network.

In the distributed mode channel, each sensor connects to the channel via a transceiver. For example, this transceiver can be a simple 802.11 interface that permits the sensors to be connected as part of a wireless network with a central computer receiving the data via a wireless access point. The distributed channel can use either polling techniques or code division multiple access techniques to give each sensor shared access to the channel. Typical environments for this mode include building temperature and fire sensing or factory process measurement and control.

153.4 Data Transmission Formats

The channel bandwidth and quality are limiting factors in the system because they restrict the volume of data that can be reliably sent and they determine the data synchronization methodology. The channel bandwidth will affect the speed at which each sensor can be sampled to ensure that the Nyquist sampling rate is satisfied. Because different sensors will have different sampling rates, a time-division multiplexing technique can be used to share the data channel. For channels where data loss due to data dropouts is a significant problem or where tight synchronization is required between the sensor system and the user interface, a continuous frame transmission data structure is used. For systems where the channel provides high reliability or there are many different sampling rates possible, a packet data structure may be preferred.

Frame telemetry is the traditional method for time multiplexing telemetry data from the source to the destination. The multiplexing structure repeats in fixed time intervals to allow the receiving side to synchronize to the data stream based on the contents of the data stream alone. Most frame systems use a format standard called IRIG 106 [2], developed by the military test ranges' Inter-Range Instrumentation Group (IRIG). This frame structure is used by all industries and not just for military systems. The frame structure is arranged like a matrix, as shown in [Figure 154.4](#), with the *major frame* being one complete

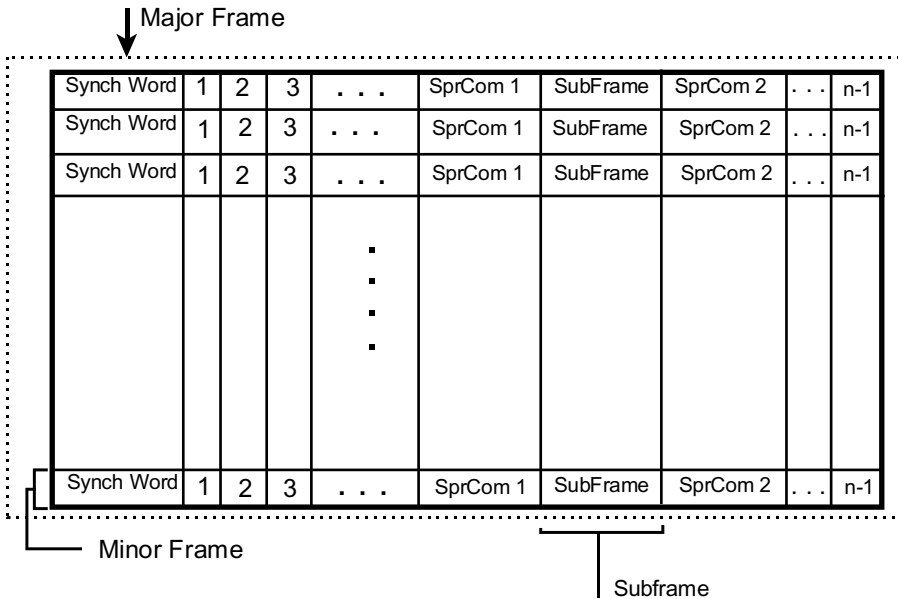

FIGURE 154.4 The standard IRIG telemetry frame structure.

cycle through the time-multiplexing sequence, during which time each sensor is sampled at least once. Each major frame is divided along rows of the matrix into *minor frames*, beginning with the synchronization word. The columns of the matrix in the major frame can represent either the output from sensors or management data repeating in each minor frame. A sensor's output reading stays in its assigned column from frame to frame. If the same sensor is sampled once per minor frame — for example, columns 1, 2, and 3 in Figure 154.4 — then it is sampled at the commutation rate for the system and is called *commutated data*. If a small number of sensors need to be sampled at a rate higher than the commutation rate, they are *supercommutated* sensors (“SprCom” locations in Figure 154.4) and take up more than one column in the matrix. Some columns in the matrix may represent a group of sensors rather than a single sensor. As shown in the column labeled “subframe” in Figure 154.4, the sensors in that group form a *subframe* within the major frame. The sensors are sampled at a rate below the commutation rate, so the data are *subcommutated*.

Standard synchronization codes are usually 16 or 32 bits long. For example, the standard 16-bit code is EB90 in hexadecimal, whereas the standard 32-bit code is FE6BA840 in hexadecimal. These codes are optimal in the sense of having the lowest autocorrelation values when shifted by 1 bit. This minimizes the probability of a false lock in the synchronization detection circuitry. All synchronization codes suffer the possibility of being mimicked by random data. Therefore, several occurrences of the code are required upon initial synchronization. The condition in which the synchronizing circuitry locks onto random data and not the synchronization word is called a false lock. The probability of this false lock condition occurring, P_{FL} , is given by

$$P_{FL} = \frac{\sum_{i=0}^k \binom{N}{i}}{2^N} \quad (154.2)$$

Here N is the length of the synchronization code in bits and k is the number of differences allowed between the received code and the exact code value.

The synchronization code can also be missed if the data become corrupted in the channel. The probability of a missed synchronization code, P_M , due to channel errors is given by

$$P_M = \sum_{i=k+1}^N \binom{N}{i} p^i (1-p)^{N-i} \quad (154.3)$$

Here p is the channel bit-error rate while N and k are as before.

If the minor frame has a length of L bits, then with a channel BER of p , the frame data have a probability of correct reception, P_0 , given by

$$P_0 = (1-p)^L \quad (154.4)$$

This can be used by the designer to estimate necessity for any error detection and correction coding to be applied to the transmission.

The synchronization process for a telemetry frame follows these steps:

1. Achieve lock onto the data signal from the data channel.
2. Find the individual bits in the data stream using a bit synchronizer circuit.
3. Find the occurrences of the frame synchronization word by using a correlator comparing the data with the desired stored pattern.
4. Once the synchronization marker is reliably found, ensure that it repeats at the minor frame rate and that any management information in the frame is intact by using a frame synchronizer.
5. Once the frame structure is fully identified, begin processing the data.

Packet telemetry systems are becoming more common, especially in systems where the data acquisition and data reception subsystems have high degrees of computational capability and the link between them can be viewed as reliable. Packet systems have several advantages over frame systems, with the main advantage being flexibility. With a packet system, instead of having a master commutation rate, the sampling rate for each sensor or sensor system can be individualized to the natural signal bandwidth. For example, battery voltages being measured may not change significantly over five minutes. With frame telemetry they may be sampled more frequently than once per minute due to the commutation rate specification. With packets the voltages may be sampled only as needed and then transmitted in a data packet. Packets also have the advantage of allowing the data to be more easily routed over a computer network for analysis and distribution to end users. Examples of packet telemetry formats are given in [3].

The general packet format is composed of a header, containing accounting and addressing information, followed by the actual data similar to the format in Figure 154.5. The packet may end with a trailer composed of error-checking codes or other administrative information. The addressing information in the packet identifies the sensor system originating the packet and the destination process for analysis. Other information included in the header might be counters to identify the sequence number or a time stamp to show when the packet was created. The header will often contain a size parameter to specify the length of the data field.

For actual transmission across the data channel, a link-layer packet may be used. This link packet may multiplex the data packets from several subsystems together for efficient transport. If the data channel is synchronous, as with a radio channel, then it is common for the channel packets to be sent at regular

FIGURE 154.5 An example of a telemetry packet.

intervals to maintain transmission synchronization. When this is done, fill packets are used to keep the channel active if there are no actual data to be sent. The packet header will then have a special code to indicate that the packet is a fill packet and should not be processed.

The packet usually begins with a synchronization marker, just as frame telemetry does. The same synchronization codes can be used in packet systems as in frame systems. After synchronization the header is analyzed to identify the type of processing to be performed based on the source of the data. The probability of missing the synchronization marker due to channel errors is computed as in Equation (154.3) and the probability of receiving the packet correctly is computed as in Equation (154.4). Many commercial protocols have error detection as part of the protocol specification so this can be used to assess data quality in the packet.

Defining Terms

Commuted data — Data that are sampled once per main sampling interval. This main sampling interval is called the *commutation rate*. Minor frames, major frames, and subframes are tied to this commutation rate.

Major frame — The set of an integer number of minor frames where each sensor value is sampled at least once.

Measurand — The physical quantity or parameter being measured.

Minor frame — The set of sensor values, synchronization markers, and other management data between successive synchronization words.

Nyquist sampling rate — The minimum sampling rate for signal recovery. If a signal of limited bandwidth is sampled at twice this rate, then the signal can be reconstructed in principle. Most signals are sampled at a higher rate than the Nyquist rate to give better reconstruction.

Pulse-coded modulation (PCM) — Modulation in which each analog sensor value is converted to a digital number once per sampling interval. The number of bits used in the representation is typically 8 to 16 bits.

Subcommuted data — Data with a sampling interval that is less frequent than the commutation rate.

Subframe — A group of sensors that are subcommuted together. Usually, the data are tied to a single physical subsystem.

Supercommuted data — Data with a sampling interval that is more frequent than the commutation rate.

- 155.7 Tradeoffs in Recorder Selection

Timothy M. Chinowsky
University of Washington

Recording instruments are needed wherever repetitive measurements must be made and stored for later review or analysis. Some general types of applications that require recording instruments include the following:

Measurements for longitudinal characterization and recordkeeping. Measurement and recording of industrial process parameters allow for process monitoring and characterization. Chart records are required by some industries to comply with regulations such as the Environmental Protection Agency (environmental monitoring), Food and Drug Administration (food and pharmaceutical), and North American Electric Reliability Council (power grid interchange). Flight data recorders record aircraft performance data to allow for diagnosis in the event of an adverse flight event. As in many applications of this type, the recorded data are generally only used when the rare problem occurs, but then the recorded data become crucial.

Measurements requiring rapid scanning and review. Medical applications such as monitoring of patient vital signs in critical care settings require that medical personnel have the ability to quickly scan and summarize a variety of patient data, such as electrocardiogram traces, blood pressure measurements, and oxygen saturation. Recorders that can measure various patient data and assemble them into a graphical presentation which can be quickly comprehended are essential for this application.

Fast measurements requiring further analysis. Measurements that possess sufficient speed and complexity to require human interpretation at a slower speed must be recorded to allow for this analysis. Whether the data are relatively simple, such as an electrocardiogram, or more complicated, such as high-speed telemetry, a data recording is necessary to make full use of the data.

Measurements of slow trends. On the other extreme, human operators cannot efficiently monitor quantities that change very slowly, due to the limited human attention span and prohibitive labor costs. Data recorders can provide cost-effective measurements of quantities that change over time periods ranging from nanoseconds to years.

Measurements in remote or unattended locations. When a measurement must be made at a location where an operator is not present, measurements must be recorded. Automated data recorders allow measurements to be made in the most appropriate location, whether or not that location is conveniently accessible to a human operator.

155.1 Characteristics of Data Recorders

A great variety of devices for data recording are available in the market today. To ensure an optimal choice of recording device, it must be matched to the application. General attributes that must be considered when choosing a recording device include the following:

Type of measurement. What type or types of signal is being recorded? Does the recorder use internal sensors or does it connect to external sensor inputs?

Number of channels. How many measurements must be recorded simultaneously?

Speed. How fast (measurements per second) is the data recorded?

Recording medium. Onto what medium are the data recorded? Are data recorded in an analog or a digital format?

Data storage. How much data can the recorder store internally? When the recorder is “full,” how are data removed and stored? Is the storage archival?

Machine readability. Is the recorded data machine readable, or is intended solely for human interpretation?

Data display. Does the recorder display the data as they are recorded, or are they stored for later viewing? Does the recorder display only the current measurement, or a complete measurement history?

Location. Is the recorder located where the measurements are made, or are the measurements made remotely and transmitted to the recorder over a wired or wireless connection? Are the recorded data viewed and analyzed where they are recorded, or are the recorded data removed from the recorder and analyzed at some other location?

Other features. Modern computerized data recorders often are capable of performing many more functions than simple data recording and display, including interfacing to personal computers (PCs) and computer networks, built-in data analysis algorithms, and the ability to control as well as monitor a process. The user must determine what combination of features will best serve to meet the short- and long-term goals of the application.

155.2 Paper Recorders: Strip Charts and Circular Charts

The oldest form of recording instrument is the paper recorder. In an all-mechanical temperature recorder, for instance, a mechanical displacement generated by a bimetallic strip moves a pen across a slowly moving piece of paper. As the paper moves, a plot of temperature against time is created. More sophisticated electromechanical pen recorders measure a wide variety of inputs such as current, voltage, RTD, or thermocouple, and convert the sensor data into mechanical motion of a pen using a servomechanism.

Paper recorders typically use either a strip chart or circular chart format. A strip chart records on a long strip of paper, typically 100 mm to 250 mm wide and many meters long. The paper is stored in either a fanfold or roll format, and is fed across the writing mechanism at a rate appropriate to the measurement rate. The circular chart records data along the radius of a slowly rotating circular paper chart, typically between 150 mm and 300 mm in diameter. The distinctive feature of the circular chart is that the chart data are inherently organized according to the chart rotation period, which is typically set to be a convenient period such as 24 hours, 7 days, or 30 days. A circular chart with a period of 24 hours would therefore be convenient for measuring and presenting parameters (temperature, for instance) expected to have a periodic daily variation.

Pen-based recorders are much improved since their invention. Modern pen recorders such as the Love Controls 16R (Figure 155.1) incorporate several ink colors, allowing for easy trace identification, and pens can provide automatic alphanumeric chart annotation as well as measurement traces. In “multi-point” recorders, each pen is not associated with a fixed trace, and many simultaneous traces in various line styles may be plotted. The ABB SR250A (Figure 155.2) allows recording of up to 24 channels, each with a unique trace style, along with a wide variety of alphanumeric annotations.

Mechanical limitations of pen recorders such as ink depletion and pen slew rate are addressed by strip chart recorders based on thermal line printer technology. These recorders digitize measurement data,

FIGURE 155.1 Love Controls 1600R 4-trace pen recorder.

FIGURE 155.2 ABB SR250A multipoint strip chart recorder.

format the data for raster display, and plot the data on a dot-matrix thermal line printer. No physical pen motion is required, so measurement speed is limited only by measurement electronics, paper speed, and printer resolution rather than pen motion. The more sophisticated display capabilities of the thermal printer allow incorporation of information other than raw display traces onto the strip chart. Grid lines may be printed at the same time as the traces, eliminating the alignment difficulty found with pen-based recorders, in which pen traces are aligned with grid lines preprinted on the chart paper. Other graphic and alphanumeric information may also be printed on the chart as it is created. For instance, the RMS Instruments GP300 (Figure 155.3) prints on a 300-mm wide strip at a resolution of 300 dots per inch

FIGURE 155.3 RMS Instruments GP300 graphic printer/recorder.

FIGURE 155.4 Avalon AE3000FL high-speed data recorder. Analog data of up to 12-MHz bandwidth is digitized and stored on conventional videotape.

FIGURE 155.5 Avalon AE7000 hard-disk data recorder.

and paper feed speeds ranging up to 260 mm/sec. Up to 32 waveform channels can be plotted simultaneously, along with many other types of information, including 16 event (logic) channels, alphanumeric information, and grayscale images.

The use of paper as the primary storage medium is both the primary feature and main liability of paper recorders. On the positive side, paper provides an ideal medium for rapid viewing and review of data. Fanfold paper, in particular, allows the user to review a large quantity of data with little effort. Storage of the chart requires little special handling, and with proper treatment can be of archival quality. On the downside, paper is bulky and must be replenished, and paper-recorded data are not easily machine readable. Finally, recorded signal bandwidth is limited to the order of 10 Hz by printing resolution, paper speed, and paper consumption.

155.3 Magnetic Media Recorders

The bandwidth limitations, lack of machine readability, and bulky consumables of paper recorders are reduced by data recorders that use magnetic media. Removable media such as floppy disks, ZIP disks, videotape, and DAT provide for unlimited storage capability, while fixed hard disks offer high-performance random-access reading and writing of data. As the cost per gigabyte for hard disks continues to fall, removable/replaceable hard drives are an increasingly attractive option for high-density data storage, and are offered on some data recorders. Magnetic media may be used as an enhancement to a paper recorder, providing a machine-readable recording simultaneous with the paper record. The capabilities of magnetic media may be used to provide performance unobtainable with a paper record. The Avalon AE3000FL (Figure 155.4) is capable of recording analog signals with 18-MHz bandwidth on standard videotape; the hot-swappable-hard-disk based AE7000 (Figure 155.5) can record signals with 50-MHz bandwidth.

155.4 Semiconductor Memory Recorders

Increasing density and decreasing cost of nonvolatile semiconductor memory (flash memory) has made semiconductor data storage an attractive alternative to magnetic media. Packaged in various formats such as CompactFlash and PC-Card ATA, removable flash memory cartridges in capacities up to several gigabytes are increasingly used in data recorders as the storage medium. Battery-backed low-power static RAM is also widely used for semiconductor-based data storage, but battery life must be taken into account. Semiconductor memory is particularly attractive for data-logger applications in which a recorder is intended to operate unattended for a long period of time. The Onset StowAway Tidbit (Figure 155.6) is a $1.2" \times 1.6" \times 0.65"$, 0.8-oz. device that can make and store over 32,000 temperature measurements at a user-programmable rate ranging from seconds to hours; its encapsulated construction makes it usable up to 1000 feet underwater. Stored data can then be read out by a noncontact optical link. More general-

FIGURE 155.6 Onset Stowaway TidBit miniature encapsulated temperature data logger. Data are read from the device by a noncontact optical interface.

FIGURE 155.7 Astro-Med Dash 8x modular data recorder.

purpose data loggers provide self-contained versatile measurement, and data storage and retrieval capability for a wide variety of types of input signals and sensors.

155.5 Hybrid Recorders

Modern recording solutions typically offer a combination of the above features. Recorders that produce both a paper and machine-readable record are termed “hybrid” recorders and are increasingly ubiquitous. The trend is for the paper output, rather than the machine readable recording, to be an optional feature. The Astro-Med Dash 8x (Figure 155.7), for instance, incorporates a modular architecture that allows up to eight inputs of various types to be sampled at up to 200 kHz, with measurements saved to the recorder’s internal hard disk. Data is displayed on an integral flat-panel touch-screen monitor. An optional printer may be attached to obtain conventional strip-chart output.

155.6 Personal Computer-Based Recorders

The ubiquity of personal computers has made personal computer (PC)-based solutions attractive for data recording applications. A typical office PC incorporates the display, storage, and printing capabilities required for most data recording applications, and requires only the addition of relatively low-cost measurement hardware and software to complete a data recording solution. Many companies have developed software and hardware for this application. National Instruments, in particular, has developed a large variety of sophisticated hardware and software programming environments for data acquisition. For instance, its VI Logger software combined with any of a variety of the company’s measurement hardware enables rapid assembly of a data recording system. This approach is economical, as it makes use of general-purpose PCs, and also versatile, as software and hardware can be modified to add more sophisticated data acquisition and control capabilities. However, systems built using commercial, multi-purpose hardware may be less rugged, less reliable, and more difficult to maintain than a self-contained piece of hardware dedicated to data recording.

155.7 Tradeoffs in Recorder Selection

The great variety of recording devices available makes it necessary to consider a large number of factors when choosing a recording device. Choosing between a paper-based recorder or a paperless recorder is

one major decision. The initial cost of the paperless unit is higher than that of its paper-based counterpart for comparable point capacity, but the lifetime cost of ownership for a paper recorder must include the purchase of pens and charts. The amount of time needed to store data, the sample rate, and the capacity of the paper, magnetic tape, disk, or memory card tape are issues that must be resolved to ensure sufficient storage capacity. The question of what is required to enable the user to record data and view data after collection should also be explored. The ease of configuring the unit using its front-panel interface or control software can make a big difference in the usability of the recorder.

Lifetime of the recorder should also be taken into consideration. For instance, many displays have a limited lifetime when used continuously. If archival storage of data is necessary, one must consider what the user must do keep the data for several years. Many units require additional steps to maintain or archive stored data for long periods after the recorder has collected the electronic information. Magnetic media may have limited storage times compared with paper. Fortunately, the data recorder industry has had many years to refine its products, and the vast selection of reasonably priced recording instruments readily available on the market virtually guarantees that an acceptable solution can be found.

Further Information

A distributor of a wide variety of data recording devices is OMEGA Engineering, INC., P.O. Box 4047, One Omega Drive, Stamford, CT 06907-0047, www.omega.com.

[156.1 Basic Bioinstrumentation Systems](#)

[156.2 Applications and Examples](#)

[156.3 Summary](#)

Biomedical instruments measure, amplify, process, record, and store physiological quantities to help physicians diagnose illnesses, set up treatment plans, and restore lost functions. The scope of such instruments is enormous, both in complexity and the range of applications. Only a few can be covered in this chapter. Since a choice among topics must be made, this chapter focuses primarily on instruments that measure physiological signals; it does not cover devices that treat diseases or restore compromised physiologic functions. For further information, see the Bibliography section.

In contrast to technical systems, physiologic systems comprise living cells and organs. This requires that measurements do not adversely affect the living system by introducing toxic substances, destroying delicate tissues, or otherwise interfering with the chemical, electrical, or mechanical balance of the living cell or organ. Furthermore, many physiologic measurement sites are either inaccessible or direct measurements are only accessible invasively, that is, by puncturing the skin. Noninvasive biomedical instruments often use indirect measurement methods, even though these methods are usually less accurate, slower, and less informative than their direct counterparts.

Physiologic measurements seldom depend on one variable alone. The electrical impedance of tissue, for instance, depends not only on resistivity, cross-sectional area, and length, but also on electrolytes, enzymes, temperature, and other factors related to life processes. To extract meaningful information from impedance measurements, the system needs to focus on one of these factors and suppress the others. Physiologic events in living systems are unstationary, stochastic, time dependent, and noisy. It takes a lot of skill and ingenuity to measure them.

Biological cells pump primarily sodium and potassium ions across the cell membrane to maintain specific concentration differences. The resulting membrane potential of about -90 mV can be calculated from a modified Nernst equation. Nerve and muscle cells are excitable cells and generate action potentials by first changing the membrane permeability of sodium and then that of potassium. Action potentials influence the electric fields in the tissues surrounding the excitable cells all the way to the skin, from where they can be detected and recorded as surface biopotentials. These biopotentials are characterized by high source impedances, small signal voltages, significant interference voltages, and a modest frequency range. Special biopotential amplifiers convert these biopotentials into high-quality signals by amplifying them, suppressing interferences, and preparing them for further signal processing, display, or recording.

Biomedical instruments operate in hospital rooms, where they interact with other devices, work in the vicinity of other devices, or connect to patients. Such interconnections not only cause unpredictable interferences, but also provide current pathways that may endanger the lives of patients and/or operators. To ensure high-quality measurements and electrical safety, requirements must be imposed on biomedical

instruments, uncommon in typical industrial measurement systems. Biomedical measurements must do the following:

- Amplify the biosignal and suppress interferences
- Protect input stages against high voltages generated by other devices
- Be electrically safe for operator and subject
- Avoid adversely affecting the living system

156.1 Basic Bioinstrumentation Systems

Figure 156.1 shows a block diagram of a basic bioinstrumentation system. The physiologic variable to be measured, the measurand, may be the result of a molecular, cellular, or systemic event, and be mechanical, electrical, or chemical in nature. Blood pressure and blood flow, for instance, are important mechanical variables of the circulatory system. The electrocardiogram, electromyogram, and electroencephalogram provide information on the electrical activity of the heart, skeletal muscle, and brain, respectively. Partial pressures of oxygen or carbon dioxide reflect the status of the chemical balance in the blood. The sensing element in Figure 156.1 interacts with the measurand, directly or indirectly, and is designed with three main goals in mind: minimize the unavoidable disturbance of the measurand and its environment, avoid interference with life processes, and provide an output signal sensitive primarily to the measurand and insensitive to other parameters.

The transducer takes the output of the sensing element and transforms it into an electrical signal. The most common analog signal-conditioning elements are amplifiers, filters, rectifiers, triggers, comparators, and wave shapers, just like in other instrumentation systems. Appropriate amplification and filtering prepare the analog signal for analog-to-digital conversion (ADC). Once in digital form, a microcomputer further processes the signal and displays it on a CRT screen or on an LCD panel, generates a hard copy on a recorder, sends it to another device, or stores it in a mass storage device. Some measurements require external energy or stimulation applied to the subject across an isolation barrier.

Medical instruments contain special circuits to safeguard patients and operators against electrical shock, suppress interferences from the noisy hospital environment, and protect sensitive input stages. The most important of these is the isolation barrier, made of transformers, capacitors, optocouplers, or a combination of these. The isolation barrier keeps current densities in the body below the safe level of $100 \mu\text{A}/\text{cm}^2$. Several national and international standards give limits for safe voltages and currents, describe methods to avoid potentially dangerous connections, and give detailed test procedures to ensure electrical safety [NFPA, 1990; AAMI, 1990; IEC, 1982].

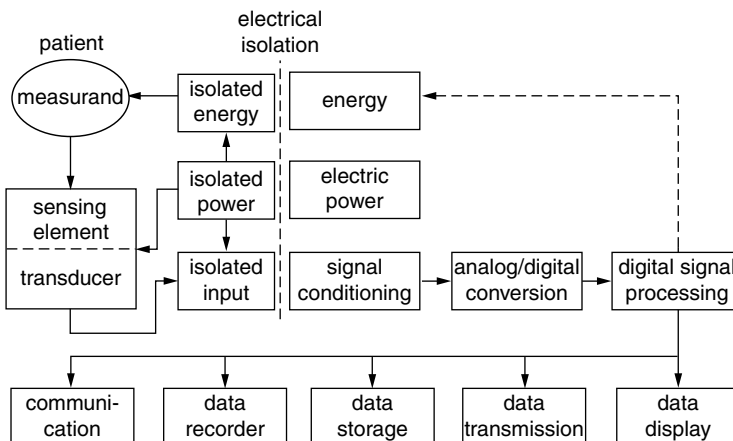

FIGURE 156.1 Schematic block diagram of a biomedical instrument.

A single hospital room may contain electrocardiographs, blood pressure monitors, x-ray machines, cardiac output monitors, respirators, electrosurgery devices, defibrillators, and other devices. The useful and beneficial output of one device may severely interfere with another. To function in the same environment, these devices must contain special hardware circuits or software algorithms that suppress undesired outputs from other devices.

156.2 Applications and Examples

Action potentials of nerve and muscle cells inside the body manifest themselves on the surface of the skin as small voltages between 10 μV and 100 mV with high source impedances and high levels of interfering noise signals. These surface biopotentials are detected with surface electrodes that function as transducers between the ionic currents inside the body and electronic currents in wires and amplifiers. Electrodes represent complicated electrochemical systems, as described in many bioinstrumentation books [Aston, 1990; Bronzino, 1986; Geddes and Baker, 1989; Norman, 1988; Profio, 1993; Webster, 1992]. Most electrodes for recording surface biopotentials are made of silver or silver chloride because they provide stable and relatively noise-free recordings.

The diagram in Figure 156.2 for obtaining a lead I electrocardiogram serves as an example of how to obtain a high-quality biopotential recording in general. Three electrodes attach to the subject — two for recording the biopotential and one for providing a reference potential. The electrodes on the left and right arms connect directly to the differential input of an isolated instrumentation amplifier; the reference electrode on the right leg connects to the floating ground terminal. This configuration separates the desired differential-mode biosignal e_S from the undesired common-mode noise e_N , as shown in the electric equivalent circuit of Figure 156.2. The instrumentation amplifier provides a high differential-mode gain and a low common-mode gain to suppress power line interferences and electrode potentials. The ratio between these two gains is called common-mode rejection ratio (CMRR). Although the CMRR of a good instrumentation amplifier may be as high as 130 dB, the CMRR of the overall circuit is seldom greater than 80 dB or 10,000:1. The primary cause for this large reduction in CMRR lies in the differences in electrode and skin impedances, represented by Z_1 and Z_2 in Figure 156.2. Some bioinstrumentation systems use additional amplifiers that set the voltage on the right leg equal to the mean voltage between the left and right arm (“driven right leg”), thereby decreasing common-mode voltages.

The most important and most investigated biopotential waveform is the *electrocardiogram* (ECG) [Webster, 1992]. Since the electrocardiogram represents the heart’s electrical activity associated with cardiac contraction, it provides diagnostic insight into many heart functions. The curve in the left panel of Figure 156.3 represents a typical ECG waveform with the standard P, QRS, and T labels. The P wave and the QRS complex represent depolarization of cardiac muscle cells — the first one of atrial cells and the second one of ventricular cells. Although atrial repolarization cannot be seen in the ECG, the T wave represents ventricular repolarization. These P waves and QRS complexes precede cardiac contraction and the pumping of blood, first of the atria and then of the ventricles.

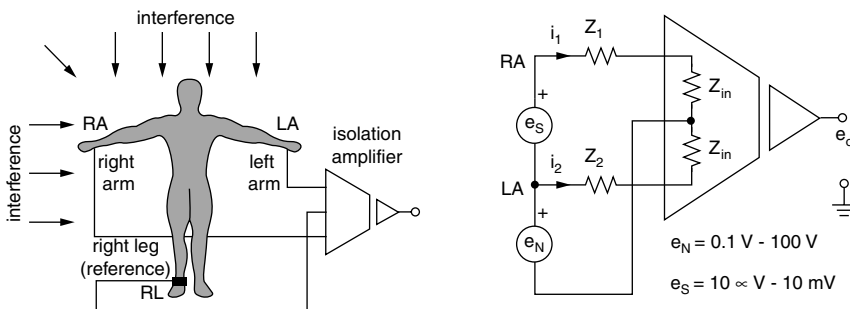

FIGURE 156.2 Schematic diagram for measuring biopotentials (left); electrical equivalent circuit (right).

FIGURE 156.3 Typical lead II ECG recording (left). Einthoven triangle (right).

To enable comparisons of waveforms between subjects, certain standardized recording techniques have evolved. Einthoven, the pioneer of electrocardiography, developed an extremity lead system still in use today. As shown in the right panel of Figure 156.3, the three recording electrodes of the Einthoven triangle are placed on the left arm, the right arm, and the left leg, whereas the reference electrode is placed on the right leg. The voltage differences between the three recording electrodes are known as lead I, lead II, and lead III recordings. The lead II recording from the right arm to the left leg runs almost in parallel to the main axis of the heart and is therefore the preferred recording of a single-channel ECG. In addition to Einthoven's recordings, physicians use augmented limb leads and unipolar chest leads.

Recordings of the electrical activities of the brain, called *electroencephalograms* (EEGs), are more difficult to obtain than recordings of the ECG. The skull is a poor electrical conductor and EEG voltages on the scalp are in the μV range, as opposed to ECG voltages in the mV range. Furthermore, it is difficult to relate EEG voltages to specific neuronal activities; they are the net result of many different neurons firing seemingly independently of each other. With a subject in a relaxed state with closed eyes, alpha waves are easily recorded between two electrodes on the scalp. As shown in Figure 156.4, alpha waves are simple periodic waveforms in the frequency band of 8 to 13 Hz with slightly varying amplitudes. Alpha waves disappear when the subject's eyes are opened. The other waveforms shown in Figure 156.4 have clinical significance, particularly in diagnosing epilepsy and sleep disorders or in providing feedback during general anesthesia. The low-frequency theta waves between 4 and 8 Hz indicate sleep, whereas the high-frequency beta waves between 14 and 22 Hz appear during high states of alertness.

Recordings of the electrical activities of skeletal muscles are called *electromyograms* (EMGs). They can be obtained with surface electrodes similar to ECG electrodes or needle electrodes. The latter puncture the skin and are positioned close to the muscle group, from which they record. The mean amplitude and mean frequency of the EMG power spectrum reveal both muscle strength and muscle fatigue, which can provide feedback information in rehabilitation engineering and functional electrical stimulation [Phillips, 1991]. Table 156.1 summarizes amplitudes and frequency ranges of ECG, EEG, and EMG. Similarly, other biopotentials originating from other nerve or muscle cells can be recorded from the surface of the body.

FIGURE 156.4 Typical EEG waveforms (left); typical EMG waveform (right).

TABLE 156.1 Amplitude and Frequency Ranges of ECG, EEG, and EMG

| Origin of Electrical Activity | Name | Amplitude (mV) | Frequency Band (Hz) |
|-------------------------------|----------|----------------|---------------------|
| Cardiac muscle | ECG | 1–10 | 0.01–150 |
| Skeletal muscle | EMG | 5–100 | 10–5000 |
| Brain | EEG | <0.2 | 1–30 |
| | β | 0.01 | 14–30 |
| | α | 0.03 | 8–13 |
| | θ | 0.05–0.1 | 4–7 |
| | δ | 0.1–0.15 | 1–4 |

FIGURE 156.5 Electrode positions and typical waveforms of electrical impedance of thorax measurements.

Bioelectric impedance measurements provide qualitative and quantitative information about volume changes in the heart and in peripheral arteries and determine body characteristics such as percent body fat, total body fluid volume, and cell volume. They are also used in sleep apnea monitoring, especially in infants, and in the detection of venous thrombus. Multiple bioelectric impedance measurements lead to computed cross-sectional images of the body, so-called *computed impedance tomograms*.

Figure 156.5 shows four band electrodes for the measurement of respiration, stroke volume, and cardiac output. A constant sinusoidal current with an amplitude in the range of 0.5 to 4 mA and a frequency between 50 and 100 kHz flows from the top electrode through the thorax to the bottom electrode. This current is maintained independent of skin or tissue impedances. The voltage drop between the two middle electrodes is amplified by a voltage amplifier with a high-input impedance. The output voltage e_0 is proportional to impedance changes ΔZ that arise from thoracic volume changes due to respiration and from blood volume changes due to the pumping heart. Figure 156.4 shows the curves for ΔZ and dZ/dt , the former being proportional to respiratory volume changes and the latter to blood flow.

The noninvasive measurement of blood pressure is important in the diagnosis of many cardiovascular problems. Blood pressure varies — often within seconds — to meet the physiologic demands of organs and muscles. Although single blood pressure readings are valuable for entry-level screening, they do not provide as much information as monitoring over a specified length of time, usually 24 hours. The most common body-worn instrument for monitoring blood pressure noninvasively is a battery-powered oscillometric blood pressure monitor. In this monitor, an inflatable cuff fits snugly around the upper or lower arm and connects to a pump and pressure transducer. The microcontroller (CPU) triggers the pump periodically to inflate the cuff up to a pressure slightly greater than systolic arterial pressure. It then controls the valve to release the cuff pressure at a rate of about 4 mmHg/s and measures the cuff pressure. The resulting cuff pressure curve consists of a descending curve superimposed by small periodic oscillations. These oscillations start just before the cuff pressure equals systolic pressure, increase rapidly, reach the maximum amplitude at mean arterial pressure, and then gradually decrease. A special algorithm suppresses motion artifacts, extracts systolic and mean pressure (P_s and P_m) from the pressure curve, and calculates the diastolic arterial pressure. The oscillations also permit the calculation of heart rate. Blood pressure data, heart rate, date, and time are displayed on an LCD panel and stored in a data logger. The

serial output permits uploading data to another computer for further evaluation. Figure 156.6 shows the block diagram of this device and an annotated typical oscillometric waveform.

156.3 Summary

This chapter has focused primarily on electrical measurement techniques and examples thereof. Many interesting subjects and instruments could not be covered, such as blood flow and blood volume, partial pressures of oxygen and carbon dioxide, oxygen saturation, glucose, and enzyme concentrations, to mention only a few. The emerging technologies related to home care could not even be mentioned. For further reading, see the texts listed in the References section.

Defining Terms

Action potential — The reversible depolarization of the membrane potential of an excitable cell in response to a mechanical, electrical, or chemical stimulus. The peak action potential of a single cell is about 70 mV.

Common-mode rejection ratio (CMRR) — The ratio of difference-mode gain over common-mode gain in a difference amplifier. It is a measure of the degree to which common-mode signals are suppressed in relation to difference-mode signals.

Christopher G. Relf

*National Instruments Certified
LabVIEW Developer*

The LabVIEW (Laboratory Virtual Instrument Engineering Workbench) development system has certainly matured beyond its original role of simple laboratory bench experiment automation and data collection — it has become a full-featured programming language (known as G) in its own right. Although National Instruments (the creators of LabVIEW) continue to push its rapid prototyping and code development virtues, an increasing number of G software developers are relying on advanced programming techniques, far beyond those initially apparent.

The documentation that ships with a standard LabVIEW installation is sufficient to assist the development of simple applications by users not initially familiar with LabVIEW, and the various online documents provided by National Instruments and third-party vendors extend that learning experience. This chapter attempts to describe some of the features, methods, and more obscure tidbits of programming expertise that are of use to the advanced G software engineer.

157.1 Data Types

Like most modern programming languages, G code uses various data types. These data types allow for efficient data storage, transmission, manipulation, and processing of information. Simple data types include the integer, floating point, strings, paths, arrays, clusters, and reference numbers (*refnums*). The

| Node | Data Type | Data Range | Data Format |
|---|-------------------------|---|--|
|  | Unsigned 8 bit Integer | 0 to 255 | |
|  | Unsigned 16 bit Integer | 0 to 65535 | |
|  | Unsigned 32 bit Integer | 0 to 4294967295 | |
|  | Signed 8 bit Integer | -128 to 127 | |
|  | Signed 16 bit Integer | -32768 to 32767 | |
|  | Signed 32 bit Integer | -2147483648 to 2147483647 | |
|  | Single Precision Float | -3.4×10^{38} to 3.4×10^{38} |  |
|  | Double Precision Float | -1.7×10^{308} to 1.7×10^{308} |  |

FIGURE 157.1 Numerical data types.

method G uses to store data depends on its type, and it is important to understand the way data will reside in memory. Savvy use of data types decreases the overall memory footprint of an application, minimizes data coercion errors, and improves system performance.

Figure 157.1 lists representations of the standard numerical data types available to G. Others exist, including the extended-precision float, although its representation is platform dependent, as shown in Figure 157.2. (The representation of an extended-precision float is identical to a double-precision float when using HP-UX.)

Unlike numerical values, strings are represented by dimension-defined arrays (Figure 157.3). Each array consists of a 4-byte integer that contains the number of characters required to represent the string, and subsequent byte integers that represent each character. Therefore, as the highest number that will fit into a 4-byte word is 4,294,967,296, the longest string that can be continuously represented has 4,294,967,296 characters.

| Node | Platform | Data Space | Data Format |
|---|-------------------|----------------------|--|
|  | Microsoft Windows | 80 Bits |  |
|  | Apple Macintosh | 128 Bits (2x64 Bits) |  |
|  | Sun | 128 Bit |  |
|  | HP-UX | 64 Bits |  |
|  | Linux | 80 Bits |  |

FIGURE 157.2 Extended precision data type.

FIGURE 157.3 String data type.

TABLE 157.1 Path Type Descriptions

| Path Type | Description | Microsoft Windows Examples |
|-----------|-----------------------------|----------------------------|
| 0 | Absolute | C:\DATA\TEMP.DAT |
| 1 | Relative | \DATA\TEMP.DAT |
| 2 | Undefined | |
| 3 | Universal naming convention | \\PC_NAME\DATA\TEMP.DAT |
| 4→∞ | Undefined | |

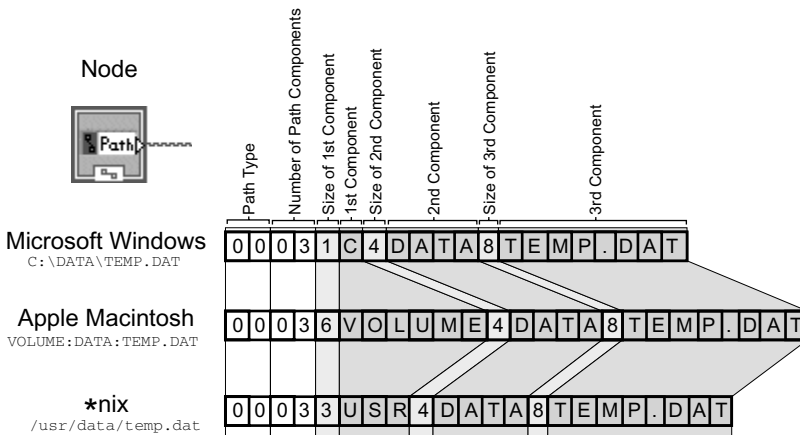

FIGURE 157.4 Path data type representations.

Paths are also stored as arrays, although the format is different from strings. The first element of a path array data format describes the *path type*, which is determined as shown in Table 157.1.

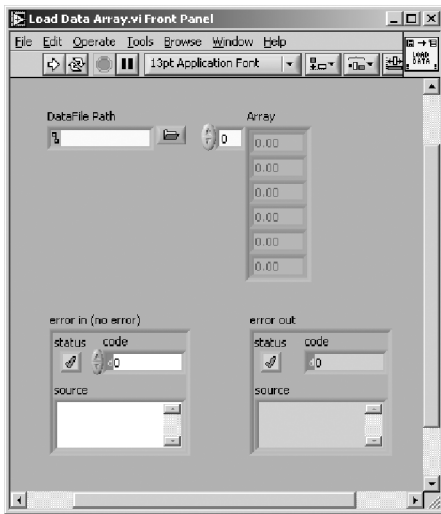

The second element of the path array data format defines the *number of path components*. For example, the following path,

\\PC_NAME\DATA\TEMP.DAT

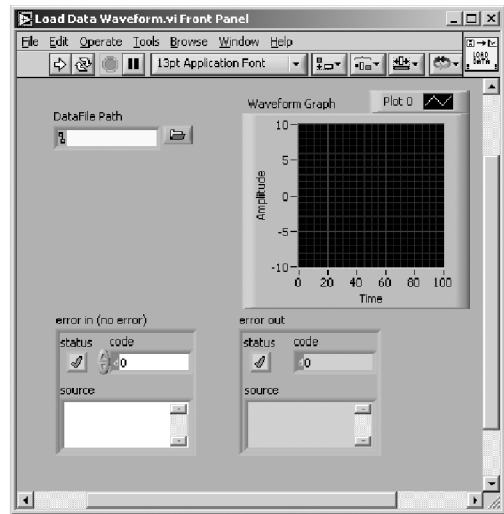

contains three components: the PC name, then a folder, and a file. Each of the components is then described in the array as a double-element pair — the first element is a byte that represents the character length of the component, and the second element is the component. As might be expected, path representations are platform dependent, as shown in Figure 157.4.

157.2 Polymorphism

Considered a generally underrated technique, polymorphic virtual instruments (VIs) are simply a collection of related VIs that can perform functions on differing data types. For example, a VI that loads a waveform from a file could return the result as an array of values or the waveform data type (Figure 157.5).

(a)

(b)

FIGURE 157.5 (a) Load data array, 5; (b) load data waveform.

While it is valid to create two separate VIs to perform these functions, it often makes more sense combining them into one polymorphic library (Figure 157.6). When a polymorphic VI is dropped onto a wiring diagram, the user can select the data “type” to use, and the appropriate VI is loaded (as shown in Figure 157.7).

It is considered good form to include a polymorphic VI and its daughter VIs in one LabVIEW library, as a polymorphic VI alone contains no code, only references to its daughters. Using this method assists in code distribution, and minimizes the incidence of broken polymorphic VIs unable to find their daughters. Using polymorphic VIs can increase the size of an application, as all of its daughters, irrespective of whether they are used in the application, are saved in the application.

Polymorphism is already used in several vi.lib VIs, including many of those found in the data acquisition function subpalette.

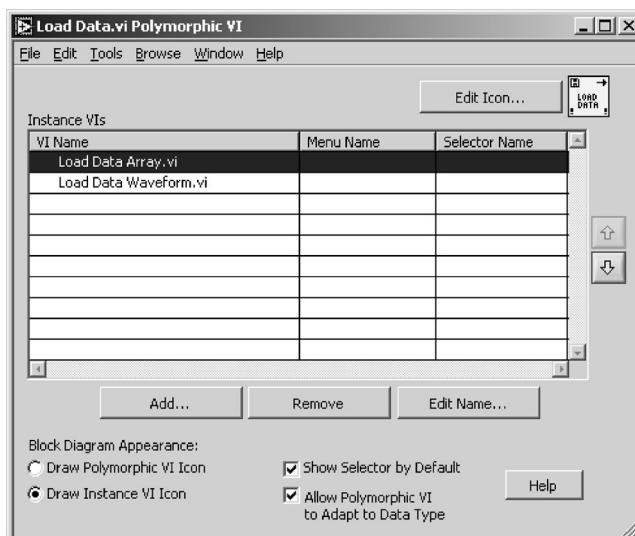

FIGURE 157.6 Creating a polymorphic VI.

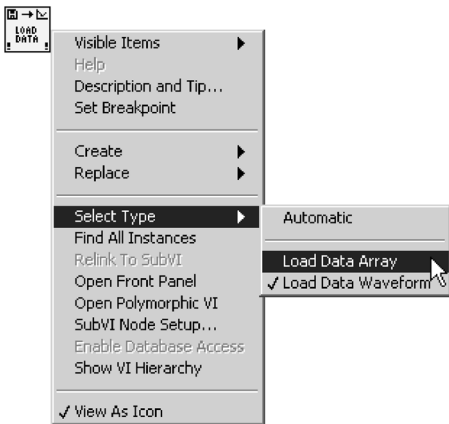

FIGURE 157.7 Select polymorphic type.

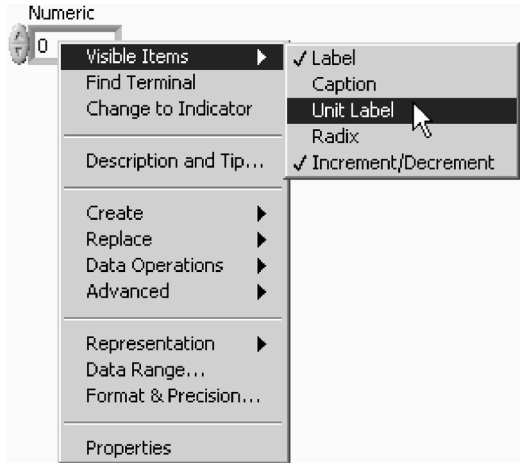

FIGURE 157.8 Selecting unit label.

(a)

(b)

FIGURE 157.9 (a) Unit example OK; (b) unit example not OK.

157.3 Units

Associating units to raw data adds an additional level of numerical checking when evaluating expressions and formulas. Incorporating units also adds the ability to display data to the user in dynamically controlled units, without the need for code to perform conversions.

A data node's unit association can be found by right-clicking on the node, and selecting Visible Items→Units (as shown in Figure 157.8). Once the unit label is displayed, the user can enter a unit type (a comprehensive list can be found in the LabVIEW online help), such as g for “grams.” Now that a unit is associated with the node, all data to that node are converted to the unit specified, and all data from it bears its unit type. VIs that do not respect mathematical unit relationships are broken, and will not run. Figure 157.9(a) shows a VI where a distance (m) value is divided by a time (s) value, resulting in a speed (ms^{-1}) value. If the distance control's unit is changed to an incompatible type (e.g., kilogram in Figure 157.9(b)), the G development system reports a bad wire between the division primitive and the ms^{-1} indicator, suggesting an incompatible unit.

The LabVIEW built-in functions, such as Add and Multiply, are polymorphic with respect to units, so they automatically handle different units. In order to build a subVI with the same polymorphic unit capability, you must create a separate daughter VI to deal with each unit configuration.

157.4 Data Coercion

When performing functions on data, it is possible to combine differing representations in the same structure. When this occurs, LabVIEW must decide on how to convert the incident types to a common

FIGURE 157.10 Data representation coercion.

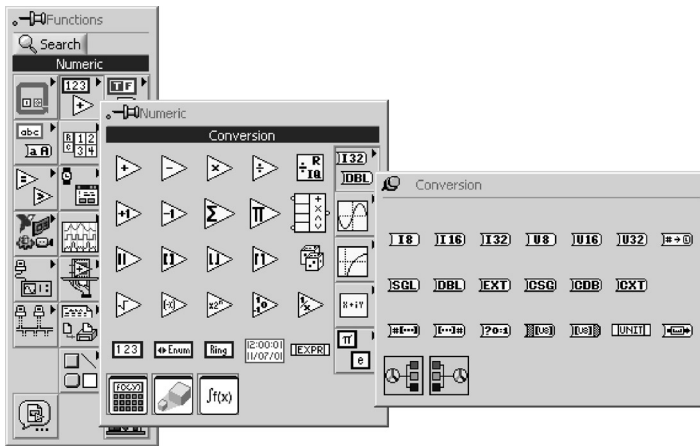

FIGURE 157.11 The conversion subpalette.

format before executing the function. As shown in Figure 157.10, the widest data representation is chosen for the operation and subsequent display and/or manipulation.

The coercion of the 32-bit integer is demonstrated by the coercion dot on the input terminal of the function, indicating that the data type of the data input at this terminal is changed before the function is executed. Although in the example shown in Figure 157.10 no data are lost (the narrower data type is expanded), data coercion can lead to inefficient memory usage (storing numbers in a data format beyond what is required to accurately represent the physical data) and occasionally the loss of data (coercing data to a type narrower than the information encoded in it, thus clipping the data to its highest permitted value, or value wrapping when using signed/unsigned conversions). It is considered good form to hunt down and remove coercion dots from one's code, as they can represent coercion of data that are either beyond the software engineer's control and/or knowledge. Explicitly performing data coercion using the Conversion subpalette (Figure 157.11) of the Numerical function palette minimizes the incidence of poor block diagram comprehension.

Data coercion can be very important when considering application memory management. For example, if a floating point is inputted to the N node of a *for loop*, its data is coerced to a 32-bit integer format. If an upstream calculation causes the floating point to become *NaN* (not a number), it coerces to a very large number (in the order of 2×10^9), resulting in a large number of *for loop* iterations. LabVIEW will attempt to allocate an appropriate amount of memory to execute the loop (and handle any data inputs and outputs), and often crash trying. This issue may seem intermittent, as it will only occur when an upstream calculation fails. (This example was provided by Michael Porter, Porter Consulting, LLC.)

157.5 Error Handling

Writing VIs and SubVIs that incorporate error handling is considered good form, not only to allow the user indication of abnormal software execution, but also to allow the software to make decisions based

FIGURE 157.12 Error cluster control palette.

FIGURE 157.13 Front panel error clusters.

on the status of previous operations. Including error clusters in your code assists in troubleshooting, modularity, and user friendliness.

The Error Cluster

The error cluster is a special predefined LabVIEW cluster that is used to contain error status information (Figures 157.12 and 157.13). The cluster contains the following three components:

| Name | Data Type | Description |
|--------|----------------|---|
| Status | Boolean | Indicates if an error has occurred (TRUE = error, FALSE = no error). |
| Code | 32-Bit integer | A standardized error code specific to the particular error. LabVIEW has a table of default error codes, although the user is able to define custom error codes. See below for more information. |
| Source | String | Textual information often describing the error, the VI it occurred within, and the call chain. |

Usage

Although one of the most obvious methods of conditional code execution might be to unbundle the *Status* Boolean of the error cluster, and feed it to the conditional terminal of a case structure (Figure 157.14(a)), the complete cluster can be wired to it instead (Figure 157.14(b)).

The functionality of the code in Figure 157.14(a) and (b) is identical, although its readability is vastly improved as the second example colors the case structure green for the *No Error* case, and red for the *Error* case. Wrapping the entire code of a SubVI within a conditional case structure based on the error input allows VIs at higher levels to continue functioning, without executing code that could be useless or even dangerous when an error has occurred. Consider the simple report generation example shown in Figure 157.15.

A report is initially created, a file is then attached, the report is printed, and finally destroyed. The dataflow link between these SubVIs is the report's reference number (*refnum*), which ensures each execute in a predefined order. If each of the SubVIs execute without error, then the process completes successfully. Conversely, if one of the SubVIs encounters an error, subsequent SubVIs are unaware of the problem and attempt to execute regardless. In the example above, an error in the *Attach a File to the Report* SubVI will not cause the *Print the Report* SubVI to fail, resulting in a blank report print. If effective error handling is introduced (Figure 157.16), the Print the Report SubVI will know if an error has occurred before its

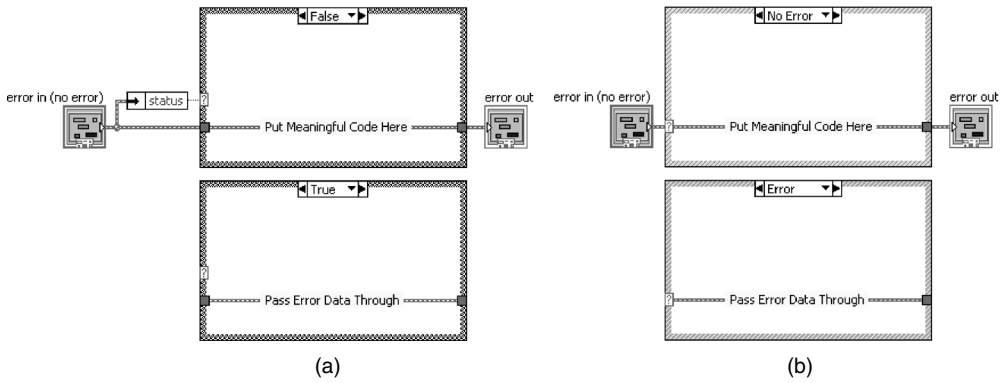

FIGURE 157.14 (a) Wire error cluster status into the conditional node 14; (b) wire error cluster directly into the conditional node.

1. Create a New Report
2. Attach a File to the Report
3. Print the Report
4. Dispose of the Report

FIGURE 157.15 Create and print report without error handling.

1. Create a New Report
2. Attach a File to the Report
3. Print the Report
4. Dispose of the Report

FIGURE 157.16 Create and print report with error handling.

execution is requested. If the functional code inside the *Print the Report* SubVI is enclosed within a conditional case structure based on the error input, the printing code is bypassed, and the data in the error cluster is passed on to the next SubVI.

To attain a higher level of user interaction, standard SubVIs exist to alert the user to an error on the error cluster, and prompt for conditional actions. The Simple Error Handler.vi (Figure 157.17) allows for a basic level of error cluster status reporting, displaying detected errors in a dialog box, and prompting the user for an action based on the *type of dialog* input (for example, OK, Cancel, Stop, etc.).

The Simple Error Handler.vi is a wrapper for the lower level General Error Handler.vi. The latter (Figure 157.18) is more configurable, and permits the dynamic definition of custom error codes, and error exception handling.

LabVIEW 7.0 brings with it an addition to the error handling function palette, Clear Errors.vi (Figure 157.19). This VI is simply an *error in* control and an *error out* indicator, which are not linked on the wiring diagram, causing any errors on the wired error link to be cancelled. This VI can be useful

FIGURE 157.17 Simple error handler.

FIGURE 157.18 General error handler.

FIGURE 157.19 Clear errors.

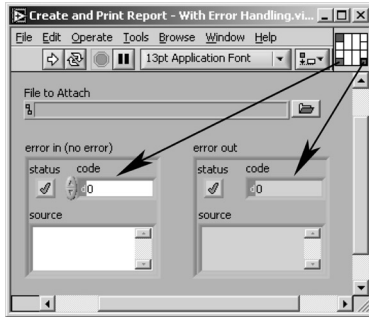

FIGURE 157.20 SubVI error cluster connector pane placement.

when constructing custom error-handling VIs, including dialog boxes allowing user interaction that is not covered by the simple and general error-handling VIs, but should not be used alone. Although dumping the errors from the error cluster may be tempting, one *must* incorporate appropriate code to handle them.

Wiring Errors into a SubVI Connector Pane

As described above, SubVIs have an associated connector pane, and the placement of error cluster inputs and output is generally in the lower quadrants (*error in* on the left, and *error out* on the right), with corresponding exclamation marks over the connectors on the SubVI's icon (as shown in Figure 157.20).

Default Error Codes

The LabVIEW execution system contains a large list of standard and specific errors, encouraging the reuse of generic codes across applications. A list of generic errors codes can be found under the LabVIEW *Help* menu (Figure 157.21).

Another method of parsing a small number of errors is to select the *Help*→*Explain Error* menu item. This will launch an interface that allows the user to enter an error code, and a brief explanation is displayed (Figure 157.22). This interface is also accessible by right-clicking on a front panel error cluster, and selecting *Explain Error*.

Custom Error Codes

National Instruments has set several error codes aside for custom use. If an existing error code does not adequately describe the error condition, the user can define custom codes that are specific to the application. Codes between 5000 through to 9999 are available for use, and do not need to conform to any other application. Although General Error Handler.vi can be used to define custom error codes, one can also create an XML file in the `labview\user.lib\errors` directory that contains custom error codes and their descriptions. This method is particularly useful if the user requires custom error codes to apply to several

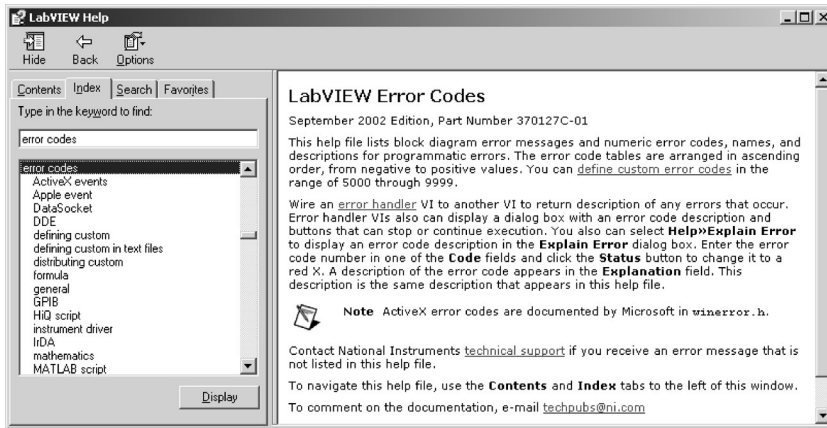

FIGURE 157.21 LabVIEW Help error codes.

applications, or if the codes are used by several software engineers in a team or are to be distributed with an application.

For example, the XML filename must be in the format `*-errors.txt` (where `*` is user definable), and the internal file structure must adhere to the following format:

```
<?XML Version="1.0">
<nidocument>
<nicomment>
This is a custom error code definition file for my application.
</nicomment>
<nierror code="5000">
User Access Denied!
Contact the Security Department to gain clearance to perform this function.
</nierror>
<nierror code="5001">
User Unknown.
Contact the People Development Department.
</nierror>
<nierror code="5100">
Driver Unable to Contact Instrument Database.
Contact the Software Engineering Department Helpdesk.
</nierror>
<nierror code="5200">
Plug-In Module in R&D mode - not to be used in Production Environment.
Contact the New Product Development Group.
</nierror>
</nidocument>
```

As can be seen, a file comment can be created within the `<nicomment>` tag space. Each custom error is defined as an `<nierror>` with its associated error code, and its error message is then placed inside the `<nierror>` tag space. Although hand coding a custom error code XML file is possible, the Error Code File Editor (**Tools**→**Advanced**→**Edit Error Codes**) provides a simple GUI for file creation and editing (see Figure 157.23). Once custom error code files have been created and/or altered, LabVIEW must be restarted for the changes to take effect.

It is often useful to define error code bands during the project planning stage, setting aside bands for specific related error groups.

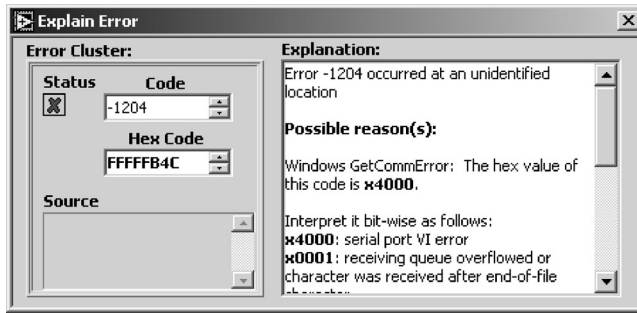

FIGURE 157.22 Explain error.

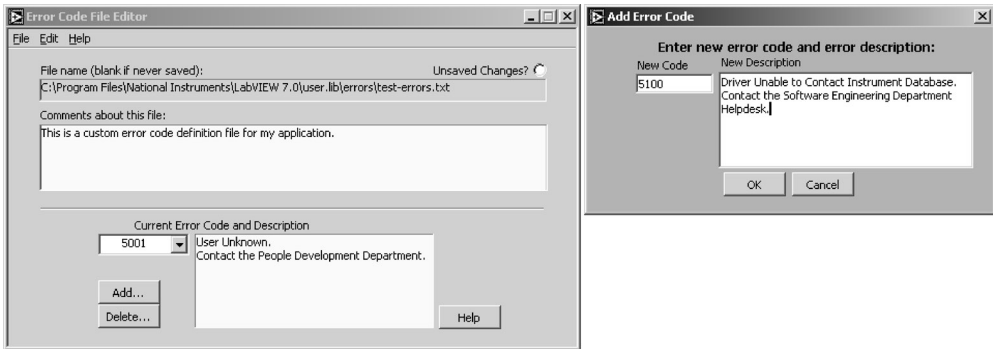

FIGURE 157.23 Error code file editor.

157.6 Shortcuts

Keyboard Shortcuts*

Most developers soon realize that their mouse or pointing device is not the only way to perform tasks; in fact some actions can only be achieved through keyboard sequences (or *shortcuts*). Once committed to memory, keyboard shortcuts are often a faster way to achieve tasks that might otherwise take several mouse maneuvers. Appearing below are most of the common and some of the obscure keyboard shortcuts that LabVIEW offers. Occasionally the only way to achieve a task is to use the keyboard in combination with the mouse, and these cases have also been included for completeness.

LabVIEW offers the developer a wealth of useful keyboard shortcuts. The shortcuts presented here refer to LabVIEW installed on the Windows operating system. Substitutions for the Ctrl key apply for other operating systems, as detailed in Table 157.2.

TABLE 157.2 Control Key Substitutions across LabVIEW-Supported Platforms

| Operating System | Control Key |
|------------------|---------------------------------------|
| Windows™ | Ctrl |
| Macintosh™ | Option or Command (context dependent) |
| Sun™/UNIX® | Meta |
| Linux™/HP-UX™ | Alt |

*This information on shortcuts was provided by Peter Badcock, engineering consultant, Australia.

The most commonly encountered tasks faced by a LabVIEW programmer focus on constructing and wiring the block diagram of a VI, while the next most common set of tasks is the manipulation of objects on the front panel. Switching between the front panel and the block diagram is a regular task. A shortcut to achieve panel/diagram switching is generally at the top of a shortcut enthusiast's "commonly used" list (assuming the enthusiast has mastered the automatic tool selection mode, and is therefore not continually switching tools with Space or Tab). Pressing Ctrl-E will change the focus between the block diagram and the front panel of the currently selected VI.

Tool Palette Shortcuts

An automatic tool selection tool palette mode was introduced with LabVIEW 6.1, where the active tool automatically changes to a selection that the development system considers the most useful as the cursor is moved over different parts of the front panel or block diagram. For the LabVIEW programmer who is accustomed to manually selecting the appropriate tool (whether by using the Tools Palette, or a keyboard shortcut), this takes some familiarization. Committing certain keyboard shortcuts to memory will enhance the automatic tool selection mode, making it a more useful (and less frustrating!) aid.

When automatic tool selection is enabled:

- Shift will temporarily switch to the positioning tool.
- Shift-Ctrl while cursor over panel or diagram space switches to the scroll tool.
- Double-click label text or constant values to edit them with the labeling tool.
- Ctrl while the cursor is over an object will switch to the next most useful tool. This is useful when the mouse pointer is over a wire, allowing the user to switch quickly between the positioning and wiring tools.

Note that Shift-Tab enables and disables the automatic tool selection mode.

When automatic tool selection is disabled:

- Tab selects the next tool on the tools palette.
- Space toggles between the positioning tool and the scrolling tool on the front panel, or the positioning tool and the wiring tool on the block diagram.

Miscellaneous Front Panel and Block Diagram Shortcuts

To create additional space in the selection, Ctrl-click (for operating systems other than Windows, use Shift+Ctrl+Click) from a clear point on the panel or diagram and select an area. The cursor keys (←, ↑, →, ↓) nudge selections one pixel in the direction chosen, whereas simultaneously holding down Shift while moving a selection with a cursor key increases the distance moved to eight pixels. Other miscellaneous shortcuts include those listed in Table 157.3.

TABLE 157.3 Other Miscellaneous Shortcuts

| Shortcut | Description |
|-------------------|---|
| Ctrl-double click | On a clear point, places text (otherwise known as a free label). |
| Shift-right click | Displays the tool palette. |
| Ctrl-double click | On a sub VI, opens its block diagram. |
| Ctrl-click-drag | An object with the positioning tool to duplicate it. |
| Shift-click | The block diagram to remove the last wiring point. |
| Esc | Cancels a wire route (dashed). |
| Ctrl-B | Removes broken wires. (Beware: nonvisible broken wires may exist.) |
| Drag-space | Activate autowiring when moving an element on the block diagram. (Autowiring only occurs when first placing an element, or a copy of an element, on the block diagram.) |

TABLE 157.4 Common Shortcuts

| Shortcut | Description | Comments |
|----------|---|---|
| Ctrl-S | Saves the currently selected VI. | |
| Ctrl-Q | Quits LabVIEW. | The user is prompted to save any open unsaved VIs. |
| Ctrl-C | Copy a selection to the clipboard. | |
| Ctrl-X | Cut a selection and place it on the clipboard. | |
| Ctrl-V | Paste the data from the clipboard. | Pasting data from a previous LabVIEW session will insert an image representing the data, and not the data itself. |
| Ctrl-F | Find object or text. | |
| Ctrl-R | Run the currently selected VI. | |
| Ctrl- | Aborts a running VI. | Only available when Show Abort Button option in VI Properties»Windows Appearance»Show Abort Button is selected. |
| Ctrl-E | Toggle focus between the front panel and block diagram. | |
| Ctrl-H | Display context help. | |
| Ctrl-W | Close the current window. | The block diagram is automatically closed when a front panel is closed using this shortcut. |
| Ctrl-Z | Undo the last action. | |

General Shortcuts

A complete list of keyboard shortcuts for the main pull-down menus can be found on the LabVIEW Quick Reference Card (shipped with LabVIEW and accessible in the online help). Some commonly used keyboard shortcuts include those shown in Table 157.4.

157.7 GOOP

G is well known for its speed of code development that provides engineers with a rapid prototyping advantage. This advantage is particularly evident when working with small projects with flat structures. However, as project complexity grows, initial stages of software architecture planning become vitally important.

GOOP (graphical object-oriented programming) is a method for developing object-oriented code, and is created using an external object model (often referred to as “LabVIEW external object” oriented programming, or LEO). Using GOOP has three main advantages to application development: code maintainability, scalability, and reusability. GOOP is the most common form of OOP with LabVIEW, and has been used successfully in many commercially available applications developed by G software engineers.

By implementing GOOP classes, you can take advantage of standard OOP analysis and design tools, including Microsoft Visual Modeler, and apply principles that describe object-oriented design and development. The OOP component-based development approach to developing applications enhances the traditional data-flow programming paradigm used in G applications, and using tools including the GOOP Wizard (access www.ni.com, and enter “GOOP” in the Search box for more information) allows you to create and manage OOP classes easily (Figure 157.24).

Once the fundamental concepts are understood, GOOP is easy to use, allows encapsulation, and permits you to create, control, and destroy as many objects as required. Both functions and data can be accessed using LabVIEW refnums, which simplifies wiring diagrams and encourages dynamic and modularized code.

157.8 Code Distribution

Distributing code to encourage multiple programmer input and commercial reward can be an important part of software development, and hence should not be considered only in the final moments of a project. Depending on the purpose of distribution, the package format created can vary significantly.

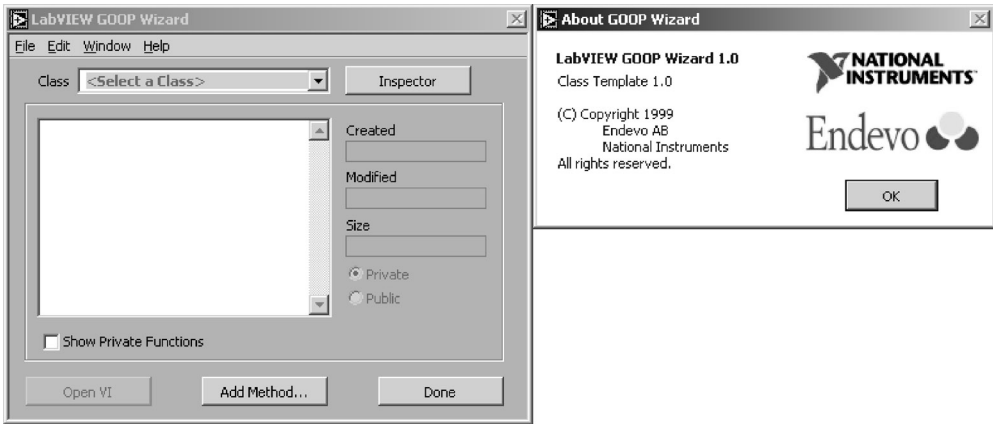

FIGURE 157.24 GOOP wizard.

llbs

A VI library (*.llb) is a National Instruments proprietary file that can contain several VIs and some of their settings. Files that are saved into an llb are lightly compressed, and can be set as *top level* (denotes which VIs should be launched when their respective llb is opened) or *companion*. Other than that, an llb is formless; all of the files reside at one level (i.e., you cannot create subdirectories or sub-llbs in a VI library). Although a library has a flat structure, it is possible to assign one of two levels to a VI in a library. A top-level VI will launch automatically when opened from your operating system's file explorer, whereas a normal-level VI will only open if explicitly opened from within the library. (A new feature to LabVIEW 7.0 allows Windows Explorer to navigate inside G libraries, effectively bypassing top-level assignments.) It is also acceptable to assign more than one VI in a library as top level, although this can make window negotiation difficult, as they all will be launched when the library is opened. [Figure 157.25](#) demonstrates a library with one top-level VI.

Development Distribution Library

A development distribution contains all custom VIs and controls that have been created in the project, so that it can be successfully opened and executed on a PC with a similar LabVIEW configuration installed. VIs from vi.lib and add-on toolkits are not included in a development library, as it is assumed that environments used for subsequent openings of the library will have these installed.

Application Distribution Library

An application library distribution is an llb file that contains all of the VIs listed in a development library, and all others that are used in the application. VIs from vi.lib and toolkits are included, as are all custom VIs and controls. Distributing an application library is useful when archiving an application, including all of the components used to execute it.

Diagram Access

Altering a user's access to a VI's diagram can minimize code theft and ensure that the VIs are opened with an appropriate version of LabVIEW. Setting a password to a VI's block diagram prevents users from accessing the code diagram and understanding hierarchical dependences between modules. To change a VI's status, access the Security VI property ([Figure 157.26](#)), and select one of the settings shown in [Table 157.5](#).

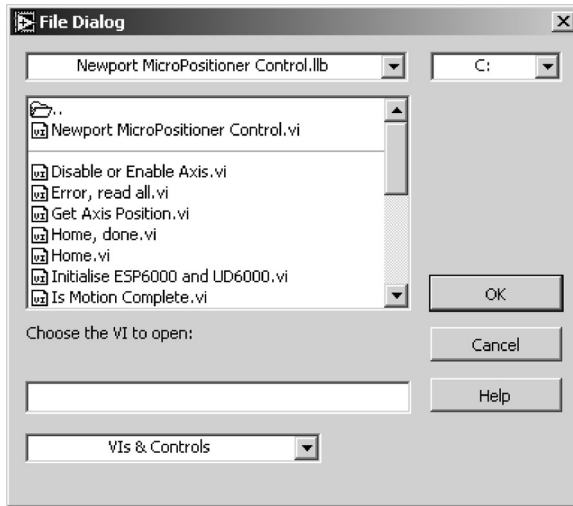

FIGURE 157.25 A library with a top-level VI.

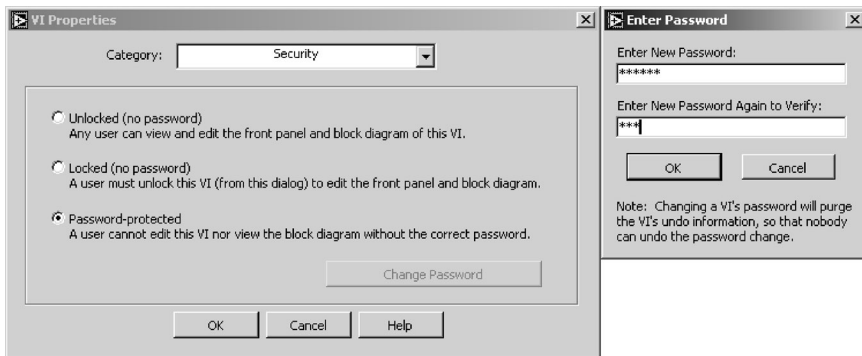

FIGURE 157.26 Set block diagram password.

TABLE 157.5 Block Diagram Security Access Levels

| Security Level | Description |
|---------------------------------|--|
| Unlocked (no password) | The default for a new VI. Permits read/write access to the block diagram. |
| Locked (no password) | Access to the block diagram is prohibited until the user changes the security to <i>Unlocked</i> . A password is not required to change security settings. |
| Password protected ^a | The highest level of block diagram security; access is prohibited unless the user enters the correct password. |

^a Due to the nature of LabVIEW VIs, the password is not recoverable from the file. If you forget a password, you are unable to parse the file to “crack” it.

An extreme method of code protection is to remove the block diagram altogether, and can be achieved by performing a custom save (Figure 157.27), using File → Save with Options.

When upgrading a VI from a previous version of LabVIEW, the diagram is recompiled; therefore, removing the diagrams from your VIs will prevent them from being opened with a version of LabVIEW other than the version used to create the VI. This minimizes conversion errors that may occur between versions (e.g., if your VI uses functions from vi.lib), and enhances commercial code control (limiting the lifetime of a VI to a particular version of LabVIEW, requiring users to obtain new versions when migrating between major versions of LabVIEW).

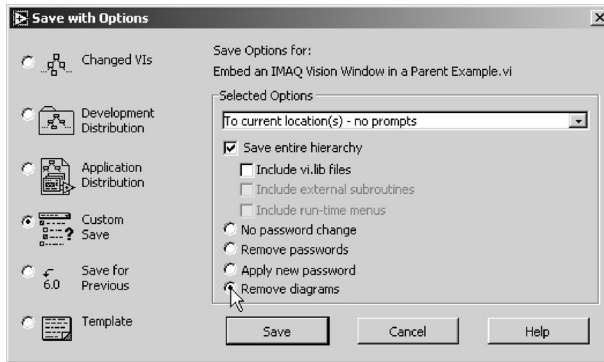

FIGURE 157.27 Remove diagrams.

157.9 Application Building (Creating Executables)

Often left to the last minute in application development, building stand-alone executable code may not be as straightforward as one might expect. External code libraries, target operating systems, engines, and licenses must be considered before attempting to build an application.

The Runtime Engine (RTE)

Built executables require elements of the LabVIEW RTE to execute. The RTE should be distributed with your applications, as the target PC may not have it installed, and your applications will therefore fail to execute. The location of the RTE installed on a LabVIEW development PC is

```
..\National Instruments\Shared\LabVIEW Run-Time\Version\
```

and the following redistributable version is located on the LabVIEW installation CD-ROM:

```
..\LVRunTimeEng\
```

Although manual distribution of the RTE is possible, it can be automated when distributing your built software, by using an installer as detailed below. In some cases, the installation of the RTE is not necessary. (This method is not authorized or supported by National Instruments and does not support DataSocket, NI-Reports, or 3D Graphs.) If an executable is a simple one, it may not need the RTE to be installed on the target machine; all one needs to do is include some of the engine's files with the exe for it to work. To determine whether this method will work with a particular built executable, copy the following files and folders into the folder containing the exe:

```
..\National Instruments\shared\nicontdt.dll
..\National Instruments\shared\nicont.dll
..\National Instruments\shared\LabVIEW Run-Time\ver\* (including all
subdirectories)
```

Using the LabVIEW 6.1 development system as an example, the exe's directory would look something like the following:

```
..\AppDirectory\MyApp.exe
..\AppDirectory\MyApp.ini
..\AppDirectory\My_Apps_DLLs (if_any)
..\AppDirectory\nicontdt.dll
..\AppDirectory\nicont.dll
..\AppDirectory\lvapp.rsc
..\AppDirectory\lvjpeg.dll
..\AppDirectory\lvpng.dll
```

```
..\AppDirectory\lvrt.dll
..\AppDirectory\mesa.dll
..\AppDirectory\serpdrv
..\AppDirectory\models\*
..\AppDirectory\errors\*
..\AppDirectory\script\*
```

When the executable is launched on a PC without the RTE installed, it should find all of the RTE files it requires in the application's root directory, and execute normally. This method can be particularly useful when distributing autorun presentations on CD-ROMs.

Reverse Engineering Built Executables

As built executables have a similar structure to VI libraries, it is possible to extract and use the diagramless VIs within. Simply change the extension of the executable file to llb, and open the library within LabVIEW. One should be careful when designing the architecture of a commercial application, as this G executable characteristic can allow users to reverse engineer an executable, effectively accessing the functionality of the SubVIs within the executable.

Run Time Licenses (RTLs)

Distributing a simple executable to the world is free; the software engineer developed the code, so he or she may sell and distribute the resulting code desired. When the software contains specialist code that the software engineer did not write, then the users may need to pay the author a small amount for each instance of their code that is on-sold as a portion of the application. Products that currently require the inclusion of a runtime license include the National Instruments Vision toolkit, meaning that any applications released that use Vision VIs must be accompanied by an official NI Vision toolkit RTL, available from NI. Always check with the vendor of any software tools that you are planning to incorporate in an application, indicating the RTL costs at the project proposal stage.

Installers

Rather than providing a single executable file to customers, it is almost always preferable to pack your application into an installer. An installer is a mechanism that encourages the simple installation of the developer's application, support files (including RTEs is required), registration of external components (ActiveX controls, DLLs, documentation, links to web pages, etc.), and manipulation of the operating system (registry alteration). Installers provide intuitive graphical user interfaces that assist end users to customize your application installation to their needs (including the selection of components, installation destination locations, readme file display, etc.) and provide a professional finish to your product. Modern installers also have automatic support for damaged installations, and a facility to uninstall your product cleanly, returning the end user's system to a state comparable to that before installation. The NI LabVIEW Application Builder contains a simple installer that is often sufficient for small applications that do not require advanced operating system alterations, whereas there are several commercially available installers available (Figure 157.28). One such installer, Setup2Go, fulfills many of the advanced installation requirements, and has a very simple interface to package your software product. More information on Setup2Go can be found at <http://dev4pc.com/setup2go.html>.

157.10 Open Source G: Distributed Development

One of the most powerful tools available to software engineers today is open source project development. Unlike other engineering branches (including structural, electrical, etc.), software engineering projects can be easily transported to all corners of the earth in seconds using the Internet. Using this unique ability, projects can be developed at many different sites by several professionals simultaneously, ultimately

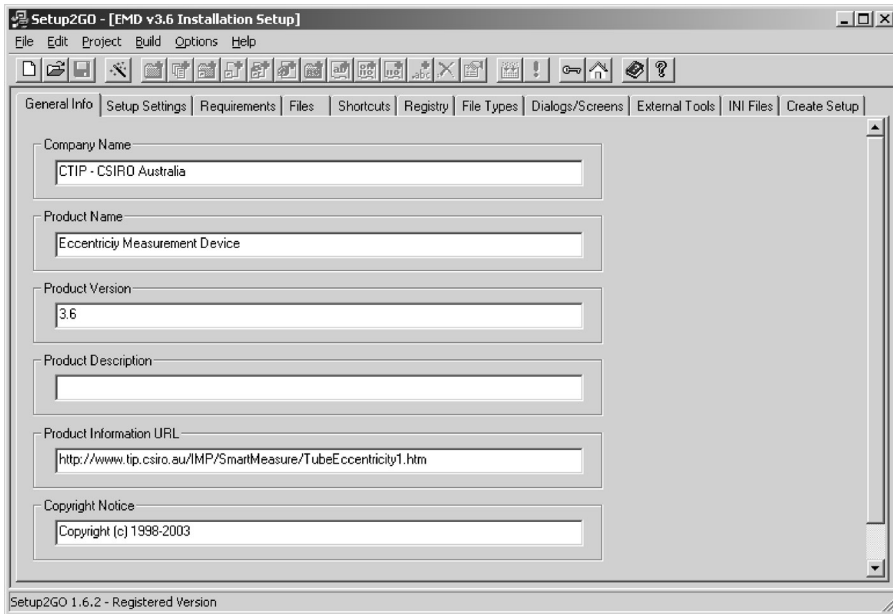

FIGURE 157.28 Custom InstallerSetup2Go.

leading to better tested software with extended features and more robust code. Sharing the burden of developing a software project allows engineers a much wider range of experience and expertise, and thus a more stable and useful application.

As you might imagine, coordinating such projects can be time intensive and legally difficult, which is why the OpenG community has been created. Spearheaded by the longtime LabVIEW expert Jim Kring, *OpenG.org* (Figure 157.29) is the home of our Open Source LabVIEW development community, hosting the largest registry of Open Source LabVIEW code and applications available on the Internet. OpenG.org is a not-for-profit venture, and provides each project a web page, where you can embed HTML, allowing you to link to software and websites, as well as embed images and other content hosted remotely.

All OpenG.org projects are covered by the *LGPL software license*, which protects source code, so that it remains Open Source, but it allows using protected code in commercial, proprietary, closed applications. Most people using LabVIEW are using it directly in commercial or industrial applications and systems that are sensitive because they contain intellectual property in the form of valuable trade secrets. The ideals of the OpenG community promote the adoption of open source everywhere that LabVIEW is used.

More information on the OpenG project, and how to develop software using open source principles is available at the OpenG website (www.openg.org) (Figure 157.29).

Defining Terms

Block (wiring) diagram — The coding portion of a VI, where the software engineer writes the G code.

Data type — The format the G development system uses to store a piece of information in memory.

Using appropriate data types decreases application execution time, decreases memory footprint, and eradicates coercion errors.

Error cluster — A special cluster containing an error code, a Boolean indicating if an error has occurred, and the source of that error. The error cluster format is consistent throughout the G development system.

Front panel — The graphical user interface of a VI, including a method in which data are passed to and from the VI.

G — The programming language used to develop applications using the LabVIEW Development System.

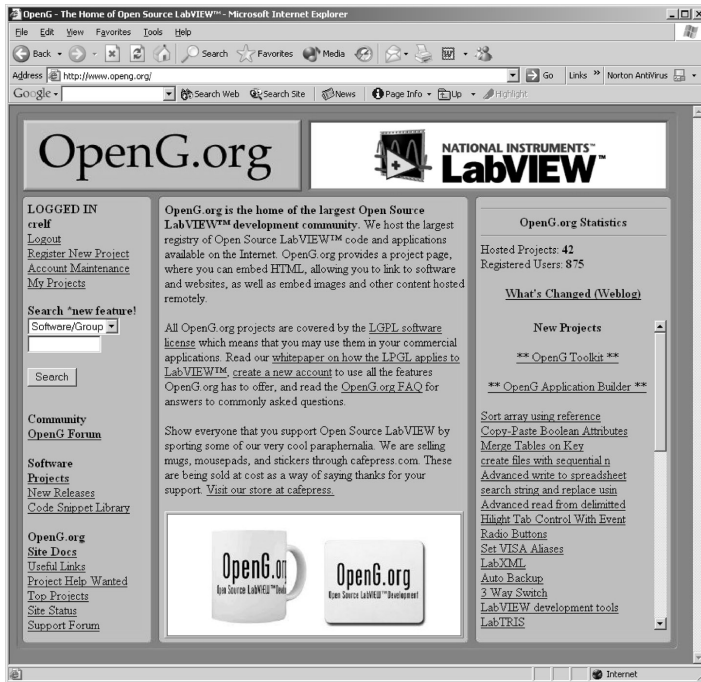

FIGURE 157.29 OpenG website.

Installer — Software that facilitates the automatic installation, upgrade, repair, or uninstallation of third-party software.

LabVIEW — The development system used to develop code in the G programming language.

Polymorphic VI — A collection of VIs with identical missions, operating on differing data types. A polymorphic VI exists on disk as a special form of a VI library.

Runtime engine (RTE) — The system under which compiled G code runs, without the presence of the G development system.

Runtime license (RTL) — A “user pays” system of charging for code portion development.

Unit — An attribute associated with a numerical value, giving it physical significance.

Polytechnic University, Hong Kong

Our capacity to interact with the environment depends on the knowledge about it. Although our physical senses help us to understand and comprehend much of the world around us, there are many situations where better understanding can be gained by using manufactured sensors and instruments. The industrial plant variables, ocean streams, and electric and magnetic fields are some examples of quantities that are conveniently sensed and measured by using sensors.

Sensors can be thought of as extensions of human senses. Sensors usually generate electrical signals that can easily be processed and transmitted by manufactured devices or systems of devices. In recent years, the use of sensors has undergone explosive growth due to the availability of processing devices to manipulate output signals and progress in communication technology. A schematic representation of a sensor is illustrated in [Figure 158.1](#).

The output signal, $y_o(t)$, is produced in response to the input signal, $x_i(t)$, thus characterizing the state of the measured system (the *measurand*). An ideal sensor should not respond to any parameters other

FIGURE 158.1 Schematic representation of a sensor.

than what it is intended for. Unfortunately, this is a simplified assumption and many sensors are unintentionally sensitive to a number of other parameters as well.

For an ideal sensor, the relation between the system input and output can be expressed by

$$y_o(t) = f(x_i(t)) \quad (158.1)$$

In practice, the output depends on various parameters affecting the system and the corresponding equations are much more complex.

158.1 Recent Trends in Sensors and Sensor Technology

Sensors and sensing technologies are well established and are widely applied in everyday life and industrial applications. In recent years, with the use of micro and nano technologies new families of semiconductor sensors are emerging such as *smart* and *soft sensors* and *microelectromechanical* sensors. In the near future, the new generation of sensors will change measurement technologies considerably, leading to new approaches in instruments and instrumentation.

Intelligent (Smart) and Soft Sensors

At present, many instruments use intelligent sensors that contain the sensor, signal processors, and intelligence capabilities in a single chip. They appear in the marketplace as pressure sensors and accelerometers, biosensors, chemical sensors, optical sensors, and magnetic sensors, among other types. Some of these sensors are manufactured with neural networks and other sophisticated intelligence techniques on board the chip. Many types of intelligent sensors are currently in use, such as neural processors, intelligent vision systems, and intelligent parallel processors.

Today's technology allows the development of *soft sensors*. A soft sensor is a device that does not include any sensing hardware but involves a microprocessor that processes data acquired from a number of devices and combines them by using a mathematical model to produce an estimation of the parameter of interest. Either the traditional models, such as the ARMAX, and NARMAX, or the more exotic neural, fuzzy, and neuro-fuzzy models, are used to obtain the required estimation capability.

Standards for Intelligent Sensors

Parallel to rapid developments in hardware aspects of modern sensors, some new standardized techniques are emerging for software, communications, and networking. This is making a revolutionary contribution to the development of electronic instruments. For example, the IEEE-1451 is a set of standards that define interface network-based data acquisition and control of sensors.

The IEEE-1451 standard aims to make it easy to create solutions using existing networking technologies, standardized connections, and common software architectures. The standards allow application software, field network, and transducer decisions to be made independently. It offers flexibility to choose the products and vendors that are most appropriate for a particular application.

Micro Electromechanical Systems

Developments of silicon-based sensors are enhanced considerably due to advances in embedded controllers, microelectronics, and micromachining. Micromachining technology combined with semiconductor processing technology provides variety of sensors. Micro Electromechanical Systems (MEMS) comprise one of the most active sensor research fields. MEMS largely use integrated circuit (IC) technology to obtain micro electromechanical systems.

Microscale physical principles can be used to build sensors with characteristics that cannot normally be obtained with traditional techniques. Therefore, IC technology provides the opportunity to construct monolithic hybrid systems that contain sensors, signal processing circuits, analog-to-digital converters, compensation circuits, and microcontrollers in the same chip. Examples of such sensors some are discussed in subsequent sections.

Sensor Communications

Communications capabilities of electronic instruments is enhancing their usability in many types of applications. There are two levels of communications: communication at the sensor level, which is mainly realized by intelligent sensors; and communication at the device level, which takes place either in wired form or infrared with RF or microwave techniques.

In the implementation of wireless communication features, the Bluetooth technology and near-field communication protocols are gaining wide acceptance. Bluetooth is considered to be a low-cost and short-range wireless technology that provides communication functionalities, ranging from wire replacements to simple personal area networks. Initially, it was aimed to bring short-distance wireless interfaces mainly to consumer products on a large scale. As the number of products incorporating Bluetooth wireless technology increases, the development of various types of instruments for a diverse range of applications becomes more important.

If the data need to be transmitted for long distances in which transmitter and receivers are out of range, wireless bridges are employed, which provide long-range point-to-point or point-to-multipoint links. Some of these devices use direct-sequence-spread spectrum (DSSS) radio technology operating at typical frequencies (i.e., 2.4 GHz). Data may be transmitted at speeds up to 11 Mbps. These bridges comply with standards, such as IEEE-802.11b, while connecting one or more remote sites to a central server or Internet connection.

Built-in Test Sensors

RF data communication is extensively applied in built-in tests (BITs) in which the sensors are embedded in operational systems, such as rotating machinery, industrial systems, or even implanted in living organisms. The information gathered from the sensors is transmitted by a built-in RF transmitter to a nearby receiver. BIT sensor quality is improving steadily through the availability of intelligent and other sophisticated sensors, instrument software, interoperability, and self-test effectiveness.

Sensor Networks

Geographically distributed sensors can be networked as a distributed sensor network (DSN). The networking requires intelligent sensors that may obey some form of hierarchical structure.

In recent years, the IEEE-1451 compatible interface between Internet/Ethernet serial port web sensors has been developed. These sensors have direct Internet addresses. The interface is realized in IEEE-451 network-capable application processors (NCAP). NCAPs connect the Internet through Ethernet. NCAP is a communication board capable of receiving and sending information using the standard TCP/IP format. The sensor data are formatted to and from the serial port by one of the following: RS232, RS485, TII, Microlan/1-wire, Eibus, or I²C.

FIGURE 158.2 Wireless websensor.

The useful lifetime of a particular sensor will probably be shaped by how it interfaces to the network to share information. The importance of sensor networks has been realized by many vendors; hence, they promote proprietary solutions to connect smart sensors into TCP/IP-based networks. A typical wireless web sensor node arrangement is illustrated in Figure 158.2. Recent developments are focused on low- and high-level interfaces.

158.2 Classification of Sensors

Sensors and transducers produce outputs in response to physical variations. These outputs are processed suitably by analogue and digital methods to obtain desired information from the physical process. Therefore, there are diverse approaches to classifying sensors based on physical process properties, sensor operational principles, or both.

One approach is by referring to the nature of the sensed parameter (temperature, pressure, etc.). This approach is useful for people who want to observe particular parameters of physical variables and select suitable devices for monitoring them. A second approach may be the classification of sensors by referring to the nature of their output signals (resistive, voltage generating, etc.). This approach is useful for people who want to design a measuring system and process sensor outputs by using appropriate hardware and software. A third approach begins with the energy input and output. From this perspective, there are three fundamental types of sensors: modifiers, self-generators, and modulators.

In this chapter, sensors are classified from the applications point of view, but basic operational principles are explained whenever possible. Sensors in the following areas are discussed:

- Voltage and current
- Magnetic and electromagnetic
- Capacitive
- Acoustic
- Temperature and heat
- Light and radiation
- Chemical and gas
- Environmental and biological
- Mechanical variables

158.3 Voltage and Current Sensors

Voltage sensing is very important in many types of instruments, since the signals generated by most sensors are in voltage form. The voltage is related to electric potential difference. Four basic types of voltage sensors are commonly used in voltage measurements: inductive, thermal, capacitive, and semiconductor.

Inductive voltage sensors are based on the characteristics of magnetic fields. They make use of voltage transformers, AC voltage inductive coils, eddy currents, and so on. Classical *electromechanical devices* are typical examples of such sensors. They are based on the mechanical interaction between currents and magnetic fields. This interaction generates a mechanical torque proportional to the voltage or the squared voltage to be measured (voltmeters), or proportional to the current or the squared current to be measured

(ammeters). A restraining torque, usually generated by a spring, balances this torque. The spring causes the instrument pointer to be displaced by an angle proportional to the driving torque, and hence to the quantity, or squared quantity, to be measured. The value of the input voltage or current is therefore given by the reading of a pointer displacement on a graduated scale.

Thermal voltage sensors are based on the thermal effects of a current flowing into a conductor. The sensor output is proportional to the squared input voltage or current.

Capacitive voltage sensors are based on the characteristics of electric fields. These sensors detect voltages by different methods, such as electrostatic force, Kerr or Pockels effects, Josephson effect, and change of reflective index of the optic fibers. Capacitive voltage sensors are generally used in low-frequency, high-voltage measurements. In high-voltage applications, the capacitive dividers are used to reduce the voltages to low levels.

Semiconductor voltage sensors constitute a wide range of voltmeters and ammeters. They are based on purely electronic circuits, and attain the required measurement by processing the input signal via semiconductor devices. The method employed to process the input signal can be either analogue or digital.

Types of Current Sensors

Current flowing through a circuit element can also be related to the properties of the circuit element and the voltage across its terminals by Ohm's law:

$$V = RI \tag{158.2}$$

where R is a quantity representing the electric behavior of the circuit element. Under DC conditions, this quantity is called "resistance" and its measurement unit is, in the SI, the "ohm" (Ω).

Fundamentally, the properties of magnetic fields, electric fields, and heat can be used for currents sensing. In addition, any magnetic field sensor can be configured for current measurements. An example is the *Rogowski coil*, illustrated in Figure 158.3. The Rogowski coil is a solenoid air core winding of a small cross-section looped around a conductor carrying the current. The voltage induced across the terminals of the coil is proportional to the derivative of the current.

One of the simplest methods of current sensing is the current-to-voltage conversion by means of resistors. In current measurements, the resistor is called the shunt resistor despite the fact that it is connected in series with the load. The shunt produces a voltage output that can be presented by a variety of secondary meters, such as analogue meters, digital meters, and oscilloscopes.

Hall-effect current sensors are typical semiconductor devices. They operate on the principle that the voltage difference across a thin conductor carrying a current depends on the intensity of magnetic field applied perpendicular to the direction of the current flow (Figure 158.4). Electrons moving through a magnetic field experience Lorentz force perpendicular to both the direction of motion and to the direction

FIGURE 158.3 Rogowski coil for current sensing.

FIGURE 158.4 Hall-effect sensor.

of the field. The response of electrons to Lorentz force creates *Hall voltage*. If a current I flows through the sensor, the Hall voltage can mathematically be expressed by

$$V = R_H IB/t \quad (158.3)$$

where R_H is the Hall coefficient (m^3/C), B is the flux density (T), and t is the thickness of the sensor (m).

Hall-effect sensors are made from metals or silicon, but mainly semiconductors with high electron mobility such as indium antimonite. They are usually manufactured in the form of probes with sensitivity down to $100 \mu\text{T}$. These sensors have good temperature characteristics, varying from 200°C to near absolute zero.

158.4 Magnetic Sensors

Magnetic sensors find many applications in everyday life and in industry. They provide convenient, noncontact, simple, rugged, and reliable operational devices compared to many other sensors.

Generally, magnetic sensors are based on sensing the properties of magnetic materials, which can be done in many ways. For example, magnetization, which is the magnetic moment per volume of materials, is used in some systems by sensing force, induction, field methods, and superconductivity. However, most sensors make use of the relationship between magnetic and electric phenomena.

Many types of magnetic sensors are available, but they can broadly be classified as *primary* or *secondary sensors*. In the primary sensors, also known as magnetometers, the physical parameters to be measured are external magnetic fields. In the secondary sensors, the external parameters are derived from other physical variables such as force and displacement.

Primary Magnetic Sensors

Primary sensors are based on measurement of external magnetic fields. They find applications in many areas from biological and geophysical measurements to the determination of characteristics of extraterrestrial objects and stars. They also find applications where sensitivity is of utmost importance, as in the case of devices for diagnosing and curing human illnesses. Superconducting quantum interface devices (SQUIDs) and nuclear resonance magnetic imaging (NMR) are examples of such devices. Types of primary sensors discussed in this section include:

- Magnetodiode and magnetotransistors
- Magnetoresistive sensors
- Magneto-optical sensors
- Magnetic thin films
- Hall-effect sensors

Magnetodiodes and magnetotransistor sensors are made from silicon substrates with undoped areas that contain the sensor between n -doped and p -doped regions forming pn , nnp , or pnp junctions. In the case of magnetotransistors, there are two collectors, as shown in [Figure 158.5](#).

FIGURE 158.5 Semiconductor magnetotransistor.

Depending on the direction, an external magnetic field deflects electron flow between emitter and collector in favor of one of the collectors. The two collector voltages are sensed and related to the current or the applied magnetic field.

In *magneto-resistive sensors*, the resistivity of some current carrying material changes in the presence of a magnetic field mainly due to the inhomogeneous structure of some materials. For example, the resistance of bismuth can change by a factor 10^6 . Most conductors have a positive magneto-resistivity. Magneto-resistive sensors are largely fabricated from permalloy stripes positioned on a silicon substrate. Each strip is arranged to form one arm of a Wheatstone bridge so that the output of the bridge can directly be related to the magnetic field strength.

As in the case of Hall-effect sensors, the basic cause of magneto-resistivity is the Lorentz force, which causes electrons to move in curved path between collisions. One advantage is that for small values of magnetic field, the change in resistance is proportional to the square of the magnetic field strength, thereby giving better sensitivity.

Magneto-optical sensors constitute an important component of magnetometers. In recent years, highly sensitive magneto-optical sensors have been developed. These sensors are based on various technologies, such as fiber optics, polarization of light, Moire effect, and Zeeman effect. These type of sensors lead to highly sensitive devices and are used in applications requiring high resolution, such as human brain function mapping and magnetic anomaly detection.

Magnetic thin-film sensors are an important part of superconducting instrumentation, sensors, and electronics in which active devices are made from deposited films. The thin films are usually made from amorphous alloys, amorphous gallium, and the like. As an example, a thin-film Josephson junction is given in Figure 158.6. The deposition of thin films can be done by several methods, such as thermal evaporation, electroplating, sputter deposition, or by some chemical means. The choice of technology depends on the characteristics of the sensors. For example, thin-film superconductors require low-temperature operations, whereas common semiconductors normally operate well at room temperatures.

FIGURE 158.6 Magnetic thin-film Josephson junction.

Principles of Hall-effect sensors are explained above. They are usually manufactured in the form of probes with sensitivity down to 100 μT . Silicon Hall-effect sensors can respond to magnetic fluxes having an operational frequency from DC to 1 MHz within the range of 1 mT to 0.1 T.

Secondary Magnetic Sensors

Secondary magnetic sensors are basically inductive sensors that make use of the principles of magnetic circuits. They can be classified as *passive sensors* or *active sensors* (self-generating). Passive sensors require an external power source; hence, the action of the sensor is restricted to the modulation of the excitation signal in relation to external stimuli. On the other hand, self-generating sensors generate signals by using the electrical generation principle based on Faraday's law of induction. That is, "when there is a relative motion between a conductor and a magnetic field, a voltage is induced in the conductor," or a varying magnetic field linking a stationary conductor produces voltage in the conductor. This relationship can be expressed as

$$e = -d\Phi/dt \quad (158.4)$$

where Φ is the magnetic flux, and t is time.

There are many different types of inductive sensors, such as linear and rotary variable-reluctance sensors; synchros; microsyn, linear variable inductors; induction potentiometers; linear variable differential transformers; and rotary variable-differential transformers. Two of these methods are briefly discussed below.

Single-coil linear variable-reluctance sensors consist of three elements: a ferromagnetic core in the shape of a semicircular ring, a variable air gap, and a ferromagnetic plate. Their performance depends on the core geometry and permeability of the materials; therefore, they can be highly nonlinear. Despite this nonlinearity, they find applications in many areas, such as force measurements. The coil usually forms one of the components of an LC oscillator circuit whose output frequency varies with applied force. Hence, the coil modulates the frequency of the local oscillator.

Linear variable-differential transformers (LVDT) make use of the principle of transformer action, that is, magnetic flux created by one coil links with the other coil to induce voltages. The LVDT is a passive inductive transducer with many applications. It consists of a single primary winding positioned between two identical secondary windings wound on a tubular ferromagnetic former. The primary winding is energized by a high-frequency 50-Hz to 20-kHz AC voltages. The two secondaries are made identical by having an equal number of turns. They are often connected in series opposition so that the induced output voltages oppose each other.

158.5 Capacitive and Charge Sensors

Many sensors are based on the characteristics of electrical charges and associated electric field properties. The electrical charge and field are related to changes in capacitances in response to physical variations. The changes in the capacitance can occur as due to variations in physical dimensions such as the area or the distance between the plates. In some cases, variations in the dielectric properties of the material between plates is made use of as in the case of some light and radiation sensors.

Capacitors are made from two charged electrodes separated by a dielectric material, as shown in [Figure 158.7](#). The capacitance C of this system is equal to the ratio of the absolute value of the charge Q to the absolute value of the voltage between charged bodies, as in:

$$C = Q/V \quad (158.5)$$

where C is the capacitance in farads (F), Q is charge in Coulombs (C), and V is voltage (V).

The capacitance C depends on the size and shape of charged bodies and their positioning relative to each other. In many sensors, it is necessary to deal with the useful capacitances as well as the stray

FIGURE 158.7 Typical capacitor.

capacitances. Stray capacitances may be introduced externally or internally whenever two charged bodies exist side by side.

Integrated circuit capacitive sensors find wide applications, particularly in MEMs, and they are made as MOS integrated circuits; monolayer versions contain tantalum or other suitable deposits. In a typical sensor, two heavily doped polysilicon layers formed on a thick layer of oxide generally comprise the plates of IC capacitors. The dielectric is usually made from a thin layer of silicon oxide. Important parameters for IC capacitors are the tolerances, voltage coefficients, temperature coefficients, and capacitance values. These capacitors are temperature stable with about 20 ppm/°C temperature coefficients. The voltage coefficients are usually less than 50 ppm/V. IC capacitive sensors are achieved by incorporating a dielectric material sensitive to physical variables.

Many capacitive IC sensors have typically one plate fixed and one that moves as a result of the applied measurand. Silicon technology combined with the surface micromachining allows the capacitance between interdigitized fingers to measure acceleration as well as other inputs. The value of nominal capacitance is 100fF to 1pF and the variations in capacitance are on the order of femtofarads.

Piezoelectric sensors can be classified as capacitive or charge sensors. They produce an electric charge when a force is applied on to it. This effect exists in natural crystals such as quartz (SiO₂), or manmade artificially from polarized ceramics and polymers. A piezoelectric sensor can be viewed to have a crystal structure with a dielectric material. When this dielectric material is arranged like a capacitor with electrodes, it behaves like an electric charge generator when stress is applied on it. Therefore, a resulting voltage, V , across the capacitor appears as a result of stress. The piezoelectric effect is a reversible physical phenomenon; that is, applying a voltage across the terminals the crystal produces a mechanical strain.

Most modern piezoelectric sensors contain lead zirconate titanate (PZT). This ceramic-based sensor is used to construct biomorph sensors for force, sound, motion, vibration, and acceleration sensing. The biomorph consists of two layers of different PZT formulations that are bonded together in rectangular strips. The rectangular shape structure can conveniently be mounted as a cantilever on structures and the motions perpendicular to the surface of the sensor generates signals of measurements.

A variation in piezoelectric technology is piezoresistive sensors, which are the most common micro-machined sensors. Their output signals are highly uniform and predictable; therefore, these signals can easily be conditioned.

158.6 Acoustic Sensors

Sound is defined as the vibrations of a solid, liquid, or gaseous medium in the frequency range of 20 Hz to 20 kHz that can be detected by the human ear. Sound travels in a media by obeying the laws of shear and longitudinal forces. In contrast to solids, liquid, or gaseous media cannot transmit shear forces; therefore, in these media the sound waves are always longitudinal, that is the particles move in the direction of the propagation of the wave. As the sound waves travel in medium, the medium compresses or expands; hence, its volume changes from V to $V - \Delta V$. As a result, the *bulk modulus* of medium elasticity, which is the ratio of change in pressure Δp relative to change in volume, can be written as

$$B = \frac{\Delta p}{\Delta V / V} = \rho_0 v^2 \quad (158.6)$$

where ρ_0 is the density outside the compression zone, and v is the speed of sound in the medium.

In practice, pressure variations of sound waves carry useful properties and find wide applications. In this case, sound waves can be viewed as the pressure waves. As these waves travel, the pressure at any given point changes constantly. The difference between instantaneous pressure and average pressure is called the *acoustic pressure*, P . The power transferred per unit area due to acoustic pressure can be expressed as

$$I = \frac{P^2}{Z} \quad (158.7)$$

where Z is the acoustic impedance that can be determined from acoustic pressure and instantaneous velocity.

Pressure levels are often expressed in decibels, as

$$P_L = 20 \log_{10} \frac{P}{P_0} \quad (158.8)$$

where P_0 is the lowest pressure level that the human ear can detect ($2 \times 10^{-5} \text{ N/m}^2$).

The sound pressure is almost always the only parameter sensed directly. All other parameters, such as sound power, particle velocity, reverberation time, and directivity, are derived from the pressure measurements. The sound pressure measurements are performed by microphones in the gaseous media and hydrophones in the liquid media. Microphone types are listed below.

- Capacitive
- Piezoelectric and electret
- Fiber optic
- Carbon
- Moving iron (variable reluctance)
- Moving coil

The most commonly used microphones for sound measurements are capacitive, piezoelectric, electret, and fiber optic microphones. They tend to have good stability, are sensitive and precise, and possess excellent temperature properties.

Piezoelectric and electret microphones use piezoelectric materials such as lead zirconate titanate (PZT). They have very high impedance levels and very broad operating frequencies, and are suitable for ultrasonic applications.

The operational principles of electret microphones are similar to piezoelectric microphones. Electret principles are similar to piezoelectric and pyroelectric materials. Electret is permanently polarized crystalline dielectric material. An electret microphone consists of a metallized diaphragm and backplane separated from the diaphragm by an air gap as shown in Figure 158.8.

FIGURE 158.8 Electret microphone.

FIGURE 158.9 Piezoelectric ultrasonic detection system.

Fiber optic microphones make use of reflection of laser beams from a vibrating diaphragm. The diaphragm vibrates in response to sound pressure, and the interference between incident light and the reflected light beams is sensed by a suitable interferometer (e.g., Michelson interferometer).

Optical microphones are suitable for hostile environments, such as monitoring the noise in rocket and jet engines. In some applications, extreme measures may be required for good sensitivity, such as cooling the temperature-sensitive components with water or other suitable fluids.

Ultrasonic sensors are used for acoustic waves of frequencies higher than 20,000 Hz, and they find many medical and industrial applications. Ultrasonics are generated naturally or by transducers, which are available over a wide range of frequencies in many sizes and shapes. An ultrasonic sensor is illustrated in Figure 158.9. A common method of transduction is piezoelectric material, but in some applications magnetostrictive materials are used as well. Both piezoelectric and magnetostrictive transducers can simultaneously function as transmitters and receivers through air, solids, or liquids.

Ultrasonic sensors in acoustic applications are commonly used in the following areas:

- Detection of defects
- Fluid and gas flow measurements
- Ultrasonic cleaner
- Security devices
- Elastic properties of solids
- Porosity and size estimation
- Acoustic microscopy
- Medical applications
- Motion, displacement, and range measurements
- Thickness measurements in process control and other applications

158.7 Temperature and Heat Sensors

Temperature is a measure of heat intensity. The simplest way of measuring temperature is the thermometer, which makes use of thermal expansion of materials, such as liquid in glass. For electronic measurements, there are many different sensors available, such as resistive sensors, thermoelectric sensors, thermocouples, thermostats, IC temperature sensors, and piezoelectric sensors.

Heat is a form of energy known as the thermal energy. The quantity of heat contained in an object cannot easily be measured, but the changes in heat can be measured as the temperature. In temperature measurements, a small portion of thermal energy of the object is transmitted to the sensors for conversion to electrical signals. The operational principles of temperature sensors depend on the heat exchange that takes place in the materials. The heat exchange can be conductive, convective, and radiative. Sensors for thermal energy measurement are listed below.

- Thermocouples
- Resistive temperature sensors
- Silicon resistive temperature sensors

- Semiconductor temperature sensors
- Pyroelectric sensors
- Thermistors
- Infrared sensors
- Optical temperature sensors
- Fiber optic thermometers
- Fluoroptic sensors
- Interferometric sensors
- Acoustic temperature sensors
- Thermal conductivity sensors
- Bimetallic thermometers
- Liquid or gas expansion sensors

The operational principles and characteristics of some of these sensors are explained below.

Thermocouples are contact-type temperature sensors made from the bonding of two different metals in the form of two symmetrical junctions. One of the junctions is kept at a constant temperature (e.g., room temperature) to act as a reference point. The output voltage between the junctions is on the order of tens of millivolts; hence the output must be amplified, usually by FET amplifiers. The most popular thermocouples that are used in portable instruments are copper-constantan (-190°C to 400°C); iron-constantan (-190°C to 870°C); chromel-alumel (-200°C to 1000°C); and platinum-platinum-rhodium (-0°C to 1760°C).

An electric potential is always produced at the junctions of two dissimilar metals bonded together. The junction potential usually exhibits temperature dependence with magnitudes varying in accordance with characteristics of the selected metals. The potential difference between the junctions, known as the *Thompson effect*, is described by

$$E_j = \alpha_1(T_1 - T_2) + \alpha_2(T_1^2 - T_2^2) \quad (158.9)$$

where E_j is the voltage (in μV) across the junctions, α_1 is the *Seebeck coefficient*, α_2 is the *Thomson coefficient*, and T_1 and T_2 are the absolute junction temperatures in Kelvin. The coefficients α_1 and α_2 are dependent on thermoelectric and bulk properties of the materials. They are also independent of homogeneous lengths and shapes of materials that form the thermocouple; hence, they have constant values. Depending on the materials used, Equation (158.9) can be expanded as a third-order or higher-order equation as a function of temperature gradient.

The component of the voltage proportional to junction temperature [$\alpha_1(T_1 - T_2)$] is known as the *Peltier effect*. The Peltier effect is considered to be localized at the junctions. The component of the voltage proportional to the square of the junction temperature [$\alpha_2(T_1^2 - T_2^2)$] is the *Thomson effect* and it is considered to be distributed along each conductor between the junctions.

For a single junction, the contact potential is not measurable. A voltage can be detected when junctions are subjected to different temperatures. A two-junction arrangement is illustrated in Figure 158.10. With the use of certain suitable physical arrangements and proper electronic compensation techniques, the temperature of the object can be measured linearly.

FIGURE 158.10 Thermocouple arrangement.

Thermoresistive sensors are based on the changes in electrical resistance with respect to temperature. Platinum is a commonly used element because of its good corrosive and resistive properties. Generally, thermoresistive sensors require simple signal-processing circuits. They have good sensitivity and stability. These sensors can be divided into three main groups: the resistance temperature detectors (RTDs), silicon-resistive sensors also known as *pn*-junction sensors, and thermistors.

RTDs are fabricated either in the form of wire or thin film. The resistivities of virtually all metals are dependent on temperature, but some metals and alloys are exclusive in their responses, stability, and durability. Platinum and its alloys are typical examples of such metals. Another popular metal is tungsten, which is used at high temperatures (over 600°C).

In general, all metallic conductors exhibit changes in resistivity when subjected to temperature variation. The resulting change in conductor resistance can be expressed by

$$R_{\theta} = R_0(1 + \alpha \theta) \tag{158.10}$$

where R_{θ} is resistance at temperature θ °C. R_0 is the resistance at 0°C, and α is the temperature coefficient of resistance at °C.

Silicon resistive sensors make use of the conductive properties of bulk silicon. Pure silicon has intrinsically a negative temperature coefficient (NTC); that is, resistance decreases as temperature increases. However, when doped with an *n*-type impurity, its temperature coefficient becomes positive at a certain temperature range. Therefore, resistance/temperature characteristics of these sensors are highly nonlinear. However, in some ranges, the characteristics transfer function can be approximated by a second-order polynomial as

$$R_T = R_0 \left[1 + A(T - T_0) + B(T - T_0)^2 \right] \tag{158.11}$$

where R_0 and T_0 are resistance and temperature (K), respectively, at a reference point. Silicon resistive sensors are used inside IC chips to detect internal temperatures.

Thermistors are based on semiconductors and often used as a part of transistor switches or as an operational amplifier inside the chips. Thermistors are a mixture of semimetal oxides (rare earths) and they can be classified into three major groups: *bead-type* thermistors, *chip* thermistors, and *semiconductive* thermistors. Each one of these types is manufactured in various sizes and shapes, as illustrated in Figure 158.11.

Thermistors can be made from NTC materials or positive temperature coefficient (PTC) materials, where resistance increases as temperature increases. Most metal-oxide thermistors have an NTC. The physical dimensions and resistivity of the material determine the value of resistance. The relation between temperature and resistance can be highly nonlinear, such as an exponential function. This relationship can be expressed as

$$R_T = R_0 e^{\beta \left(\frac{1}{T} - \frac{1}{T_0} \right)} \tag{158.12}$$

where R_T is the resistance at temperature T measured in K, and β is the characteristic temperature coefficient of the thermistor.

FIGURE 158.11 Various types of thermistors.

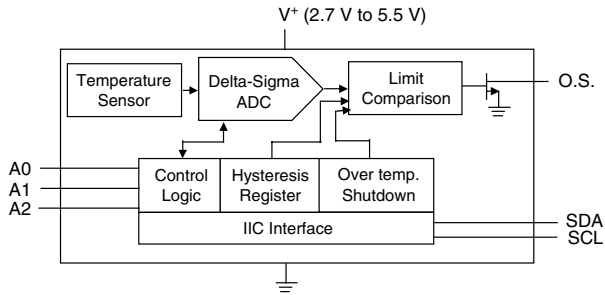

FIGURE 158.12 Typical IC temperature sensor.

PTC thermistors are generally made from polycrystalline ceramic materials such as barium titanate and strontium titanate. PTC thermistors are capable of maintaining their temperature coefficients constant.

Semiconductor temperature sensors consist of a *pn*-junction diode, and bipolar transistors exhibit strong thermal dependence. For example, the current-to-voltage equation of a diode can be expressed as

$$I = I_0 e^{\left(\frac{qV}{2kT}\right)} \quad (158.13)$$

where I_0 is the saturation current, q is the charge of an electron, k is the Boltzman constant, and T is the temperature in K.

In principle, the transistors themselves can be used as sensing elements, since they exhibit exponential negative temperature characteristics. Indeed, an inherent amplification property of transistors makes them very attractive for temperature measurements. Particularly, the use of temperature sensitivity of base-emitter voltage becomes a good proposal since the output can be taken in amplified form from the collector. However, this needs extensive compensation due to high degree of nonlinearity. Therefore, the use of transistors as temperature sensors is confined mainly to IC circuits. A transistor-based IC temperature sensor is illustrated in Figure 158.12.

Heat Sensors

Heat can be viewed as a form of radiated energy. But, radiant energy can take many other forms, such as light, radio waves, or ionizing radiation. Therefore, the operational principles and manufacturing techniques of sensors for radiant energy differ according to the type of radiation. For example, black body radiation is sensed by bolometers, light is sensed by photometers, radio waves are sensed by antenna, and particles are measured by various types of radiation sensors.

Thermal sensors known as *pyrometers* are based on the conversion of thermal radiation into heat, and then converting the heat into electrical signals. All thermal radiation sensors can be divided into two groups: *passive* and *active*. Passive sensors absorb incoming radiation and convert it into heat. Active sensors, on the other hand, emit thermal radiation directed toward the object under investigation. There are many different types of thermal sensors, including the following:

- Pyroelectric
- Thermopile
- Infrared

Pyroelectric sensors are made from pyroelectric materials, which are crystals capable of generating charge in response to heat flow. Pyroelectric sensors consist of thin slices or films with electrodes deposited on the opposite side to collect the thermally induced charges. The most common pyroelectric materials are lead zirconate titanate, triglycine sulphate, lithium tantalite, and polyvinyl fluoride. Most commercial pyroelectric sensors are made from single crystals, such as triglycine sulphate, PZT ceramics, or LiTaO_3 . The polyvinyl fluoride-based sensors exhibit high-speed responses and good lateral resolutions.

FIGURE 158.13 Pyroelectric detector and its equivalent circuit. **FIGURE 158.14** Thermopile.

Pyroelectric sensors are manufactured by having metallized surfaces and a protective window, as shown in Figure 158.13(a). In the case of infrared (IR) detectors, the thin-slice films are made from the dielectric materials whose surfaces are electrically charged by the incoming radiation. Therefore, these detectors are primarily capacitive types with very high impedances. The equivalent circuit of a pyroelectric sensor is illustrated in Figure 158.13(b). Although many plastic films are suitable, in most applications, a lithium tantalate film forms the basic material of passive IR detectors. These detectors are constructed just like capacitors. A metal plate forms one of the electrodes, and the other side of the pyroelectric material contains a conductive material that acts as the second plate. The voltages across the plates alter since the radiated energy alters the charge of the pyroelectric material. In practical applications, most pyroelectric detectors and signal processing circuits are integrated in a MOSFET structure.

Thermopiles are passive infrared sensors. They operate on the same principles as thermocouples; that is, they have a number of serially connected hot junctions (Figure 158.14) with improved absorptivity and a cold junction that gives the temperature difference between the two. The sensor is hermetically sealed in a metal can with a hard, infrared transparent window such as silicon, germanium, or zinc selenite. The operating frequency is determined by the thermal capacity, and thermal conductivity of the membrane is sandwiched between the hot junctions and the cold junction. These sensors have excellent noise properties.

158.8 Light and Radiation Sensors

Light is basically an electromagnetic radiation that consists of an electric field and a magnetic field component. Compared to radio waves, light has a short wavelength, and hence a very high frequency. Many different properties of light are used for instrumentation and measurement purposes. Applications vary from photographic imaging to high-speed data transmission via fibers. Once the light is generated and propagated from a source, it can be expanded, condensed, collimated, reflected, polarized, filtered, diffused, absorbed, refracted, and scattered to develop sensors and measurement systems. Some of these properties of light are manipulated on purpose to serve particular application needs, and sometimes manipulations are not necessary since they happen naturally due to the optical properties of the media and physical characteristics of light.

Like the other electromagnetic waves in the electromagnetic range, light has a velocity, c , in space 3×10^8 mps so that the relationship between frequency, f , and wavelength, λ , can be written as

$$c = \lambda \times f \quad (158.14)$$

Also, the energy is carried by photons. The energy of a single photon is given by

$$E = h \times f \quad (158.15)$$

where h is the Planck's constant ($h = 6.63 \times 10^{-34}$ J or 4.13×10^{-15} eV.s)

When a photon strikes a surface of a conductor, part of the photon energy, E , is used to generate some free electrons in the conductor. This is known as the photoelectric effect and it can be described by

$$h \times f = \phi + K_m \tag{158.16}$$

where ϕ is called the work function of the emitting surface, and K_m is the maximum kinetic energy attained by the electron.

Light sensors can be divided into two major groups: *quantum* sensors and *thermal* sensors. Within each group, there are many different types, such as photoconductive sensors and photovoltaic sensors that operate on quantum principles. The phototransistors, charge-coupled sensors, and photoemissive sensors are other types that operate on thermal principles. These sensors are available in many different configurations, some built with powerful lenses and high-speed responses to monochromatic light, and others having different color sensitivities to chromatic light.

Photosensors

Photosensors are essentially photon detectors that are sensitive to photons with energies greater than a given intrinsic gap energy of the sensor. Some of the most common photon detectors make use of properties of cadmium and lead, such as cadmium sulphides (CdS) and cadmium selenite (CdSe), lead sulphide (PbS) and lead selenite (PbSe) devices. Their response times can be less than 5 μ s. The main classes of photosensors are photodiodes/phototransistors, photovoltaic cells, and photoresistors/photoconductors.

Photodiodes and *phototransistors* are semiconductor devices that are sensitive to light. In a photodiode, as the incident light falls on a reverse-biased *pn* junction, the photonic energy carried by the light creates an electron-hole pair on both sides of the junction causing current to flow in a closed circuit (Figure 158.15). The output voltage of photodiodes may be highly nonlinear, thus requiring suitable linearization and amplification circuits.

Photodiodes are constructed like any other diodes, but without the opaque coating, so that light can fall onto the junction. The current generated at the junction can be linearly related to the amount of illumination falling on the junction. The response time of photodiode sensors is very short, typically 250 ns. The short response time of photodiodes allows these devices to be used in modulated light-beam applications.

Wide ranges of photodiodes are available such as *pn* photodiodes, *PIN* photodiodes, Schottky photodiodes, and avalanche photodiodes.

Phototransistors are the most used light sensors. In addition to converting photons into charge carriers, they have current gain properties. Particularly, Darlington phototransistors possess high sensitivity and high current gain.

A phototransistor (Figure 158.16) is a form of transistor in which the base-emitter junction is sealed with a transparent package. As in the case of photodiodes, this junction is affected by incident light and acts as a diode. The light at the junction promotes electrons from valence to conduction band. The current in this junction is then amplified by the normal transistor action to provide a much larger

FIGURE 158.15 Typical structure of a photodiode.

FIGURE 158.16 Phototransistor for sensing light.

FIGURE 158.17 Si-photodiode.

collector current. The spectral responses of these devices are limited to red and near-infrared portions of the spectrum. The response of the phototransistor can be adjusted by applying an appropriate bias voltage to the base. The response times of phototransistors are much longer than photodiodes (microseconds). Phototransistors are manufactured in the IC forms, containing light sensors integrated with the amplifiers and other processing circuits.

Photovoltaic sensors are based on silicon cells that generate voltages in response to a beam of light. The response time of these sensors is slow and it takes a long time to stabilize the output (up to 20 s). The wavelength response of a photovoltaic silicon cell covers the entire visible spectrum, which makes them very useful for environmental light measurements.

The first form of photovoltaic device was the selenium cell, which produced voltage across the cell in proportion to the illumination. Modern photovoltaic devices are constructed from silicon, thus acting as a silicon photodiode with a large area junction and used without bias (Figure 158.17). These devices find applications in camera exposure controls and control of light levels in manufacturing processes, because with some suitable filtering the response curves can be made very similar to the response of the human eye to the same light.

Photoresistors/photoconductors make use of changes in resistance of many materials when exposed to light. The materials are known as the light-dependent resistors, such as CdS and CdSe. In photoresistors, the material (e.g., cadmium sulphide) is deposited as a thread pattern on an insulator in a zigzag form. The cell is then encapsulated in a transparent resin or encased in glass to protect the material from the contamination by the atmosphere. A typical sensor has a spectral response of 610 nm corresponding to a color in the yellow-orange region, the dark resistance is 10 M Ω and the cell resistance decreases typically from 2.4 k Ω at 50 lux to 130 Ω at 1000 lux. However, the changes in the resistances against illumination are not linear, thus requiring additional linearization circuitry.

The response time of photoconductors is fairly slow and the resistance changes in response to light might take a few seconds. Consequently, these sensors are unsuitable in applications where fast responses are required.

The *image sensor* is a device that transforms an optical image into electrical signals. A standard image sensor converts the light photons falling onto the image plane into the corresponding spatial distribution of electric charges. The accumulated charge at the point of generation is transferred suitably and converted to useable voltage signals. Each of these functions can be accomplished by a variety of approaches, such as vacuum tube and solid-state technologies. Solid-state sensors are primarily based on photodiodes and charge-coupled devices.

The simplest image sensors are the parallel types, in which a matrix of photodiodes is used in small-scale applications such as optical character recognition. A photodiode consists of a thin surface region of p-type silicon formed on an n-type silicon substrate. A negative voltage applied to a surface electrode reverses the biases of the p-n junction. This creates a depletion region in the n silicon, which contains only an immobile positive charge. Light penetrating into the depletion region creates electron-hole pairs, which discharges the capacitor linearly in time. Solid-state image sensors are quite complex and made in IC forms; there are two basic types — the serially switched photodiode arrays (Figure 158.18) and the charge-coupled photodiode arrays. In these arrays, the basic principle is to use light intensity to charge a capacitor and then to read the capacitor voltage by shifting it through the register. These arrays have long life and high reliability, small in size, and immune to damage from bright lights.

FIGURE 158.18 IC image transducer.

Optical fiber sensors are used in varying forms, such as temperature sensors and optical gyroscopes. They are based on the properties of light as well as those of optical materials that are constructed suitably for specific applications. Operational principles of the sensors vary considerably. Some make use of the scattering properties of light while others make use of attenuations and losses. There are three basic types of fibers: single-mode step-index, multimode step index, and multimode graded index.

Photoemissive sensors are vacuum tubes with treated metal surfaces. Light falling on the surface causes electrons to be ejected to be picked up by an anode. Photoemissive sensors are available with many different spectral sensitivities. These sensors have low power demands but require a high voltage. The most commonly used photoemissive device is the photomultiplier.

Radiation Sensors

Because of the health and safety implications to humans and other living organisms, the correct sensing of radiation has been taken very seriously. Therefore, a wide range of sensors are available. Many radiation sensors use ionization as the basic physical principle behind operations. There are two types of ionizing radiation: particle radiation such as alpha particles, beta particles, neutrons, and cosmic rays; and electromagnetic radiation such as X-rays and gamma rays.

There are four basic types of radiation sensors: gas filled, scintillation, semiconductor, and thin film. The film detectors primarily consist of chemical thin films, which are sensitive to incoming radiation. The intensity of the darkening of the film indicates the amount of radiation that a person who is wearing the detector has been exposed to.

A *gas-filled sensor* consists of a cylindrical container filled with an inert gas (e.g., argon). A voltage is applied in a wire placed in the cylinder and the cylinder wall. Radiation entering the container ionizes some of the gas atoms to give negatively charged and positively charged ions. Free electrons travel to the anode (the wire) and the cathode (the cylinder wall). The resulting electronic pulse is amplified and recorded as a count. In some gas-filled detectors, electrons traveling to the anode can cause further ionization, magnifying the incoming radiation. Instruments based on these principles can be very sensitive to small amounts of incoming radiation.

A typical and widely used example of gas-filled detectors is the Geiger–Müller detector, also known as the Geiger counter, shown in [Figure 158.19](#). In this arrangement, the anode is a tungsten or platinum wire, while the cylindrical tube acts the cathode for the circuit. The tube is filled with argon with a slight amount of hydrocarbon gas. Internal pressure is kept at slightly less than atmospheric pressure. The radiation particle is transmitted through the cathode material. Interaction of the particle produces ionization of the gas molecules, thus causing a voltage pulse for each particle.

Semiconductor radiation sensors are made from semiconductor materials. When an electric field is placed across the semiconductor, a region is created such that no free electrons exist. An incoming radiation ionizes atoms in this region producing free electrons, which can be collected and counted. The semiconductor sensors are highly sensitive, accurate, and have high resolution compared to gas-filled counterparts. They can distinguish between radiation particles that are close together in energy content.

There are many different types of semiconductor radiation sensors: diffused junction, ion implanted, strip types, drift types, CCD sensors, and so on. As a typical semiconductor radiation sensor, a position-sensitive silicon-strip type of sensor is illustrated in [Figure 158.20](#). This sensor is

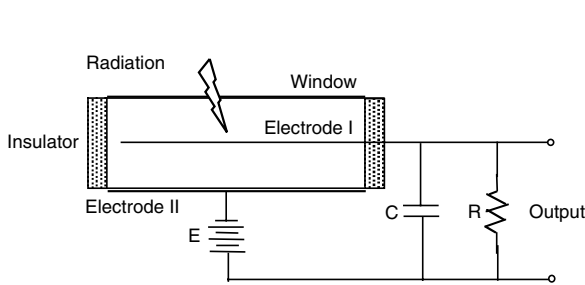

FIGURE 158.19 Geiger–Müller radiation detector.

FIGURE 158.20 Semiconductor radiation detector.

suitable for detecting radioactive particles with greater than 5 μm localized hit rates. They are often used in particle physics experiments.

158.9 Chemical and Gas Sensors

Chemical sensors are extensively used for identifying chemical compounds and elements in industrial, environmental, food processing, and domestic applications. Some of the applications are air and water quality measurements, pollution level determination, detection of chemical and gas leaks, determination of toxicity levels, prospecting of minerals in mining and metallurgy industries, finding explosives, detecting drugs, fire warning, and many other types of domestic, medical, industrial, and health- and safety-related applications.

Chemical sensors can be classified as *contact types* and *noncontact types*. The contact types involve the physical interaction of the sensor with the chemicals under observation. The chemicals can be in gas, liquid, solid, or mixture forms. The noncontact types use remote sensing techniques that are based on the analysis of the gaseous part of the chemical substances under investigation.

Some of the many methods of sensing chemicals include catalytic sensors, enzyme sensors, chemosensors, chromatographic sensors, electrochemical sensors such as potentiometric and amperometric sensors, radioactive sensors, thermal sensors, optical sensors, mass sensors, concentration sensors, titration sensors, and semiconductor sensors. Out of this vast repertoire of sensors only a few are discussed here.

Enzyme sensors consist of a special type of catalyst, proteins found in living organisms. Enzymes exist in aqueous environment in the form of immobilization matrices as gels or hydrogels. As sensors, enzymes tend to be very effective in increasing the rate of certain chemical reactions and also are strongly selective to a given substrate.

Figure 158.21 illustrates a typical enzyme sensor. The sensing element can be a heated probe, electrochemical, or optical sensor. The enzyme, acting as a catalyst, is immobilized inside the layer into which the substrate diffuses; hence, it reacts with the substrate and the product is diffused out of the layer into the sample solution.

Radioactive chemical sensors are most commonly used in home smoke alarms. In this arrangement, two metal plates exist inside the chamber, and a small radioactive source emits alpha radiation that ionizes the air in between the metal plates and allows a current to flow. If chemicals/particles in the air enter

FIGURE 158.21 Arrangement of an enzyme sensor.

FIGURE 158.22 Optical semiconductor chemical sensors.

the space between the plates and bind with the ions, then the amount of normal current is altered, thus triggering an alarm. This method may be applied only to certain analytes.

Chemosensors are based on molecules that can bind selectively and reversibly to the analyte of interest. A chemosensor binds and/or unbinds easily with the dissolved gas molecules of interest. The constituents and physical properties of a chemosensor may be unique to each analyte, depending on chemical composition; that is, a different chemosensor will be required for each analyte. The analyte can be made from various compounds; for instance methane dissolves into the chemosensor solution and is randomly bound to the chemosensor.

Sensors with light and properties of optics are based on the interaction of electromagnetic radiation with matter. As a result of this interaction, some property of light is altered, such as intensity, polarization, and velocity.

Figure 158.22 illustrates a typical semiconductor-based optical chemical sensor. This sensor consists of two chambers, one acting as a reference containing a reference concentration chemical, and the other acting as the sensor. These chambers are illuminated by a common light-emitting diode (LED). The surfaces of chambers are metallized to improve internal reflectivity, and the bottom of chambers are covered by glass. One of the chambers has slots covered with a gas-permeable membrane. The slots allow the penetration of gas to be measured (e.g., CO₂) into the chamber. Wafers A and B form optical waveguides. The chamber filled with reagent is used to monitor the optical absorbency for comparison with that obtained from the reference chamber.

Absorption and emission sensors act as a binding agent of analytes to some chemosensor. The absorption and emission spectrum gives distinctive bands of colors that may be analyzed and compared against known spectra for determining the chemical composition. This method is also used in the analysis of gases, such as oxygen.

Gas Sensors

Gas sensors could be included in the section of chemical sensors since gas, in chemical terms, is any matter that is in the gaseous state characterized by high molecular kinetic energy and a tendency to expand out of an open container. In practice, the word *gas* takes distinct and separate meanings. For example, natural gas is a fossil fuel that is collected in the gas phase, and gasoline, which is also called gas, is a liquid mixture of hydrocarbon fuels that becomes gaseous in the combustion chamber of an engine. In this article, gas will be taken in the chemical sense. For the purpose of detecting gases, there are effectively two types of gases: *inorganic*, such as sulfur dioxide, hydrogen sulphide, nitrogen oxides, hydrochloric acid, silicon tetrafluoride, carbon monoxide and carbon dioxide, ammonia, ozone; and *organic*, such as hydrocarbons, terpins, mercaptans, formaldehyde, dioxin, and fluorocarbons.

The most popular methods of sensing gases are infrared and fluorescent spectrometry and light absorption methods, colorimetry or photometry, chromatographic methods, flame ionization, indicator tubes, test papers, titration, semiconductor methods with electric conductivity and amperimetric methods, and ring oven methods. Some of these methods have already been discussed, and others will briefly be discussed below.

FIGURE 158.23 Amperimetric oxygen sensor.

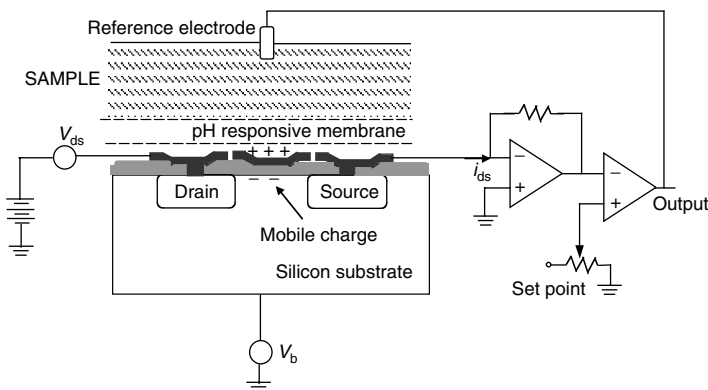

FIGURE 158.24 A pH sensor based on ion-selective FET.

Amperimetric chemical and gas sensors are based on the generation of electric current or potential by free elements or compounds. For example, sulfur dioxide and other reducing gases in an air sample react with electrically generated free iodine or bromine in a detection cell. The cell has an anode and a cathode electrode and contains a constant titrant concentration. Any sulfur compound introduced into the cell reacts with titrant and changes the concentration to produce a potential change in the solution to be picked up by electrodes. The range of the instrument is 0.0001 ppm to 0.2 ppm.

In amperimetric sensors, the chemical reaction occurs at the active electrodes by means of an exchange of electrodes leading to the flow of current. A typical amperimetric cell contains three electrodes inserted in the solution to be measured. The desired reaction takes place in the working electrodes (WE). The WE are usually made from materials, such as mercury, platinum, carbon, or gold, that show different responses to specific chemicals. The potential of the WE relative to the solution is measured by a reference electrode (RE). The WE carries current but the RE does not. In some cases, the chemical reaction is encouraged by setting a potential difference between the electrodes by counter electrodes, called the *potentiostat*.

Basic components of amperimetric sensors are illustrated in Figure 158.23. The cathode is made from platinum. The reference electrode, called the Clark oxygen sensor, is made from AgCl, which results in the generation of electrons. The cathode is maintained at a fixed reference condition by establishing constant chloride ion concentration. The cathode is separated from the sensing fluid by an oxygen-permeable membrane made from silicone polymer.

Potentiometric chemical and gas sensors act as an electric battery. A typical example of potentiometric sensors based on semiconductors is given in Figure 158.24. These sensors are based on the use of ion-selective field-effect transistors (ISFETs). They are derived from metal-oxide semiconductor FETs or MOSFETs with hydrogen ion-sensitive elements. These silicon chips contain a pH-responsive membrane much like glass electrodes. The signals are amplified and processed on the same chip.

In these sensors, the potential or current signals generated by the electrochemical process between the solution and the sensors are processed. Potentiometric sensors have two important characteristics: very small current needs to be drawn during measurements, thus implying alterations in the characteristics; and the response is not linear but usually logarithmic.

158.10 Biological and Environmental Sensors

Biological Sensors

Traditionally, biological detectors require human intervention in a laboratory environment. However, in recent years, automatic devices and robots are involved in biological applications, such as detection of

FIGURE 158.25 Magnetic biosensor.

microorganisms and their concentration levels. For example, for detecting microorganisms in air, the following three methods are used:

1. *Biochemical*, which detects a DNA sequence and protein that are unique to a bioagent through its interaction with test modules
2. *Chemical*, for example, mass spectrometry, which works by breaking down a sample into its components such as amino acids and then comparing their weights with those of known bioagents and other molecules
3. *Biological tissue-based systems*, in which a bioagent or biotoxin affects live mammalian cells, causing them to undergo some measurable response

Some classes of biological sensors rely on comparing the DNA taken from a microorganism with the DNA of a known agent. These sensors are built on prior knowledge of the bioagent. In automatic systems, a sensor collects samples and then multiple copies of the DNA are made by using a polymerize chain reaction (PCR). In this method, the samples are heated and cooled periodically to produce copies of the DNA. As the DNA is copied, the resulting strands are mixed with fluorescent DNA probes. The probe bound with the bioagent glows under ultraviolet light. By using different probe markers, several PCR reactions can run at the same time, thus enabling detection of more than one agent at a time.

There are microfluidic devices, which contain tiny channels, valves, and chambers in a single chip. Once the microorganisms are in the chip, their cells are cracked open ultrasonically. The PCR is applied by means of small thin-film heaters.

Apart from optical and fluorescent methods, magnetic methods, illustrated in Figure 158.25, are also used to detect DNA. These devices comprise an array of wire-like magnetic field microsensors. These sensors are coated with single-stranded DNA probes specific to a gene from a bioagent. Once a strand of bioagent DNA in a sample binds with a probe, the resulting double strand binds a single magnetic microbead. When a magnetic bead is present above a sensor, the resistance of the sensor decreases in proportion to the number of microbeads.

Some sensors use fluorescent antibodies to bind to bacterial cells. In these devices, the sample passes through a portable flow cytometer, which counts cells by measuring their fluorescent or other properties as they move in a liquid.

Another commonly used method in biological sensors uses live tissues. Many toxins trigger measurable or differentiable reactions in living cells. Mammalian cells, such as heart cells, are cultured in a lab, and then seeded into a cartridge containing a microelectrode array. When a biotoxin is introduced, the cells create voltages detectable in millivolts at the electrodes.

Environmental Sensors

Humidity and moisture measurements are very important in agricultural applications and international food commodity trading. Moisture is the amount of water, in some cases the amount of liquid, in materials. The presence of moisture in a gas is termed as humidity. The absolute humidity of a gas is the

mass of water per unit mass of gas. The maximum humidity that can be attained is called the saturation humidity. The saturation humidity heavily depends on temperature. For many purposes, relative humidity is important. The relative humidity is the ratio of absolute humidity to saturation humidity at a particular temperature.

Another measure of relative humidity is the dew point. When a surface is cooled and in contact with gas, a temperature will be reached such that gas-containing water deposits the water onto the surface by condensation. This surface temperature is called the dew-point temperature.

Many methods are available for moisture and humidity sensing. These methods range from a change of electrical properties to changes in optical properties or even changes in mechanical characteristics of the sensors. Diverse techniques may be designed and developed for specific application in a particular process.

The oldest method of measuring humidity is the *hygrometer*. A human hair, free from oil or grease, is strongly affected by humidity, shrinking in dry conditions and expanding in moist conditions. Relative humidity sensors are constructed by slightly tensioned hair along with some method of detecting changes in the length of materials. Some of these methods include the use of linear potentiometers, LVDTs, capacitive techniques, or some forms of oscillatory circuits.

Use of *lithium chloride* for moisture measurement is very common. Lithium chloride has very high resistance in its dry state, but resistance drops considerably in the presence of water with a reasonable linearity in proportion to the amount of water. The lithium chloride cell is made part of a measuring bridge, and the output of the bridge is appropriately processed.

A common method for measuring humidity and moisture content is by using *microwave energy*. Microwave energy at various frequencies (e.g., 2.45 GHz) is absorbed strongly by water. The attenuations and phase shifts of the microwave across the moist media become a good way measuring water content of the media. Microwave techniques are extensively used in agricultural products such as grain moisture determinations.

Moisture of solids is usually sensed in terms material conductivity, changes in permittivity, or microwave absorption. For moisture content in materials of fixed composition, resistance measurements between the conductors set at fixed distances is sufficient, but need lengthy calibration procedures.

Conductive humidity and moisture sensors make use of changes in resistance of materials doped in semiconductor structures. The sensing elements are made from many different materials such as polystyrene films (Pope cells) treated with sulfuric acid. In some cases, solid polyelectrolides are used. Solid-state humidity sensors are fabricated from silicon substrate as illustrated in Figure 158.26.

Capacitive humidity and moisture sensors find extensive applications. In capacitive methods, changes in permittivity of atmospheric air as well as changes in permittivity of many solid materials are used. The permittivity of most dielectric materials is a function of moisture content and temperature. The capacitive humidity sensor is based on changes in permittivity of the dielectric material between plates of capacitors.

Thin-film capacitive sensors can be fabricated on silicon substrates as shown in Figure 158.27. In this construction, a SiO_2 layer is deposited on the *n*-type silicon substrate. The two metal electrodes, shaped in interdigitized patterns, are located on the SiO_2 . These electrodes may be made from aluminium, tantalum, chromium, or phosphorous-doped polysilicon. Since there are many types of capacitive humidity sensors operating on similar principles, only the aluminium and tantalum types will be introduced as typical examples.

FIGURE 158.26 Aluminium oxide thin-film conductive moisture sensor.

FIGURE 158.27 Capacitive thin-film humidity sensor.

FIGURE 158.28 A pH sensor.

Aluminium-type capacitive humidity sensors constitute the majority of capacitive humidity sensors. In these types of sensors, high-purity aluminium is chemically oxidized to produce a prefilled insulating layer of partially hydrated aluminium oxide, which acts as the dielectric. A water-permeable but conductive gold film is deposited onto the oxide layer, usually by vacuum deposition, which forms the second electrode of the capacitor.

Acidity and Alkalinity Sensors

Acidity and alkalinity of water are important factors in monitoring water supplies for industrial and domestic water use, at hydroelectric power-generation stations, and in various agriculture and horticulture applications. The acidity and alkalinity of water are measured on the pH scale, which is based on free hydrogen ions in the water. Natural water has a pH value of 7, fairly strong acid solutions have a pH of 2, and fairly strong alkaline solutions have a pH of 12.

The sensing of pH makes use of changes in ionization. Natural water with 7.0 pH levels has a very high resistivity, but ionization causes the resistivity to drop very sharply. The standard electrical system of sensing acidity depends on the glass electrode system as shown in Figure 158.28. In this arrangement, a thin glass bulb contains a mildly acidic solution with good conducting properties. A suitable reference electrode, calomel, and a sensing element inside the bulb provide electrical signals for pH levels.

158.11 Mechanical Variables Sensors

Mechanical variable measurements can be divided into two broad categories: solids and fluids. Solid variable measurements consist of stress and strain, mass and weight, density, acceleration, velocity, force, torque, and power measurements. Variables for fluids can be categorized as pressure, velocity, flow, level, viscosity, and surface tension measurements. In this section, only a few sensors associated with mechanical variables will be discussed.

Position, Displacement, and Proximity Sensors

The measurement of distances or displacements is an important aspect in many industrial, scientific, and engineering applications. Sensors for position and displacement sensing may be based on many different techniques, such as capacitive, inductive, resistive, magnetic, optical, ultrasound, and so on.

Designing and selecting position and displacement sensors depend on the type of displacement (linear, nonlinear, rotary), required resolution, type of material being applied for, environmental conditions, availability of power, and so on. For example, the microswitches are small devices and they can be easily mounted on object surfaces, and hence are used in many position- and displacement-sensing applications. Alternatively, interruption of light beams can be used instead of mechanical switches. In some cases, the location of a reflected beam can be used to measure the distance of objects. Other methods may include potentiometers, ferrite core inductors with movable cores, or variable capacitors to track the movements of an attached object.

Capacitive position, displacement, and proximity sensors consist of two simple electrodes with capacitance C . There are three basic methods for realizing such sensors: varying the distance between the plates, varying the area between plates, and making use of dielectric properties of the material between the plates.

Magnetic position, displacement, and proximity sensors are based on magnetic properties of materials and circuits. The many types include the following:

- Inductive
- Hall effect
- Magnetoresistive
- Eddy current proximity

Inductive proximity sensors operate on the principle of change inductance of a coil in the presence of a metal in the proximity of the core. For signal processing, the coil can be configured as part of a bridge circuit or as a part of a tuned circuit. When used as part of a bridge, the presence of metal near the coil forces the bridge output to be off balance, thus registering a voltage output. In the case of tuned circuits, change in the tuned frequency due to variations in the magnetic properties can easily be processed.

Hall-effect sensors are usually fabricated as monolithic silicon chips and encapsulated into epoxy or ceramic packages. There are two types of Hall-effect sensors: linear and threshold sensors. A linear sensor incorporates an amplifier and other electronic circuits for interfacing with peripherals. Compared to basic Hall-effect sensors, they tend to be more stable and operate over wider voltage ranges. The threshold sensors have a Schmitt trigger with a built-in hysteresis to eliminate spurious oscillations.

Magnetoresistive sensors are based on the change in resistance of some materials such as permalloys in the presence of magnetic fields. In these materials, current passing through the material magnetizes the material in a particular magnetic orientation. The resistance is highest when the magnetization is parallel to the current and lowest when it is perpendicular to the current. Hence, depending on the intensity of the external magnetic field, the resistance of the permalloy changes in proportion. The magnetoresistive sensors are manufactured as thin films and are usually integrated as part of an appropriate bridge circuit. They have good linearity and low-temperature coefficients. These devices have sensitivity ranging from 10^{-6} T to 50 mT. By choosing good electronic components and suitable feedback circuits, sensitivity can be as low as 10^{-10} T. They can operate from DC to frequencies in several gigahertz.

Eddy current sensors are inductive-type sensors that contain two coils in the shape of probes. One of the coils, known as the active coil, is influenced by the presence of a target with conductive properties. The second coil, known as the balance coil, serves as an arm of a bridge that balances the circuit. This also provides temperature compensation. The magnetic flux from the active coil passes into the conductive target from the probe. When the probe is brought close to the target, the flux from the probe links with the target, producing eddy currents within the target. The eddy currents change the magnetic properties of the sensors, thus yielding unbalanced conditions of the bridge.

Many other sensors are used for position, displacement, and proximity sensing. Most of these sensors can also be used as motion detectors by the use of suitable signal processing and display techniques. Some of these sensors include:

- Position-sensitive detectors
- Proximity sensors with polarized light
- Photo beam sensors
- Fiber optic sensors
- Grating sensors such as encoded discs
- Ultrasonic sensors
- Microwave and Doppler radar sensors

Some of these are briefly discussed below.

Position-sensitive detector (PSD) optical systems operating at the near-infrared region can be a very effective way of sensing short- and long-range displacements and positions. As in the case of cameras, PSDs are used in conjunction with LEDs. A PSD operates on the principle of photoelectric effect. The

FIGURE 158.29 One-dimensional silicon position-sensitive detectors.

surface resistance of a silicon photodiode changes depending on the light falling on it. These sensors can be single dimensional or two dimensional. A single-dimensional sensor, illustrated in Figure 158.29, is fabricated with high resistance silicon with p - and n^+ -type layers. It has two electrodes to form contact with the p -type layer. The photoelectric effect occurs in the upper pn junction.

Photo beam sensors, or optical position, displacement, and proximity sensors of this type mostly use a reflection technique — the transmitted beam reflects from the stationary or moving object. The light source is usually an LED working in the visible red or invisible infrared region. Visible red makes sensor configuration easier, but the infrared type is less affected by interference from other light sources. These sensors make use of pulse-modulated signals and polarizing filters to avoid stray light and multiple reflection effects.

Ultrasonic sensors mainly make use of reflected energy from the target or time of flight of the ultrasonic beam between the transmitter and receiver. They operate on diffuse-scan or through-scan modes. The diffuse-scan mode uses a single transducer as transmitter and receiver, whereas through-scan mode uses two transducers. In proximity detection applications, using an ultrasonic frequency of 215 kHz is an industrial norm. The transmitted signal is modulated, using frequencies in the range of 30 to 360 Hz to minimize interference.

Pressure Sensors

Pressure is defined as the normal component of the force exerted on the unit surface area of an object. Most pressure sensors operate on the principle of converting pressure to some form of physical displacement, such as compression of a spring or deformation of an object. If displacement is used, there are many options for converting displacement into electrical signals. However, because of heavy reliance on physical displacement, many pressure sensors are sensitive to vibration and shock, which introduce a drawback to their use in many applications.

Pressure can be sensed indirectly or directly. Indirect methods rely on the action of pressure to cause displacement of a diaphragm, piston, or other device, so that the electronic sensing of displacement can be related to the pressure. The most commonly employed method is indirect pressure sensing.

Indirect pressure sensors are commonly known as aneroid barometers. There are many different versions of aneroid barometers, defined by the sensing elements of the electrical components. Figure 158.30 illustrates a semiconductor, piezoresistive indirect-pressure sensor. In this sensor, p -type doping material is introduced into an n -type silicon diaphragm using ion implementation technology. Another method of sensing pressure is using piezoelectric crystals such as the PZT. These sensors are useful in measuring pressure that varies in time.

Force Sensors

Force sensors make use of physical behavior of the body under external force. Force can be measured by the following methods:

- Balancing the force against a standard mass through a system of levers
- Measuring the acceleration of a known mass

FIGURE 158.30 Semiconductor piezoresistive pressure sensor.

- Equalizing the force to magnetic force by suitable coil and magnet arrangements
- Measuring the pressure caused by the force on a surface
- Converting the force into the deformation of an elastic element

Consequently, a vast range of sensors is suitable for force measurements:

- Accelerometers
- Strain gauge load cells
- Piezoelectric sensors
- Resistive sensors
- Force sensing polymers
- Magnetoresistive sensors
- Inductive sensors
- Magnetoelastic sensors
- Piezotransistors
- Capacitive sensors

The basic operational principles of most of these sensors are explained above. Because of diverse range and large volume of applications, only selected examples of accelerometers are discussed below.

Accelerometers

Acceleration sensors, also called accelerometers, are extensively used in absolute motion measurements and vibration and shock sensing. Modern accelerometers are quite advanced; they are manufactured as intelligent sensors, providing good examples of advanced IC technologies. Accelerometers find a diverse range of applications and they are commercially available in a wide variety of ranges and types to meet specific requirements. They are manufactured to be small in size, light in weight, and rugged and robust to operate in harsh environments. They can be configured as active or passive sensors. An active accelerometer (e.g., piezoelectric) provides an output without the need for an external power supply, while a passive accelerometer only changes its electric properties (e.g., capacitance) and requires an external electrical power source.

Accelerometers can be classified in a number of ways, such as deflection or null-balance types, mechanical or electrical types, and dynamic or kinematic types. The majority of industrial accelerometers can be classified as deflection or null-balance types. Accelerometers used in vibration and shock measurements are usually the deflection types, whereas those used for measuring vehicle motion (automotive, aircraft, and others) for navigation purposes may be of either type. In general, null-balance types are used when extreme accuracy is needed.

FIGURE 158.31 Typical seismic accelerometer.

FIGURE 158.32 Double-ended tuning fork accelerometer.

Many practical accelerometers are of the deflection type; the general configuration is shown in Figure 158.31. Although the principles of operation are similar, deflection-type models differ in minor details, such as the spring elements used, types of damping provided, and types of relative motion.

Piezoresistive accelerometers are essentially semiconductor strain gauges with large gauge factors. High gauge factors are obtained since the material resistivity is dependent primarily on the stress, not only on the dimensions of the device. This effect can be greatly enhanced by appropriate doping of semiconductors such as silicon. The increased sensitivity is critical for vibration measurements since it allows miniaturization of the accelerometer. Most piezoresistive accelerometers use two or four active gauges arranged in a Wheatstone bridge form. Extra-precision resistors are used, as part of the circuit, in series with the input to control the sensitivity, balancing, and offsetting the temperature effects.

Piezoelectric accelerometers are used widely for general-purpose acceleration, shock, and vibration measurements. They are basically motion transducers with large output signals and comparatively small size. These accelerometers are available with very high natural frequencies, and are therefore suitable for high-frequency applications and shock measurements.

Microaccelerometers come in many different sizes and shapes. An example of microaccelerometers is the vibrating-beam accelerometer, also termed resonant-beam force transducer. This type is made in such a way that acceleration along a positive input axis places the vibrating beam in tension. Thus, the resonant frequency of the vibrating beam increases or decreases with the applied acceleration. A mechanically coupled beam structure, also known as a double-ended tuning fork (DETF), is shown in Figure 158.32.

In DETF, an electronic oscillator capacitively couples energy into two vibrating beams to keep them oscillating at their resonant frequency. The beams vibrate 180° out of phase to cancel reaction forces at the ends. The dynamic cancellation effect of the DETF design prevents energy from being lost through the ends of the beam. Hence, the dynamically balanced DETF resonator has a high Q factor, which leads to a stable oscillator circuit. The acceleration signal appears as an output from the oscillator in the form of a frequency-modulated square wave, which can be used in a digital interface.

Stress and Strain Sensors

Strain is a fractional change in the dimensions of an object. An example of strain is the change in the length of an object divided by its original length; therefore, strain does not have any dimensions. Stress, on the other hand, is the force applied on an object divided by the area. Consequently, strain takes place as a result of stress. Tensile stress is applied force divided by the area over which it is applied, whereas bulk stress is force per unit of area. The most common strain sensors are produced for tensile strain measurements. Strain measurement also allows calculation of the amount of stress by using knowledge of the object's elasticity, using elastic modules such as Young's modulus, shear (twisting) modulus, and bulk (pressure) modulus in the calculations.

Sensing tensile strain involves the measurement of small changes in the length of a sample. The commonest form of strain measurement uses resistive strain gauges, semiconductor strain gauges, piezoelectric strain gauges, and optical interferometry. The basic principles behind the resistive, semiconductor, and piezoelectric types are explained elsewhere in this chapter. An advanced method for measuring the

strain is achieved by interferometry and fiber optic sensors. In these methods, generally high sensitivities are achieved when lasers are used. A laser consists of a coherent light beam resulting in a good interference effect. Other methods involve various types of fiber optic sensors.

Density Sensors

Density of a substance is defined as the mass per unit volume ($\rho = m/V$) under fixed conditions. The term is applicable to solids, liquids, and gases. Density depends on temperature and pressure, which is much greater in gases. Although there are many different units in use, usually density values are given in terms of grams per cubic centimeter.

There is no single universally applicable density measurement technique available. Different methods must be employed for solids, liquids, and gases. The measurement of fluid densities is much more complex than for solids; therefore, diverse techniques have been developed. Hydrometers, pycnometers, hydrostatic weighing, flotation methods, drop methods, radioactive methods, and optical methods are examples of liquid density measurement approaches. Flask methods, gas balance methods, optical methods, and X-ray methods are typical techniques employed for gas density measurements. Some of these sensors are briefly discussed below.

Magnetic methods are used for both liquids and gases. These methods allow the determination of effects of pressures and temperatures down to the cryoscopic range. Basically, these devices contain a small ferromagnetic cylinder encased in a glass jacket. The jacket and ferromagnetic material combination constitutes a buoy or float. The cylinder is held at a precise height within the medium by means of solenoid that is controlled by a servo system integrated with a height sensor. The total magnetic force on the buoy is the product of the induced magnetic moment by the solenoid and the field gradient in the vertical direction. The total magnetic force at a particular distance in the vertical direction in the solution compensates for the difference in the opposing forces of gravity (downward) and buoyancy (upward) exerted by the medium through the Archimedes principle. The magnetic force is directly proportional to the square of the current in the solenoid. If the buoyant force is sufficient to make the ferromagnetic assembly float on the liquids of interest, the force generated by the solenoid must be downward to add to the force of gravity for equilibrium.

Vibrational methods make use of the changes in natural frequency of vibration of a body containing or surrounded by fluid. The natural frequency of the vibrating body is directly proportional to the stiffness and inversely proportional to the combined masses of the body and the fluid. It also depends on the shape size and elasticity of materials, induced stresses, and the total mass and mass distribution of the body. Vibrational methods include vibrating tube densitometers, vibrating cylinder densitometers, and tuning fork densitometers, all of which make use of the natural frequency of a low-mass tuning fork. In some cases, the liquid or gas is taken into a small chamber in which the electromechanically driven forks are situated. In the other cases, the fork is inserted direct into the liquid. Calibration is necessary in each application.

Hydrometers are direct reading instruments, and are the most commonly used devices for measuring liquid density. They are so common that specifications and procedures of use are described by national and international standards such as ISO 387. The buoyancy principle is used as the main technique of operation. Almost all hydrometers are made from high-grade glass tubing. The volume of fixed mass is converted to a linear distance by a sealed-bulb, shaped glass tube containing a long-stem measurement scale. The bulb is ballasted with a lead shot and pitch, the mass of which is dependent on the density range of the liquid to be measured. The bulb is simply placed into the liquid and the density is read from the scale. The scale may be graduated in density units such as kilograms per cubed meter. Hydrometers can be calibrated at different ranges for surface tensions and temperatures.

Absorption techniques are also used for density measurements in specific applications. X-rays, visible light, ultraviolet (UV), and sonic absorptions are typical examples of this method. Essentially, attenuation and phase shift of a generated beam going through the sample are sensed and related to the sample density. Most absorption-type densitometers are custom designed for applications having particular

characteristics. Two typical examples are UV absorption or X-ray absorption used for determining local densities of mercury deposits in arc discharge lamps; and ultrasonic density sensors used in connection with difficult density measurements such as density measurement of slurries. Lime slurry, for example, is a very difficult material to handle. It has a strong tendency to settle out and to coat all equipment it comes into contact with. An ultrasonic density control sensor can fully be emerged into agitated slurry, thus avoiding the problems of coating and clogging.

Rotation Sensors

Sensing and measurement of rotational movement are necessary in many industrial applications since many industrial machines have rotating shafts. The simplest form of sensing angular velocity is by using AC or DC generators, commonly known as *tacho-generators*.

In some applications, signals are generated for each revolution of the wheel or shaft by optical or piezoelectric or magnetic-pulsing arrangements. These pulses enable the determination of the angular velocities as well as positions of shafts or wheels.

Angular methods for displacement measurements can be grouped to be small or large angular measurements. Small displacements are measured by the use of capacitive, strain gauge, or piezo sensors. For larger displacements, potentiometric or inductive techniques are more appropriate. Rotary digital encoders also find wide applications.

159.2 Applications for Particle Characterization and Separation

159.3 Conclusions

Certain types of particles, when subjected to an electric field, will polarize; charges associated with given particles will move to form a dipole or higher-order pole. These poles then interact with the electric field and generate electrostatic forces. If the field is nonuniform, and the particle carries no net charge, the greater electric field strength across one side of the particle means that the forces generated by Coulombic interactions between charge and field will be greatest on the charges where the field is highest, so that the particle will experience a net force toward or away from the field gradient, according to the sign of the charge where the field is greatest. Since the dipole is induced, reversing the orientation of the field will also reverse the orientation of the dipole, so that the direction of force is independent of the direction of the applied electric field. This force is known as dielectrophoresis (shown schematically in [Figure 159.1](#)), and was first reported by Herbert Pohl in 1951 [1], although previous observations of the effect do exist [2].

The orientation of the dipole in particles on the scale to which dielectrophoresis is most often applied — from tens of nanometers up to hundreds of micrometers — is usually governed by the relative contributions of charge induced in the dipole formed in the particle, and the relative amount of countercharge formed at the interface of the particle, supplied from the material that the particle is suspended in (typically an aqueous electrolyte). The relative amounts of charge supplied to this interface by particle and medium will affect the net charge of the dipole and hence the direction of the dipole, which in turn governs the direction of the force, as shown in [Figure 159.2](#). If there is greater charge supplied from the particle (i.e., it is more polarizable than the medium), the dipole will oppose the field and the particle will be attracted up the field gradient. If the medium is more polarizable than the particle, then the dipole will align with the field and the particle will be repelled and move down the field gradient. These phenomena are termed “positive dielectrophoresis” and “negative dielectrophoresis,” respectively. Since the polarizability of the particle and medium are dependent on the electrical impedance of those materials (and hence conductance and capacitance), which are frequency dependent, the net dielectrophoretic behavior of the particle will depend on the frequency of the applied electric field; the magnitude and direction of the force on a given particle can change with the frequency of the applied electric field. Homogeneous particles typically exhibit one *dielectric dispersion*, a frequency region where the dielectric behavior of the particle changes from being medium dominated to being particle dominated. Complex dielectric particles containing more than one dielectric material can exhibit more than

FIGURE 159.1 A schematic of a polarizable particle suspended within a point-plane electrode system. When the particle polarizes, the interaction between the dipolar charges and the local electric field produces a force. Due to the inhomogeneous nature of the electric field, the force is greater in the side facing the point than that on the side facing the plane, and there is net motion toward the point electrode. This effect is called *positive dielectrophoresis*. If the particle is less polarizable than the surrounding medium, the dipole will align counter to the field and the particle will be repelled from the high field regions, which is called *negative dielectrophoresis*.

one transition between behaviors, such as exhibiting negative dielectrophoresis at low and high frequencies with a window of positive dielectrophoresis in between. While this variation in behavior is the main advantage in using the AC rather than DC field, there are other advantages including a reduction in the effects of electrode screening and an elimination of DC (electrophoretic) forces due to net charge on the particle.

Pohl's work advanced the use of dielectrophoresis for investigating the properties of suspensoids, and for providing a means of separating particles from suspension. Similar investigations have been conducted using a frequency-based examination of dielectrophoretic response of cell populations [3,4], yeast [5,6], and bacteria [7], including work by Nobel laureate Albert Szent-Györgyi. Practical applications of dielectrophoresis have included the collection of cells for cellular fusion in biological experiments [8–10]. The use of positive and negative dielectrophoresis has been used to separate mixtures of viable and nonviable yeast cells [5,11] and mixtures of healthy and leukemic blood cells [12]. Work by Rousselet et al. [13] and others applied dielectrophoresis to the induction of continuous linear motion of particles, expanding on the basic concept of dielectrophoresis as a means of trapping particles in a specific region in space. An important class of electrokinetic particle manipulator is the levitator — a device used to propel a particle against gravity — resulting in it hovering in mid-solution (or mid-air) at a height governed by its dielectric properties, allowing those properties to be measured, and allowing those particles to be selected and trapped [14,15]. Early experiments used electric fields generated by (relatively) large electrodes and high voltages to trap particles; more recently, electrode structures have been fabricated using techniques borrowed from the computer industry [6,11,13] to manipulate much smaller particles at much lower voltages.

A related electrokinetic effect is observed when the electric field contains a *phase* gradient instead of a *magnitude* gradient. Although this phenomenon produces quite different particle behavior to dielectrophoresis, the two are closely related in origin [16,17], and produces phenomena where particles rotate *in situ* (electrorotation) or move along the direction of increasing phase gradient (traveling-wave dielectrophoresis). In these phenomena, the fundamental principle is the same; the dipole takes a finite time (relaxation time) to form, by which time the electric field has rotated slightly. There is thus a lag between the orientation of the electric field and that of the dipole moment, and a torque or force is induced as the dipole moves to reorient itself with the electric field. Due to the continuous rotation of the electric

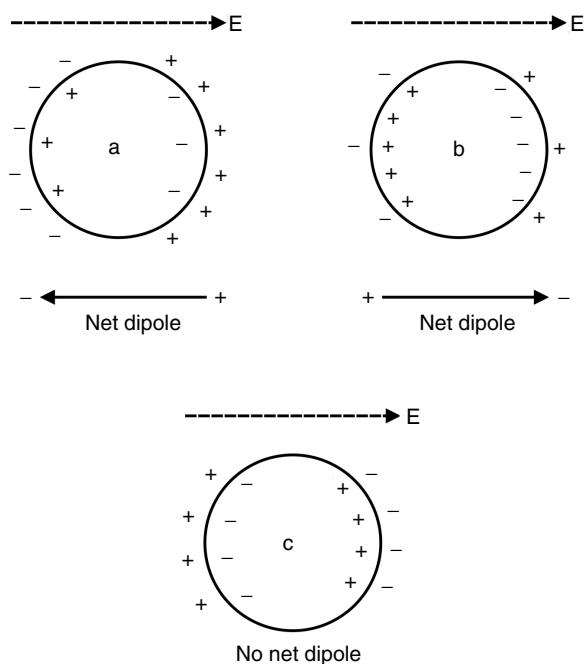

FIGURE 159.2 A lossy dielectric sphere in a lossy dielectric medium, and exposed to an electric field, will experience interfacial polarization. The amount of charge on each side of the interface will depend on the relative capacitances and conductances of the particle and medium, leading to a net dipole across the particle. (a) Particle more polarizable than medium. (b) Particle less polarizable than medium. (c) Particle and medium equally polarizable.

field, the torque is induced continually and the cell rotates, in the case of electrorotation, or translates, in the case of traveling-wave dielectrophoresis. The direction of movement is determined by the displacement between the dipole moment and the electric field. For example, in electrorotation, if the phase lag is less than 180° , the particle rotation will follow that of the applied field, referred to as co-field rotation. If the phase angle is greater than 180° , the shortest path for the dipole to align with the electric field is by rotating in a contrary fashion to that of the electric field, and hence particle rotation will act in this direction (anti-field rotation). As with dielectrophoresis, the rate and direction of cell rotation are related to the dielectric properties of both the particle and the suspending medium. Traveling-wave dielectrophoresis is effectively an extension of the principle of electrorotation to include a linear case. An AC electric field is generated which travels linearly along a series of electrodes. Particles suspended within the field establish dipoles which, due to the relaxation time, are displaced from the regions of high electric field. This induces a force in the particle as the dipole moves to align with the field. If the dipole lags within half a cycle of the applied field net motion acts in the direction of the applied field, while a lag greater than this results in motion counter to the applied field.

Cell rotation was observed and reported by experiments on AC dielectrophoresis [18], and was later suggested to be the result of the dipole-dipole interaction of neighboring cells [19]. This led Arnold and Zimmermann [20] to the principle of suspending single particles in a rotating field, and thus to a more amenable means of studying the phenomenon. Electrorotation has been used to study the dielectric properties of matter, such as the interior properties of biological cells and biofilms [21,22]. Traveling-wave dielectrophoresis was first reported by Batchelder [23] and subsequently by Masuda et al. [24,25], where the electric fields “travel” along a series of bar-shaped electrodes where low-frequency (0.1 Hz to 100 Hz) sinusoidal potentials, advanced 120° for each successive electrode, were applied. This was found to induce controlled translational motion in lycopodium particles [25] and red blood cells [17]. At low frequencies, the translational force was largely electrophoretic, and it was proposed that such traveling fields could eventually find application in the separation of particles according to their size or electrical

charge. However, later work by Fuhr et al. [26], using applied traveling fields at much higher frequency ranges (10 kHz to 30 MHz), demonstrated the induction of linear motion in pollen and cellulose particles, and demonstrated that the mechanism inducing traveling motion at these higher frequencies is dielectrophoretic, rather than electrophoretic, in origin. Since then, Huang et al. [27] and others have, for example, used traveling fields to linearly move yeast cells and separate them from a heterogeneous population of yeast and bacteria. A large corpus of work now exists, including theoretical studies [27,28], devices for electrostatic pumping [29], and large-scale cell separators [30].

159.1 Theory

The dielectrophoretic force, F_{DEP} , acting on a spherical, homogeneous body suspended in a local electric field gradient is given by the expression:

$$F_{\text{DEP}} = 2\pi r^3 \epsilon_m \text{Re}[K(\omega)] \nabla E^2 \quad (159.1)$$

where r is the particle radius, ϵ_m is the permittivity of the suspending medium, ∇ is the Del vector (gradient) operator, and E is the *rms* electric field. $\text{Re}[K(\omega)]$ is the real part of the Clausius–Mossotti factor, given by

$$K(\omega) = \frac{\epsilon_p^* - \epsilon_m^*}{\epsilon_p^* + 2\epsilon_m^*} \quad (159.2)$$

where ϵ_m^* and ϵ_p^* are the complex permittivities of the medium and particle, respectively; and $\epsilon^* = \epsilon - \frac{j\sigma}{\omega}$ with σ the conductivity, ϵ the permittivity, and ω the angular frequency of the applied electric field. The limiting (DC) case of Equation (159.2) is

$$K(\omega = 0) = \frac{\sigma_p - \sigma_m}{\sigma_p + 2\sigma_m} \quad (159.3)$$

The frequency dependence of $\text{Re}[K(\omega)]$ indicates that the force acting on the particle varies with the frequency. The magnitude of $\text{Re}[K(\omega)]$ varies depending on whether the particle is more or less polarizable than the medium. If $\text{Re}[K(\omega)]$ is positive, then particles move to regions of highest field strength (positive dielectrophoresis); the converse is negative dielectrophoresis where particles are repelled from these regions. The frequency dependence of $K(\omega)$, both real and imaginary parts, is shown in Figure 159.3 for a homogeneous, solid, spherical latex particle of diameter 216 nm in a dilute electrolyte.

FIGURE 159.3 A plot of the real (solid line) and imaginary (dotted line) parts of the Clausius–Mossotti factor calculated for a 216-nm latex bead in a 1 mS m^{-1} solution, neglecting surface charge effects. The magnitude and signs of the real and imaginary parts govern the magnitude and direction of the dielectrophoretic force and electrorotational torque, respectively.

FIGURE 159.4 A mixture of live and dead (heat-treated) yeast cells undergoing dielectrophoresis in a quadrupolar electrode array; the live cells are collected at regions of high electric field (A) at the electrode edges, while the dead cells are repelled from these regions and collect in the interelectrode space (B).

By careful construction of the electrode geometry that creates the electric field, it is possible to create electric field morphologies so that potential energy minima are bounded by regions of increasing electric field strengths. An example of yeast cells in such an array (often called a *quadrupolar* or *polynomial* electrode array) is shown in Figure 159.4. In such electrodes, particles experiencing positive dielectrophoresis are attracted to the regions of highest electric field (typically the electrode edges, particularly where adjacent electrodes are close), while particles experiencing negative dielectrophoresis are trapped in an isolated field minimum at the center of the array.

The second type of AC electrokinetic phenomenon described above depends on the interactions between an *out-of-phase* dipole with a spatially moving electric field. Since an induced dipole may experience a force with both an in-phase and out-of-phase component simultaneously, the induced forces due to these components will be experienced at the same time, with the respective induced forces superimposed. If our particle is suspended in a rotating electric field, the induced dipole will form across the particle and should rotate in synchrony with the field. However, if the angular velocity of the field is sufficiently large, the time taken for the dipole to form (the *relaxation time* of the dipole) becomes significant and the dipole will lag behind the field. This results in a nonzero angle between field and dipole, which induces a torque in the body and causes it to rotate asynchronously with the field; the rotation can be with or against the direction of rotation of the field, depending on whether the lag is less or more than 180° . This phenomenon was called *electrorotation* by Arnold and Zimmermann [20], and is shown schematically in Figure 159.5. The general equation for time-averaged torque Γ experienced by a spherical polarizable particle of radius r suspended in a rotating electric field E is given by:

$$\Gamma = -4\pi\epsilon_m r^3 \text{Im}[K(\omega)] E^2 \quad (159.4)$$

where $\text{Im}[K(\omega)]$ represents the imaginary component of the Clausius–Mossotti factor shown in Figure 159.4. The minus sign indicates that the dipole moment lags the electric field. When viscous drag is accounted for, the rotation rate $R(\omega)$ of the particle is given by

FIGURE 159.5 A schematic of a polarizable particle suspended in a rotating electric field generated by four electrodes with 90° advancing phase. If the electric field E rotates sufficiently quickly, the induced dipole M will lag behind the electric field by an angle related to the time taken for the dipole to form (the relaxation time). The interaction between the electric field and the lagging dipole induces a torque Γ in the particle, causing the particle to rotate. This effect is known as *electrorotation*.

$$R(\omega) = -\frac{\epsilon_m \text{Im}[K(\omega)] E^2}{2\eta} \quad (159.5)$$

where η is the viscosity of the medium. Note that unlike the dielectrophoretic force Equation (159.1), the relationship with the electric field is as a function of the square of the electric field rather than of the *gradient* of the square of the electric field. Furthermore, the torque depends on the *imaginary* rather than the real part of the Clausius–Mossotti factor. A particle may experience both dielectrophoresis and electrorotation simultaneously, and the magnitudes and directions of both are related to the interaction between the dielectric properties of particle and medium; the relative magnitudes of force and torque are proportional to the real and imaginary parts of the Clausius–Mossotti factor.

Where the electric field has a phase gradient that moves in space rather than induces rotation, the particles within that field will experience a translational force rather than torque in particles, an effect known as *traveling wave dielectrophoresis*. This shares with dielectrophoresis the phenomenon of translational induced motion, but rather than acting toward a specific point (that of the highest electric field strength), the force acts to move particles *along* an electrode array in the manner of an electrostatic “conveyor belt” as shown in Figure 159.6.

FIGURE 159.6 A schematic showing a polarisable particle suspended in a traveling electric field generated by electrodes on which the applied potential is 90° phase-advanced with respect to the electrode above. If the electric field moves sufficiently quickly, the induced dipole M will lag behind the electric field, inducing a force in the particle. This causes the particle to move along the electrodes, a phenomenon known as *traveling-wave dielectrophoresis*.

Consider a particle in a sinusoidal electric field that travels — that is, rather than merely changing magnitude, the field maxima and minima move through space, like waves on the surface of water. These waves move across a particle, and a dipole is induced by the field. If the speed at which the field crosses the particle is great enough, then there will be a time lag between the induced dipole and the electric field, in much the same way as there is an angular lag in a rotating field that causes electrorotation. This physical lag between dipole and field induces a force on the particle, resulting in induced motion; the degree of lag, related to the velocity (and hence the frequency) of the wave, will dictate the speed and direction of any motion induced in the particle. The underlying principle is closely related to electrorotation; it could be argued that the name “traveling wave dielectrophoresis” is misleading because the origin of the effect is not dielectrophoretic; that is, it does not involve the interaction of dipole and field gradient. Instead, the technique is a linear analogue of electrorotation, in a similar manner to the relationship between rotary electric motors and the linear electric motors used to power magnetically-levitated trains. As with the rotation of particles, the movement is asynchronous with the moving field, with rates of movement of 100 $\mu\text{m/s}$ being reported. The value of the force F_{TWD} is given by [27]:

$$F_{\text{TWD}} = \frac{-4\pi\epsilon_m r^3 \text{Im}[K(\omega)] E^2}{\lambda} \quad (159.6)$$

where λ is the wavelength of the traveling wave, and is usually equal to the distance between electrodes that have signals of the same phase applied.

It is possible to extend the model of dielectric behavior to account for more complex particle structure. Two cases of this will be considered here; the first is that of nonhomogeneous (shelled) particles, and the second case is that of nonspherical ellipsoids. In the first case, we can extend the models described above by replacing the Clausius–Mossotti factor for a homogeneous sphere with a more complex term representing the many dielectric materials in a layered or “shelled” object (such as a cell, where the inner cytoplasm is enclosed by an enveloping membrane). The model most widely used now was developed by Irimajiri et al. [31], and works by considering each layer as a homogeneous particle suspended in a medium, where that medium is in fact the layer surrounding it. So, starting from the core we can determine the dispersion at the interface between the core and the layer surrounding it, which we will call shell 1. This combined dielectric response is then treated as a particle suspended in shell 2, and a second dispersion due to that interface is determined; then a third dispersion due to the interface between shells 2 and 3 is determined, and so on. In this way, the dielectric properties of all the shells combine to give the total dielectric response for the entire particle. This is illustrated schematically in [Figure 159.7](#). In order to examine this mathematically, let us consider a spherical particle with N shells surrounding a central core. To each layer i we assign an outer radius a_i , with a_1 being the radius of the core and a_{N+1} being the radius of the outer shell (and therefore the radius of the entire particle). Similarly, each layer has its own complex permittivity given by

$$\epsilon_i^* = \epsilon_i - j \frac{\sigma_i}{\omega} \quad (159.7)$$

where i has values from 1 to $N+1$. In order to determine the effective properties of the whole particle, we first replace the core and the first shell surrounding it with a single, homogeneous “core.” This new core has a radius a_2 and a complex permittivity given by

$$\epsilon_{\text{leff}}^* = \epsilon_2^* \frac{\left(\frac{a_2}{a_1}\right)^3 + 2 \frac{\epsilon_1^* - \epsilon_2^*}{\epsilon_1^* + 2\epsilon_2^*}}{\left(\frac{a_2}{a_1}\right)^3 - \frac{\epsilon_1^* - \epsilon_2^*}{\epsilon_1^* + 2\epsilon_2^*}} \quad (159.8)$$

FIGURE 159.7 (a) A sphere comprises a core and inner and outer shells, with radii r_1 , r_2 , and r_3 . (b) These three layers have complex permittivity ϵ_1^* , ϵ_2^* , and ϵ_3^* . We can find the total polarizability of the particle by successively combining the two innermost layers to find the effective combined complex permittivity (i to iii).

We now have a “core” surrounded by $N - 1$ shells. We then proceed by repeating the above calculation, but combining the “new” core with the second shell:

$$\epsilon_{2eff}^* = \epsilon_3^* \frac{\left(\frac{a_3}{a_2}\right)^3 + 2 \frac{\epsilon_{1eff}^* - \epsilon_3^*}{\epsilon_{1eff}^* + 2\epsilon_3^*}}{\left(\frac{a_3}{a_2}\right)^3 - \frac{\epsilon_{1eff}^* - \epsilon_3^*}{\epsilon_{1eff}^* + 2\epsilon_3^*}} \quad (159.9)$$

If this procedure is repeated a further $N - 2$ times, then the final step will replace the final shell and the particle will be replaced by a single homogeneous particle with effective complex permittivity ϵ_{Peff}^* given by

$$\epsilon_{Peff}^* = \epsilon_{Neff}^* \frac{\left(\frac{a_{N+1}}{a_N}\right)^3 + 2 \frac{\epsilon_{N-1eff}^* - \epsilon_{N+1}^*}{\epsilon_{N-1eff}^* + 2\epsilon_{N+1}^*}}{\left(\frac{a_{N+1}}{a_N}\right)^3 - \frac{\epsilon_{N-1eff}^* - \epsilon_{N+1}^*}{\epsilon_{N-1eff}^* + 2\epsilon_{N+1}^*}} \quad (159.10)$$

FIGURE 159.8 A schematic diagram of an elliptical particle, showing axes x and y , along which the particle extends by distances a and b . The particle extends along the z axis (beyond the page) by length c . If $c = b$, the particle is prolate; if $c = a$, the particle is oblate.

This value provides an expression for the combined complex permittivity of the particle at any given frequency ω . It can also be combined with the complex permittivity of the medium to calculate the Clausius–Mossotti factor, as demonstrated by Huang et al. [29] for yeast cells.

Moving to the behavior of ellipsoidal particles, we find that the dipole moment exerted along the different axes has different dispersion frequencies, so that for example, a prolate (football or rugby ball shaped) ellipsoid will have dispersion along its long axis of different relaxation frequency to the dispersion across its short (but equal) axes. The dispersion frequency of the dipole formed along the long axis will be of lower frequency than that formed across the shorter axes (because the charges have farther to travel from end to end in an alternating field), but the magnitude of the dipole formed will be greater due to the greater separation between the charges.

Consider an elliptical particle such as that shown in cross-section in Figure 159.8. It consists of two axes in projection, x and y , plus a third axis projecting from the page, z . The radii of the object along these axes are a , b , and c , respectively. It can be demonstrated [32,33] that the particle will undergo three dispersions at different frequencies according to the thickness of the ellipsoid along each axis. However, in addition to the dielectrophoretic force experienced by the particle, it will also experience a torque acting so as to align the longest nondispersed axis with the field. This phenomenon, often observed in practical dielectrophoresis, is *electro-orientation* [32,33]. When a nonspherical object is suspended in an electric field (for example, but not solely, when experiencing dielectrophoresis), it rotates such that the dipole along the longest nondispersed axis aligns with the field. Since each axis has a different dispersion, the particle orientation will vary according to the applied frequency. For example, at lower frequencies, a rod-shaped particle experiencing positive dielectrophoresis will align with its longest axis along the direction of electric field; the distribution of charges along this axis has the greatest moment and therefore exerts greatest torque on the particle to force it into alignment with the applied field. As the frequency is increased, the dipole along this axis reaches dispersion, but the dipole formed *across* the rod does not and the particle will rotate 90° and align perpendicular to the field. This smaller axis has a shorter distance for charges to travel between cycles and so the dispersion frequency will be higher; however, the shorter distance means the dipole moment is smaller. This will result in the force experienced by the particle being smaller in this mode of behavior.

When aligned with one axis parallel to the applied field, a prolate ellipsoid experiences a force given by the equation

$$F_{\text{DEP}} = \frac{2\pi abc}{3} \epsilon_m \text{Re}[X(\omega)] \nabla E^2 \quad (159.11)$$

where

FIGURE 159.9 The DEP collection spectrum for cancer cell lines K562 (drug sensitive, open circles) and K562AR (drug resistant, closed circles) scaled to fit the polarization model. The simulation models are denoted by solid and broken lines, respectively. K562 collection starts from 10^4 Hz and starts to decrease at approximately 3 MHz; K562AR collection also starts around 10^4 Hz, but starts decreasing at about 8 MHz, indicating a higher internal conductivity.

$$X(\omega) = \frac{\epsilon_p^* - \epsilon_m^*}{(\epsilon_p^* - \epsilon_m^*)A_\alpha + \epsilon_m^*} \quad (159.12)$$

where α represents the x , y , or z axis and A is the *depolarization factor*, which represents the different degrees of polarization along each axis and takes a value between 0 and 1.

159.2 Applications for Particle Characterization and Separation

As can be seen from Equations (159.1) and (159.2), the frequency-dependent dielectrophoretic response is governed by the Clausius–Mossotti factor. If we can determine the frequency-dependent variation of force or torque, we may then be able to directly determine the value of $K(\omega)$. In fact, this is only truly possible for solid homogeneous spheres or ellipsoids, for which a unique solution of Equation (159.2) exists. Where a particle consists of one or more shells surrounding a central core, the solution can often only be known when the dimensions of each layer are known accurately. Even then, a number of different possible outcome sets often exists, or the solution is insensitive to infinite variation of a particular parameter in the inner core, particularly where there is more than a single shell. In order to overcome this problem, it is often best to approximate the system to a single shell, such as modeling the response of a cell as a membrane surrounding the cytoplasm.

Analysis of the frequency-dependent value of $K(\omega)$ can be performed using dielectrophoresis, usually by measuring the rate at which a population of particles is collected at an electrode array at different frequencies. Examples of dielectrophoretic collection spectra are shown in Figure 159.9, where cancer cells (K562 leukemic cells) have been collected at an electrode edge. The plot shows two sets of data with accompanying best-fit lines according to Equation (159.8); one set was collected for drug-sensitive cells, the other for a drug-resistant counterpart. The model indicates that the resistant cell line has similar membrane properties to the parental line (as indicated by the similar behavior at low frequencies), but has a considerably higher cytoplasmic conductivity, as shown by the continued plateau of high collection extending to higher frequencies before beginning to reduce. The principal drawback with this method of dielectrophoretic data analysis is that it cannot be used to determine the response of a single cell; this would entail returning the cell to an identical position in the electrode array and applying fields of different frequency in order to monitor the force exerted on that cell. For the analysis of single cells the

preferred electrokinetic method is electrorotation, since electrorotation does not exert a translational force on the particle and therefore the induced rotation as a function of frequency can directly give an indication of the imaginary part of the Clausius–Mossotti factor.

Dielectrophoretic methods have been used to analyze the properties of a wide range of particle types. In recent years, the majority of such research has been directed at the study of bioparticles such as cells and viruses, since AC electrokinetic methods offer the opportunity to probe the interior cytoplasm of cells noninvasively and to study the cell interior over time. Common cell types include yeast cells that have been examined in live and dead states [6], and that have been examined across the frequency spectrum to over 1 GHz [34]. Other common cell types include human cells such as blood cells [35] and cancers [36]. Since electrokinetic means are highly sensitive to interior changes, the method has allowed the study of changes occurring in oocytes following fertilization [37], in kidney cells following infection with Herpes viruses [38], and the discrimination among different forms of parasite spores [39]. Dielectrophoretic analysis also offers potential for the analysis of the electrical characteristics of nanoparticles [40,41].

It is possible that in a heterogeneous mixture of particles, groups of particles with different crossover frequencies will experience forces of different sign in the frequency window bounded by the crossover frequencies of the two populations, causing one population to be attracted to high field regions (by ascending the field gradient by positive dielectrophoresis), while the other is repelled (down the field gradient by negative dielectrophoresis) when exposed to an electric field of a particular frequency, allowing the particles to be separated. Similarly, particles with differences in dielectric makeup can be driven in opposite directions along a traveling electric field. Furthermore, a more heterogeneous mix of particles may be fractionated by exploiting small differences in polarizability (and hence force), or by using dielectrophoretic force in conjunction with other factors such as imposed flow or particle diffusion. All these phenomena allow the physical separation of particles according to electrical or other characteristics using dielectrophoresis as the means by which separation is realized. Dielectrophoretic separation devices are presently receiving a great deal of attention, particularly for applications in cell analysis; this is because they have the ability to noninvasively discriminate between cells with identical membrane characteristics but different interior properties. Examples of cell separation by dielectrophoresis include the separation of cancerous and healthy erythrocytes [42], viable and nonviable cells [43], leukemic cells from blood cells [44], species of bacteria [45], and placental cells from maternal blood [46]. Technological advancements have allowed smaller electrode structures to be constructed, which have in turn shown that dielectrophoretic separation of nanoparticles is also possible. Examples of such separations have included those of 92-nm diameter latex beads with varying surface charge [47]; later studies showed that modification of the surface allowed detection of the presence of antibodies [48].

As with cells, so dielectrophoretic separation can be applied to nano-scale bioparticles; for example, different species of virus [49], or components of the same virus [50], have been separated on an electrode array. Furthermore, dielectrophoresis is sensitive enough to detect variations in the state of virus particles when treated with antibiotics [51], with potential applications for drug discovery. Finally, dielectrophoretic separation has also been applied to biological macromolecules such as proteins and DNA fragments [52] by fractionating a mixture of protein and DNA molecules by a combination of field flow and dielectrophoresis.

Many practitioners of dielectrophoresis assert that the most likely future role of these phenomena is in the development of devices called “laboratories on a chip” [53]. Laboratories on a chip are devices wherein the components of a modern laboratory — fluid handling, reactors, heaters, pumps, separators and sensors — are integrated in miniature onto a single device, typically of a size between that of a postage stamp and a credit card. The original “labs on chips” were miniaturized chemistry devices such as capillary electrophoresis columns and liquid chromatographs, but since then the term has expanded to include a wide range of devices from DNA microarrays to miniaturized chemical assays to dielectrophoretic particle sorters. Implementations vary, but a common presentation is to enclose the lab-on-a-chip in a cartridge format that is inserted into another unit containing the ancillary electronics (power supplies, signal generation, optics for analysis, and so forth) and liquid handling (reservoirs and pumps). The liquid

sample to be analyzed is inserted either into the control unit, or into the cartridge itself, where it is processed and analyzed. From a commercial perspective, the reduction in size, with benefits for mass production, transportability, and ease of use, mean that such devices have great potential for point-of-care diagnostics; portable water-screening equipment; and rapid cell, protein, and DNA analysis for rapid drug discovery. Such devices could, for example, potentially allow the testing of blood samples at the patient's bedside, or at least provide the potential for cheap analysis of blood or urine samples on a hospital-by-hospital basis. Another application is for the identification of pathogens such as toxic viruses used for biological warfare. The integrated nature of these devices, combining many analysis methods, lends itself to another general term — micro-total analytical systems, abbreviated microTAS or μ TAS.

Since cells are easily manipulated using dielectrophoresis, and it is possible to discriminate between cell types on the basis of both surface and interior properties, much of the work on dielectrophoretic laboratory-on-a-chip devices has been aimed at the development of particle detectors for medical applications. However, most lab-on-a-chip devices have features in common, the principal one being that they are fabricated using semiconductor methods and operate on small samples (of the order of microliters) using channels etched into glass, photoresist, or some other polymer, through which material is pumped from an external source.

There have been a number of approaches to the application of dielectrophoretic techniques to the laboratory-on-a-chip concept. Perhaps the first example of the use of microengineering techniques to construct a dielectrophoretic laboratory on a chip is the “dielectrophoretic fluid integrated circuit” described by Washizu et al. [54,55]. This device was able to move cells around microfabricated channels and sort them into different outlets. Some researchers have described attempts to perform a range of functions using dielectrophoresis, from separation to trapping and analysis [56]; others have used dielectrophoresis as part of a broader system including electroporation or biochemical methods for cell detection, and using dielectrophoresis primarily as a method for isolating specific cells at a preliminary stage [57].

A complete laboratory-on-a-chip device requires the integration of many subsystems in order to perform useful functions such as particle separation and analysis. A number of workers in the field have constructed such systems, either relying totally on dielectrophoretic methods of particle manipulation, or integrating other methods. Both approaches have advantages; using only dielectrophoresis allows the entire device to be fabricated in a single operation, and since dielectrophoresis requires no extra material beyond what is used (except some ancillary devices for detection fluid handling), operation of the device is easier. However, by restricting the device to all-dielectrophoretic methods, other possibilities of particle discrimination according to factors that do not affect electrical properties — such as the presence of a certain gene — cannot be used, whereas methods borrowed from molecular biology, such as flow cytometry and polymerase chain reaction (PCR) are sensitive to these types of factors.

Where the system relies largely on dielectrophoresis to provide many different functions, there are additional requirements that are placed on the dielectrophoretic system; for example, particles entering a separator should be guided into the device in an appropriate place (where electric field gradient is greatest) or time. An example of this was presented by Cui et al. [58] as part of a traveling-wave dielectrophoresis-based particle separator. Traveling wave methods offer the possibility of highly sensitive particle fractionation, but only if the particles start from one end of the array at the same time; if they drift onto the array at different times, fractionating different types of particles is impossible. In order to avoid this, Cui et al. employed an extra pair of individually addressable electrodes at the beginning of the array. When the traveling field is applied to the remainder of the electrodes, the phases applied to the trapping electrodes can be changed so that they become part of the traveling array, ensuring that all particles start at the same point. Once moving, particles can be detected using laser interrogation of the particles by splicing an optical fiber into the path of the particles, allowing both detection and identification by using fluorescent dyes.

Another proposal for a traveling-wave-based lab-on-a-chip was proposed by Pethig et al. in 1998 [56]. However, unlike the Cui design, traveling wave dielectrophoresis is employed principally as a means of transporting particles between inlets, analysis electrodes and dielectrophoretic traps. However, a novel idea is proposed: by using a forked junction in the traveling wave “conveyor belt,” energized at two

different frequencies, particles could be encouraged into one of the two forward paths according to their dielectrophoretic properties, thereby allowing separation. These junctions could theoretically shift particles toward different dielectrophoretic traps, analysis electrodes, or outlets.

Other workers have used conventional dielectrophoresis as a means of sorting and analyzing particles as they are pumped around the microsystem by using a conventional external pump. In order to organize particles into a single-file sequence for analysis, devices such as dielectrophoretic funnels and concentrators were used [59,60], constructed of triangular electrode arrays placed across the flow. Electrodes are placed at the top and bottom of the array and energized so as to repel the oncoming particles. This forces them toward the constriction at the end of the array, where the gap between the electrodes is small enough to let only a single particle pass. The device was shown to be effective for flow rates up to 3.5 mm/sec^{-1} , allowing high-speed processing of cells to be achieved. Subsequent arrays provide dielectrophoretic trapping, analysis, and switching, the latter process operating by energizing one or two electrodes by negative dielectrophoresis to selectively move the particles toward one of two outlets. Other workers in the field have sought to integrate dielectrophoretic manipulation with other methods. For example, the U.S. company Nanogen has integrated dielectrophoretic trapping of cells with hybridization techniques for bacterial analysis [61–63]. Dielectrophoresis is used to provide initial cell sorting to isolate the bacteria from blood cells, and then trap them on electrodes where a high voltage is used to break apart the bacteria. The DNA then being allowed to drift free, PCR is used to identify the type of bacterium. Other workers have used dielectrophoresis with laser trapping to sort cells, with unwanted cells being trapped by positive dielectrophoresis, and an automated tracking system used to identify bacteria and move them to an outlet port [63]. Finally, some researchers are attempting to move away from traditional planar (semi-two-dimensional) electrode configurations. Our group at Surrey has developed fully three-dimensional electrode arrays using a laminate construction to create electrodes on the scale of those used in conventional dielectrophoresis electrodes, but arranged into tubes; this dramatically increases the throughput of the device, making it possible to analyze many milliliters of analyte in a relatively short time. Furthermore, the device has the advantage of being inexpensive to make, and is not reliant on microengineering principles used for the majority of dielectrophoresis electrodes. An example of this type of array is shown in Figure 159.10.

FIGURE 159.10 A novel multilayered electrode structure formed from laminated conductors and insulators, and with a much higher throughput than two-dimensional (planar) electrode arrays.

159.3 Conclusions

AC electrokinetic phenomena such as dielectrophoresis and electrorotation offer a number of benefits for manipulating particles on the micrometer and nanometer scales. In particular, the phenomena can be applied to the manipulation, separation, and analysis of bioparticles, including cells, viruses, and proteins, as well as allowing analysis of colloids and other particles.

Defining Terms

Dielectrophoresis — The manipulation of matter in nonuniform electric fields.

Electrorotation — The exertion of torque on dielectric particles in rotating electric fields.

Electrokinetics — Imparting forces using electric fields.

Dielectric — Material in which an electrical dipole can be induced.

Trinity College

160.1 Activities of Biomedical Engineers

Today, many of the problems confronting health professionals are of extreme interest to engineers because they involve the design and practical application of medical devices and systems, which are processes that are fundamental to engineering practice. These medically related design problems can range from very complex large-scale constructs, such as the design and implementation of automated clinical laboratories, multiphasic screening facilities (i.e., centers that permit many clinical tests to be conducted), and hospital information systems, to the creation of relatively small and “simple” devices, such as recording electrodes and biosensors, that may be used to monitor the activity of specific physiologic processes in either a research or clinical setting. They encompass the many complexities of remote monitoring and telemetry, including the requirements of emergency vehicles, operating rooms, and intensive care units. Today these problems also include bioprocessing systems, bioinformatics, and biorobotics critical to exploit the information provided by the human genome project. The U.S. healthcare system, therefore, encompasses many problems that represent challenges to *biomedical engineers*.

Although what is included in the field of biomedical engineering is considered by many to be quite clear, there are some disagreements about its definition. For example, consider the terms *biomedical engineering*, *bioengineering*, and *clinical* (or medical) *engineering*, which have been defined in Pacela (1992). While bioengineering has been defined as the broad umbrella term used to describe this entire field, bioengineering is usually defined as a basic research-oriented activity closely related to biotechnology and genetic engineering, that is, the modification of animal or plant cells, or parts of cells, to improve plants or animals or to develop new microorganisms for beneficial ends. In the food industry, for example, this has meant the improvement of strains of yeast for fermentation. In agriculture, bioengineers may be concerned with the improvement of crop yields by treatment of plants with organisms to reduce frost damage. It is clear that bioengineers of the future will have a tremendous impact on the quality of human life. The potential of this specialty is difficult to imagine. Consider the following activities of bioengineers:

- Development of improved species of plants and animals for food production
 - Invention of new medical diagnostic tests for diseases
 - Production of synthetic vaccines from clone cells
 - Bioenvironmental engineering to protect human, animal, and plant life from toxicants and pollutants
 - Study of protein–surface interactions
 - Modeling the growth kinetics of yeast and hybridoma cells
 - Research in immobilized enzyme technology
 - Development of therapeutic proteins and monoclonal antibodies
-

THE WORLD OF BIOMEDICAL ENGINEERING

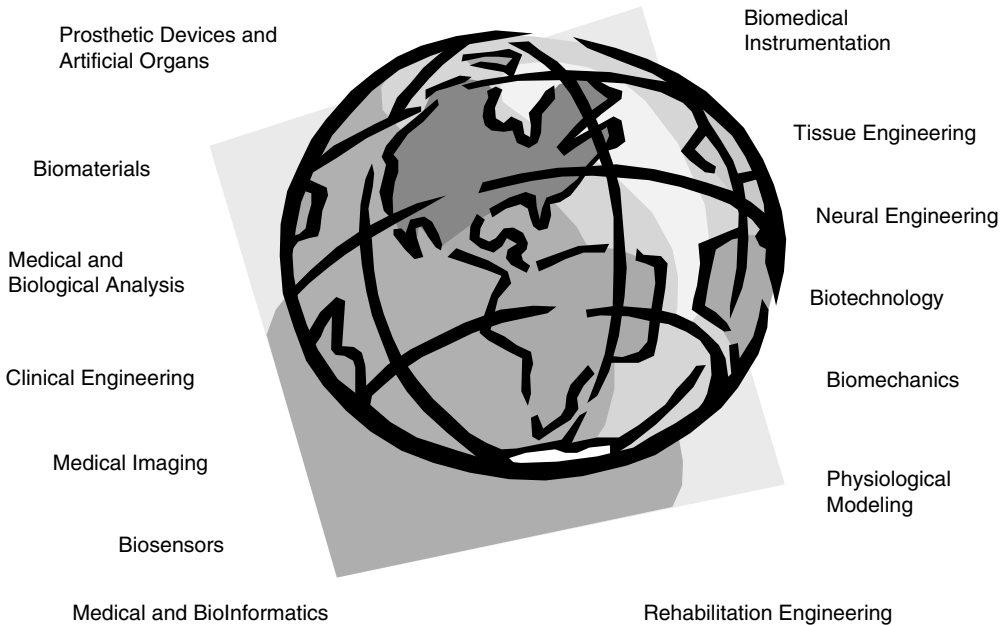

FIGURE 160.1 The world of biomedical engineering.

160.1 Activities of Biomedical Engineers

Biomedical engineers, on the other hand, apply electrical, mechanical, chemical, optical, and other engineering principles to understand, modify, or control biologic (i.e., human and animal) systems, as well as design and manufacture products that can monitor physiologic functions and assist in the diagnosis and treatment of patients. When biomedical engineers work within a hospital or clinic, they are more properly called clinical engineers.

The breadth of activity of biomedical engineers is significant (Figure 160.1). The field has moved significantly from being concerned primarily with the development of medical devices in the 1950s and 1960s to include a more wide-ranging set of activities. The field of biomedical engineering now includes many new career areas, including the following:

- Application of engineering system analysis (physiologic modeling, simulation, and control) to biologic problems
- Detection, measurement, and monitoring of physiologic signals (i.e., biosensors and biomedical instrumentation)
- Diagnostic interpretation via signal-processing techniques of bioelectric data
- Therapeutic and rehabilitation procedures and devices (rehabilitation engineering)
- Devices for replacement or augmentation of bodily functions (artificial organs)
- Computer analysis of patient-related data and clinical decision making (i.e., medical informatics and artificial intelligence)
- Medical imaging, that is, the graphic display of anatomic detail or physiologic function
- The creation of new biologic products (i.e., biotechnology and tissue engineering)

Typical pursuits of biomedical engineers, therefore, include:

- Research in new materials for implanted artificial organs

- Development of new diagnostic instruments for blood analysis
- Computer modeling of human heart function
- Writing software for analysis of medical research data
- Analysis of medical device hazards for safety and efficacy
- Development of new diagnostic imaging systems
- Design of telemetry systems for patient monitoring
- Design of biomedical sensors for measurement of human physiologic systems variables
- Development of expert systems for diagnosis of disease
- Design of closed-loop control systems for drug administration
- Modeling of the physiologic systems of the human body
- Design of instrumentation for sports medicine
- Development of new dental materials
- Design of communication aids for the handicapped
- Study of pulmonary fluid dynamics
- Study of the biomechanics of the human body
- Development of material to be used as replacement for human skin

Biomedical engineering, then, is an interdisciplinary branch of engineering that ranges from theoretical, nonexperimental undertakings to state-of-the-art applications. It can encompass research, development, implementation, and operation. Accordingly, like medical practice itself, it is unlikely that any single person can acquire expertise that encompasses the entire field. Yet, because of the interdisciplinary nature of this activity, there is considerable interplay and overlapping of interest and effort between them. For example, biomedical engineers engaged in the development of biosensors may interact with those interested in prosthetic devices to develop a means to detect and use the same bioelectric signal to power a prosthetic device. Engineers engaged in automating the clinical chemistry laboratory may collaborate with those developing expert systems to assist clinicians in making decisions based on specific laboratory data. The possibilities are endless.

Perhaps a greater potential benefit occurring from the use of biomedical engineering is identification of the problems and needs of our present healthcare system that can be solved using existing engineering technology and systems methodology. Consequently, the field of biomedical engineering offers hope in the continuing battle to provide high-quality health care at a reasonable cost; if properly directed toward solving problems related to preventive medical approaches, ambulatory care services, and the like, biomedical engineers can provide the tools and techniques to make our healthcare system more effective and efficient. For detailed examples of specific research and development activities in this field, see Bronzino (2000).

Surveyors collect measurements that are often critical in supporting the needs and decision-making processes of others. They serve the general public by providing information about property lines, and they serve the engineer by providing a proper stakeout of a subdivision, the distances between pillars of a bridge or the fine placement of machinery in a paper mill. They may provide a state department with an accurate location for a global positioning system (GPS) base station, to which the department ties all its geographic information system (GIS) data. A surveyor may provide geologists with regularly remeasured distances between two monuments on each side of a fault zone in order to monitor movement along that fault zone, or may provide the Federal Aviation Authority with proper coordinates of GPS beacons that aid automated landings of commercial aircraft. A surveyor may monitor the location of large-scale physical experimental apparatus, such as cyclotrons, to ensure that the system is meeting design specifications. In addition, a surveyor provides local departments of natural resources with proper heights for the mapping of flood plains.

Measurement science is one of the main foundations of surveying. Measurements rarely stand by themselves; they are usually part of a larger set, a measurement system. Design of the measurement system — from deciding what results are needed, through deciding on the particular measurements and how they are to be made, to knowing the quality of the measurements and the results and making sure that the required quality is achieved — is a fundamental part of a surveyor's work.

An area of measurement science that is currently considered very little in surveying literature is that of attribute measurement. With the growth of GIS, the collection of attribute data, nonspatial data that describe what is at a location, is becoming a larger part of a surveyor's work. How well can tree species, vegetation type, soil type, land value, land use, and innumerable other attributes be determined? The quality of these measurements has a significant impact on the quality of GIS and the decision making that GIS support. In many cases, working with these data is more difficult than the spatial measurement

data, as statistical tools for the latter are well developed and well understood. We cannot ignore the impact of the quality of nonspatial data in a GIS world.

The importance of the positions, heights, distances, or attributes resulting from various measurements makes the surveyor very careful about the quality of the measurement data, as well as the quality of the results computed from those measurements. Quality control is a central feature of measurement science.

161.1 Assumptions

When a surveyor measures a quantity, such as a distance or an angle, there are some important basic assumptions involved in the measurement processes. As these can have a significant impact on the quality of the results, both actual and perceived, we need to think about these assumptions. The most important assumptions are about independent measurements and the types and distribution of measurement errors.

Most raw measurements that surveyors collect are independent of all other measurements that are being made. A distance measured along one line has no relationship to a distance measured along a different line; an angle at one point is independent of an angle at another point. As such, the raw measurements are usually independent or uncorrelated with each other. But this is not always the case.

As technology becomes more complex with the aim of simplifying the measurement process, the independence assumption may no longer apply to the measurement values that a complex system produces. GPS measurements are very highly correlated to each other (both a point's coordinates and vectors between points). Total station results (e.g., coordinates, horizontal distances) often show correlations, owing to the internal processing of raw measurements. So we must be very careful about how we model our measurements.

For measurements that are independent, there is usually a distribution of random errors, which follows the normal or Gaussian distribution. This is the usual situation for most measurements, but derived quantities may have different distributions. For example, variances follow a chi-square (χ^2) distribution.

We must also define our terminology. Two terms often causing confusion are *accuracy* and *precision*. By precision we mean the repeatability of a measurement. If I measure a distance several times, what is the spread or range of measurements? We often use the standard deviation statistic to tell us something about precision. A large spread or standard deviation suggests poor precision, whereas a small spread or standard deviation suggests good precision. Related to this is how finely we can measure the quantity, but this is a very limited way of looking at precision, as it focuses at just one small part of the situation. By accuracy we mean how close a measurement is to the "true" or "real" value. But we can never know the true value; instead we can only approximate it by measuring the quantity, thereby incurring some error. So the term "accuracy" isn't used a great deal in its common sense, as it does not really tell you anything. However, it is used in a specialized and restricted way, as described in Section 161.6.

While precision can be interpreted as *repeatability*, we would like to narrow the definition of this term. We can consider repeatability to be how well I can repeat the measurement with the same equipment and in much the same circumstances, at about the same time. This will be the case if I measure a distance or angle several times at the same time I am at the site.

We can define the term *reproducibility* as a measure of how well someone else is able to measure the quantity, usually with different equipment, in different conditions and at a different time. This is important in work that must be repeated over time, such as deformation surveys, or that provides data for later work, such as control surveys. The up-to-date-ness (or currency) of the work is important here, as well as what changes might be happening to the objects being measured.

161.2 Errors

Even the most careful surveyor, like anybody else, makes errors — errors in judgment and, not necessarily more important, measurement errors. Some errors cannot be controlled or known at the moment of making the measurement. Some errors cannot be avoided, but should and can be foreseen and a

measurement system designed accordingly. To distinguish among a variety of classes of errors (and this is not a game of semantics), one speaks of the precision of a measurement, the accuracy of a measurement, the reliability of a measurement, and, last but not least, the “up-to-dateness” of a measurement. In this respect, we have to view a measurement in a very loose manner: we may want to address the accuracy of the measurement itself or the accuracy of the variable directly or indirectly related to the actual measurement. In subsequent sections, each type will be addressed.

The classification of errors that will be used in this chapter is often found in the statistical literature (see Papoulis and Unnikrishna [2001], among many others) and the surveying literature:

- Stochastic or random errors
- Systematic errors, including periodic errors
- Blunders or gross errors

The usefulness of this classification is that it suggests causes, and thus ways to deal with and minimize or eliminate the different types of error.

Blunders or gross errors are usually caused by carelessness and can be kept to a minimum by relentless checking (particularly by building independent check measurements into the measurement system) and repeated measurements. For example, we may write down a digit incorrectly or sight to the wrong point. If we have the proper checks built into our entire measurement system, we would expect to detect these errors.

Systematic errors are the result of a mismatch between the model of the measurement process being used to understand and interpret the measurement and the reality of the measurement. For example, I may measure a distance between two points, but neglect to keep the tape horizontal. My model (that I am measuring a horizontal distance) and the reality (that I am measuring a slope distance) are not in agreement. An important characteristic of systematic errors is that a better model of the measurement system can be used to eliminate or minimize them.

Stochastic or random errors are intrinsic to the measurement process and cannot be eliminated by measuring more finely. As the name suggests, they have random individual behavior, but collectively they tend to follow definite statistical patterns. Because of this, we can model their general behavior and take steps to minimize their impact. As a simple example, I measure a distance several times, each measurement having some random error in it. If I compute the mean of the various measurements, this will give me a better estimate of the true value than any individual measurement could have done.

It is important to design the measurement system so that blunders and systematic errors are eliminated, or minimized to the point where these errors are indistinguishable from the stochastic or random errors. The statistical adjustment theory used to minimize the effect of the stochastic or random errors usually assumes that there are only random errors present, and can produce unreliable results if this assumption is not true.

The one constant in our world is change. We know that the very bedrock we always used for long-term stability of marks moves measurably over time, but many other things in the world change much more quickly. Nonspatial, descriptive, or attribute data can change suddenly, such as the owner of a property, or slowly over time, such as the salinity of groundwater. We need to include a time component in our work that acknowledges the fact of change, and if possible a rate of change. GPS Continuously Operating Reference Stations (CORS) include estimates of their movement over time in their general station descriptions, and it is important that this information is available for all types of survey data.

Stochastic errors and blunders first come to mind when talking about precision. Systematic errors are often viewed as an issue of accuracy. Reliability addresses all three types of errors. There are cases where a measurement is very precise but not accurate. In other cases, the measurement or related outcome may be very precise and accurate, but not reliable. In still other cases, a measurement or the resulting parameter may be very precise, very accurate, and very reliable, but not up-to-date, so that the overall quality is still low.

For nonspatial data that are measured, we may find that they do not follow a Gaussian error distribution, as they may be categorical or some other form of data. As Chrisman (2002) has pointed out, there are about ten different basic types of nonspatial data that may have to be dealt with, each requiring

different statistical tools. Section 161.9 deals briefly with nonspatial data, but it is important to be aware that this is another major field of data collection and brings with it a new range of errors.

161.3 Precision

Precision in the classical sense deals with the repeatability of an experiment. A surveyor measures a distance over and over again, and the outcome differs each time. These are errors of a stochastic nature, over which the surveyor has no control. If the readings give the same outcome, the surveyor can make them a little more precise, for instance by reading the tape not to the nearest centimeter but to the nearest millimeter, to make the errors (deviations) appear more obviously random. The surveyor may compute the arithmetic mean of ten distance measurements, according to

$$\hat{\mu} = \frac{\sum_{i=1}^n l_i}{n} \tag{161.1}$$

where $\hat{\mu}$ is the estimate of the true mean μ based on the sample of n observations l_i .

Based on this sample of ten distance measurements l_i , with $i = 1, \dots, 10$ ($n = 10$), the surveyor gets an estimate of the mean distance \hat{l} . Collecting an additional ten distance measurements would undoubtedly give a different mean. This is why we say that the calculated mean \hat{l} is just an estimate of the mean based on that sample. So, for this example, we have

$$\hat{l} = \frac{\sum_{i=1}^{10} l_i}{10} = \frac{l_1 + l_2 + l_3 + \dots + l_{10}}{10} \tag{161.2}$$

In statistics this average is known as the first moment.

A second interesting quantity to look at is the spread of the n observations. If the n observations are close together, we may call our measurement process precise. If the n values vary over a large range, we tend to think of them as the result of a less precise measurement process. To compute the spread, we compute the variations with respect to the estimated mean \hat{l} . We subtract the estimated mean from each individual observation to get a residual v_i :

$$v_i = l_i - \hat{l} \tag{161.3}$$

If we counted how many observations happen to fall within a specified range, we would obtain a histogram, as in Figure 161.1.

FIGURE 161.1 Histogram for n observations l_i .

If we add all the squared residuals, divide the sum by $n - 1$, and take the square root, we obtain an estimate of the standard deviation (we do not divide by n since we already extracted one piece of information from the sample of n observations: the estimate of the mean — and we used this estimate to compute the spread). The sample variance is the square of the sample standard deviation. We have for the sample standard deviation

$$\hat{\sigma} = \sqrt{\frac{\sum_{i=1}^n v_i^2}{n-1}} \quad (161.4)$$

and for the sample variance

$$\hat{\sigma}^2 = \frac{1}{(n-1)} \sum_{i=1}^n v_i^2 \quad (161.5)$$

In statistics the variance is also known as the second moment.

161.4 Law of Propagation of Errors

Often one is interested not so much in the standard deviation of the individual observations (say, those ten distance measurements), but in the standard deviation of the variable x computed from those n observations. Differentially small errors will propagate according to the rules of total and partial derivatives of multivariate calculus. An error dl_i in an observation l_i will propagate into the vector of variables x_j as an error dx_j according to

$$dx_j = \sum_{i=1}^n \frac{\partial x_j}{\partial l_i} dl_i \quad (161.6)$$

For all u variables x_j ($j = 1, \dots, u$), we have

$$\begin{aligned} dx_1 &= \frac{\partial x_1}{\partial l_1} dl_1 + \dots + \frac{\partial x_1}{\partial l_n} dl_n \\ dx_2 &= \frac{\partial x_2}{\partial l_1} dl_1 + \dots + \frac{\partial x_2}{\partial l_n} dl_n \\ &\vdots \\ dx_u &= \frac{\partial x_u}{\partial l_1} dl_1 + \dots + \frac{\partial x_u}{\partial l_n} dl_n \end{aligned} \quad (161.7)$$

or, in matrix form,

$$\vec{dx} = \mathbf{J}_{ji} \vec{dl} \quad (161.8)$$

where the matrix J_{ji} is the so-called Jacobian.

If we collect all the variances of the observations into a matrix V_b , the variances of the variables x_j are computed from

$$\begin{aligned}
 \mathbf{V}_x &= \bar{d}x\bar{d}x^T \\
 &= \mathbf{J}_{ij} \bar{d}l(\mathbf{J}_{ji} \bar{d}l)^T \\
 &= \mathbf{J}_{ij} \bar{d}l\bar{d}l^T \mathbf{J}_{ji} \\
 &= \mathbf{J}\mathbf{V}_l\mathbf{J}^T
 \end{aligned} \tag{161.9}$$

where \mathbf{J}^T is the transpose of the Jacobian in Equation (161.8).

V_x represents the variance/covariance matrix of the variables. Consequently, for the observations l_i , the matrix V_l is

$$\mathbf{V}_l = \begin{bmatrix} \sigma_{l_1 l_1} & \sigma_{l_1 l_2} & \cdots & \sigma_{l_1 l_n} \\ \sigma_{l_2 l_1} & \sigma_{l_2 l_2} & \cdots & \sigma_{l_2 l_n} \\ \vdots & \vdots & \cdots & \vdots \\ \sigma_{l_n l_1} & \sigma_{l_n l_2} & \cdots & \sigma_{l_n l_n} \end{bmatrix} \tag{161.10}$$

In Equation (161.10), $\sigma_{l_i l_i}$ is the variance, as in Equation (161.5). So we have

$$\sigma_{l_i l_i} = \sigma_{l_i}^2 \tag{161.11}$$

In Equation (161.10) $\sigma_{l_i l_j}$ is the covariance. From the covariance, the so-called correlation coefficient $\rho_{l_i l_j}$ can be computed:

$$\rho_{l_i l_j} = \frac{\sigma_{l_i l_j}}{\sqrt{\sigma_{l_i}^2 \sigma_{l_j}^2}} \tag{161.12}$$

The values of the correlation coefficient will range between -1 and 1 . Values close to 1 indicate high positive correlation, or that an error in quantity l_i will cause an error of equal sign and size in quantity l_j . Likewise, values close to -1 indicate that an error in l_i will cause an error with opposite sign in quantity l_j . In general, we have

$$-1 \leq \rho_{l_i l_j} \leq +1 \tag{161.13}$$

In surveying we strive for uncorrelated observations, meaning that $\sigma_{l_i l_j}$ (and so $\rho_{l_i l_j}$) is equal to zero. This results in a diagonal variance/covariance matrix V_l for the observations.

Example: Standard Deviation of the Sample Mean

To compute the standard deviation of the sample mean $\hat{\mu}$, we have to apply the law of propagation of errors. For the error in the sample mean, we have from Equation (161.1) and Equation (161.6),

$$d\hat{\mu} = \sum_{i=1}^n \frac{\partial \hat{\mu}}{\partial x_i} dx_i = \frac{1}{n} \sum_{i=1}^n dx_i \tag{161.14}$$

This leads to the variance of the sample mean

$$\hat{\sigma}_{\bar{\mu}}^2 = n \frac{1}{n^2} \hat{\sigma}_{x_i}^2 = \frac{1}{n} \hat{\sigma}_{x_i}^2 \quad (161.15)$$

or, for the standard deviation of the sample mean,

$$\hat{\sigma}_{\bar{\mu}} = \sqrt{\frac{\sum_{i=1}^n V_i^2}{n(n-1)}} \quad (161.16)$$

This tells us that the standard deviation of the mean of a set of observations is smaller than the standard deviation of the individual measurements from which it was derived, by a factor of the square root of the number of observations:

$$\hat{\sigma}_{\bar{\mu}} = \frac{1}{\sqrt{n}} \hat{\sigma}_{x_i} \quad (161.17)$$

The implication is that to improve the precision of our measurements, we can make more of them. Four times as many observations should reduce the standard deviation of the mean by half, but to improve the standard deviation by an order of magnitude (make it one-tenth of what it was before) would require 100 times as many observations. There is a law of diminishing returns at work here.

Monte Carlo Simulation

The above discussion of the theory of error propagation assumes that determining the Jacobian associated with the measurement process being modeled is fairly straightforward. In some cases involving complex processes, this may not be the case. An alternative is to consider Monte Carlo simulation for a simplified form of error propagation analysis.

With Monte Carlo simulation of error propagation, we take the measurement model and randomly assume a value for each observation, based on actual observation and expected precision. A random number generator is typically used for this purpose, with the results scaled to the appropriate precision and applied to the actual observation. We repeat the process some reasonable number of times, generating different values of each of the observations, based on the statistical behavior of the random errors associated with each observation, and using the random number generator. Modern spreadsheets often include random number generators that can simulate a number of different distributions, and it is very simple to generate a thousand normally distributed values based on the actual observation (as the mean) and the measurement precision (as the standard deviation) and apply these values to the measurement model.

The result is a large number of answers for the derived value, which have a statistical pattern of behavior. The standard deviation can be determined, and the surveyor can see if the specifications for precision of the derived quantities have been met, for example. It is also possible to adjust the various precisions of individual measurements, and thus use this technique as a planning tool to design the measurement system.

In complex measurement environments, it is possible to find points that are particularly sensitive, in that a small change in one variable can lead to a large change in the results. Sometimes this sensitivity is widespread; other times it is restricted to a small range of values. Monte Carlo simulation allows the surveyor to run a wide range of values through the proposed measurement system and undertake a sensitivity analysis of the measurement system as part of the design process.

Monte Carlo simulation is not a replacement for proper error propagation analysis, but it can be a very useful approximate tool for the measurement system design process.

161.5 Statistical Testing

We can test the individual observation against an arbitrary number or against the sample mean. Since the possible outcomes of an experiment, including the values of their sample means and sample standard deviations, are limitless, we work with normalized observations l_i^n :

$$l_i^n = \frac{l_i - \hat{\mu}}{\hat{\sigma}} \quad (161.18)$$

The advantage of the normalized observations is that the expected outcome of the mean is equal to zero, and the standard deviation of the normalized observations is equal to 1. Tables are available in the statistical literature to test any normalized observation against any value.

The probability that an observation lies in the interval $[a, b]$ is readily computable follows:

$$\begin{aligned} P(a \leq l_i \leq b) &= P\left(\frac{a - \hat{l}}{\hat{\sigma}} \leq \frac{l_i - \hat{l}}{\hat{\sigma}} \leq \frac{b - \hat{l}}{\hat{\sigma}}\right) \\ &= P\left(\frac{a - \hat{l}}{\hat{\sigma}} \leq l_i^n \leq \frac{b - \hat{l}}{\hat{\sigma}}\right) \\ &= P\left(l_i^n \leq \frac{b - \hat{l}}{\hat{\sigma}}\right) - P\left(l_i^n \leq \frac{a - \hat{l}}{\hat{\sigma}}\right) \end{aligned} \quad (161.19)$$

Assuming that the standard deviation of a distance measurement is 5 cm and the sample mean is 38.95 m, the probability that an individual observation will fall between 38.90 and 39.10 m is

$$\begin{aligned} P(38.90 \leq l_i \leq 39.05) &= P\left(\frac{38.90 - 38.95}{0.05} \leq \frac{l_i - 38.95}{0.05} \leq \frac{39.05 - 38.95}{0.05}\right) \\ &= P(-1 \leq l_i^n \leq +2) \\ &= P(l_i^n \leq +2) - P(l_i^n \leq -1) \\ &= 0.9772 - 0.1587 = 0.8185 \\ &= 81.85\% \end{aligned} \quad (161.20)$$

Similarly, the probability that the sample mean lies in an interval $[a, b]$ is computed according to Equations (161.16) and (161.19):

$$\begin{aligned} P(a \leq \mu_i \leq b) &= P\left(\frac{a - \hat{\mu}}{\sigma_{\hat{\mu}}} \leq \frac{\mu_i - \hat{\mu}}{\sigma_{\hat{\mu}}} \leq \frac{b - \hat{\mu}}{\sigma_{\hat{\mu}}}\right) \\ &= P\left(\frac{a - \hat{\mu}}{\sigma_{\hat{\mu}}} \leq \mu_i^n \leq \frac{b - \hat{\mu}}{\sigma_{\hat{\mu}}}\right) \\ &= P\left(\mu_i^n \leq \frac{b - \hat{\mu}}{\sigma_{\hat{\mu}}}\right) - P\left(\mu_i^n \leq \frac{a - \hat{\mu}}{\sigma_{\hat{\mu}}}\right) \end{aligned} \quad (161.21)$$

Given the example of ten distance measurements, using Equation (161.5), we first determine that the standard deviation of the mean is

$$\sigma_{\bar{\mu}} = \frac{\sigma_{l_i}}{\sqrt{n}} = \frac{5 \text{ cm}}{\sqrt{10}} = 1.6 \text{ cm} \quad (161.22)$$

Knowing that the standard deviation of the mean of the ten distance measurements is 1.6 cm and the sample mean is 38.95 m, the probability that the mean will fall between 38.94 and 38.97 m is

$$\begin{aligned} P(38.94 \leq \mu_i \leq 38.97) &= P\left(\frac{38.94 - 38.95}{0.016} \leq \frac{\mu_i - 38.95}{0.016} \leq \frac{38.97 - 38.95}{0.016}\right) \\ &= P(-0.625 \leq \mu_i^n \leq +1.250) \\ &= P(\mu_i^n \leq +1.250) - P(\mu_i^n \leq -0.625) \\ &= 0.8944 - 0.2659 = 0.6285 \\ &= 62.85\% \end{aligned} \quad (161.23)$$

Actually, various tests have to be distinguished, depending on the type of variable investigated and whether its standard deviation is considered to be known or unknown [Hamilton, 1964]. When the standard deviation is known, we invoke a normalized test, as in the example above. For tests of variables with an unknown sample standard deviation, we use the Student's *t*-test. Under these circumstances, the mean would fall within the specified limits with a probability of

$$\begin{aligned} P(38.94 \leq \mu_i \leq 38.97) &= P\left(\frac{38.94 - 38.95}{0.016} \leq \frac{\mu_i - 38.95}{0.016} \leq \frac{38.97 - 38.95}{0.016}\right) \\ &= P(-0.625 \leq \mu_i^t \leq +1.250) \\ &= P(\mu_i^t \leq +1.250) - P(\mu_i^t \leq -0.625) \\ &= 0.877 - 0.274 = 0.603 \\ &= 60.3\% \end{aligned} \quad (161.24)$$

To test individual observations and errors attached to them, two tests are available: the normalized residual test, as part of the B-method of statistical testing [Baarda, 1968], and the τ -test, as proposed by Pope [1976].

Normalized Residual Test

The first test computes the normalized residual according to

$$w_i = -\frac{v_i}{\sigma_{v_i}} \quad (161.25)$$

At a specified significance level α_0 , the residuals, v_i of the observations l_i are tested in the following standardized way:

$$|w_i| < \sqrt{F_{1-\alpha_0;1,\infty}} \quad (161.26)$$

with F the related critical value of the F -statistic for one degree of freedom. It should be noted that Equation (161.25) only holds for uncorrelated observations. For the more general case of correlated observations, one is referred to Baarda [1968]. The multidimensional test on the sum of the squared residuals is

$$\frac{\hat{\sigma}_0}{\sigma_0} < \sqrt{F_{1-\alpha_0; r, \infty}} \quad (161.27)$$

where σ_0^2 and $\hat{\sigma}_0^2$ are the *a priori* and *a posteriori* variances of unit weight, respectively; r = the number of degrees of freedom (generally the difference between the number of observations and the number of parameters to be estimated from the observations); and α = the significance level of testing for r degrees of freedom.

For the estimation of the mean (one parameter) from ten distance measurements, we would have $r = n - 1 = 10 - 1 = 9$.

Sigma Zero

To take this type of testing to a practical situation, let us assume that we have adjusted a set of measurements using the method of least squares. Each observation, l_i , will have been adjusted by some amount, v_i , its residual or correction. It is instructive to compare the residuals with the standard deviations of each measurement and see what happened. A large residual compared to the standard deviation may point to a gross error in the observation.

It should be noted that the adjustment process will attempt to adjust out the large residual caused by a gross error over a region of the measurement network, so that adjacent observations may have significant residuals as well. A plot of the residuals mapped over the network can show a “peak” at the location of the gross error.

As a “first pass” at this type of error monitoring, it is a good move to compute a value commonly called *sigma zero* or *the standard deviation of a measurement of unit weight* or the *a posteriori standard deviation of unit weight*. We compute sigma zero as

$$\sigma_0 = \sqrt{\frac{\mathbf{v}^T \mathbf{V}_l^{-1} \mathbf{v}}{n - m}} \quad (161.28)$$

where \mathbf{v} is the vector of residuals (\mathbf{v}^T is that vector transposed), \mathbf{V}_l^{-1} is the inverse of the variance-covariance matrix of the measurements, n is the number of observations and m is the number of unknowns.

In Equation (161.28), the numerator is a single value (actually a 1×1 matrix), which is a χ^2 variable with $n - m$ degrees of freedom. The expected value of such a variable is $n - m$, so Equation (161.28) simply normalizes it to unity.

With the expectation that σ_0 will be 1, we can examine it as a quick check on the quality of an adjustment. If σ_0 is significantly greater than 1, the possibilities are that there is at least one gross error in the observations, or that the assumed precisions of the measurements were too small (i.e., we thought we were better than we actually were). If all the residuals are larger than the standard deviations of the measurements by about the same factor, this may be the problem. Gross errors will usually show up as large corrections in a single region.

If σ_0 is significantly less than 1, it may mean that the standard deviations were estimated too large, or there has been preliminary adjustment of the measurements. The latter case destroys the assumption of uncorrelated observations, rendering the adjustment incorrect in any case.

In the statistical literature, σ_0 is sometimes used to re-scale the original variance-covariance matrix, \mathbf{V}_p , so that the precision of the derived values (usually coordinates of points) is corrected to allow for the

reestimated precisions of measurements. However, while algebraically defensible, this is not always a reasonable or sensible thing to do. If the surveyor has made a reasoned assessment of the precision of the measurements, a value of σ_0 significantly different from 1 is a warning of possible problems in the measurement system or the adjustment and must be followed up. The author knows of only one case where this approach was reasonable and justifiable, and that was over 40 years ago.

What is “significantly different from 1” for σ_0 ? As a very rough guide, $0.8 \leq \sigma_0 \leq 1.3$ is a start, but better values for each particular case can be obtained using Equation (161.27).

Tau-Test

The τ -test avoids the cumbersome computations of the variance/covariance matrix of the residuals [Pope, 1976] needed in the denominator in Equation (161.25). The standard deviation of the residual σ_{v_i} is approximated by

$$\sigma_{v_i} \cong \sqrt{\frac{n-u}{n}} \sigma_{l_i} = \sqrt{\frac{r}{n}} \sigma_{l_i} \quad (161.29)$$

Testing of Variances

For tests of variables of a quadratic nature, such as the variance, we use the so-called χ^2 -test. The probability that the standard deviation lies in the interval $[a, b]$ is readily computable from

$$\begin{aligned} P(a \leq \sigma_{l_i}^2 \leq b) &= P\left(\frac{1}{a} \geq \frac{1}{\sigma_{l_i}^2} \geq \frac{1}{b}\right) \\ &= P\left(\frac{r\hat{\sigma}^2}{a} \geq \frac{r\hat{\sigma}^2}{\sigma_{l_i}^2} \geq \frac{r\hat{\sigma}^2}{b}\right) \\ &= P(\chi_{r;\alpha_0/2}^2 \geq \chi^2 \geq \chi_{r;1-\alpha_0/2}^2) \\ &= 1 - \alpha_0 \end{aligned} \quad (161.30)$$

In our example, we compute that our standard deviation falls, with a probability of 95%, in the interval

$$\left[\sqrt{\frac{r\hat{\sigma}^2}{\chi_{r;\alpha_0/2}^2}} \leq \sigma \leq \sqrt{\frac{r\hat{\sigma}^2}{\chi_{r;1-\alpha_0/2}^2}} \right] \quad (161.31)$$

with the substituted values

$$\left[\sqrt{\frac{9 \cdot 25}{19.02}} \leq \sigma \leq \sqrt{\frac{9 \cdot 25}{2.70}} \right] \quad (161.32)$$

or

$$[3.44 \text{ cm} \leq \sigma \leq 9.13 \text{ cm}] \quad (161.33)$$

For testing ratios of two squared estimates of the same (squared) variable, we use the F -test. Consult [Chapter 166](#) and the statistical literature for more details.

From statistical tables for normally distributed data (see the statistical literature for the definition of a normal distribution), it can be seen that, for instance, 95% of the observations fall in the region $[-1.96\sigma, +1.96\sigma]$. However, in 5% of the cases we may expect to have an observation that is more than 1.96σ away from its mean. This is a good observation (it belongs to the distribution just described) but will probably be removed from the data set. If we make such an “error,” we speak of an *error of the first kind*, or the so-called producer’s error (e.g., a TV manufacturer erroneously rejects a good although deviating specimen). However, if this data set contained a systematic error, such an outlier may be an observation belonging to a set of observations for which the systematic error had been removed. The surveyor is, in this sense, a producer as well: a producer of survey results who does not want to erroneously reject good data. On the other hand, the erroneous acceptance of false data is an *error of the second kind*, or the consumer’s error (e.g., a person purchasing a TV accepts a faulty specimen that erroneously slipped through the manufacturer’s testing procedures). The client of the surveyor should be most worried about this type of error. However, the surveyor generally serving the public or any other client has to design the measurement system in such a way as to minimize these types of errors, or at least the effect of errors of the second kind. The latter type of error brings us to the notions of accuracy and reliability.

161.6 Accuracy

Assume that a surveyor using a tape measures a distance very diligently (the proper tension is applied, temperature corrections are being applied, and so forth), but because of an earlier breakage the tape was repaired, resulting in an even 50 millimeters missing. All distances (assuming that all distances measured are shorter than one tape length) will have outcomes which are highly repeatable (the $\hat{\sigma}_\mu$ is very small); however, all the distance measurements will be 50 millimeters too long. The surveyor got inaccurate results despite a very precise measurement procedure. Inaccuracy is the deviation of the measurement outcomes from the “real” or “true” value of the quantity the surveyor tried to measure. (The adjectives *real* and *true* are in quotes because it can be easily argued that the true value of, say, a distance will never be known, since any measurement process will only provide us with a sample mean, never the true value.)

A very dangerous but widespread practice is to increase the standard deviations of the measurements (remember, the standard deviations reflect precision or repeatability, not accuracy) by a factor of 2 to 10 in order to catch any inaccuracies caused by mismodeling, uncalibrated instrumental errors, setup errors, warming-up effects on a tripod that cause it to torque, personal errors, and so on. So we have

$$\sigma_{\text{accuracy}} = c \cdot \sigma_{\text{precision}} \quad (161.34)$$

with

$$\Sigma_{L_b} = \Sigma_{L_b(t)}(t) \quad (161.35)$$

This procedure is, in effect, an admission of the surveyor’s inability to work to the standards expected with the equipment and situation, as well as a poor understanding of error propagation and analysis.

The preferred procedure is to apply any correction to the observations, such as the personal equation of the surveyor who experiences a consistent delay in the triggering of a chronometer between the moment a star crosses a cross wire and the moment of an audible time signal. Similarly, it is better to strive for the correct atmospheric setting on a total station, rather than increasing the standard deviation of the distance measurements.

It is also important that the surveyor has a good idea of the probable precision of survey measurements and their derived values, so that measurements of a lesser precision are noticed as early as possible. The surveyor must understand the error propagation process, both mathematically and intuitively, so that results can be checked for unexpected errors. In the example of the missing 50 mm in the tape, the measurements should have been checked by measuring enough additional lines to allow

FIGURE 161.2 The one-dimensional test of the normal standardized variable w , shown for hypothesis H_0 and alternative hypothesis H_a .

a closing figure to be developed. Any misclosure in the figure would suggest something was wrong with the tape or the procedures.

Despite all precautions, the surveyor wants, on behalf of the client, to have insight into the size of any inaccuracies that may be avoided by following certain measurement procedures as part of an overall network of measurements. This leads us to the notion of reliability.

161.7 Reliability

Having calibrated the survey equipment, applied temperature corrections, and so on, the surveyor is able to assure himself and the client about the size of the error (inaccuracies) that can be detected with a certain probability under the given circumstances. This is often subject to a cost-versus-effect analysis.

Internal Reliability

To be able to detect distance measurement errors of 10 cm with a probability of 80%, one has to evaluate the distance measurements as an intrinsic part of the overall network design. Increasing the probability from 80% to 90% will increase the cost of the survey. Similarly, the ability to detect errors smaller than 10 cm with a probability of 80% will also considerably increase the cost of the survey. This is an issue of *internal reliability*: what size of measurement error is detectable with what probability? Such errors are referred to as *marginally detectable errors* (MDE). The marginally detectable error is denoted by a nabla (∇).

λ_0 denotes the distance between the normal distribution under the hypothesis (H_0) that the observation belongs to this distribution, and the distribution corresponding to the alternative hypothesis (H_a) (see Figure 161.2). In the statistical literature, one can find tables or graphs depicting λ_0 as a function of the level of significance α_0 and the power of the test β_0 [Baarda, 1968]. Common values for α_0 and β_0 are 5% and 80%, respectively. It can be shown that for uncorrelated observations the marginally detectable error is

$$\nabla_{\sigma} l_i = \frac{\sigma_{l_i}^2}{\sigma_{v_i}} \sqrt{\lambda_0(\alpha_0, \beta_0)} \quad (161.36)$$

Following are three sets of examples for values of α_0 and β_0 :

1. $\lambda_0 = 11.70 [(2.58 + 0.84)^2]$ for $\alpha_0 = 0.01$ (1%) and $\beta_0 = 0.80$ (80%). The alternative distribution is shifted by $\sqrt{11.70} = 3.42$ units.

2. $\lambda_0 = 7.84 [(1.96 + 0.84)^2]$ for $\alpha_0 = 0.05$ (5%) and $\beta_0 = 0.80$ (80%). The alternative distribution is shifted by $\sqrt{7.84} = 2.80$ units.
3. $\lambda_0 = 10.50 [(1.96 + 1.28)^2]$ for $\alpha_0 = 0.05$ (5%) and $\beta_0 = 0.90$ (90%). The alternative distribution is shifted by $\sqrt{10.50} = 3.24$ units.

If we apply Equation (161.36) to the example of section 161.3 (ten uncorrelated distance measurements), we may be able to detect an error of 17.5 cm ($= 25 \cdot 2.8/4$) with a probability of 80% (and level of significance 5%) if $\sigma_l = 5$ cm and the standard deviation of the residuals is $\sigma_v = 4$ cm.

External Reliability

Rather than the size of the marginally detectable error, we are more interested in the effect of the MDE on the actual results computed from the measurements. Repeating Equation (161.8), we assume that variables x_j depend on the measurements l_i according to

$$\vec{dx} = \mathbf{J}_{ji} \vec{dl} \quad (161.37)$$

The influence of a marginally detectable error of the size of $\nabla l_{(i)}$ on the variables x_j can be computed from

$$\nabla \vec{x} = \mathbf{J}_{ji} \nabla l_{(i)} \quad (161.38)$$

It should be noted that the parentheses around the subscript i denote that the vector $\nabla l_{(i)}$ in Equations (161.36) and (161.38) contains all zeros except for the i th observation for which the influence on all variables x_j is computed.

Surveyors design networks to minimize the influence of MDEs in the observations. For classical terrestrial networks this leads to designs avoiding triangles with small angles. Survey resection problems with small top angles lead to large MDEs with large negative effects on the positional accuracy for the point to be resected. In modern surveying using the global positioning system (GPS), dilution of precision (DOP) (see [Chapter 167](#) for an explanation) similarly lead to large MDEs in the GPS observables. In these cases precise and accurate measurements may lead to highly unreliable results because of the system's incapability to flag errors of small magnitude. Large errors in the GPS network positions may go undetected as a result (see [FGCC, 1984] and [FGCC, 1989]).

161.8 Up-to-date-ness or Currency

Precise, accurate, and reliable measurements and the resulting maps may be worthless if they tend to represent locations of a network in a highly dynamic environment. Leveled heights referring to some vertical datum in an area of large annual subsidence may be worthless. Maps showing property boundaries or a GIS land use database for an area where the land use rapidly changes soon become worthless also. We usually want current, up-to-date information, not historical information.

The vector \vec{x}_j of results should be time tagged and reflect the epoch t_0 during which the situation is measured:

$$\vec{x}_j = \vec{x}_j(t_0) \quad (161.39)$$

Models may be available to represent the time history of the vector \vec{x}_j . Transformation parameters are capable of expressing the current result vector $\vec{x}_j(t)$ as a function of the result vector at reference epoch t_0 . In this case, a Jacobian matrix Φ will relate the state of $x_j(t)$ at t to the state of $x_j(t_0)$ at t_0 :

$$\begin{aligned}\bar{d}x(t) &= \frac{\partial \bar{x}(t)}{\partial \bar{x}(t_0)} \bar{d}x(t_0) \\ &= \Phi_{t,t_0} \bar{d}x(t_0)\end{aligned}\tag{161.40}$$

with the state transition matrix being

$$\Phi(t, t_0) = \begin{pmatrix} \frac{\partial x_1(t)}{\partial x_1(t_0)} & \frac{\partial x_1(t)}{\partial x_2(t_0)} & \dots & \frac{\partial x_1(t)}{\partial x_u(t_0)} \\ \frac{\partial x_2(t)}{\partial x_1(t_0)} & \frac{\partial x_2(t)}{\partial x_2(t_0)} & \dots & \frac{\partial x_2(t)}{\partial x_u(t_0)} \\ \vdots & \vdots & \dots & \vdots \\ \frac{\partial x_u(t)}{\partial x_1(t_0)} & \frac{\partial x_u(t)}{\partial x_2(t_0)} & \dots & \frac{\partial x_u(t)}{\partial x_u(t_0)} \end{pmatrix}\tag{161.41}$$

Analytic expressions for the behavior of a set of coordinates as a function of time may be available. These functions may have the character of polynomials or may reflect more realistic (geo)physically or geometrically oriented time behavior.

The ability to represent changes in measurements over time is the essence of deformation surveying, which would also bring us back to the issues of repeatability and reproducibility. If the reproducibility of a set of measurements is significantly lower than its repeatability, it is important to look for causes. Movement of control points is a common cause, as are differences in measurement techniques.

For control and deformation work, the long-term viability of measurement quality includes the issue of stability of marks or monuments. If a surveyor determines the elevation of a mark to first-order standards, but the mark moves enough that the new elevation is now to third-order standards with respect to the measurement from the original mark, the work becomes third order, regardless of its internal quality. Any effort made to achieve higher results was a waste of time and money. So we must pay close attention to stability of control marks. For deformation surveys, the control marks must be assured of being stable, and the measured points must be able to be reoccupied exactly, if the surveyor wishes to ensure the reproducibility precision of the work meets required standards.

161.9 Attribute Data Errors

Nonspatial data collected for GIS are becoming an increasingly important part of a surveyor's work as GIS becomes ubiquitous. As surveyors have a responsibility to know something about the errors involved in the data they collect, it is important that they understand errors in the attribute data.

Attribute data of a location would be the information that a particular point represents a fire hydrant, that a particular line represents Main Street or a property boundary, or that a particular polygon represents Fred Smith's property, a school, or the State of Ohio.

Attribute data must be analyzed in ways that suit the nature of the data themselves. For continuous attribute data, we can often express the error level in ways very similar to spatial measurement data, such as with a standard deviation or confidence interval. However, some types of continuous attribute data encountered in GIS do not lend themselves to this approach, such as probabilities and fuzzy set membership values. It is critical to understand the particular data being handled, their meaning and statistical nature, before embarking on error analysis. Chrisman (2002) outlines some of the types of data encountered.

Categorical attribute data is usually discrete and refers to distinct types of features, such as soil types and land use classifications. While gross errors may be relatively few with careful data collection, a lot of the categorical data are used over a region, and it may be possible to classify a region to more than one category, such as river or vegetation, depending on the spatial resolution of the area being classified. This is a significant problem with remotely sensed data, especially satellite imagery.

TABLE 161.1 Misclassification Matrix

| Class in Database | Class on Ground | | | |
|-------------------|-----------------|---|---|---|
| | A | B | C | D |
| A | — | — | — | — |
| B | — | — | — | — |
| C | — | — | — | — |
| D | — | — | — | — |

One way to test the quality of categorical attribute data is with a misclassification matrix (also called a confusion or error matrix) (Table 161.1). The surveyor selects a number of points at random, using a suitable method of selection, and examines their attributes in the field and as recorded by previous measurements. The appropriate classification is determined in the field, and the matrix is completed for all of the points, with counts for each cell in the matrix being recorded.

Ideally, we want all the points to fall along the diagonal, indicating that all the points are correctly classified. The matrix should not be too large, or the classification process may induce additional errors which are not real errors.

Errors of omission occur when a point's classification on the ground is incorrectly recorded in the database. Errors of commission occur when the classification recorded in the database does not exist on the ground.

To summarize the matrix, we can simply state the number of points correctly classified as a percentage of all points checked. However, even in a totally random data set, we would expect some points to be correct purely by chance. We can adjust the percentage by using Cohen's kappa (sometimes also called the Kappa index of agreement or KIA), as described in Lillesand and Keifer (1999).

Kappa is determined using

$$\kappa = \frac{(d - q)}{(N - q)} \tag{161.42}$$

where d is the number of cases in diagonal cells, q is the number of cases expected in diagonal cells by chance, and N is the total number of cases. $\kappa = 1$ indicates a perfect result, while $\kappa = 0$ indicates agreement no better than chance.

Kappa is sensitive to the number of classes being tested, as well as the number of polygons whose classifications are to be tested. Fewer classes and polygons lead to a better result for kappa. Kappa may well vary over a large region, so it may be misleading to use a single kappa for a large area.

How many points should we test to determine attribute data quality? To some extent, this depends upon the expected level of error. For continuous attribute data, we can estimate the likely error, and call it an estimated standard deviation, s . We look up the standard normal statistical score, z , for the required confidence interval, e (e.g., $e = 95\%$ has $z = 1.96$), and compute the number of points required, n ,

$$n = \frac{z^2 s^2}{(1 - e)^2} \tag{161.43}$$

For categorical attribute data, standard deviations are meaningless, so we estimate p , the proportion of points that will be correct (as a number between 0 and 1), and hence $q = (1 - p)$. The number of points to be sampled, n , is computed by

$$n = \frac{z^2 pq}{(1 - e)^2} \tag{161.44}$$

Examples: Number of Sampling Points

1. We want to test a continuously varying attribute, e.g., elevation, so that we can be 95% confident that the precision is 0.5. How many sample test points do we need to measure?

For $e = 95\%$ (0.95), $z = 1.96$ (from statistical tables), and for $s = 0.5$ we have

$$n = \frac{1.96^2 \times 0.5^2}{(1-0.95)^2} = 384 \text{ points}$$

2. We want to test a categorical attribute, e.g., land use or soil type, so that we are 95% confident that no more than 10% of point are incorrect. How many sample test points do we need to measure?

For $e = 95\%$ (0.95), $z = 1.96$, and for $p = 0.9$ and $q = 0.1$ we have

$$n = \frac{1.96 \times 0.9 \times 0.1}{(1-0.95)^2} = 138 \text{ points}$$

Methods of deciding which points to test on the ground come in three basic schemes: random, regular, or stratified. With random sampling, the surveyor selects the required number of points by some random method, such as a random number generator producing coordinates or sticking pins in a map. It is also possible to draw a regular grid of points over the area of interest and select sufficient points at random from that grid. For a regular selection of points, a grid of a suitable point density is laid over the map, so that all the points on the grid are measured to provide the required number of points. With a stratified scheme, the surveyor selects the areas where the most difficult cases are likely, and concentrates the points in those areas, although still being random in their final location within the area. For checking vegetation types, for instance, more points would be allocated to areas with small polygons of each classification, while proportionally fewer points would be allocated to areas with little variation in vegetation. For checking elevation data, more points would be allocated to areas with greater variation in elevation, and fewer points to those that are relatively flat. This allows better discrimination from a given number of points to be tested.

Journals and Organizations

The latest results from research of statistical applications in geodesy, surveying, mapping, and photogrammetry are published in a variety of journals.

The following are two international magazines under the auspices of the International Association of Geodesy, both published by Springer-Verlag (Berlin/Heidelberg/New York): *Bulletin Géodésique* and *Manuscripta Geodetica*.

Geodesy- and geophysics-related articles can be found in the following publications:

American Geophysical Union, Washington, DC: *EOS* and *Journal of Geophysical Research*
Royal Astronomical Society, London: *Geophysical Journal International*

Statistical articles related to kinematic GPS can be found in:

Institute of Navigation: *Navigation*

Many national mapping organizations publish journals in which recent statistical applications in geodesy/surveying/mapping/photogrammetry are documented, including:

American Congress of Surveying and Mapping; Surveying and Land Information Science; Cartography and Geographic Information Systems

American Society of Photogrammetry and Remote Sensing: *Photogrammetric Engineering & Remote Sensing*

American Society of Civil Engineers: *Journal of Surveying Engineering*

Deutscher Verein für Vermessungswesen: *Zeitschrift für Vermessungswesen*, Konrad Wittwer Verlag, Stuttgart

The Canadian Institute of Geomatics: *Geomatica*

The Royal Society of Chartered Surveyors: *Survey Review*

Institution of Surveyors of Australia: *The Australian Surveyor*

Worth special mention are the following trade magazines:

GPS World, published by Advanstar Communications, Eugene, OR

P.O.B. (Point of Beginning), published by P.O.B. Publishing Company, Canton, MI

Professional Surveyor, published by American Surveyors Publishing Company, Arlington, VA

Geodetical Info Magazine (GIM), published by Geodetical Information & Trading Centre bv., Lemmer, the Netherlands

National mapping organizations such as the U.S. National Geodetic Survey (NGS) regularly make software available (free and at cost). Information can be obtained from: National Geodetic Survey, Geodetic Services Branch, National Ocean Service, NOAA, 1315 East-West Highway, Station 8620, Silver Spring, MD 20910-3282.

Elevation is the distance above or below a specified reference surface. In engineering and surveying, the surface most commonly used to reference elevation is the geoid. The geoid is defined as an equipotential surface that closely approximates mean sea level. However, the geoid and mean sea level surfaces are not coincident. They may be separated by a meter or more at any specific location.

By definition, the potential due to gravity is equal at all points on the geoid, and the force of gravity is perpendicular to the geoid at all points. The geoid is an irregular surface that is affected by density variations within the Earth. The geoid is not readily defined by mathematical equations. The mathematical ellipsoid used as a datum surface for geodetic position can approximate the geoid, but the ellipsoid and geoid will be separated by up to 100 meters or more for a mean global fit. [Figure 162.1](#) illustrates the general relationship between the geoid and some approximating geodetic ellipsoid.

162.1 Measures of Elevation and Height

The vertical distance referenced to the geoid is called an orthometric height (elevation), H . Orthometric height is measured along the plumb line. A height referenced to the ellipsoid is called an *ellipsoidal height*, h . Ellipsoidal height is measured along the normal to the ellipsoid. Geoid height, N , is the distance between the geoid and the ellipsoid measured along the normal to the ellipsoid. Neglecting the deviation between the plumb line and the ellipsoidal normal, the geoid height is related to the orthometric and ellipsoidal heights by the following equation:

$$h = H + N$$

Thus, [Figure 162.2](#) shows a negative geoid height, which is typical in the United States. Values of N can be estimated using the geoid models published by the National Geodetic Survey, National Oceanic and Atmospheric Administration. The current model for the continental United States is GEOID99, and it is available from the National Geodetic Survey at the address given at the end of this chapter.

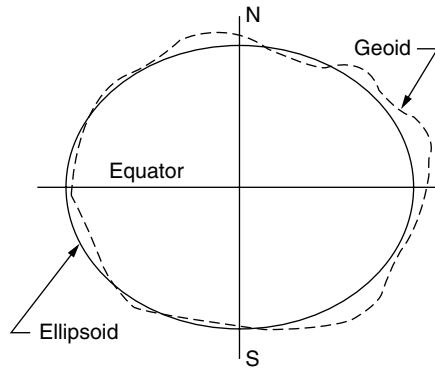

FIGURE 162.1 Relationship between geoid and approximating geodetic ellipsoid.

FIGURE 162.2 Illustration of negative geoid height.

Equipotential surfaces (level surfaces) are not parallel to one another. The distance between the surfaces decreases toward the Earth's north pole. Each level surface has a different gravity potential relative to the geoid that can be expressed as a geopotential number, C , measured in terms of geopotential units: 1 geopotential unit (gpu) = 1000 gal-meters. As an expression of height, the geopotential number (a potential) is constant for a given level surface, whereas the orthometric height decreases for a given level surface proceeding toward the pole. Geopotential numbers can be converted to distance units of height by dividing by a defined value of gravity. Helmert orthometric heights are computed using an estimated mean gravity value based on a constant crustal density, fixed free-air gravity gradient, and linear variation of gravity from geoid to the surface. Known as the Poincaré–Prey model for mean gravity, the calculation is

$$H_{Helmert} = \frac{C}{\bar{g}_H}$$

$H_{Helmert}$ is the Helmert orthometric height, C is the geopotential number on the level surface, and \bar{g}_H is the mean value of gravity along the plumb line between the geoid and the surface. The change in orthometric height between two surface stations can be calculated using the formula found at the end of this chapter.

Another definition of height is dynamic height, H_D , given as

$$H_D = \frac{C}{g_{Constant}}$$

where H_D is the dynamic height, C is the geopotential number on the level surface, and $g_{Constant}$ is some constant value of gravity calculated on the ellipsoid, often at 45° latitude, using a standard gravity formula. The computation simply scales the geopotential number to a linear height value. In the dynamic height system, the elevation of a large body of water would be constant. In the Helmert orthometric height system, the height distance above the geoid at the north end of the water body would be smaller than height distance above the geoid at the south end of the water body.

FIGURE 162.3 Definition of deflection of the vertical.

162.2 Deflection of the Vertical

A vertical or plumb line is perpendicular to the geoid and therefore parallel to the direction of gravity. A normal line is perpendicular to the ellipsoid. Because the geoid and ellipsoid are generally not parallel, a vertical line and a normal line are not coincident for most points on the Earth's surface. The deflection of the vertical is the angle between these two lines at a point on the Earth's surface. Figure 162.3 illustrates the definition of the deflection of the vertical. The deflection of the vertical is generally resolved into two components: ξ in the N-S direction and η in the E-W direction.

The deflection of the vertical has been modeled by the National Geodetic Survey. Program DEFLEC99 estimates the deflection components in the continental United States. The program is available from the National Geodetic Survey at the address given at the end of this chapter.

162.3 Vertical Datums

Vertical datums are defined for the purpose of specifying the elevation of points with respect to the geoid. There are two relevant continental vertical datums within the U.S.: the National Geodetic Vertical Datum of 1929 (NGVD 29) and the North American Vertical Datum of 1988 (NAVD 88).

The NGVD 29, a long-used reference for mean sea level in the U.S. was the product of a 1929 general adjustment of the U.S. and Canadian vertical control networks. The 1929 adjustment was based, in part, upon the assumption that the local mean sea level at the tide stations used in the adjustment was equal (same equipotential surface). This is not a valid assumption since the elevation of mean sea level varies from the Atlantic coast to the Pacific coast of the U.S. This distortion of the vertical datum caused the official name of the 1929 datum to change from "Sea Level Datum of 1929" to "National Geodetic Vertical Datum of 1929" in 1976. Other distortions, including those from upheaval and subsidence of the Earth's crust, are present in the NGVD 29; however, it remains a datum of reference for the U.S.

The most recent adjustment of the vertical datum for North America is known as the NAVD 88. It is a least-squares readjustment of over 600,000 benchmarks across the North American continent, resulting in a better approximation of the geoid. The project includes releveling of approximately 83,000 km of first-order vertical control within the U.S. Leveling data from Canada, Mexico, and Central America are included in the adjustment. The result of the NAVD 88 adjustment is a computer database of vertical control stations and elevations across the U.S. The published values are Helmert orthometric heights. This improved model of the geoid is beneficial for the determination of Helmert orthometric heights using global positioning system (GPS) derived heights above the ellipsoid.

The change in elevations from NGVD 29 to NAVD 88 varies, depending on the area of the country involved. The relative elevation between existing benchmarks changes only by a few millimeters. The

absolute elevation of benchmarks may change by as much as a few decimeters. An elevation correction constant between the two datums will suffice for most project areas.

162.4 Elevation Measurement

Elevation may be measured by several methods. Some of these methods measure elevation directly, such as GPS satellite ranging, photogrammetric aerotriangulation, inertial surveying methods, and barometric altimetry. Some of these methods measure the difference in elevation from a reference benchmark to the point to be determined, such as ordinary and precise differential leveling and trigonometric leveling. It should be noted that the direct methods typically must also be referenced to benchmarks so that translations and rotations can be performed to establish the proper relationship to the elevation datum. Thus, the difference in elevation is, fundamentally, the important value to be measured.

Ordinary Differential Leveling

Differential leveling is a very simple process based on the measurement of vertical distances from a horizontal line. Elevations are transferred from one point to another through the process of using a leveling instrument to read a rod held vertically on, first, a point of known elevation and, then, on the point of unknown elevation.

A single-level setup is illustrated in Figure 162.4. The known elevation of the backsight point is transferred vertically to the line of sight by adding the known elevation and the backsight rod reading. The elevation of the line of sight is the height of instrument, HI. By definition, the line of sight generates a horizontal plane at the instrument location when the telescope is rotated on the vertical axis. The line-of-sight elevation is transferred down to the unknown elevation point by turning the telescope to the foresight, subtracting the rod reading from the height of instrument. Note that the difference in elevation from the backsight station to the foresight station is determined by subtracting the foresight rod reading from the backsight rod reading.

A level route consists of several level setups, each one carrying the elevation forward to the next foresight using the differential leveling method. A level route is typically checked by closing on a second known benchmark or by looping back to the starting benchmark. At the closing benchmark, closure = computed elevation – known elevation. Since differential leveling is usually performed with approximately equal setup distances between turning points, the level route is adjusted by distributing the closure equally to each setup:

$$\text{Adjustment} = \left(-\frac{\text{Closure}}{n} \right) \text{per setup}$$

where n is the number of setups in the route. When a network of interconnected routes is surveyed, a least-squares adjustment is warranted.

FIGURE 162.4 Using differential leveling to measure elevation.

Precise Leveling

Precise leveling methods are used when the highest accuracy is required for engineering and surveying work. Instruments used in precise leveling are specifically designed to obtain a high degree of accuracy in leveling. Improved optics in the telescope, improved level sensitivity, and carefully calibrated rod scales are all incorporated into the differential leveling process.

Typically when performing precise leveling, a method of leveling called *three-wire leveling* is used. This involves reading the center crosshair as well as the upper and lower “stadia” crosshairs. The basic process of leveling is the same as ordinary differential leveling, except that the three crosshair readings are averaged to improve the precision of each backsight and foresight value.

Another method that can be used to improve the precision of the level rod reading is to use an optical micrometer on the telescope. The optical micrometer is a rotating parallel-plate prism attached in front of the objective lens of the level. The prism enables the observer to displace the line of sight parallel with itself and set the horizontal crosshair exactly on the nearest rod gradation. The observer adds the middle crosshair rod reading and the displacement reading on the micrometer to obtain a precise rod reading to the nearest 0.1 millimeter.

Trigonometric Leveling

Trigonometric leveling is a method usually applied when a total station is used to measure the slope distance, S , and the vertical angle, α , to a point. Assuming the total station is set up on a station of known elevation and the height of instrument, HI, and reflector, HR, are measured, the elevation of the unknown station is

$$V = S \sin \alpha$$

$$P_{\text{Elev}} = A_{\text{Elev}} + \text{HI} + V - \text{HR}$$

The precision of trigonometric elevations is determined by the uncertainty in the vertical angle measurement and the uncertainty caused by atmospheric refraction effects. When the effects of Earth curvature and atmospheric refraction must be included, a useful reduction method for trigonometric leveling observations using short- and medium-range total station observations is

$$V = S \left[\sin \alpha + (c - r)_{\text{radians}} \cos \alpha \right]$$

where $(c - r)$ is the combined effect of curvature and refraction. Assuming an average Earth radius and standard atmospheric refraction of light, the effect may be approximated as 4.24 seconds per 1000 feet of distance or 2.055 radians per 1000 feet.

Global Positioning System Heights

The global positioning system (GPS) determines heights relative to the ellipsoid. The ellipsoid heights can be converted to orthometric heights as noted in Section 162.1. However, because of biases in horizontal and vertical datums, the absolute orthometric elevation may not be referenced to the desired datum. GPS survey networks should be adjusted to known benchmarks on the perimeter of the network. Detailed suggested survey and network adjustment procedures are published by the National Geodetic Survey. Results of GPS-determined heights using proper network geometry, adjustment methods, and the GEOID99 model to convert between NAD 83 GPS-derived ellipsoid heights and NAVD 88 Helmert orthometric heights can meet accuracy requirements for some applications.

Instruments

Altimeters

Surveying altimeters are precise aneroid barometers that are graduated in feet or meters. As the altimeter is raised in elevation, the barometer senses the atmospheric pressure drop. The elevation is read directly

on the face of the instrument. Although the surveying altimeter may be considered to measure elevation directly, best results are obtained if a difference in elevation is observed by subtracting readings between a base altimeter kept at a point of known elevation and a roving altimeter read at unknown points in the area to be surveyed. The difference in altimeter readings is a better estimate of the difference in elevation, since the effects of local weather changes, temperature, and humidity that affect altimeter readings are canceled in the subtraction process. By limiting the distance between base and roving altimeters, accuracies of 3 to 5 feet are possible. Other survey configurations utilizing low- and high-base stations or leapfrogging roving altimeters can yield good results over large areas.

Level Bubble Instruments

Level bubble instruments, or spirit levels, contain a level vial with a bubble that must be centered to define a horizontal plane. Field instruments consist of three main components: a telescope to define a line of sight and magnify the object sighted, a level vial attached to the telescope to define the orientation of the instrument with respect to gravity, and a leveling head to tilt and orient the instrument.

All level bubble instruments are designed around the same fundamental relationships. These relationships are as follows:

- The axis of the level bubble (or compensator) should be perpendicular to the vertical axis.
- The line of sight should be parallel to the axis of the level bubble.

When these instrument adjustment relationships are true and the instrument is properly set up, the line of sight will sweep out a horizontal plane that is perpendicular to gravity at the instrument location.

Instruments that use a level bubble to orient the axes to the direction of gravity depend on the bubble's sensitivity for accuracy. Level bubble sensitivity is defined as the central angle subtended by an arc of one division on the bubble tube. The smaller the angle subtended is, the more sensitive the bubble is to dislevelment. A bubble division is typically 2 millimeters long, and bubble sensitivity typically ranges from 60 seconds to 1 second.

Builder's Level

The builder's level typically is less precise than other instruments in this category, but it is one of the most inexpensive and versatile instruments used by field engineers for construction layout. In addition to being able to perform leveling operations, it can be used to turn angles, and the scope can be tilted for inclined sights.

Transit

Although the primary functions of the transit are for angle measurement and layout, it can also be used for leveling because it has a bubble attached to the telescope. However, the field engineer should be aware that the transit may not be as sensitive and stable as a quality level.

Dumpy Level

The engineer's dumpy-type level has been the workhorse of leveling instruments for more than 150 years. Even with advancements in other leveling instruments, such as the automatic level and the laser, the dumpy may still be the instrument of choice in a construction environment because of its stability.

Automatic Compensator Levels

Compensators were developed about 50 years ago and incorporated into field levels. The compensator is a free-swinging pendulum arrangement in the optical path that maintains a fixed relationship between the line of sight and the direction of gravity. If the instrument is an adjustment, the line of sight will be maintained as a horizontal line. Compensator instruments are extremely fast to set up and level.

Laser Levels

A laser level uses a laser beam directed at a spinning optical reflector. The reflector is oriented so that the rotating laser beam sweeps out a horizontal reference plane. The level rod is equipped with a sensor

to detect the rotating beam. By sliding the detector on the rod, a vertical reading can be obtained at the rod point. Laser levels are especially useful on construction sites. The spinning optics can also be oriented to produce a vertical reference plane.

Digital Levels

Digital levels are electronic levels that can be used to more quickly obtain a rod reading and make the reading process more reliable. The length scale on the level rod is replaced by a bar code. The digital level senses the bar code pattern and compares it to a copy of the code held in its internal memory. By matching the bar code pattern, a rod reading length can be obtained. Digital levels are available for ordinary and precise leveling applications.

Level Rods

In addition to the chosen leveling instrument, a level rod is required to be able to transfer elevations from one point to another. The level rod is a graduated length scale affixed to a rod and held vertically on a turning point or benchmark. The scale is read to obtain the vertical distance from the point to the line of sight.

Level rods are graduated in feet, inches, and fractions; feet, tenths, and hundredths, or meters and centimeters. Rods used in ordinary leveling may be multipiece extendable rods with graduations marked directly on the rod material or on a metal strip affixed to the rod for support. Rods used in precise leveling are one-piece rods with a stable invar metal graduated scale supported under constant tension by the rod. A precise rod can be calibrated for changes in length caused by temperature.

Accurate field leveling work is also aided by the use of rod targets, rod levels, and stable turning points when required.

162.5 Systematic Errors

Earth Curvature

The curved shape of the Earth results in the equipotential surface through the telescope departing from the horizontal plane through the telescope as the line of sight proceeds to the horizon. This effect makes actual level rod readings too large by the following approximate relation:

$$C = 0.0239D^2$$

where C is the error in the rod reading in feet and D is the sight distance in thousands of feet.

Atmospheric Refraction

The atmosphere refracts the horizontal line of sight downward, making the level rod reading smaller. The typical effect of refraction is equal to about 14% of the effect of Earth curvature. Thus, the combined effect of curvature and refraction is approximately

$$(C - r) = 0.0206D^2$$

Instrument Adjustment

If the geometric relationships defined in the preceding discussion are not correct in the leveling instrument, the line of sight will slope upward or downward with respect to the horizontal plane through the telescope. The test of the line of sight of the level to ensure that it is horizontal is called the “two-peg test.” If the line of sight is inclined, the difference in elevation obtained from the two setups will not be equal. Either the instrument must be adjusted, or the slope of the line of sight must be calculated. The slope is expressed as a collimation factor, C , in terms of rod reading correction per unit of sight distance. It may be applied to each sight by the following:

$$\text{Corrected rod reading} = \text{Rod reading} + (C_{\text{Factor}} \cdot D_{\text{Sight}})$$

In ordinary differential leveling, these effects are canceled in the field procedure by always setting up so that the backsight distance and foresight distance are equal. The errors are canceled in the subtraction process. If long unequal sight distances are used, the rod readings should be corrected for curvature, refraction, and collimation error.

Orthometric Correction

When long, precise level routes are surveyed, it is necessary to account for the fact that the equipotential surfaces converge as the survey proceeds north. The correction to be applied for convergence of equipotential surfaces at different elevations can be calculated by

$$\text{Correction} = -0.0053 \sin(2\phi) H \Delta\phi_{\text{rad}}$$

where ϕ is the latitude at the beginning point, H is the elevation at the beginning point, and $\Delta\phi$ is the change in latitude from the southerly station to the northerly station expressed in radians. A useful program has been developed by the National Geodetic Survey to assist with this solution. Program LVL_DH converts the published orthometric height difference between two NAVD 88 benchmarks into a leveled height difference by removing the orthometric correction from the published relative height. The program is available from the National Geodetic Survey at the address given at the end of this chapter.

Defining Terms

Benchmark (BM) — A benchmark is a permanent object having a mark of known elevation, such as, a cross-chiseled on a boulder or a concrete monument with an embedded brass disk.

Datum — Any quantity or set of such quantities that may serve as a reference or basis for calculation of other quantities.

Datum sea level — An equipotential surface passing through a specified point at mean sea level that is used as a reference for elevations; a surface passing through mean sea level at certain specified points to which elevations determined by leveling are referred. Note that, in general, the latter surface is not an equipotential surface.

Elevation — The distance, measured along the direction of gravity (plumb line), between a point and a reference equipotential surface, usually the geoid.

Height — The distance, measured along a perpendicular, between a point and a reference surface, such as the ellipsoidal height; the distance, measured along the direction of gravity, between a point and a reference surface of constant geopotential, such as the orthometric height. Note that the term *elevation* is preferred when the geoid is used as the reference surface.

Mean sea level — The arithmetic mean of elevations (heights) of the water's surface observed hourly over a specific 19-year cycle.

Vertical — The direction in which gravity acts.

When the word “distance” is used in surveying without qualification, it is usually construed to mean *horizontal distance* — that is, a distance either measured directly along a horizontal line or measured along a slope and then mathematically projected to the horizontal. If linear measurements along other alignments are being discussed, they are given specific designations, such as *slope distance* or *vertical distance* (elevation difference).

Since ancient times, direct distance measurements have been made using lines, cords, ropes, rods, chains, tapes, and other such devices. Distances have also been measured indirectly, employing stadia and other tacheometric methods, as well as trigonometrically, using a combination of distance and angle measurements and calculations. Technological advances during the last half of the 20th century have created changes in the methods used to measure many distances. During the 1960s and 1970s, most surveyors made a gradual shift from the chain and tape to electronic distance measurement systems that measure distances with light waves or microwaves. During the 1980s, this trend continued into using *total station* systems, which measure both distances and angles electronically and process the combined measurements into a Cartesian coordinate form for the survey points. Thus, many distances are determined by computations from coordinate positions rather than by direct measurements. Most recently, there has been a trend toward using the global positioning system (GPS) for precise determination of positions of points, and these positions are then used to determine indirectly the distances between survey points. Eventually, GPS positioning may replace both the tape and electronic distance instruments (including the total station) for most surveying measurements, including angles, elevations, and distances. GPS is covered in [Chapter 167](#).

An overview of the concepts of direct and indirect distance measurements will be given here. Only the basic measuring procedures and the appropriate corrections needed to achieve optimum accuracy are discussed in this chapter; the geometric, electronic, and other physical principles of the measurement systems will not be discussed in detail. See [Chapter 161](#) for discussion of quality control issues and the basic terminology used here for that aspect of distance measurement.

In a surveying world increasingly dominated by GPS and total stations, it may seem strange to spend as much time and space on taping as this chapter does. The reason for this is that taping manages to include most of the common forms of corrections and errors found in all distance measurements, while allowing them to be studied in a way that is easy to understand.

163.1 Fundamentals of Distance Measurement

The Need for Corrections

Measurements, whether of distance or any other quantity, are but estimates of the magnitude of the quantity. Few initial readings (observations) in surveying contain the accuracy desired without some correction for systematic errors. Much of the consideration today regarding measurements is not so much of how to operate the instruments and perform the calculations to reduce the data, but of how to identify and evaluate the magnitude of the corrections that must be applied to the readings. The “true value,” theoretically, is always equal to the reading plus the corrections. That is, $T = R + \Sigma C$. If the true value is known (which is highly unusual, but a standard distance for calibration would be an example), the reading needed to achieve this is $R = T - \Sigma C$. We can also think of this as knowing a *required* value, such as for setting out points, and computing the actual reading needed to achieve this in the prevailing conditions. Application of this basic concept will be illustrated subsequently. The following sections discuss the typical methods of determining survey distances.

Taped Measurements

Most taped measurements are made using a steel tape, usually of 100-ft length. The tape is laid along a line between points and stretched tight. If the distance desired is longer than the length of the tape, more than one tape length is employed, the ends of the tape being marked with taping pins (sometimes called “arrows”). Alignment of the ends of the tape, to keep the tape on a straight line, is achieved either by hand signals from a rear tapeman or by a transit or theodolite centered over one end of the overall line.

The tape is either allowed to rest on the ground surface (“fully supported”), or suspended throughout its length (“end supported”), with the distance mark on the tape being transferred to the ground using plumb bobs at one or both ends. In the former case corrections for ground slope must be made, the slope having been measured using other instruments, such as hand levels, clinometers, or theodolites. In the latter case, the two ends of the tape are usually held near the same elevation as determined by hand levels or clinometers. End-supported taping requires corrections for the sag of the tape, but possibly not the slope. In either type of taping, corrections must usually be made (depending on the accuracy desired) for calibrated length, changes from calibration temperature to field temperature, and tension (if different from that used when calibrated).

Steel tapes are made in various lengths other than 100 ft, including 25 m, 50 m, 100 m, 200 ft, and so forth. The principles in the use and correction of readings is much the same for various tapes, regardless of length.

Tapes are also made of other materials, including woven fiber and invar (an iridium-nickel-vanadium-steel alloy). The fiber (“cloth”) tapes are used only for rough measurements, and there is usually no attempt to apply corrections to the readings. In contrast, invar tapes are used for precise surveys, such as the establishment of calibration base lines for electronic distance measurements, and all applicable corrections must be made. The use of these more precise tapes and the less precise “cloth” tapes will not be covered here.

Tacheometric Measurements

The most common method in the tacheometry category uses the stadia. Such measurements are made through the telescope of a transit, theodolite, or level instrument. The measurement is achieved by observing where the two horizontal stadia hairs, viewed through the telescope, strike a graduated rod

held vertically on a survey point. The difference between the two readings is a function of the separation of the stadia hairs, the focal length of the telescope, and the distance between the instrument and the rod. When the line of sight is other than horizontal, the vertical or zenith angle must also be considered. Stadia distances are generally accurate to only about 1 or 2 ft for normal sight distances, and thus there is little need to be concerned about corrections to the data, other than for slope. Stadia tacheometry has been largely superseded by total stations, but it is still used occasionally to get a quick, approximate distance, especially when leveling, and to check that level sight lengths are about equal.

The subtense bar is another tacheometric instrument. The principle is the precise measurement of the horizontal angle subtended between two distinct targets at the two ends of the bar. The bar is erected on a tripod so as to lie horizontally and perpendicular to the line of sight, centered over one end of the line. The theodolite is centered over the other end of the line. The separation between the two targets defining the bar is a known length (commonly 2 m). Using this known length and the measured angle, the horizontal distance is computed by trigonometry. For relatively short distances (up to perhaps 150 to 200 ft) this method can exceed the precision of both taping and electronic measurements, and thus it is very useful for measurements across busy streets or other small, inaccessible places. Because this method has no error caused by sloping lines, it is useful for measuring to high places, such as to the tops of buildings. Its application is overlooked nowadays because of the ease of using electronic instruments, even though it is often more precise for short measurements, has advantages similar to those of electronic distance measurement, and avoids slope corrections. We can consider the use of subtense bars for distance measurement to have been totally superseded by total stations.

Electronic Distance Measurements

The most common electronic distance measurement instruments (EDMs) employ an infrared beam reflected off a system of reflectors called *retroprisms*. The infrared beam is reflected onto the instrument for interpretation of the wavelengths and partial wavelengths comprising the double-slope distance between the instrument and the reflector. Older EDMs are individual units, measuring distance only. The most modern versions are part of the aforementioned total station systems, which also measure angles. Whether an individual unit or part of a more complete survey system, the principle of EDM operation is much the same.

A common fallacy, particularly when using total station systems, is that the measurements are free of errors. As has been mentioned, there is error in any measurement system. When measuring with an EDM, the surveyor must be concerned with calibration, just as with any distance-measuring system. For example, the electronic center of the instrument may not be located precisely along the same vertical line as the geometric center plumbed over the ground station. The instrument will usually have this small, constant instrument error, as well as a scale error that is proportional to the distance measured (often called the *parts per million* or *ppm correction*). Also, the reflector has a “constant,” and the optical plummets in the tribrach mounting system can be out of adjustment. Some EDMs may have a “cyclic error,” caused by errors in the determination of the phase differences between the incoming and outgoing signals, which can cause small differences in distance that vary in a cycle with distance. The magnitude and sign of these errors should be determined by field tests for best accuracy. EDMs are also affected by variations in atmospheric pressure and temperature. Microwave measurements are also affected by humidity.

All measurements made with EDMs are “slope” measurements between the center of the EDM and the reflector, and thus must be corrected to horizontal distances using measured vertical or zenith angles, together with instrument and reflector heights.

How Does EDM Work?

The basic idea is that a carrier beam is sent out by the main piece of equipment (the master instrument in microwave systems, or the instrument in visible light and infrared systems) and returned by the other piece of the equipment (the reflectors for visible light and infrared systems, or the remote instrument for microwave systems). Another frequency is superimposed on the carrier wave and it is this that is used

to measure the distance. The superimposition can be done by amplitude modulation, AM (for visible and infrared systems), or frequency modulation, FM (for some of the later microwave equipment). Note that the frequency of the carrier wave remains practically constant, and the meteorological corrections are applied on the basis of the carrier frequency, not the modulating frequencies.

There have been several ways to measure the distance using the superimposed modulating frequencies. The first of these was used by the early Tellurometers, such as the MRA series. Here, the modulating frequencies were set up so that the difference between the different frequencies allowed the determination of parts of the overall distance, in such a manner that the transit time was not the critical factor in measuring the distance. See Bannister et al. (1998) for more detail.

A later method is discussed in Moffitt and Bossler (1999). Here the phase difference of the signal at different frequencies is used to build up the measurement, generally in powers of ten (meters or feet, or some other suitable unit); hence, the term *decade modulation*. Thus, the finest (highest frequency) modulation would yield a measurement of the parts of 10 m, the next would provide the parts of 100 m, the next parts of 1000 m, and so on. This was the approach adopted in the Tellurometer CA1000 and MA100, and the HP 3800 series. The user generally switched between the different modulation frequencies manually, and grouped the recorded measurements to produce the final measurement. The advantage of this method was that the oscillators in the EDM did not have to be good enough to measure the time for the beam to travel, they only had to give a good performance for phase difference measurement and calibration, and to be read out to two or three significant figures. This reduced the cost and weight of EDM.

The process of decade modulation suffered two problems. The first was that measurement was rather time consuming, and that the operator had to change the frequencies manually (and at both ends of the line for microwave systems). Rather than include a lot of servo or heavy electronic equipment, a new method was developed, mainly in infrared laser-based EDMs, of measuring using two modulations that were very close together in wavelength. One of these, set to a 10-m wavelength for example, would yield the parts of 10 m in the distance, generally to the nearest millimeter, that is, 1 in 10,000 precision. The other frequency would measure the distance with a 9.990 m wavelength (as an example only) as the modulation value. The difference between the resulting phase differences from the two frequencies would give the overall distance with no ambiguity up to 10 km. With high-speed electronics and high-quality oscillators in the EDMs, the required 1:10,000 measurement precision is generally well exceeded and two frequencies only are required. The EDM switches between the two to establish the overall distance and then measures a great many “fine” measurements to obtain the mean. The resulting measurement, obtained in a matter of a few seconds, will contain perhaps hundreds of actual measurements averaged to give the best results. Many modern machines continue to update their result as the machine stands, and you may see the last digit change from time to time. See Bannister et al. (1998).

The second problem with decade modulation was that you still needed fairly high-precision oscillators (for the time) in the EDM, and problems with these affected the overall measurements, as well as making the overall machine very expensive. For example, the Tellurometer MA100 (known as the Modlite) needed a small oven to be running to keep the oscillator at the correct temperature, which drained a lot of power. In addition, the decade system in the early days was susceptible to beam interruption, which caused problems with the whole measurement.

Despite all these difficulties, even the most inconvenient EDM was far quicker, a lot easier, and a great deal better than triangulation and taped baseline measurement. The equipment was expensive in the early days, and so out of the reach of most small businesses, but as it became cheaper, it revolutionized the way that surveying was done. It is a classical example of the effects of introducing a new and powerful technology.

The latest development in EDMs is pulsed lasers. These use a timing system for distance measurement, as this is possible with the improved oscillators now available. By making the laser more powerful and the detector more sensitive, you can dispense with the reflector over short distances. This allows you to measure to inaccessible objects easily. Using a visible spot, you can be sure you are measuring to the correct point. These EDM are rather more expensive than conventional systems, but they do allow you to do things you could not do before. See Bannister et al. (1998) for more details.

Today, the two-frequency system is almost universally used in EDMs, with the newer pulsed laser systems starting to appear in more specialized equipment. As the price of the latter falls, we can expect to see greater adoption of the newer technology. Of particular note is the absence of long-range EDM on the market. Distances over a few miles are more commonly measured using GPS today, so most available EDM equipment is capable of only relatively short ranges.

Indirect Computational Methods

Distances are commonly determined by indirect measurement using trigonometric principles. The most common of these methods are *intersection* and the coordinate *inverse*. Using intersection, a distance is measured (or computed from other measurements) and angles measured to a common point from the two ends of this *base line*, which forms an oblique triangle. The unknown sides of the triangle are solved using the sine law. Using the inverse, the computation starts with determination of the departure (difference in x coordinates) and the latitude (difference in y coordinates) of the line defined by the two coordinate points. The distance is the hypotenuse of a right triangle whose sides are the departure and latitude of the line; it is determined using the Pythagorean theorem. Many variations of these indirect methods occur in practice and usually involve some variation of an oblique triangle solution or the coordinate inverse. Some of these concepts are discussed in Section 163.2.

The usual method of coordinate inverse outlined above can be implemented as follows. If we know the coordinates of the two points in some orthogonal coordinate system, for example, (X_1, Y_1) and (X_2, Y_2) , then the distance, d , of the line connecting them can be computed using

$$d = \sqrt{(X_2 - X_1)^2 + (Y_2 - Y_1)^2}$$

The above formula gives the horizontal distance between the two points. If the heights of the points, Z_i , are known, then the slope distance, l , between the points can be calculated using the three-dimensional (3D) extension of the Pythagorean theorem:

$$l = \sqrt{(X_2 - X_1)^2 + (Y_2 - Y_1)^2 + (Z_2 - Z_1)^2}$$

The azimuth of the line, θ , going from point 1 to point 2, based on whatever the zero direction of the coordinate system represents, can be computed using

$$\theta = \arctan \left(\frac{(X_2 - X_1)}{(Y_2 - Y_1)} \right)$$

Note that it is necessary to determine the correct quadrant in which the line lies. The ATAN2() function in the MS-Excel spreadsheet and Fortran can compute this automatically, based on the signs of the numerator and denominator in the formula above.

Photogrammetry is another method for determining distances. After proper orientation of a stereo-model, coordinates can be read from it, from which distances can be determined by the same inverse computation as discussed above. The science of photogrammetry is briefly explained in [Chapter 165](#).

Approximate Methods

As mentioned, all measurements are estimates of an unknown quantity. The method used to determine a distance is chosen as dictated by the precision needed. The above methods are typical for measurements where precisions of a few millimeters to a fraction of a meter are desired. If less precision is needed, a range finder, a measuring wheel, pacing, the odometer on a bicycle or vehicle, map scaling, digitizing coordinates from maps (with subsequent “inverse” computations), or even visual estimation can be used.

Range finders are optical instruments that might be considered under the classification of tacheometric methods. These instruments and the calibrated measuring wheel or an odometer on a bicycle have precisions comparable to the stadia method. A car odometer can yield a precision of perhaps 50 to 100 ft in a mile, if calibrated. The accuracies of the other approximate methods depend on several factors, particularly the map scale and the map accuracy. It must be emphasized that digitizing from maps cannot yield high precisions of positions or distances. Even for a fairly large-scale map, the accuracy of such methods is seldom better than 10 ft.

The importance of approximate methods is that they provide a quick and easy check of the precise methods for gross errors. They can also be used to help find previously placed marks, to help with setting out points on construction and as an aid to data collection for topographic surveys. Skill in using approximate methods can make the overall process much quicker and easier, especially as modern equipment becomes more self-contained and less useful for quick, approximate measurements. For example, one cannot easily use a precise, survey-grade GPS receiver to help look for old monuments or to help draw up a recovery diagram for the surveyed point, but a tape is very useful.

163.2 Applications and Calculations

Taping

The variables affecting a horizontal distance using a tape, with their correction equations, are as follows:

1. *Calibration.* $C_l = l_t - l_r$. The correction per tape length is the actual (“true”) length of the tape minus the nominal length (reading between the end marks). The actual length is determined by calibration at some observed temperature, tension, and support condition, comparing the tape’s length with an accurate baseline.
2. *Temperature.* $C_t = K_t(l)(t_f - t_s)$. Temperature correction is given by the coefficient of thermal expansion multiplied by the nominal length of the tape times the difference between the field temperature and the calibration temperature. The correction is positive when $t_f > t_s$, since the tape expands when the temperature is warmer. The value for K_t is 0.000 006 45 units per unit per degree Fahrenheit (the constant is 0.000 011 6 if degrees Centigrade are used).
3. *Pull (tension).* $C_p = [(P_f - P_s)l]/AE$. This is the correction for tension if the field tension is different from the standardization tension. In this equation, A is the cross-sectional area of the tape and E is the modulus of elasticity, which is 29,000,000 lb/in². Care should be taken that the field tension appears first in the equation, subtracting the standardization tension from it.
4. *Sag.* $C_s = -(w^2l)/(24P^2)$. This is the correction for sag, where w and l are the weight and length of the portion of the tape suspended between supports. The pull, P , is the actual tension on the tape. It has no relationship to the standardization pull.
5. *Slope.* $C_g = -(v^2)/(2s)$. This is the correction for grade or slope, which, when added to the slope length, yields the horizontal distance. This correction is applied when the tape ends are not at the same elevation. In this equation s is the slope distance being corrected and v is the elevation difference between the two tape ends at this length. This equation is approximate but is satisfactory for slopes less than about 10%. The Pythagorean theorem can be used in any case, solving the equation $h = \sqrt{s^2 - v^2}$ for the horizontal distance, h . In the event that vertical or zenith angles have been measured, h can be computed from $h = s \cos \alpha$ or $h = s \sin z$, where α is the measured vertical angle and z is the measured zenith angle. In this case, no correction is computed, but the horizontal distance is calculated directly.

The alignment error is generally not corrected in practice, but instead rendered negligible by the process of careful tape alignment. The correction for pull or tension can be avoided by always using the correct tension. It is common to combine the calibration and temperature correction, by computing the temperature for which the tape is the correct length, and using this as the standardized temperature. This reduces the number of computations, which in turn reduces the potential for gross errors in calculation.

For many errors the correction can usually be made for one tape length and then multiplied by the number of tape lengths, as long as the condition causing the error does not vary between tape lengths. This generally always applies to the calibration, temperature, and tension errors, and sometimes to the sag and slope errors.

Taping problems are of two types: (1) calculation of the horizontal distance between two established points; and (2) calculation of the reading to be observed to establish a given distance. The theory of systematic errors is applicable in making taping corrections. Solving for the true value $T = R + \Sigma C$ is the first type of problem. If “layout” is required, then the reading $R = T - \Sigma C$ is computed from the given value and the corrections.

The following problems will use a calibrated 100-ft tape, found to be 99.992 ft long at 70°F, 15 lb tension, fully supported. It has a cross-sectional area of 0.006 in² and weighs 2.2 lb. In the solutions, N is the number of tape lengths.

Example 163.1

A reading of 458.97 ft is observed between two points when the field temperature is 40°F, along a 4% slope. Find the correct horizontal distance.

Solution. There are three systematic errors to consider: calibration, temperature, and slope.

$$C_L = (l_t - l_r)N = (99.992 - 100.000) \times 4.59 = -0.037 \text{ ft}$$

$$C_t = K_t l (t_f - t_s)N = 0.00000645 \times (100) \times (40 - 70) \times 4.59 = -0.089 \text{ ft}$$

$$C_s = -\frac{v^2}{2l}N = [4^2 \div (2 \times 100)] \times (4.59) = -0.367 \text{ ft}$$

$$\Sigma C = -0.493 \text{ ft, from which } T = 458.97 - 0.49 = 458.48 \text{ ft.}$$

We could also set the standardized temperature for this tape to be the temperature when the tape is exactly 100 ft long:

$$C_t = K_t l (t_f - t_s)$$

$$t_f = \frac{C_t}{K_t l} + t_s$$

$$t_f = \frac{0.008}{(0.00000645 \times 100)} + 70$$

$$t_f = 82.4^\circ \text{ F}$$

Consequently, in future we could apply the temperature correction and allow for the calibration of the tape at the same time, by adopting $t_s = 82.4^\circ \text{ F}$ (or more reasonably 82°F). Note that this temperature will have to be updated with each calibration of the tape.

Example 163.2

A distance of 200 ft is to be laid out along a horizontal alignment. The tape must be suspended for 60 ft of one of its tape lengths. A tension of 30 lb is used for this portion of the layout; otherwise, 15 lb is used. Temperature is 70°F.

Solution. There are three systematic errors to consider: calibration, tension, and sag.

$$C_L = (l_t - l_r)TL = (99.992 - 100.000)2.00 = -0.016 \text{ ft}$$

$$C_p = (P_f - P_s)l \div AE = (30 - 15)60 \div (0.006 \times 29 \times 10^6) = 0.005 \text{ ft}$$

$$C_s = -\frac{w^2 l}{24P^2} = -(2.2 \times 0.6)^2 60 \div (24 \times 30^2) = -0.005 \text{ ft}$$

$$\sum C = -0.016 \text{ ft} \quad \text{and} \quad R = 200.00 - (-0.016) = 200.016 = 200.02 \text{ ft}$$

It is seen in this example that the added tension for the end-supported part of the taping compensated for the sag effect. This works in this case, but it is not recommended as a general practice, as it is necessary to compute the sag correction first, and then find the appropriate tension to correct that effect, when it would be a lot easier and less error-prone to use the correct tension and compute the corrections once after the fact.

What is the quality of taped distances? This depends very much on the care taken with the measurements, whether the tape is calibrated, and the effort put into determining the systematic errors, especially calibration of thermometers and spring balances. For conventional taping with calibrated tapes of about 100 m in length, applying all corrections and taking considerable care about the measurements, we would expect the precision of a single measured distance to be on the order of $\pm 0.020 \text{ m} + 20 \text{ ppm}$. This also assumes that the lines are not longer than about 1 km.

To achieve better results than this, we have to move to invar tapes and the processes used for baselines in the past. This allowed precisions of 10 to 12 parts per million over lines of up to 20 miles.

It can be seen that for high-precision distance measurement EDM is now usually quicker, cheaper, easier and better, but there is still a place for taping, especially if care is taken in its operation.

Stadia

Stadia hairs or lines are placed in most telescopes so that the *stadia interval factor*, K , equals 100. This makes it convenient to measure distance, merely computing the difference between the two stadia hair readings and multiplying by 100 to get the distance between the rod and the theodolite. Since the stadia hairs are each read with a precision of approximately $\pm 0.01 \text{ ft}$ at ordinary distances, the precision of a stadia distance is no better than $\pm 1.0 \text{ ft}$, with variation according to how clearly the rod is seen and how carefully it is read. Elevations are good to no better than $\pm 0.2 \text{ ft}$.

Old *external focusing* telescopes had a *stadia constant*, C , of about 1 ft. However, the instruments of recent generations (post-1920 for European instruments, post-1960 for many U.S. instruments), being *internally focusing*, eliminate this constant, that is, $C = 0$.

For a horizontal sighting $H = KI + C$, assume that K and C are as defined earlier and I is the rod intercept (difference between the upper and lower rod readings). When vertical angles are involved, $H = KI \cos^2 \gamma + C \cos \gamma$, where γ is the vertical angle.

For modern instruments, with a zenith angle of z , we can use

$$H = KI \cos^2 \gamma = KI \sin^2 z$$

$$EL = EL_{IP} + h_t + \frac{KI}{2} \cos 2z - r_C$$

where EL is the elevation of the point sighted, EL_{IP} is the elevation of the point over which the instrument is set, h_t is the height of the instrument's telescope above the point, and r_C is the reading on the rod beneath the center stadia wire (the horizontal crosshair).

Example 163.3

A modern theodolite has a stadia interval factor of 100. The reading on the upper stadia hair is 7.54 ft, and on the lower hair it is 3.66 ft. The zenith angle to the center crosshair is $96^{\circ}36'36''$. What is the horizontal distance, to the nearest foot?

Solution. Assuming the stadia constant to be zero, the appropriate values in the preceding equation are as follows:

$$H = 100 \times (7.54 - 3.66) \sin^2(96^{\circ}36'30'') = 383 \text{ ft}$$

Subtense Bar

After the horizontal angle is measured between the two end targets on the bar, the horizontal distance is computed from $H = \frac{1}{2}bc \cot \alpha / 2$, where b is the bar length and α is the horizontal angle. Using a bar of the usual 2-meter length, the value of H is in meters, since half the bar length is 1 m.

Note that the distance is *always* horizontal, since the horizontal angle is the same regardless of the relative elevation of the two points. Thus, no slope corrections are ever required. In practice, a 1'' theodolite is generally used and several angles are measured, in order to achieve adequate precision.

Example 163.4

A 1'' theodolite is used to measure the angle between the targets on the ends of a 2-meter subtense bar. The mean of six independent readings of the angle is $0^{\circ}45'46''$. Compute the horizontal distance between the theodolite and the bar.

$$H = \frac{1}{2}bc \cot \alpha / 2 = \frac{1}{2}(2 \text{ meters}) \cot(0^{\circ}45'46'' / 2) = 75.110 \text{ m}$$

Electronic Distance Measurements

Although the instrument constant is, in practice, usually adjusted to zero whenever the instrument is serviced, calibration can discover a small instrument constant. Similarly, the reflector constant is usually keyed into the instrument by the surveyor and thus compensated, but a field test of reflector constants can discover slight discrepancies between what the manufacturer states the constant to be and what it actually is. Likewise, the atmospheric errors are generally keyed into the instrument after reading the temperature and pressure but are sometimes overlooked, and an old setting remains in the instrument. The surveyor should be aware of these possible error sources. The following example assumes that the atmospheric errors and reflector constant have been handled properly.

Example 163.5

An EDM has been calibrated using a four-station NGS base line, and errors are found as follows: $C = +0.003 \text{ m}$ and $P = +0.000\ 004\ 56$, where C is the constant correction and P is the "scale" correction, which may be expressed as 4.56 ppm. The zenith angle along the line is $88^{\circ}34'42''$. The observed slope distance is 1789.783 m. What is the corrected horizontal distance?

Solution. The ppm correction is $+0.000\ 004\ 56 (1789.8 \text{ m}) = +0.0082 \text{ m}$. The constant correction is $+0.003 \text{ m}$. The corrected slope distance is

$$1789.783 + 0.008 + 0.003 = 1789.794 \text{ m}$$

$$H = 1789.794 \sin 88^{\circ}34'42'' = 1789.243 \text{ m}$$

An additional correction might be necessary if the reflector is not set at the same height as the EDM because, in this case, the measured slope angle does not correspond to the slope of a line connecting the two ground points. The correction involves adjusting the measured zenith angle before calculating the horizontal distance as done previously.

What is the effect of the meteorological corrections? We find that for the common infrared EDMs, a 1 ppm error in distance is caused by a 1°C error in temperature, a 3.6-hPa error on atmospheric pressure, or a 25-hPa error in vapor pressure. As a consequence, we can generally ignore the effect of humidity for infrared instruments. (However, humidity is the biggest meteorological factor in microwave EDM and should also be allowed for when using infrared EDM in hot, humid conditions.) Thus, for good results from EDM, we must measure the temperature and pressure for each line, and apply the corrections. We should also ensure that the thermometer and barometer used for the EDM are properly calibrated, so that they produce accurate readings. In most cases, the temperature and pressure can be keyed into the total station, which makes the process very quick and simple.

Reflector constants are another source of concern. There are a number of different reflector systems on the market today. The “standard” reflector systems produced by Leica are designed to have their weight balanced, and so have a reflector constant of around –30 mm. Most other standard reflector systems are produced with a zero reflector constant. Leica’s 360° prisms have a reflector constant of around –19 mm, while some of the other 360° systems have different reflector constants. This means that it is important to determine which reflectors are being used, and that the correct constant has been entered into the total station. Most organizations prefer to standardize on one particular type of reflector to avoid this problem, but sometimes it cannot be avoided and the reflector constants in use must be checked in detail.

With some of the reflector mounts currently available, it is possible to set the reflector in two positions: zero constant or –30 mm constant. It is a good idea to check that the reflectors are properly mounted for the settings that are to be used, and all the reflectors are mounted the same way.

With modern total stations that allow any reflector constant to be keyed in, as opposed to earlier EDM that was either pre-set at the factory or had a switch for just the two common settings, it is possible to include the EDM’s offset or constant error in the reflector constant, thereby removing it from consideration. This underlines the importance of thinking about a total station and its reflectors as a single measurement system.

Most modern EDMs are able to achieve a high level of precision, which is commonly expressed using two numbers in the form $\pm x$ mm + y ppm. The first number, x , relates to the constant error of the instrument, plus the effect of centering by the user, plus any cyclic error. The second number, y , is a scale factor and includes the scale error and (mostly) uncertainty in the meteorological correction. EDMs commonly have manufacturers’ claimed precisions of the order of ± 10 mm + 10 ppm, but with the improvement in electronics and the shorter ranges more common today, some instrument makers claim ± 5 mm + 5 ppm for some machines.

If the EDM is properly calibrated, the biggest component of the precision is the meteorological correction. A 10°C error in temperature can lead to a 10-ppm systematic error in the distance, which may exceed the manufacturer’s figures substantially. This is why it is important to pay proper attention to collecting temperature and pressure data for each line.

Sea Level Correction

Distances in surveying are not only assumed to be horizontal distances, but for consistency are also reduced to the equivalent distance at sea level. This is because the distance between two locations on the Earth (expressed using some coordinate system) differs with the elevation of the points. For many applications, this correction is smaller than the other errors in the measurements and can safely be ignored. However, with EDM and GPS being able to span long distances, this correction is necessary to ensure consistency of distances, especially when the surveyor is working with state plane coordinates or trying to tie in to national control points.

The rigorous formula for sea level correction will not be given here, since it is mainly of interest for geodetic surveys, but two useful approximations follow:

$$s = d \left(1 - \frac{h_m}{R + h_m} \right) \text{ or}$$

$$s = d \left(1 - \frac{h_m}{6,365,400} \right)$$

where s is the sea level distance, d is the measured distance, reduced to a horizontal distance, h_m is the elevation of the midpoint of the line, and R is the radius of the Earth. The second, simplified formula can be used for most practical purposes when distances are in meters.

A note on the h_m term: if the h_m is the geoidal or orthometric height, s will be the geoidal distance. If h_m is the ellipsoidal height, then s will be an ellipsoidal distance.

Example 163.6

A surveyor measures a distance with EDM and reduces it to a horizontal distance. The horizontal distance is 5,607.234 m. The midpoint of the line is 348.23 m above the ellipsoid. What is the corrected ellipsoidal distance?

Solution. Substituting the values into the simplified formula above, we obtain

$$s = 5,607.234 \times \left(1 - \frac{348.23}{6,365,400} \right)$$

$$s = 5,606.928$$

We can see that the correction was -0.306 m, which is 54.5 parts per million. This is larger than most meteorological corrections and must be applied for all geodetic work, and for work that ties into a state, national, or international coordinate system.

Laser Scanning

A recent development in surveying equipment has been laser scanners. These work by using a steered pulsed laser beam to scan the field of view before the instrument at a fine resolution. The pulsed laser gives a range to any object that allows a return signal to be reflected, and knowing the direction that the beam was transmitted, the 3D location of the object can be calculated. The result is a large number of 3D points measured to various parts of objects in the field of view, out to a distance of perhaps 100 m.

These points are processed by software that searches for neighboring points and joins those that seem to go together by a series of surfaces. The resulting surfaces and the measurements points can then be downloaded to a suitable 3D CAD package, where a 3D map of the object could now be used as needed. For complex objects, it is possible to link together several scans, based on knowing the scanner's location and orientation at each observation location.

This equipment is capable of recording several thousand 3D points in a matter of minutes, allowing very rapid mapping of complex 3D objects with relatively little effort. It is a direct competitor to digital terrestrial photogrammetry, with the differences that the laser scanner can work well at night, while the photogrammetric equipment can measure longer distances and has a recording system that allows easier interpretation of objects at a later date (although you can always take photographs while running the laser scanner). Laser scanners are still quite expensive, but so is a terrestrial digital photogrammetric system.

Laser scanners have similar errors to pulsed laser total stations, in that distance and direction must be calibrated to ensure that the computed 3D coordinates are of sufficient quality. Measurement of a standardized test range is one method of calibration, with the advantage of being fairly realistic. Some of the autocalibration and in-flight calibration methods used in photogrammetry may be able to be used for laser scanner calibration.

163.3 Calibration of Distance Measuring Equipment

The equipment that the surveyor uses to measure distances must be regularly calibrated to ensure that it is providing results that are both accurate and precise. In some jurisdictions, tapes and EDM must be calibrated every 6 months, and most jurisdictions place a burden of proof of quality of equipment on the professional surveyor.

For most other distance measurement methods, calibration is rarely necessary. This is the case with stadia and estimated methods, although it is necessary to recalibrate one's pacing from time to time. However, tapes and EDM, which carry the work in most serious distance measurement jobs, need to be regularly calibrated.

As mentioned in [Chapter 161](#), there are three main types of errors: gross, systematic, and random. Gross errors can be dealt with by independent checking and additional care. Random errors are intrinsic to the measurement process and can be handled statistically. Systematic errors are the result of a mismatch between the measurement process in reality and the abstract model in use to interpret the measurements. The purpose of calibration is to determine the systematic errors, so that they can be eliminated or minimized by making the measurement model better accord with the reality of the measurement process.

Tapes

Calibration of a tape is fairly simple, once one has established a base line of known length. It is often a good idea for surveyors to set up such a line close to their headquarters. The ideal situation is a flat, level surface for the full length of the tape, preferably in a completely shaded area. If all the tapes to be calibrated are nominally the same length, a zero point fixed in the surface is required at one end, while a second mark is fixed at around the correct distance. It is often handy to fix a small segment of a finely marked measuring tape at the second end, as it can make measuring the tapes a great deal easier.

The surveyor should have a tape that is used as a standard. In some jurisdictions, such tapes must be reserved for calibration purposes only and sent to a government office for regular recalibration. If there is no such facility, a tape should be set aside for calibration purposes only, and calibrated by EDM or some other means (e.g., subtense measurements).

The surveyor begins by allowing the tapes to gain the same temperature as the calibration area, and then measures the line with the standard tape. The advantage of having the piece of tape at the end of the line is that it is fairly simple to determine the point on the ground that corresponds with the correct nominal distance. To do this, the point at which the end of the standard tape falls is noted, and then the distance is corrected to allow for the various systematic errors, which should be only temperature and any calibration constant of the standard.

The tape to be calibrated is then compared to the line and its length noted against the piece of tape. It is then fairly simple to compute the actual length of the tape at that time, and using the temperature correction, compute the temperature at which it is correct.

With a simple calculator program or spreadsheet and some practice, this whole procedure can be done in little more than the time it takes to unroll and roll up the two tapes, and the tape's calibration values are then known.

It is important to ensure that the correct tension is being used during calibration. A little thought in the design of the base line will ensure that all the other corrections are zero, and that temperature is practically constant for the full length of the line. This will help achieve a high quality calibration of the tape.

Electronic Distance Meters

EDM equipment has a slightly different set of systematic errors that must be determined before quality results can be expected. The three systematic errors that are commonly determined by calibration are the zero, offset or constant error, the scale error, and the cyclic error.

The zero, offset or constant error, as mentioned above, is caused by the electronic center of the instrument not being vertically above the measurement mark. It can also be considered to include the reflector constant. It is characterized by appearing with the same sign and magnitude in all measurements that the instrument makes. In most cases, it remains fairly constant over time.

The zero, offset, or constant error can be simply determined by measuring a line in one piece, and then in two (or more) pieces. Each measurement will have the same constant error in it. It is a good idea to ensure that all the meteorological corrections are applied, and that the test line is level.

Example 163.7

A surveyor measures a line with an EDM from one end to the other and finds that it is 210.273 m long. The EDM is then moved to a point lined in on the same line between the end points, and the line measured in two parts from the new point. The two distances are found to be 142.916 m and 67.363 m. What is the zero, offset, or constant error of the EDM?

Solution. Each measurement that the EDM makes, d , can be considered to have two components: the “true” distance, t , and the constant error, e . So the measurement model is $d = t + e$.

For the whole line, the result is

$$d_w = t_w + e$$

For the partial line measurements, the results are

$$d_1 = t_1 + e$$

and

$$d_2 = t_2 + e$$

Now,

$$t_w = t_1 + t_2$$

So,

$$d_1 + d_2 = t_1 + t_2 + 2e = t_w + 2e$$

Therefore

$$(d_1 + d_2) - d_w = e$$

In this example,

$$e = (142.916 + 67.363) - 210.273 = 210.279 - 210.273 = 0.006 \text{ m}$$

The correction, being of the opposite sign to the error, is -0.006 m. Check:

$$t_1 = 142.916 - 0.006 = 142.910$$

$$t_2 = 67.363 - 0.006 = 67.357$$

$$t_w = 210.273 - 0.006 = 210.267 = 142.910 + 67.357$$

EDM scale error is caused by the measurement frequency that is superimposed on the carrier wave being incorrect. This leads to the wavelength of the measurement wave being incorrectly scaled by some

factor, which in turn translates into an error that is directly proportional to the distance that the beam travels. The difficulty in determining this error is that it cannot be checked by the EDM alone, as a constant scale factor applies to all its measurements. The only way to determine this error outside a workshop is to measure lines whose lengths are precisely known. Naturally, the longer the line, the better, which means that the known lines need to be determined by a carefully calibrated high-precision EDM. The preferred machines for this are the Kern Mekometer 3000 and 5000, which use a different form of measurement compared to other EDM and can achieve consistent submillimeter precision.

To calibrate the EDM, it is run over several lines previously calibrated using a high-precision instrument, such as the Mekometer. Once the constant error has been eliminated, the data are used to determine the scale error. The alternative to this is calibration of the EDM's oscillators in an electronics workshop.

It is important to be able to monitor the behavior of the scale error over time. A known, constant scale error can be corrected, but one that varies indicates faulty oscillators, which must be replaced. This requires a workshop visit and takes the instrument out of operation.

Cyclic error in EDM is caused by variability in the reading of the phase differences used to determine the distance. The result is a small difference between the measured value and the correct value that varies in a sinusoidal pattern with a period equal to the wavelength of the measurement unit, commonly 10 m. This was more of a problem in earlier EDMs, and today could be expected to be less than 5 mm.

Cyclic error can be detected in two ways. The first is to place a tape, suitably tensioned, along a flat surface about as long as the wavelength of the measurement unit. The top of an even garden wall is good for this. A reflector is then moved along the tape and a measurement made using the EDM at regular intervals along the tape. The EDM distance and the tape distance are compared to see if there is any pattern to the differences between them. If a sinusoidal pattern of differences appears, this can indicate the presence of cyclic error.

The amplitude and phase offset of the cyclic error are noted, and the correction can then be applied to subsequent measurements. While it can be ignored for some measurements, it is necessary to allow for any cyclic error in the EDM for high-precision work. This means that the surveyor should know if any cyclic error exists in the machine.

The ideal form of calibration for EDM is a purpose-built test range. An example of good ranges can be found in the surveying literature. They commonly consist of up to seven concrete pillars spread over a distance of perhaps 1.2 km. The pillars are often offset, so that it is possible to place reflectors on all the pillars and measure them all at a single setup, without having to turn reflectors away to avoid interference.

The surveyor travels along the line placing reflectors, then returns along the line, setting up the EDM at each pillar in turn and measuring to all the pillars with reflectors. As a result, all combinations of lines are measured.

By careful design of the range, the pillars can be placed so that the various distances provide a complete and even coverage of the wavelength of the measurement unit, allowing the cyclic error to be assessed. Calibration of the range at regular intervals by a high-precision unit, such as a Mekometer, allows the distances to be known and so the scale error to be computed. The process of cumulative distances in Example 163.7 allows the constant error to be determined.

On some test ranges, a form is provided for the results, which are then computed as a service to the surveyor. A least squares adjustment provides the best estimate of the calibration values for the instrument, and a report and certificate of calibration may be issued. If the service also tracks each instrument's calibration history, it is possible to pick up stability problems in oscillators and other problems that may require repair or replacement of the unit.

Defining Terms

Distance — A linear value, either measured or computed. Unless qualified otherwise, it is understood to lie along the horizontal. The observed distance is considered inaccurate until corrected for systematic errors caused by instruments, nature, or other sources.

Electronic distance instrument — An instrument that measures distances using reflected light waves or microwaves.

Indirect measurement — A measurement that has been computed from other measurements, usually employing trigonometric principles.

Mekometer — A high-precision EDM developed at the UK's National Physical Laboratory and produced by the former Kern instrument company. Precision of $\pm 0.2 \text{ mm} + 0.2 \text{ ppm}$ is claimed over distances up to 8 km.

Tacheometry — A distance-measuring procedure that involves measuring intervals between cross hairs on a rod or angles subtended between marks on a bar of known length, or a similar indirect method. The term derives from *fast measurement*.

Tape — A surveying instrument used to measure distance by stretching it, end for end, along a line between points. Also termed a *chain* or *band*.

- [164.2 Meridians](#)
- [164.3 Direction](#)
- [164.4 Back Bearing and Back Azimuth](#)
- [164.5 Applications](#)

In surveying, direction is the term used to denote the course or heading of a line. Here, a line is defined by its end points, giving it a magnitude (length) and direction, much like a vector. By convention, direction is specified in terms of angles and is separated into horizontal and vertical components. This chapter deals primarily with the horizontal component of direction within the context of plane surveys. In geodetic surveys, where the Earth's curvature is taken into account, the fundamental concepts of direction still apply, although their use in subsequent calculations is far more complex.

Traditionally, the basis for direction has been established through astronomic observations or compass readings. Although these traditional approaches may still be applicable in certain situations, the global positioning system is now preferred due to its accuracy and convenience.

164.1 Angles

Angles form the basis for quantification of direction. There are several conventions available for specification of angular units. In the U.S., the sexagesimal system is currently the most commonly used for surveying applications. In this system a full circle is divided into 360 degrees, with further subdivisions into minutes and seconds. Sixty minutes is equivalent to 1 degree and 60 seconds is equivalent to 1 minute. Thus, an angle can be expressed in degrees ($^{\circ}$), minutes ($'$), and seconds ($''$), much like time is expressed in terms of hours, minutes, and seconds. As an alternative, angles can be expressed in terms of degrees and a decimal fraction thereof; however, this is not conventional surveying notation.

Other angular units are available, such as radians, grads, or mils (see equation below for unit equivalents). The radian is a dimensionless unit that utilizes the ratio of the length of a circular arc to its radius to express the magnitude of the subtended angle. The grad (or *gon*) is a unit of measure in the centesimal system (widely used in Europe) that corresponds to $1/400$ of a full circle. The mil is an angular unit corresponding to $1/6400$ of a full circle and is used by the U.S. military, primarily in artillery applications. These three alternate systems are decimal based, as opposed to the base-60 approach of the sexagesimal system.

$$\text{Right angle} = 90 \text{ degrees} = 100 \text{ grads} = 1600 \text{ mils} = \pi/2 \text{ radians} \quad (164.1)$$

Horizontal angles are measured in a plane perpendicular to the direction of gravity. There are many types of horizontal angles, such as angles to right (clockwise) or left (counterclockwise), interior angles,

FIGURE 164.1 Illustration of various types of horizontal angles.

exterior angles, and deflection angles. Figure 164.1 shows the various types of angles. Angles to the right — with the backsight, occupied, and foresight points specified — are recommended for modern surveys due to their applicability to electronic data collectors and computer software. An illustration of this notation is given in Figure 164.1(a), where point A is the backsight, B is occupied, and C is the foresight point.

Vertical angles are measured in a plane perpendicular to the horizontal. There are two fundamental types of vertical angles: zenith angles and altitude angles. A zenith angle (or zenith distance), illustrated in Figure 164.2(a), is the angle from the observer's zenith direction to the target. Zenith angles range

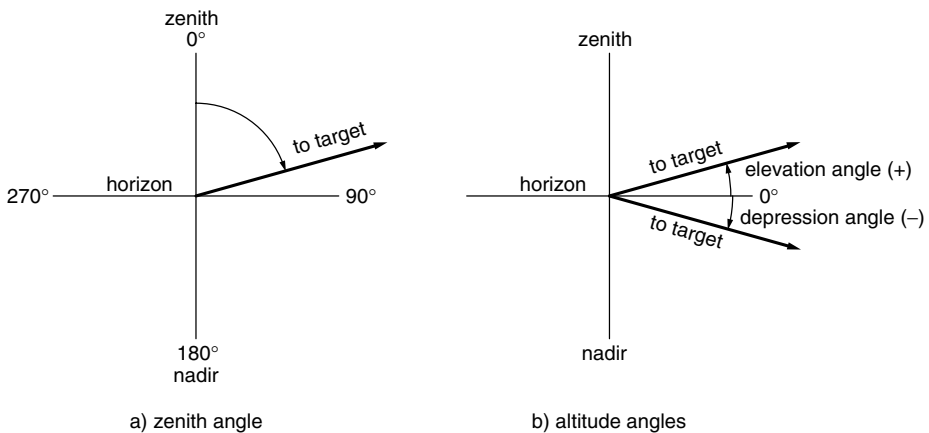

FIGURE 164.2 Profile view illustrating two types of vertical angles.

from 0° to 360° , with 90° and 270° corresponding to the direction of the horizon in the direct and reverse positions, respectively. An altitude angle, illustrated in [Figure 164.2\(b\)](#), is the angle from the observer's horizon to the target. Altitude angles above the horizon are called *elevation angles* and are considered positive by convention, whereas those below the horizon are called *depression angles* and are considered negative.

Surveyors determine angles with instruments known as *transits* or *theodolites*. Both instruments enable the user to perform the same basic functions, that is, to measure or establish horizontal and vertical angles. Generally, theodolites are more accurate and precise than transits, although this is not always the case. Many modern theodolites have electronic angle-reading systems and are incorporated into total stations, which also have the capability of measuring distances electronically. Total stations are particularly convenient due to their ability to transfer recorded data directly to a computer.

164.2 Meridians

In order to specify the horizontal component of direction, it is first necessary to specify the reference meridian. A meridian is an imaginary line that is selected as the nominal north–south indicator in the observer's horizon plane. It can be based on any one of several references: geodetic, astronomic, magnetic, grid, or assumed.

A geodetic (also called *geographic*) meridian is based on the north and south poles as defined by a particular latitude and longitude reference or graticule. It has been demonstrated that the rotational axis of the Earth changes slightly over time, so in essence the geographic graticule is a “snapshot” in time. This reference becomes standardized by virtue of published coordinates for a network of monumented points, based on its definition.

An astronomic meridian is based on the rotational axis of the Earth and the direction of gravity. It derives its name from the means by which it is typically established: astronomic observation. The angular difference between astronomic and geodetic meridians is expressed in terms of the Laplace equation. For most practical purposes in plane surveying, this difference is negligible and both meridians are often collectively referred to as the “true” meridian.

A magnetic meridian is based on the magnetic north and south poles of the Earth. These poles are distinct from the geographic poles and change appreciably over time. The angle from true north to magnetic north is called the *magnetic declination* and is a function of the observer's location with respect to the poles. The effect of magnetic declination can be quite large; for example, in parts of Alaska, magnetic declination is greater than 30° east.

A map projection is a distorted rendition of a portion of the curved Earth's surface projected onto a surface that can be laid out flat. The projection has an inherent x, y coordinate system, with y in the general direction of north. In the projection any line parallel to the y axis is a grid meridian. They are different from the three meridians previously mentioned, in that grid meridians are parallel to each other, whereas the others are not.

Assumed (arbitrary) meridians are chosen for convenience. Here, a direction is arbitrarily specified for a line connecting two survey monuments. This direction is often chosen so as to approximate some specific meridian; however, no actual observation of a meridian is performed. There is an inherent risk associated with assumed meridians. If one or both of the survey monuments is lost, the assumed meridian becomes unrecoverable.

164.3 Direction

In mathematics, polar coordinates are often used to specify the position of a point. Here, the direction of the line from the origin to the point is based on the angle from the positive x axis, with counterclockwise angles being positive. In surveying, the direction of a line can be expressed either in terms of bearing or azimuth. Both forms depend on the meridian definition mentioned earlier. No matter which approach is used, it is important to clearly specify the meridian upon which the direction is based.

FIGURE 164.3 Examples of bearings of selected lines and their equivalent azimuths.

The bearing of a line is specified as an acute horizontal angle between the line and meridian, along with letters specifying the proper quadrant. It is expressed in the form of the letter N or S, followed by an angle (less than or equal to 90°), followed by the letter E or W.

Azimuth is specified as the clockwise horizontal angle from the meridian to the line. The angular value is positive and less than 360° . Azimuths are commonly specified from the north, although this is not a universally accepted standard. Some applications use azimuths that are referenced from the south. Due to this possible ambiguity, one should clearly indicate whether a north or south reference is implied. Figure 164.3 gives examples of bearings and azimuths (from north) for selected lines.

164.4 Back Bearing and Back Azimuth

Back bearings are expressions of the opposite direction of a line. The expression is formed by starting with the original (forward) bearing and then changing the “sense” of the letters. An N is changed to an S (or vice versa), and an E is changed to a W (or vice versa); however, the angular value remains the same. For example, if the bearing from point 1 to point 2 is $N47^\circ15'W$, its back bearing (i.e., the bearing from point 2 to point 1) is $S47^\circ15'E$.

Back azimuths are also expressions of the opposite direction of a line. The expression is formed by adding 180° to or subtracting 180° from the original (forward) azimuth, keeping in mind that the result must be in the range of 0 to 360° . For example, if the azimuth from point 1 to point 2 is $312^\circ45'$, its back azimuth (i.e., the azimuth from point 2 to point 1) is $132^\circ45'$.

The foregoing simple relations for back bearings and back azimuths are applicable only to plane surveys of a limited extent, where it can be assumed that all meridians are parallel. In surveys covering a large area, Earth curvature and meridian convergence are appreciable factors and therefore a more complicated relation must be used.

164.5 Applications

There are many applications in surveying that call for the use of directions. Property surveys, geodetic control surveys, transportation corridor (route) surveys, and topographic surveys are but a few. Most applications involving directions utilize plane trigonometry in the solution. Computations involving addition and subtraction of angles, sine and cosine laws, right triangle relationships, and sum of angles in a closed polygon are routinely performed.

Defining Terms

Azimuth — An expression for the direction of a line consisting of the clockwise horizontal angle ($\geq 0^\circ$ and $< 360^\circ$) from one end of the meridian. Azimuths from the north are generally used; however, some conventions employ azimuth from the south.

Bearing — An expression for the direction of a line consisting of the horizontal angle ($\leq 90^\circ$) that the line makes with the meridian in conjunction with prefixed and postfixed letters that specify the quadrant.

Geodetic survey — A survey in which the Earth's true three-dimensional shape and gravity field are taken into account.

Global Positioning System — A system of satellites and ground receivers that enables users to determine geodetic coordinates of points to a high degree of accuracy. The system is under the control of the U.S. Department of Defense, but has been used for civilian applications since the 1980s.

Horizontal angle — An angle that is defined in a plane perpendicular to the direction of gravity.

Meridian — In a global context a meridian is the intersection of the plane containing the north pole, the south pole, and the observer's position with the spheroidal figure that approximates the Earth. In a local context, a meridian is a reference line that defines the north-south direction. This reference can be on a geodetic, astronomical, magnetic, grid, or assumed basis.

Plane survey — A survey of limited extent and accuracy in which the Earth's surface is assumed to be a plane. This assumption permits the use of plane trigonometry in computations involving coordinates and other parameters.

Total station — A device used in surveying that incorporates an electronic theodolite with an electronic distance-measuring instrument and a computer. The device can automatically read and record horizontal and vertical angles and slope distances.

Vertical angle — An angle that is defined in a plane parallel to the direction of gravity.

165.3 Topographic Mapping in a Geographic Information System

165.4 Delaunay Triangulation and Dirichlet Tessellation

The original introductory written material by Jim Bethel is included here, as well as selected original references [5,6,14,16,17,20,23]. In subsequent sections, Arlinghaus and Austin add their own approach to this material.

The term *photogrammetry* refers to the measurement of photographs and images for determining the size, shape, position, and other spatial attributes of features appearing in the images. The most common application of this technique is aerial photogrammetry, in which nominally vertical photographs are used to produce topographic maps, which are often used for engineering design and land development. Aerial cameras are made to precise tolerances; small systematic errors that may be present in such photographs can be modeled mathematically so that accurate ground positions and elevations can be inferred from measurements based on these photographs. The mathematical basis of the imaging equations that relate object points (three dimensional) to image points (two dimensional) is that of a perspective projection, with a point (actually two points) in the lens assembly serving as the perspective center(s). The geometric relationship between the image and object spaces may be modeled in *analog* fashion by optical rays or by mechanically gimbaled steel rods. Today it is more commonly modeled mathematically in an *analytical* instrument.

Historically, the production of topographic maps from aerial photographs has been a very labor-intensive operation, beginning with the establishment of *ground control points*, proceeding through *aerial triangulation* to densify the ground control, and culminating in the meticulous tracing of planimetric features from adjacent *stereo pairs* and the tracing of contour lines to depict the shape of land forms. In recent years, several trends have emerged which promise to make the mapping process more efficient. The use of the *global positioning system* (GPS), for ground control as well as for direct observation of the *exposure stations* in the aircraft, is greatly simplifying the preliminary steps in the photogrammetric

mapping process. High-level image processing of photographs converted to digital form is replacing the tedious operations of point selection, orientation and even feature extraction.

The following sections discuss the status of photogrammetric technique and suggest one approach to topographic mapping based on the use of GIS software.

165.1 Traditional Methodology

Planning

Typically, the first step in data collection is to obtain planning maps for the project area. These maps are used for the delineation of aircraft flight lines. The maps also are used for preliminary estimates of the numbers of aerial photographs and stereo models to be produced.

After defining the project area on the planning maps, analytical aerial triangulation (“analytics”) technicians identify the location of the control points needed for proper registration and rectification of imagery. These points are noted on the map sheets, which then are delivered to the project surveyors.

During these preliminary stages of production, the surveyors conduct a review of the project’s accuracy specifications, paying particular attention to benchmark and monument requirements. After receiving the annotated map sheets from the analytics technician, the surveyors identify and mark existing benchmarks and monuments within the project area. From these existing positions, the surveyor plans the traverse and bench lines required for horizontal and vertical control, respectively. To supplement the existing benchmarks and monuments, the surveyor establishes temporary benchmarks and temporary stations. These recoverable positions are supplemented, if necessary, to satisfy the requirements defined by analytics technicians.

Photography Acquisition

At this point in production, aerial photography is obtained. The aircraft pilot obtains the annotated planning maps from the surveyor and plans the required flight lines. In some instances, permission to fly over may be needed (particularly if military bases or civil airports are located nearby).

Aerial photography traditionally was collected using panchromatic, black-and-white film, primarily due to cost considerations. In recent years, color film has replaced black-and-white media for many applications due in part to reductions in the costs of the color film and film processing and in part to the benefits of color for image analysis. Nevertheless, certain special-purpose applications continue to use black-and-white film, particularly when budgets are restrictive. Whether color or black-and-white, the film emulsion used for a typical project should be fine grained, low distortion, and high resolution, and the entire project should be flown with one type of film.

Cameras of appropriate focal length (generally 3.5 or 6 in.), certified as calibrated to U.S. Geological Survey (USGS) specifications within the required period of time (most commonly, 3 years), are used. The camera should be equipped with a forward motion-compensating device and a high-resolution, distortion-free lens. A typical resolution for aerial photography would be between 6 in. per pixel and 3 ft per pixel: the smaller the pixel size, the greater the detail that can be seen.

The optimal times for taking aerial photography for topographic mapping are the autumn and spring seasons when there is a reduction of vegetation (i.e., “leaf-off”) and the greatest frequency of clear weather conditions. Aerial photography is acquired after flight plan approval and ground control target placement (for image registration) as weather and ground conditions permit. Photography is done only when the sun angle is greater than 30° to minimize shadows and reduce contrast.

The aerial flyover should be performed with an airborne GPS/IMU (inertial measurement unit) system for direct georeferencing of the aerial photography during the flight. To maintain GPS data quality, aerial photography should be acquired only when at least four and preferably five satellites are observable with a positional dilution of precision (PDOP) of less than three and a cutoff angle/elevation mask greater than 20°.

The altitude at which photography is acquired depends in part on the intended purpose and in part on the project budget. For example, the National Aerial Photography Program (NAPP) that began in 1987 acquired photography on a 5- to 7-year cycle from an altitude of 20,000 feet. The predecessor National High Altitude Photography (NHAP) program acquired photographs at an altitude of 40,000 feet. Contemporarily, aerial photography intended for use in large-scale mapping typically would be captured at an average altitude of 7200', yielding a photonegative scale of 1" = 1200'.

The flight lines for data capture should be oriented in an east-west direction with approximately 7500' spacing, yielding a sidelap (side overlap) of approximately 30% between adjacent flight lines. The flight lines should be extended as required to provide stereo coverage of the designated mapping area and peripheral ground control points. The aerial photography typically provides 60% stereoscopic endlap (end overlap) between exposures in the flight line. The GPS navigation and flight management system are used to trigger the camera automatically with sufficient endlap. Camera tip, tilt, and crab should be limited to not more than 3°.

For quality control purposes, samples from each roll of film are checked for acceptable levels of base fog and density before the film is used. The aerial camera should directly title each frame of the aerial photography at the time of exposure. The title information includes the date, photo scale, camera serial number/focal length, site/project name, project number, and exposure number. Once processed, the aerial photography is checked for acceptable exposure, resolution, contrast, overlap, camera crab, tip and tilt level, and the absence of extraneous markings.

Survey Control

Ground-based survey points consist of targeted control points and checkpoints distributed throughout, and around the perimeter of, the target area. The combination of airborne and ground-based control points supports accurate aerotriangulation of the aerial photography and production of base mapping. Where possible, surveyors should use existing control monuments for the ground control network in place of newly surveyed points.

All new control points should have coordinates established on an appropriate horizontal coordinate system (e.g., NAD83) and elevations established on an appropriate vertical datum (e.g., NAVD88). The horizontal coordinates should be surveyed to at least second-order Class I (1:50,000) accuracy and elevations should be surveyed to at least third-order, 3-cm accuracy. Examples of appropriate new points include easily recognized points (e.g., the intersection of the edge of a bridge with the edge of a paved road) or points that can be made easily recognizable with limited preparation (e.g., painting selected manholes).

After photography is complete, the film is processed, typically by a firm or agency that specializes in aerial photography processing. Two sets of 9" × 9" prints and one set of diapositives, for internal use, typically would be produced in the photography lab. One set of prints generally is reserved for archiving, while the second set of prints is prepared for the field survey. The diapositives are reserved for processing in a later step.

The next production step is selecting photo control. The photographs are laid out and control points are selected and marked on the photographs. Four control points per stereo model (two per photograph) are required for vertical control. Three points are required for horizontal control. Enlargements of the high-altitude flight negatives centered on each section are used to identify horizontal control points.

After selecting and noting photo control, the photogrammetrist delivers the photographs to the surveyor. During the field survey, survey crews determine the elevations and horizontal coordinates for the control points. Description sheets of temporary benchmarks and temporary station recoverable positions are prepared. Depending on the project's specifications, complete field survey notebooks may be maintained for delivery to the client.

The surveyor prepares an overall map of points used (also known as a "control diagram"). The surveyor also performs the computations necessary to close traverses and bench lines. After the survey is completed, the surveyor posts the control point data on the back of the photographs. The photographs then are returned for analytical triangulation.

Fieldwork for a GPS/IMU survey typically involves the operation of one or more GPS base station receivers on the ground for the duration of the flight. The base station receiver(s) should be first-order-certified dual-frequency systems. Within the United States, the station locations should be coordinated with appropriate high-accuracy reference network (HARN) stations. The base stations should be positioned to within approximately 50 km of the aircraft receiver during the flight. Within the United States, National Geodetic Survey (NGS) Continuously Operating Reference Stations (CORS) in the area may be used to provide redundancy. Data from all base stations are processed so that the camera position at the time of exposure can be calculated independently for each station and compared to permit independent confirmation of position.

Analytical Triangulation

Analytical triangulation is performed in the following three phases: (1) photograph plan and layout; (2) point marking and measuring; and (3) data processing with bundle adjustments. With the advent of computers, many technicians use standard software packages for processing. Analytics technicians commit the model coordinates to a computer disk or drive, transfer these data to an appropriate computer, and reformat the data. Technicians then use appropriate computer hardware and software to manipulate the coordinate file to obtain X, Y, Z ground coordinates. The technicians reformat the coordinates and place them in a separate computer file used to achieve registration for digitizing.

For analytical photogrammetry, the positions of all control, orientation, and triangulation pass points (nine points per photo) and orthophoto orientation points (five points per photo) are marked on a set of contact prints. Technicians then “pug” (drill) into the set triangulation diapositives created previously using a calibrated, 1-micron accuracy point-marking-and-transfer device equipped with diamond tip drills. A calibrated analytical stereoplotter with appropriate pointing accuracy interfaced with a data collection station is used to record photo coordinates of the pugged points and fiducials, with the system performing a preliminary triangulation adjustment during the point reading to identify point reading/pugging errors.

The triangulation programs are block-and-bundle refinement-adjustment programs run on an appropriate workstation. The triangulation software accepts ground and/or airborne GPS control data and analytical triangulation pass point input. The software produces a simultaneous polynomial solution with RMS (root mean square) residual values as output.

For the completed triangulation, a triangulation report is prepared. The triangulation report contains summaries of the procedures used, results achieved, printouts of the triangulation input and output (including control points) and weighting factors, adjustment iterations, and triangulation point listings and residuals.

Traditional Photogrammetry

Following analytics processing, stereo compilation is performed. Using stereo compilation instruments, contours are compiled manually to represent contour (hypographic) data. Pairs of overlapping images are examined using stereoscopic viewing instruments, which permit the perception of depth in the image, and are used to identify and draw lines of constant relative elevations. These lines are registered using the control points obtained from surveys and from analytics processing. These manuscripts then are submitted for board (vector) digitizing or scanning.

The process of board digitizing involves the use of highly accurate digitizing tables and digitizing cursors to trace the manuscript contours. In the case of scanning, the stereo compiled sheets are scanned at a relatively high resolution of 12 to 15 lines per millimeter. After scanning is complete, raster system operators edit the data to ensure that contour coalescence is eliminated. The pixel data array then is thinned and prepared for vectorization. The vectorizing process generates a file containing data whose number had been reduced using some standard point-reduction algorithm.

One fairly common adaptation of this traditional method of photogrammetry in later years involved retrofitting the stereo compilation instruments to permit direct interaction with a computer. In this method, contours were digitized directly during compilation, eliminating the manuscript step.

Softcopy Photogrammetry

Contemporary photogrammetry is performed increasingly, and in many cases exclusively, using softcopy techniques. Softcopy, or digital, photogrammetry is based on the use of digital (softcopy) images, as opposed to conventional photogrammetry, which is based on film negative or diapositive (hardcopy) images. "Digital systems are considered third generation photogrammetric instruments, after analytical (second generation) and analog (first generation) stereo plotters" [11: 1-1].

The digital photo imagery used for the project digital orthophotography should be produced by scanning aerial film directly. The scanning should be performed immediately after the film is processed and checked and while it is still in a relatively "pristine" state (i.e., free of surface scratches and dust). The scanning aperture used should be at least 1200 dots per inch (dpi). The scanned imagery should be resampled to the final pixel resolution needed.

For each selected exposure, the scanning covers the entire frame, including fiducials. The imagery initially is rasterized using a project-specific "lookup table" defined by the film type, photographic characteristics, and desired image characteristics. This process permits very fine adjustments of the color balance at the scanning stage. The scanner is recalibrated periodically to ensure proper color distribution.

The interior orientation parameters of each photographic exposure are computed automatically during the scanning phase. These measurements are saved for each image and used for production quality assurance testing as well as softcopy aerotriangulation and stereo compilation. If the root mean square error of the fiducial measurements exceeds predefined tolerances, the negative is scanned again.

Directly scanning the aerial film transparencies is preferable to scanning diapositives, especially if the imagery will subsequently be used to produce digital orthophoto imagery. Direct negative scanning provides better detail visibility in shadow and highlight areas. It also reduces film-handling time prior to scanning, reducing opportunities for dust particles, micro-scratches, and other anomalies that may affect the imagery. In general, direct scanning results in improved image quality, and less time and less cost for digital image production.

In this approach, softcopy analytical aerotriangulation of the aerial photography is used to densify and check the project control and generate orientation parameters as required for the image rectification and mapping work to be performed. The initial input to the triangulation process includes the accurate photo center coordinate data derived from the airborne GPS/IMU survey. This allows the process to converge to a final solution with minimal iteration.

A softcopy aerotriangulation workstation uses image correlation technology to join digital photo image pairs and automatically generate hundreds of pass points for each stereo pair. The generated pass points are run through a preliminary triangulation adjustment with a limited number of measured control points to determine the pass point residuals, with pass points having a greater than predefined residual filtered out. The final triangulation is performed with the accepted pass points and all control points.

Analog and analytical stereo plotters allowed technicians to view film images or photographic prints in stereo by merging adjacent overlapping images through a view piece similar in appearance to fixed-mount binoculars. In softcopy photogrammetry, adjacent digital images are merged in an overlapping fashion to simulate the three-dimensional display. Most commonly, stereo viewing is accomplished using special-purpose eyewear. "A flickerless view is achieved by splitting the high monitor vertical scan rate of 120 fields/sec into alternating left/right fields, each at 60 fields/sec. The viewing system presents to the left and right eye sequentially the corresponding perspective image (aerial camera view), in synchronization with the LCD shutter eyewear at 60 Hz/sec (twice the frequency of VHS video or television. The human brain does the rest" [11: 2-4].

Using this viewing system with a high-power computer workstation and a large monitor (typically 19" or larger), technicians can perform direct stereodigitizing of contours (and planimetric features) with

extremely high accuracy. This approach has several advantages over traditional photogrammetry, including insensitivity to vibration, which permits placement on any floor of an office building, a smaller floor space footprint, and lower cost.

165.2 Recent Enhancements and Advances

Digital Orthophotography

Aerial photo rectification is a process in which the effects of camera crab, tip, and tilt on photographic images are corrected. As a camera points down on the Earth's surface, the image it collects is most accurate at the center of the frame. Rectification also corrects for the distortion of imagery away from the center of the frame. This process allows the assembly of multiple frames into a mosaic of images used as the basis for mapping.

Orthophoto rectification is a process that performs the same function as normal rectification, but also removes the effects of object displacements due to ground relief. This is done mathematically by moving the camera's perspective from the actual flight altitude to "infinity" much like an orthographic map projection. This is based on the use of a terrain model.

In simple terms, the orthophoto is modeled by draping the imagery over a terrain surface model (see Section 165.3), permitting localized adjustments to the rectification. Until recently, there would have been no further correction for objects on the terrain surface (e.g., buildings). However, new modes of data acquisition have made it possible to incorporate object elevations to produce a true continuous surface model.

During digital orthophoto production, compilers accomplish the stereocompilation using softcopy stereoplotting systems interfaced with photogrammetric data collection stations. Data are collected in three dimensions from parallax-cleared stereomodels of the triangulated aerial photography. Stereomodel orientation residuals should be limited to a predetermined error tolerance. The three-dimensional stereocompilation process ensures a correct representation of hydrographic feature elevations and "true" positioning of buildings and other vertical surface features.

The terrain model consists of a grid of spot elevations and "breaklines" compiled along significant breaks in grade. The spot elevations should be collected at an interval averaging 75 ft. The breakline data should generally include major road edges and/or centerlines, railroads, major driveways, major drainage features, large retaining walls, ridges, and other prominent linear discontinuities that would affect the image rectification. Where bridges and elevated overpasses are located, analysts collect breaklines representing the bridge decks, overpass structures, and roofs of taller buildings to support proper orthorectification of these features.

The orthophotography produced should be mosaicked, with consistent balance, tone, and contrast ranges within and between images, ensuring a smooth transition between images, although details in dark tone and highlight areas should be preserved. Mosaicking should be performed using a seaming process that eliminates image distortions caused by aboveground features mosaicked from adjacent photographs. With current technology, image processing and tiling procedures that previously took weeks to accomplish and review manually are now carried out in a matter of hours or days with minimal need for operator interaction.

Digital Image Acquisition

In 1999, Heier and Hinz observed that digital airborne cameras offered several advantages over traditional film-based aerial mapping cameras, including "higher radiometric resolution, reproducible color information, cost savings for film, cost savings for film processing, cost savings for scanning and immediate availability of the image data" [9: 2]. However, they also noted that the technology had not matured to the point that digital airborne cameras offered a complete replacement alternative to traditional camera systems.

As with ordinary digital cameras, the primary data collection mechanism in an airborne digital camera is an array of charge-coupled devices (CCD) that gather light reflected from the Earth's surface. The ideal sensor would be a single large CCD element with the same dimensions (or greater) of traditional camera film (240 mm × 240 mm). At present, technical and economic considerations preclude the use of such a sensor, hence an array of multiple smaller elements.

The greatest relative deficiency of airborne digital cameras is geometric resolution: "230 mm aerial film can be digitized . . . with a pixel size of 7 μm. This resolution would correspond to a sensor resolution of 32,800 pixels" [9: 2]. No airborne digital camera currently offers this resolution. Moreover, an uncompressed 12-bit color image would require approximately 4.5 gigabytes of storage and a complete roll of aerial film would require approximately 2.7 terabytes. While this volume of storage is not an insurmountable obstacle (at least on the ground), it does represent a technical issue to be overcome.

These deficiencies notwithstanding, digital airborne cameras have become an integral part of the cartographer's tool set. It is clear that the benefits of digital imagery will encourage continued technical evolution.

Light Detection and Ranging

Remote sensing is the science and art of collecting information about an object, area, or phenomenon through the analysis of data acquired by a device that is not in physical contact with the object, area, or phenomenon under investigation. On July 23, 1972, the U.S. National Aeronautics and Space Administration launched the first in a series of remote sensing satellites. Initially designated Earth Resources Technology Satellite-A (ERTS-A), this platform was renamed ERTS-1 after launch. Since that time, satellite remote sensing (originally relatively small-scale imagery) has evolved to the point that 0.5-m imagery is commercially available.

The small-scale imagery acquired by satellite platforms offers several advantages over aerial photography. The imagery provides a regional view (large areas) and provides repetitive views of the same areas. The imagery views a broader portion of the spectrum than the human eye and focuses on very specific bandwidths in an image simultaneously. Finally, the imagery provides georeferenced, digital data and the system operates in all seasons, in bad weather, and at night.

However, the comparatively small scale of the imagery can be a limitation for many mapping applications. In parallel with the development of increasingly sensitive satellite sensors, the remote sensing industry has adapted digital sensors that focus on the visible spectrum to aircraft platforms (i.e., digital airborne cameras). The industry also has adapted or developed sensors that focus on nonvisible portions of the electromagnetic spectrum and that offer benefits for a variety of mapping activities.

Light detection and ranging (LIDAR or lidar), perhaps the most significant innovation to date, is similar in many respects to radio detection and ranging (radar). Lidar can be used to measure characteristics of a remote target, including distance, speed, rotation, and chemical composition and concentration. Known initially as optical radar or laser radar, lidar can be thought of as a radar system that uses electromagnetic radiation at higher, optical frequencies — most commonly a laser.

In operation, a lidar instrument transmits light to a target. The transmitted light interacts with and is changed by the target. Some of this light is reflected and/or scattered back to the sensing instrument and analyzed. Change in the properties of the light enables some property of the target to be determined and the time that the light travels to the target and back is used to determine the distance to the target.

This last characteristic is particularly important for topographic data collection. Lidar systems perform an "echo time" distance conversion based on an assumed speed of light (*c*) equal to 3.0E8 mps as follows:

| | | |
|------------------|--------|--------------------|
| 1 nanosecond | 0.15 m | 5.9 inches |
| 1 microsecond | 150 m | 492 feet |
| 10 microseconds | 1.5 km | 0.93 statute miles |
| 100 microseconds | 15 km | 9.32 statute miles |
| 1 millisecond | 150 km | 93.2 statute miles |

The elevation of aircraft carrying lidar sensors can be fixed using GPS/IMU technology. As the aircraft flies over an area, laser pulses are emitted with high rapidity toward the ground. Pulses are reflected by the ground and/or objects on it (e.g., trees and buildings). The elapsed time between the emitted and returning signals is measured for each pulse, to compute a slant distance. The position and altitude of the aircraft are measured with airborne GPS and inertial measurement unit (IMU) systems.

After post-processing, the positional data are combined with the slant distance, information on atmospheric conditions, hardware characteristics, and other relevant parameters to generate an X, Y, Z coordinate triplet of a point on the ground. Millions of such points are captured as the mission progresses, providing a dense digital terrain model.

Frequently, the greatest problem posed during this post-processing is thinning of the data array. Lidar systems typically are transmitting 10,000 pulses per second and often achieve pulse rates in excess of 50,000. In this higher-resolution mode, lidar data have been used, for example, to support mapping of floodplains. The level of detail has been sufficient to support hydrographic and hydrologic modeling for the Federal Emergency Management Agency's (FEMA) digital flood insurance rate maps (DFIRM) program.

In effect, the measurement of terrain elevations using laser light produces an accurate data set for the creation of digital elevation models (DEMs) and contours. Lidar data sets generally are expected to have vertical accuracies of less than 1 ft, producing smaller contour intervals with minimal additional effort. By measuring the ground height and the height of buildings, lidar supports creation of low-cost, true continuous surface models for orthophoto production.

This extremely fine granularity in observations offers the possibility of intriguing new applications, including, for example, the ability to distinguish the heights of transmission cables over the ground below and the heights above the ground of tree canopies, the latter a function of the ability in many situations to penetrate the canopy and capture ground heights.

Another example of the use of this level of detail is offered by the wireless communications industry. The modeling requirements of the wireless market (especially the broadband wireless segment) include line-of-sight calculations for unobstructed transmission. These translate to technical specifications of 1-m (or better) vertical and horizontal accuracy, 1-m spatial DEM postings, separate terrain layers for structures, bare earth and vegetation, and good structure/building definition. Lidar data collection satisfies these criteria, and use of this technology is growing rapidly as the number of sensors in the commercial marketplace increases.

Synthetic Aperture Radar and Interferometric Synthetic Aperture Radar

Synthetic aperture radar (SAR) provides the means to obtain large-area imaging at high resolutions even in inclement weather or at night. SAR systems take advantage of the long-range propagation characteristics of radar signals to provide high-resolution imagery. SAR complements photographic and digital optical imaging capabilities by overcoming time-of-day and atmospheric constraints. Originally developed for military and large-scale economic applications (such as petroleum exploration), reductions in cost of SAR technology have combined to make it economically feasible for smaller commercial and public interest users.

Traditionally, SAR systems produced a two-dimensional image. One dimension, called the "range" (or cross track), is a measure of the "line-of-sight" distance from the radar to the target. As with other radar systems, range is determined by precisely measuring the time from the transmission of a pulse to the time of receiving the echo from a target.

The second dimension, called the "azimuth" (or along track), is perpendicular to the range. The resolution of the azimuth measurement is dependent on the concentration of the pulsed radar beam. For ground-based systems, large-aperture receivers can be used to improve image resolution, but even moderate SAR resolutions would require an antenna physically larger than reasonably could be carried aboard an aircraft. Airborne SAR systems overcome this limitation by simulating a large antenna with multiple observations along the flight light; the observations are combined (with appropriate consideration of Doppler effects) to simulate or "synthesize" a much larger antenna; hence the name for the technology.

FIGURE 165.1 Hypothetical dot scatter. Each dot has positional and elevation data associated with it.

A variation of SAR technology called Interferometric synthetic aperture radar (IFSAR) has been used to generate three-dimensional building models. High resolutions at pixel sizes down to 10 cm and single-pass interferometry support the geometric reconstruction of relatively small objects. Although the resolutions typically are less than those of lidar, ISSAR systems ultimately may represent an important commercial source of terrain information.

165.3 Topographic Mapping in a Geographic Information System

Data points collected either by field methods or by photogrammetric methods can be processed in a number of ways to make them useful in a variety of applications [14]. We focus on applications that employ GIS software to process them. Consider a hypothetical array of dot scatter representing collected data points and assume that elevation and positional data have been associated with each dot (Figure 165.1). The following methods of interpolating values between dots use ArcView 3.2 GIS (Environmental Systems Research Institute, Redlands, CA) with ArcView Spatial Analyst and ArcView 3D Analyst extensions loaded on the computer (both from ESRI). In addition, the Animal Movement and Home Range extension package is also loaded on the computer [10].

Use Animal Movement to calculate a triangulation of the data points (Figure 165.2). For any given set of points there is a unique network of triangles, with the points as vertices, that most closely satisfies the criterion that the triangles be as nearly equilateral as possible. This triangulation, called the Delaunay triangulation, has the property that it maximizes the minimum angle over all triangles in the triangulation. The triangulation may be calculated easily in ArcView [10]. That calculation is based on one of several algorithms, all of which lead to the same result [4,21].

Use the Home Range extension to calculate the minimum convex polygon containing the dot scatter (Figure 165.3) [10]. The convex hull (minimum convex polygon) is useful for constraining other calculations.

Use ArcView 3D Analyst (ESRI) to calculate a triangulated irregular network (TIN) from the dot scatter (Figure 165.4). As with the Delaunay triangulation, both may be easily done in ArcView in “blackbox” mode, without understanding the theory behind the software.

FIGURE 165.2 Delaunay triangulation of dot scatter in [Figure 165.1](#).

FIGURE 165.3 Minimum convex polygon containing the dot scatter.

FIGURE 165.4 Triangulated irregular network (TIN) calculated by the GIS using the dot scatter.

Superimpose the Delaunay triangulation on the TIN (Figure 165.5): Note that the Delaunay triangulation itself generates the TIN. Suitable partition of Delaunay triangles causes the surface of the TIN to appear to be three-dimensional. Hence, we reveal the need to understand that the Delaunay triangulation is the conceptual backing of the TIN and that the Watson geometric algorithm is one characterization of the triangulation [4,21].

Calculate contours from the TIN using ArcView 3D Analyst. In this case, the conceptual background is the calculus application of calculating level curves of the three-dimensional surface represented by the TIN: note that the contours (Figure 165.6) follow the TIN (Figures 165.4 and 165.5). Remove the TIN and the surface is contoured, as is a topographic map (Figure 165.6).

FIGURE 165.5 Delaunay triangulation superimposed on the TIN.

FIGURE 165.6 Remove the TIN to see the contours alone as a topographic map.

This sequence of examples is designed to illustrate the need to understand the theory behind practice. The strategy of using a geometric algorithm to generate a Delaunay triangulation, which is then used to create a TIN, which is then used to find level curves of the TIN as contours, which are then used on a topographic map, is a standard conceptual design that endures far beyond the life of any software package. It is a procedure that has been employed in mapping from the conventional to the modern, and it rests on a clear understanding of geometry and calculus. Software changes frequently, but theory does not. Thus, it is critical to have at least some theoretical grounding in methods if one wishes to keep current.

165.4 Delaunay Triangulation and Dirichlet Tessellation

Indeed, theory not only serves as an enduring underpinning for practice; it also serves to lead to other theoretical results. Such a situation is the case with the Delaunay triangulation and another partition of the dot scatter, known variously as a Dirichlet tessellation, Voronoi polygons, or Thiessen polygons.

In 1911, Thiessen and Alter [21] wrote on the analysis of rainfall using polygons surrounding rain gauges. Given a scatter of rain gauges, represented abstractly as dots, partition the underlying plane into polygons containing the dots in such a way that all points within any given polygon are closer to the rain gauge dot within that polygon than they are to any other gauge dot. The geometric construction usually associated with performing this partition of the plane into a mutually exclusive, yet exhaustive, set of polygons is performed by joining the gauge dots with line segments, finding the perpendicular bisectors of those segments, and extracting a set of polygons with sides formed by perpendicular bisectors. It is this latter set of polygons that has come to be referred to as “Thiessen polygons” (and earlier names such as Dirichlet region or Voronoi polygon; see Coxeter [7]). The construction using bisectors is tedious and difficult to execute with precision when performed by hand. Kopec (1963) [22] noted that an equivalent construction results when circles of radius of the distance between adjacent points are used. Indeed, that construction is but one case of a Euclidean general construction. Like Kopec, Rhynsburger (1973) [19] also sought easier ways to construct Thiessen polygons: Kopec through knowledgeable use of geometry and Rhynsburger through the development of computer algorithms. GIS software affords an opportunity to combine both [1].

Figure 165.7 shows the Dirichlet tessellation of the dot scatter in Figure 165.1 calculated using the Animal Movement [10] extension to ArcView GIS. Imagine that each dot represents a rain gauge. A cell

FIGURE 165.7 Dirichlet tessellation of the hypothetical dot scatter.

in the Dirichlet tessellation about a point (rain gauge) is the region that is closer to, or as close to, any other point (rain gauge).

The Dirichlet tessellation and the Delaunay triangulation are graph-theoretic duals; thus, one may be derived from the other [8]. To see this relationship, consider Figure 165.8. Replace each Dirichlet cell with a point interior to it (rain gauge). Join two points with an edge if there is a boundary of a cell of the Dirichlet tessellation separating these two points. Repeat the process for all pairs of points, creating the Delaunay triangulation.

FIGURE 165.8 Graph-theoretic duality of Dirichlet tessellation and Delaunay triangulation.

Links between mathematics and the real world are everywhere [2,3,14,17]. All too often, though, one is caught up in the mechanics of implementing software programs and loses sight of the theoretical underpinnings of process. Here we seek to encourage engineers to look to the conceptual base of the wonderful tool kit already available in software, and consider not only how practice derives from that conceptual base but also how that base may extend to other concepts, as well. To do so is to be at the leading edge of both theory and practice.

Surveyors collect measurements (observations, data, etc.) for the purpose of determining a wide variety of variables (parameters, unknowns, etc.). These measurements may be distances, directions, angles, look angles, azimuths, elevation angles, height differences, time, and so on. From these observations, the surveyor deduces results in terms of parameters, such as coordinates of an intersection point of two boundary lines or the height of a marker on a bridge. Rather than identifying a variety of (classical) survey problems such as point positioning through traversing or height determinations through spirit leveling, this chapter follows a more general approach by discussing a general relationship between observational data and parameters. In Section 166.6 an example is presented.

166.1 Principles of Multivariate Calculus

A general relationship between two classes of variables may exist. One class of variables is denoted by l and the other by x . The two classes of variables refer to the two main classes that a surveyor deals with: observations or the input data (l) and the results or output data (x). The variable l represents a group of n variables l_i with $i = 1, \dots, n$. The other variable x represents a group of u variables x_j with $j = 1, \dots, u$. A functional relationship F exists between these two groups of variables. This functional relationship is nothing other than the mathematical model that expresses the assumed interdependency between the variables in question. Realize, though, that it is the surveyor who makes this enormously important judgment call on this mathematical relationship: like a car driver engages a gear, the surveyor engages at a certain moment a mathematical model, or at least follows the spiritual ancestor of the model provided in terms of a survey software package. The number of functional relationships does not need to be equal to n or u ; we may have F_k ($k = 1, \dots, r$) relationships. Summarizing, we have

$$F_k = F(l_p, x_j) \quad (166.1)$$

with

$$k = 1, \dots, \gamma \quad (166.2)$$

$$i = 1, \dots, n \quad (166.3)$$

$$j = 1, \dots, u \quad (166.4)$$

A simple example will illustrate. Suppose that we observe four pairs of coordinates $\{X_p, Y_p\}$ that we assume lie on a circle. So the model F_k is the equation of a circle, centered at an arbitrary coordinate $\{X_c, Y_c\}$ with an arbitrary radius R :

$$F_k = (X_k - X_c)^2 + (Y_k - Y_c)^2 - R^2 \quad (166.5)$$

Geometry dictates that a circle is defined through three points (six coordinates), provided that those three points are not on a line. Thus, four sets of coordinates will not quite fit the “circle” model. Small adjustments to the eight coordinates will be necessary to end up with one unique circle. In addition, we may have to slightly adjust the unknown circle centered at $\{X_c, Y_c\}$ and its unknown radius R . We will probably have to slightly adjust any initial guess of these three variables $\{X_c, Y_c, R\}$ to find the optimum circle passing through those four pairs of coordinates. These small adjustments to the variables l and x , which we call dl and dx , will make the variables fit the circle model just right. Adding the small corrections dl and dx to l and x will make the equations F_k become equal to zero:

$$F_k = F(l_i + dl_i, x_j + dx_j) = 0 \quad (166.6)$$

The problem of finding these hopefully small corrections dl_i and dx_j will be made much easier if we linearize the model according to the rules of multivariate calculus:

$$F_k(l_i + dl_i, x_j + dx_j) = F_k(l_i, x_j) + \frac{\partial F_k}{\partial l_i} dl_i + \frac{\partial F_k}{\partial x_j} dx_j + \dots = 0 \quad (166.7)$$

With the wealth of variables r equations F_k , n variables l_p , and u variables x_j in Equation (166.7) at hand, it is much more practical to use the tools (vectors and matrices) of linear algebra.

166.2 Principles of Linear Algebra

Equation (166.7) can be rewritten in terms of vectors and matrices. We define the vectors (shown below in transposed form) L , X , and W and the matrices A and B according to

$$\mathbf{L}^T = [l_1, l_2, \dots, l_p, \dots, l_n]^T \quad (166.8)$$

$$\mathbf{X}^T = [x_1, x_2, \dots, x_j, \dots, x_u]^T \quad (166.9)$$

$$\mathbf{W}^T = [F_1, F_2, \dots, F_k, \dots, F_r]^T \quad (166.10)$$

and

$$\mathbf{A} = \begin{bmatrix} \frac{\partial F_1}{\partial l_1} & \dots & \frac{\partial F_1}{\partial l_n} \\ \vdots & \dots & \vdots \\ \frac{\partial F_r}{\partial l_1} & \dots & \frac{\partial F_r}{\partial l_n} \end{bmatrix} \quad (166.11)$$

$$\mathbf{B} = \begin{bmatrix} \frac{\partial F_1}{\partial x_1} & \dots & \frac{\partial F_1}{\partial x_u} \\ \vdots & \dots & \vdots \\ \frac{\partial F_r}{\partial x_1} & \dots & \frac{\partial F_r}{\partial x_u} \end{bmatrix} \quad (166.12)$$

Matrix \mathbf{A} is the Jacobian of the model equations F with respect to the variables l , and consists of r rows and n columns. Similarly, the matrix \mathbf{B} is the Jacobian of the model equations F with respect to the variables x , and consists of r rows and u columns. The vector/matrix notation enables us to shorten Equation (166.7) to

$$\mathbf{W} + \mathbf{B} \, d\mathbf{L} + \mathbf{A} \, d\mathbf{X} + \dots = 0 \quad (166.13)$$

Referring back to our circle fitting example, we have, for instance,

$$d\mathbf{L}^T = [dX_1, dY_1, dX_2, dY_2, dX_3, dY_3, dX_4, dY_4]^T \quad (166.14)$$

$$d\mathbf{X}^T = [dX_c, dY_c, dR]^T \quad (166.15)$$

The matrix element $A_{3,2}$ (third row, second column) is equal to

$$A_{(\text{row}=3, \text{col}=2)} = \frac{\partial F_3}{\partial Y_c} = -2 \times (Y_3 - Y_c) \quad (166.16)$$

The matrix element $B_{3,5}$ (third row, fifth column) is equal to

$$B_{(\text{row}=3, \text{col}=5)} = \frac{\partial F_3}{\partial X_3} = 2 \times (X_3 - X_c) \quad (166.17)$$

Matrix \mathbf{A} is a full matrix; however, the \mathbf{B} matrix is of the nature

$$\mathbf{B} = \begin{bmatrix} X & X & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & X & X & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & X & X & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & X & X \end{bmatrix} \quad (166.18)$$

with the X 's denoting nonzero elements.

In this example, the running indices i, j, k (see Equations (166.3), (166.4), and (166.2), respectively) have ranges

$$\begin{aligned}
i &= 1, \dots, 8 \\
j &= 1, \dots, 3 \\
k &= 1, \dots, 4
\end{aligned}
\tag{166.19}$$

denoting eight observations and three parameters to be estimated, all being part of four equations.

166.3 Model of Two Sets of Variables, Observations, and Parameters: The Mixed Model

The linearized version of Equation (166.6), Equation (166.7), demands closer inspection of the definition of all variables involved. The surveyor has the benefit of observed values and approximate values for the parameters; however, they should not be mixed. With subscripts we indicate the nature of the variable. Subscript b denotes “observed value,” subscript 0 denotes “approximate value,” and subscript a denotes the value of the observable quantity or the (unknown) parameter that perfectly fits the model F . V denotes the residual, which is the value that must be added to the observed value L_b to obtain the value for L_a that perfectly fits the model F . Similarly, X denotes the correction that needs to be added to the approximate values of the parameter X_0 to obtain the value for the parameter X_a that perfectly fits the model F .

The following steps need to be taken to arrive at the linearized model (Equation (166.7) or (166.26)), starting from Equation (166.6) or (166.20), with the linearization around the Taylor point $\{L_0, X_0\}$:

$$F(\mathbf{L}_a, \mathbf{X}_a) = 0 \tag{166.20}$$

or

$$F(\mathbf{L}_b + \mathbf{V}, \mathbf{X}_0 + \mathbf{X}) = 0 \tag{166.21}$$

$$F(\mathbf{L}_0, \mathbf{X}_0) + \frac{\partial F}{\partial \mathbf{L}}(\mathbf{L}_a - \mathbf{L}_0) + \frac{\partial F}{\partial \mathbf{X}}(\mathbf{X}_a - \mathbf{X}_0) = 0 \tag{166.22}$$

$$\mathbf{W}_0 + \mathbf{B} \times (\mathbf{L}_a - \mathbf{L}_b + \mathbf{L}_b - \mathbf{L}_0) + \mathbf{A} \times (\mathbf{X}_a - \mathbf{X}_0) = 0 \tag{166.23}$$

$$\mathbf{W}_0 + \mathbf{B} \times (\mathbf{V} + \mathbf{L}) + \mathbf{A} \times \mathbf{X} = 0 \tag{166.24}$$

$$\mathbf{A}\mathbf{X} + \mathbf{B}\mathbf{V} + (\mathbf{W}_0 + \mathbf{B}\mathbf{L}) = 0 \tag{166.25}$$

or, arriving at the linearized form of Equation (166.20),

$$\mathbf{A}\mathbf{X} + \mathbf{B}\mathbf{V} + \mathbf{W} = 0 \tag{166.26}$$

with

$$\begin{aligned}
\mathbf{A} &= \frac{\partial F}{\partial \mathbf{X}} & \mathbf{X} &= \mathbf{X}_a - \mathbf{X}_0 \\
\mathbf{B} &= \frac{\partial F}{\partial \mathbf{L}} & \mathbf{V} &= \mathbf{L}_a - \mathbf{L}_b \\
& & \mathbf{L} &= \mathbf{L}_b - \mathbf{L}_0 \\
& & \mathbf{W} &= \mathbf{W}_0 + \mathbf{B}\mathbf{L}
\end{aligned}
\tag{166.27}$$

In words, the variables denote

- L_a : adjusted observations
- L_b : observed values
- V : residuals
- L_0 : approximate observations
- L : residual observations
- X_a : adjusted parameters
- X_0 : approximate parameters (initial guess)
- X : unknown correction to parameters
- W_0 : misclosure vector
- W : misclosure vector
- A : design matrix (partial derivative matrix for the parameters)
- B : partial derivative matrix for the observations

Equation (166.26) is a set of r equations with u unknowns. This is an inconsistent set of equations and cannot be solved since often $r > u$. The method of Lagrangian multipliers provides a set of u equations with u unknowns under the conditions that the sum of the squared residuals is minimum. This leads to a minimum variance estimate for the vector X (see, for example, Hamilton, 1964; Strang, 1986; and Strang, 1988). The unknown vector X can be computed from the u equations with u unknowns, also known as the “normal equations.” Without derivation, the normal equations are

$$A^T M^{-1} A X + A^T M^{-1} W = 0 \quad (166.28)$$

or, in short,

$$N X + U = 0 \quad (166.29)$$

with

$$N = A^T M^{-1} A \quad (166.30)$$

$$U = A^T M^{-1} W \quad (166.31)$$

and

$$M = B B^T \quad (166.32)$$

The model that mixes the observations L_a and the parameters X_a can be further generalized, assuming a statistical model (variance/covariance matrix for the observations) (see also [Chapter 161](#)):

$$\Sigma_{L_b} = \begin{bmatrix} \sigma_{l_1 l_1} & \sigma_{l_1 l_2} & \cdots & \sigma_{l_1 l_n} \\ \sigma_{l_2 l_1} & \sigma_{l_2 l_2} & \cdots & \sigma_{l_2 l_n} \\ \vdots & \vdots & \cdots & \vdots \\ \sigma_{l_n l_1} & \sigma_{l_n l_2} & \cdots & \sigma_{l_n l_n} \end{bmatrix} \quad (166.33)$$

Factoring a common (standard unit weight) constant out, we get

$$\Sigma_{L_b} = \sigma_0^2 Q_{L_b} = \begin{bmatrix} q_{l_1 l_1} & q_{l_1 l_2} & \cdots & q_{l_1 l_n} \\ q_{l_2 l_1} & q_{l_2 l_2} & \cdots & q_{l_2 l_n} \\ \vdots & \vdots & \cdots & \vdots \\ q_{l_n l_1} & q_{l_n l_2} & \cdots & q_{l_n l_n} \end{bmatrix} \quad (166.34)$$

The Q matrix is called the weight coefficient matrix. In terms of the weight matrix P, we get

$$\Sigma_{L_b} = \sigma_0^2 \mathbf{P}_{L_b}^{-1} = \begin{bmatrix} P_{l_1 l_1} & P_{l_1 l_2} & \cdots & P_{l_1 l_n} \\ P_{l_2 l_1} & P_{l_2 l_2} & \cdots & P_{l_2 l_n} \\ \vdots & \vdots & \cdots & \vdots \\ P_{l_n l_1} & P_{l_n l_2} & \cdots & P_{l_n l_n} \end{bmatrix}^{-1} \quad (166.35)$$

For weighted observations, the matrix M, Equation (166.32), is simply replaced by

$$\mathbf{M} = \mathbf{B} \mathbf{P}^{-1} \mathbf{B}^T = \frac{1}{\sigma_0^2} \mathbf{B} \Sigma_{L_b} \mathbf{B}^T \quad (166.36)$$

The least squares estimate for the solution vector can be obtained from

$$\begin{aligned} \mathbf{X}_a &= \mathbf{X}_0 + \mathbf{X} \\ &= \mathbf{X}_0 - [\mathbf{A}^T \mathbf{M}^{-1} \mathbf{A}]^{-1} \mathbf{A}^T \mathbf{M}^{-1} \mathbf{W} \\ &= \mathbf{X}_0 - [\mathbf{A}^T (\mathbf{B} \mathbf{P}^{-1} \mathbf{B}^T)^{-1} \mathbf{A}]^{-1} \mathbf{A}^T (\mathbf{B} \mathbf{P}^{-1} \mathbf{B}^T)^{-1} \mathbf{W} \end{aligned} \quad (166.37)$$

The variance/covariance matrix of the parameter vector X or X_a , after applying the law of propagation of errors, can be shown to be equal to

$$\Sigma_{X_a} = \Sigma_X = \sigma_0^2 (\mathbf{A}^T \mathbf{M}^{-1} \mathbf{A})^{-1} \quad (166.38)$$

The relationship between the *a priori* variance of unit weight σ_0^2 and the *a posteriori* variance of unit weight $\hat{\sigma}_0^2$, the latter being computed from

$$\hat{\sigma}_0^2 = \frac{\mathbf{V}^T \mathbf{P} \mathbf{V}}{r - u} \quad (166.39)$$

can be tested according to

$$\frac{\chi_{r-u; 1-\alpha/2}^2}{r-u} < \frac{\hat{\sigma}_0^2}{\sigma_0^2} < \frac{\chi_{r-u; \alpha/2}^2}{r-u} \quad (166.40)$$

Equation (166.40) reflects the probability that the ratio of the variances will fall within the specified bounds, and is equal to $1 - \alpha$ (= 95% if $\alpha = 0.05$ or 5%). This test gives insight between the expected observational precision and the overall behavior of the residuals once a model has been “engaged.” Rejection of the test may also lead to rejection of the particular model — for instance, in our example, if the observations were actually to lie on an ellipse rather than a circle.

From the “mixed model” $F(L_a, X_a) = 0$, two special models can be derived, which will be treated in the following two sections.

166.4 Observations as a Function of Parameters Only: The Model of Observation Equations

From the r (linearized) equations with u unknowns, a special case results if it so happens that each individual observation can be expressed as a function of the unknowns only. In this case we have $L_a = F(X_a)$, which can be derived directly rewriting Equation (166.26) as

$$-BL - BV = AX + W_0 \quad (166.41)$$

If B is assumed to be equal to a negative unit matrix (a square matrix with zeros and -1 as diagonal elements), Equation (166.41) becomes simply, with W_0 being absorbed in the L vector (see Equations (166.44) and (166.45)),

$$L + V = AX \quad (166.42)$$

with

$$\begin{aligned} A &= \frac{\partial F}{\partial X} \\ X &= X_a - X_0 \\ V &= L_a - L_b \\ L &= L_b - L_0 \\ L_0 &= F(X_0) \end{aligned} \quad (166.43)$$

When you start from the unlinearized model $L_a = F(X_a)$, we find similarly

$$\begin{aligned} L_a &= F(X_a) \\ L_b + V &= F(X_0 + X_a - X_0) \\ L_b + V &= F(X_0) + \frac{\partial F}{\partial X} \cdot (X_a - X_0) \\ L_b + V &= L_0 + A \cdot X \end{aligned} \quad (166.44)$$

Bringing the L_0 vector to the left side,

$$\begin{aligned} L_b - L_0 + V &= A \cdot X \\ L + V &= A \cdot X \end{aligned} \quad (166.45)$$

In words, the variables denote

- L_a : adjusted observations
- L_b : observed values
- V: residuals
- L_0 : approximate observations
- L: residual observations
- X_a : adjusted parameters
- X_0 : approximate parameters (initial guess)
- X: unknown correction to parameters
- A: design matrix (partial derivative matrix for the parameters)

The normal equations simplify to

$$NX + U = 0 \quad (166.46)$$

with

$$\mathbf{N} = \mathbf{A}^T \mathbf{P} \mathbf{A} \quad (166.47)$$

$$\mathbf{U} = -\mathbf{A}^T \mathbf{P} \mathbf{L} \quad (166.48)$$

The solution vector X_a is equal to

$$\begin{aligned} \mathbf{X}_a &= \mathbf{X}_0 + \mathbf{X} \\ &= \mathbf{X}_0 + [\mathbf{A}^T \mathbf{P} \mathbf{A}]^{-1} \mathbf{A}^T \mathbf{P} \mathbf{L} \end{aligned} \quad (166.49)$$

The variance/covariance matrix of the parameter vector \mathbf{X} or \mathbf{X}_a , applying the law of propagation of errors, can be shown to be equal to

$$\Sigma_{\mathbf{X}_a} = \Sigma_{\mathbf{X}} = \sigma_0^2 (\mathbf{A}^T \mathbf{P} \mathbf{A})^{-1} \quad (166.50)$$

The relationship between the *a priori* variance of unit weight σ_0^2 and the *a posteriori* variance of unit weight $\hat{\sigma}_0^2$, the latter being computed from

$$\hat{\sigma}_0^2 = \frac{\mathbf{V}^T \mathbf{P} \mathbf{V}}{n - u} \quad (166.51)$$

Note that the denominator of Equation (166.51) represents the degrees of freedom, which are equal to $n - u$ since we deal with n (linearized) equations with u unknowns.

The method of observation equations is also known as “adjustment of indirect observations” (see, for instance, Mikhail, 1976).

Notation

The linearized observation equation, Equation (166.45),

$$\mathbf{L} + \mathbf{V} = \mathbf{A} \mathbf{X} \quad (166.52)$$

appears under a variety of notations in the literature. For instance, Mikhail [1976] and Mikhail and Gracie [1981] use

$$\mathbf{I} + \mathbf{v} = -\mathbf{B} \Delta \quad (166.53)$$

In the statistics literature one often finds

$$\mathbf{y} - \boldsymbol{\varepsilon} = \mathbf{X} \boldsymbol{\beta} \quad (166.54)$$

or, as in Gelb [1974],

$$\mathbf{z} - \mathbf{v} = \mathbf{H} \mathbf{x} \quad (166.55)$$

Also, a more tensor-oriented notation may be found, as in Baarda [1967]:

$$\mathbf{x}^i + \boldsymbol{\varepsilon}^i = \mathbf{a}_\alpha^i \mathbf{Y}^\alpha \quad (166.56)$$

166.5 All Parameters Eliminated: The Model of Condition Equations

From the r (linearized) equations with u unknowns, another special case may be derived by eliminating the u unknowns from the linearized model, Equation (166.26):

$$\mathbf{AX} + \mathbf{BV} + \mathbf{W} = 0 \quad (166.57)$$

After elimination, we obtain $r - u$ equations which reflect the mathematical relationship between the observations only. The equations are of the type

$$\mathbf{B}'\mathbf{V} + \mathbf{W}' = 0 \quad (166.58)$$

They reflect the existing conditions between the observables — hence the name of the method. The classical example in surveying is that in a (not too large) triangle, the three measured angles have to sum to π . Another example concerns the loop closures between the leveled height differences, which have to sum to zero in each loop.

Starting from the nonlinearized model $F(\mathbf{L}_a) = 0$, we find

$$\begin{aligned} F(\mathbf{L}_a) &= 0 \\ F(\mathbf{L}_b + \mathbf{V}) &= 0 \\ F(\mathbf{L}_0 + \mathbf{L}_b - \mathbf{L}_0 + \mathbf{V}) &= 0 \\ F(\mathbf{L}_0 + \mathbf{L} + \mathbf{V}) &= 0 \\ F(\mathbf{L}_0) + \frac{\partial F}{\partial \mathbf{L}} \cdot (\mathbf{L} + \mathbf{V}) &= 0 \\ \mathbf{W}_0 + \mathbf{B} \cdot \mathbf{L} + \mathbf{B} \cdot \mathbf{V} &= 0 \\ \mathbf{W} + \mathbf{BV} &= 0 \end{aligned} \quad (166.59)$$

with

$$\begin{aligned} \mathbf{B} &= \frac{\partial F}{\partial \mathbf{L}} \\ \mathbf{V} &= \mathbf{L}_a - \mathbf{L}_b \\ \mathbf{L} &= \mathbf{L}_b - \mathbf{L}_0 \\ \mathbf{W}_0 &= F(\mathbf{L}_0) \\ \mathbf{W} &= \mathbf{W}_0 + \mathbf{BL} \end{aligned} \quad (166.60)$$

In words, the variables denote

- \mathbf{L}_a : adjusted observations
- \mathbf{L}_b : observed values
- \mathbf{V} : residuals
- \mathbf{L}_0 : approximate observations
- \mathbf{L} : residual observations
- \mathbf{W}_0 : misclosure vector

W: misclosure vector

B: partial derivative matrix for the observations

166.6 An Example: Traversing

Various methods are presented in the survey literature (see, for instance, Wolf and Brinker, 1995, chapters 12 and 13) to adjust data collected as part of a traverse. The (two-dimensional) least squares example discussed illustrates the formation of observation equations and can be adapted to reflect any traverse method. The example here involves the measurements of directions and distances along a traverse which stretches between two known points A and B , in coordinates $\{x_A, y_A\}$ and $\{x_B, y_B\}$. In these terminal points two closing directions are measured to two known azimuth markers, the points P and Q , respectively. The traverse is to solve for parameters such as the unknown coordinates of points 1 through n , the orientation unknowns for each point where directional measurements took place. Finally we assume the existence of an unknown scale factor λ between the distance measurement equipment and the distances implied by the known coordinates of points A , B , P , and Q .

Directional Measurements r_{ij}

In point A two directions are measured, a backsight direction to P and a foresight direction to point 1. In point 1 two directions are measured, to the previous point A and to point 2; in point 2 directions are measured to 1 and 3; and so on. In the next to last point n a backsight direction is measured to point $n - 1$ and a foresight direction to point B . In point B two directions are measured, to n and to the azimuth marker Q . The directional measurements can be written as a function of differences of azimuths Az_{ij} between points i and j and the unknown azimuths of the directional zero orientations o_i . The latter refer to the (unknown) azimuths of the “zero” reading on the horizontal circle of the theodolite. This so-called zero “reading” is not a reading on the circle at all, but the result of an analysis of a series of directional measurements taken in the point in question. The azimuths Az_{ij} are in turn a function of the coordinate unknowns $\{x_p, y_j\}$ and $\{x_p, y_j\}$.

The first two observation equations, Equations (166.61) and (166.62), generated by the two directional measurements in point A are

$$r_{AP} = Az_{AP} - o_A = \arctan\left(\frac{x_P - x_A}{y_P - y_A}\right) - o_A \quad (166.61)$$

Note that o_A in Equation (166.61) is the only unknown since we adopted the coordinates of A and P . However, the second (forward) direction in A (r_{A1}) is dependent for three unknowns, o_A , x_1 , y_1 :

$$r_{A1} = Az_{A1} - o_A = \arctan\left(\frac{x_1 - x_A}{y_1 - y_A}\right) - o_A \quad (166.62)$$

The next two directional measurements, Equations (166.63) and (166.64), in point 1 are dependent on five unknowns, o_1 , x_1 , y_1 , x_2 , and y_2 :

$$r_{1A} = Az_{1A} - o_1 = \arctan\left(\frac{x_A - x_1}{y_A - y_1}\right) - o_1 \quad (166.63)$$

For the foresight direction,

$$r_{12} = Az_{12} - o_1 = \arctan\left(\frac{x_2 - x_1}{y_2 - y_1}\right) - o_1 \quad (166.64)$$

In point i , in the middle of the traverse, we have the backsight direction

$$r_{i,i-1} = Az_{i,i-1} - o_i = \arctan\left(\frac{x_{i-1} - x_i}{y_{i-1} - y_i}\right) - o_i \quad (166.65)$$

and the foresight direction

$$r_{i,i+1} = Az_{i,i+1} - o_i = \arctan\left(\frac{x_{i+1} - x_i}{y_{i+1} - y_i}\right) - o_i \quad (166.66)$$

In the last point of the traverse, point B , we have

$$r_{Bn} = Az_{Bn} - o_B = \arctan\left(\frac{x_n - x_B}{y_n - y_B}\right) - o_B \quad (166.67)$$

and the foresight direction to azimuth marker Q ,

$$r_{BQ} = Az_{BQ} - o_B = \arctan\left(\frac{x_Q - x_B}{y_Q - y_B}\right) - o_B \quad (166.68)$$

So far, these directional measurements have generated $2(n+2)$ observational equations with $(n+2)$ directional unknowns and $2n$ unknown coordinates, totaling $3n+2$ unknown parameters. The problem would not be solvable: $2n+4$ equations with $3n+2$ unknowns, a fact known to a surveyor because of geometric considerations alone. The addition of distance measurements will make traversing an efficient survey tool.

Note that one may have to add or subtract multiples of 360° to keep the directional measurements r_{ij} between 0 and 360° .

Distance Measurements s_{ij}

The distance measurements with unknown (common) scale λ can be written in terms of the following functions. Since no distance measurements between point A and the azimuth marker P were assumed, we have in point A only one (forward) distance measurement

$$s_{A1} = \lambda[(x_1 - x_A)^2 + (y_1 - y_A)^2]^{1/2} \quad (166.69)$$

In point 1 we have a backsight distance s_{1A} and a foresight distance s_{12} , generating the following two observation equations:

$$s_{1A} = \lambda[(x_A - x_1)^2 + (y_A - y_1)^2]^{1/2} \quad (166.70)$$

and

$$s_{12} = \lambda[(x_2 - x_1)^2 + (y_2 - y_1)^2]^{1/2} \quad (166.71)$$

In point i , in the middle of the traverse, we have for the backsight distance

$$s_{i,i-1} = \lambda[(x_{i-1} - x_i)^2 + (y_{i-1} - y_i)^2]^{1/2} \quad (166.72)$$

and the foresight distance,

$$s_{i,i+1} = \lambda[(x_{i+1} - x_i)^2 + (y_{i+1} - y_i)^2]^{1/2} \quad (166.73)$$

In the last point of the traverse, in point B , we have for the backsight distance

$$s_{Bn} = \lambda[(x_n - x_B)^2 + (y_n - y_B)^2]^{1/2} \quad (166.74)$$

We assumed that no foresight distance measurement to azimuth marker Q took place.

The distance measurements added $2(n + 1)$ observation equations and only one additional unknown, the scale factor λ . The $2n$ coordinates $\{x_i, y_i\}$ were already included in the previous directional observation equations. Summing the equations for both the directions and distances, we have for this particular traverse $2(n + 2) + 2(n + 1) = 4n + 6$ observations with $(3n + 2) + 1 = 3n + 3$ unknowns. The degrees of freedom are in this case $(4n + 6) - (3n + 3) = n + 3$ for the traverse under mentioned measurement conditions.

166.7 Dynamical Systems

Modern survey techniques incorporate the element *time* in two different aspects: first of all, in classical survey systems the assumption is made that we deal with stationary systems. That is, the random behavior of, say, the residuals is invariant of time. Second, during a kinematic survey — for instance, having an aircraft make aerial photographs equipped with a GPS receiver — we have to deal with estimating a vector of unknowns, say the position of the GPS antenna fixed on top of the airplane's fuselage, which is not independent of time anymore. We get for the variance/covariance matrix of the observations, Equation (166.33), and the linearized version of Equation (166.52), respectively,

$$\Sigma_{L_b} = \Sigma_{L_b(t)}(t) \quad (166.75)$$

and

$$L(t) + V(t) = A(t)X(t) \quad (166.76)$$

The vector $X(t)$ reflects the state of the parameters at epoch t . At the same time, a different model may be at hand that describes the rate of change of this vector (vector velocity),

$$\dot{X}(t) = F(t)X(t) + \varepsilon' \quad (166.77)$$

One may similarly be able to write the state of the vector X at epoch $(t + dt)$ as a function of the state at t , according to

$$X(t + dt) = \Phi(t + dt, t)X(t) + \varepsilon \quad (166.78)$$

The (Jacobian) matrix Φ (see also Section 161.7 elsewhere in this book) is called the state transition matrix. A new estimate $X(t + dt)$ is computed from a new measurement through Equation (166.76) and through the use of the previous estimate $X(t)$ through Equation (166.77) or (166.78).

Equations (166.75) through (166.78) lead to dynamical estimation models. One of the better-known estimation (filtering) models has been developed by Kalman and others. These models are developed in the so-called time domain (as opposed to the frequency domain). The reader is referred to the vast literature in this area (see, for instance, Gelb, 1974).

Journals and Organizations

The latest results from research of least squares applications in geodesy, surveying, mapping, and photogrammetry are published in a variety of journals.

Two international magazines under the auspices of the International Association of Geodesy, both published by Springer-Verlag (Berlin/Heidelberg/New York), are *Bulletin Geodésique Manuscripta* and *Geodetica*.

Geodesy- and geophysics-related articles can be found in:

American Geophysical Union, Washington, D.C.: *EOS* and *Journal of Geophysical Research*
Royal Astronomical Society, London: *Geophysical Journal International*

Statistical articles related to kinematic GPS can be found in Institute of Navigation: *Navigation*

Many national mapping organizations publish journals in which recent statistical applications in geodesy/surveying/mapping/photogrammetry are documented:

American Congress of Surveying and Mapping: *Surveying and Land Information Systems* and *Cartography and Geographic Information Systems*

American Society of Photogrammetry and Remote Sensing: *Photogrammetric Engineering & Remote Sensing*

American Society of Civil Engineers: *Journal of Surveying Engineering*

Deutscher Verein für Vermessungswesen: *Zeitschrift für Vermessungswesen*, Konrad Wittwer Verlag, Stuttgart

Canadian Institute of Geomatics: *Geomatica*

Royal Society of Chartered Surveyors: *Survey Review*

Institute of Surveyors of Australia: *Australian Surveyor*

Worth special mention are the following trade magazines:

GPS World, published by Advanstar Communications, Eugene, OR

P.O.B. (Point of Beginning), published by P.O.B. Publishing Co., Canton, MI

Professional Surveyor, published by American Surveyors Publishing Co., Arlington, VA

Geodetical Info Magazine, published by Geodetical Information & Trading Centre bv., Lemmer, the Netherlands

National mapping organizations such as the U.S. National Geodetic Survey (NGS) regularly make software available (free and at cost). Information can be obtained from: National Geodetic Survey, Geodetic Services Branch, National Ocean Service, NOAA, 1315 East-West Highway, Station 8620, Silver Spring, MD 20910-3282.

Control

The distance to an object can be calculated by measuring the time that it takes for a transmitted signal to reach us. In the case of the global positioning system (GPS), we can use the time it takes for transmitted signals to reach us from four different satellites to calculate our position. GPS is a tool used widely both within and outside engineering.

Positioning has become possible with accuracies ranging from the subcentimeter level — for high-accuracy geodetic applications as used in state, national, and global geodetic networks, deformation analysis in engineering, and geophysics — to the hectometer level in navigation applications. Similar to the space domain, a variety of accuracy classes may be assigned to the time domain: GPS provides position and velocity determinations averaged over time spans from fractions of seconds (essentially instantaneous) to one or two days. Stationary applications of the observatory type are used in GPS tracking for orbit improvement.

167.1 A Satellite Orbiting the Earth

The path of an Earth-orbiting satellite is similar to that of a planet around the sun. In history the solution to the motion of planets around the sun was found before its explanation. Johannes Kepler discovered certain regularities in the motions of planets around the sun. Through the analysis of his own observations and those made by Tycho Brahe, he formulated the following three laws:

First law (1609):

The orbit of each planet around the sun is an ellipse, with the sun is at one focus.

Second law (1609):

A ray (vector) from the sun to a planet sweeps out equal areas in equal time periods.

FIGURE 167.1 Celestial sphere with projected orbital ellipse and equator.

Third law (1611):

This ratio between the square of a planet's orbital period and the third power (cube) of its average distance from the sun is constant.

Kepler's third law leads to the famous equation,

$$n^2 a^3 = GM \quad (167.1)$$

where n is the average angular rate and a is the semimajor axis of the orbital ellipse.

In 1665–1666, Newton formulated his more fundamental laws of nature and showed that Kepler's laws follow from those fundamental laws (Newton, 1686).

167.2 The Orbital Ellipse

In a (quasi-) inertial frame, the ellipse of an Earth-orbiting satellite must be positioned: the focal point will coincide with the center of mass (CoM) of the Earth. Instead of picturing the ellipse itself, we project the ellipse on a celestial sphere centered at the CoM. On the celestial sphere we also project the Earth's equator (Figure 167.1).

The orientation of the orbital ellipse requires three orientation angles with respect to the inertial frame XYZ : two for the orientation of the plane of the orbit, Ω and I , and one for the orientation of the ellipse in the orbital plane, for which one refers to the point of closest approach, the perigee, ω (Satellite Observing).

Ω represents the right ascension (α) of the ascending node. The ascending node is the (projected) point where the satellite rises above the equator plane.

I represents the inclination of the orbital plane with respect to the equator plane.

ω represents the argument of perigee — the angle from the ascending node (in the plane of the orbit) to the perigee (for planets, the perihelion), which is that point where the satellite (planet) approaches the closest to the Earth (sun), or, more precisely, the center of mass of the Earth (sun).

Similar to the Earth's ellipsoid, we define the orbital ellipse by a semimajor axis a and the eccentricity e . In orbital mechanics it is unusual to describe the shape of the orbital ellipse by its flattening.

The position of the satellite in the orbital plane is depicted in Figure 167.2. The major variables in Figure 167.2 are defined as follows:

a = the semimajor axis of the orbital ellipse

FIGURE 167.2 The position of the satellite (S) in the orbital plane.

b = the semiminor axis of the orbital ellipse
 e = the eccentricity of the orbital ellipse, with

$$e^2 = \frac{a^2 - b^2}{a^2} \quad (167.2)$$

The relationship between the true anomaly and the eccentric anomaly can be derived as:

$$\tan\left(\frac{E}{2}\right) = \sqrt{\frac{1-e}{1+e}} \cdot \tan\left(\frac{v}{2}\right) \quad (167.3)$$

where v = the true anomaly, sometimes denoted by f and E = the eccentric anomaly.

The Cartesian coordinates of the satellite position are

$$X_T = \begin{pmatrix} X \\ Y \\ Z \end{pmatrix} = \mathfrak{R}_3(-\Omega) \cdot \mathfrak{R}_1(-I) \cdot \mathfrak{R}_3(-\omega) \cdot \begin{pmatrix} a \cdot (\cos E - e) \\ a \cdot \sqrt{1-e^2} \cdot \sin E \\ 0 \end{pmatrix} \quad (167.4)$$

In Equation (167.4), the Cartesian coordinates are expressed in terms of the six so-called Keplerian elements: a , e , I , Ω , ω , and E . If we know the position of the satellite at an epoch t_0 through $\{a, e, I, \Omega, \omega, E_0\}$, we are capable of computing the position of the satellite at an arbitrary epoch t through Equation (167.4) if we know the relationship in time between E and E_0 . In other words, how does the angle E increase with time?

We define an auxiliary variable (angle) M that increases linearly in time with the mean motion n [$= (GM/a^3)^{1/2}$] according to Kepler's third law. The angle M , the mean anomaly, may be expressed as a function of time by:

$$M = M_0 + n \cdot (t - t_0) \quad (167.5)$$

Through Kepler's equation,

$$M = E - e \cdot \sin E \quad (167.6)$$

the (time) relationship between M and E is given. Kepler's equation is the direct result of the enforcement of Kepler's second law (the "equal area" law).

Combining Equations (167.5) and (167.6) yields an equation that expresses the relationship between a given eccentric anomaly E_0 (or M_0 or v_0) at an epoch t_0 and the eccentric anomaly E at an arbitrary epoch t :

$$E - E_0 = e \cdot (\sin E - \sin E_0) + n \cdot (t - t_0) \quad (167.7)$$

The transformation is complete when we express the velocity vector $\{\dot{X}, \dot{Y}, \dot{Z}\}$ in terms of those Keplerian elements. Differentiating Equation (167.4) with respect to time and combining the position and velocity components into one expression, we find:

$$[X_T | \dot{X}_T] = \begin{bmatrix} X | \dot{X} \\ Y | \dot{Y} \\ Z | \dot{Z} \end{bmatrix} \quad (167.8)$$

$$= \mathfrak{R}_3(-\Omega) \cdot \mathfrak{R}_1(-I) \cdot \mathfrak{R}_3(-\omega) \begin{bmatrix} a(\cos E - e) & | & -a\dot{E} \sin E \\ a\sqrt{1-e^2} \sin E & | & a\dot{E}\sqrt{1-e^2} \cos E \\ 0 & | & 0 \end{bmatrix} \quad (167.9)$$

The remaining variable \dot{E} is obtained through differentiation of Equation (167.6):

$$\dot{E} = \frac{n}{1 - e \cdot \cos E} \quad (167.10)$$

Now all six Cartesian orbital elements (state vector elements) are expressed in terms of the six Keplerian elements.

167.3 Relationship between Cartesian and Keplerian Orbital Elements

To compute the inertial position of a satellite in a central force field, it is simpler to perform a time update in the Keplerian elements than in the Cartesian elements. The time update takes place through Equations (167.5), (167.6), and (167.7).

Schematically, the following procedure is to be followed:

$$\begin{array}{ll} t_0: & \{X, Y, Z, \dot{X}, \dot{Y}, \dot{Z}\} \\ & \downarrow \text{Conversion to Keplerian elements} \\ t_0: & \{a, e, I, \Omega, \omega, E_0\} \\ & \downarrow \text{Equation of Kepler, Equation (167.7)} \\ t_1: & \{a, e, I, \Omega, \omega, E_1\} \\ & \downarrow \text{Conversion to Cartesian elements} \\ t_1: & \{X, Y, Z, \dot{X}, \dot{Y}, \dot{Z}\} \end{array}$$

The conversion from Keplerian elements to state vector elements was treated in the previous section. For the somewhat more complicated conversion from position and velocity vector to Keplerian repre-

sensation, the reader is referred to textbooks such as Escobal [1976]. Basically we “invert” Equations (167.8) and (167.9) by solving for the six elements $\{a, e, I, \Omega, \omega, E\}$ in terms of the six state vector elements.

167.4 Orbit of a Satellite in a Noncentral Force Field

The equations of motion for a real satellite are more difficult than implied by Equations (167.8) and (167.9). First of all, we do not deal with a central force field: the Earth is not a sphere, nor does it have a radial symmetric density. Second, we deal with other forces, including the gravity of the moon and the sun, atmospheric drag, and solar radiation pressure. Equations (167.8) and (167.9) get a more general meaning if we suppose that a potential function is being generated by the sum of the forces acting on the satellite:

$$V = V_c + V_{nc}^t + V_{sun}^t + V_{moon}^t + \dots \quad (167.11)$$

where V_c is the central part of the Earth’s gravitational potential,

$$V_c = \mu |X| \quad (167.12)$$

and V_{nc}^t is the noncentral and time-dependent part of the Earth’s gravitational field. (The upper index t has been added to various potentials to reflect their time variance with respect to the inertial frame.)

The equations of motion to be solved are

$$\begin{aligned} \ddot{X} &= \nabla(V_c + V_{nc}^t + V_{sun}^t + V_{moon}^t + \dots) \\ &= \nabla V_c + \nabla V_{nc}^t + \nabla V_{sun}^t + \nabla V_{moon}^t + \dots \end{aligned} \quad (167.13)$$

For the Earth’s gravitational field, we have (in an Earth-fixed frame):

$$V_c + V_{nc} = \frac{\mu}{r} \left[1 + \sum_{l=1}^{\infty} \sum_{m=0}^l \left(\frac{a_e}{r} \right)^l \cdot (C_{lm} \cos m\lambda + S_{lm} \sin m\lambda) \cdot P_{lm}(\sin \phi) \right] \quad (167.14)$$

With Equation (167.14), one is able to compute the potential at each point $\{\lambda, \phi, r\}$ necessary for the integration of the satellite’s orbit. The coefficients C_{lm} and S_{lm} of the spherical harmonic expansion are in the order of 10^{-6} except for C_{20} ($l = 2, m = 0$), which is about 10^{-3} . This has to do with the fact that the Earth’s equipotential surface at mean sea level can be approximated best by an ellipsoid of revolution. One must realize that the coefficients C_{lm} and S_{lm} describe the shape of the potential field and not the shape of the physical Earth, despite a high correlation between the two. $P_{lm}(\sin \phi)$ are the associated Legendre functions of the first kind, of degree l and order m ; a_e is some adopted value for the semimajor axis (equatorial radius) of the Earth. (For values of a_e , $\mu (= GM)$, and $C_{20} (= -J_2)$, see IAG, 1971; IAG, 1980; IAG, 1984; IAG, 1988a; IAG, 1988b; DMA, 1988; McCarthy, 1992; and Cohen and Taylor, 1988.)

The equatorial radius a_e , the geocentric gravitational constant GM , and the dynamic form factor J_2 characterize the Earth as an ellipsoid of revolution with an equipotential surface.

If we restrict ourselves to the central part ($\mu = GM$) and the dynamic flattening ($C_{20} = -J_2$), then Equation (167.14) becomes:

$$V_c + V_{nc} = \frac{\mu}{r} \left[1 + \frac{J_2 a_e^2}{2r^2} \cdot (1 - 3 \sin^2 \phi) \right] \quad (167.15)$$

with

$$\sin \phi = \sin \delta = \frac{z}{r} \quad (167.16)$$

where ϕ is the latitude and δ the declination (Figure 167.2).

The solution expressed in Keplerian elements shows periodic perturbations and some dominant secular effects. An approximate solution using only the latter effects is (position only)

$$X_I = \mathfrak{R}_3[-(\Omega_0 + \dot{\Omega}\Delta t)] \cdot \mathfrak{R}_1(-I) \cdot \mathfrak{R}_3[-(\omega_0 + \dot{\omega}\Delta t)] \cdot X_{\omega_0} \quad (167.17)$$

with

$$\Delta t = t - t_0 \quad (167.18)$$

$$\dot{\Omega} = -\frac{3}{2} \frac{J_2 a_e^2}{a^2 (1-e^2)^2} n \cos I \quad (167.19)$$

$$\dot{\omega} = \frac{3}{2} \frac{J_2 a_e^2}{a^2 (1-e^2)^2} n (2 - 2 \frac{1}{2} \sin^2 I) \quad (167.20)$$

$$n = n_0 \cdot \left[1 + \frac{3}{2} \frac{J_2 a_e^2 \sqrt{1-e^2}}{a^2 (1-e^2)^2} (1 - \frac{1}{2} \sin^2 I) \right] \quad (167.21)$$

with

$$n_0 = \sqrt{\frac{GM}{a^3}} \quad (167.22)$$

Whenever

| | | |
|----------------------------|---------|-------------------------------|
| $I = 0^\circ$ | we have | an equatorial orbit |
| $0^\circ < I < 90^\circ$ | | a direct orbit |
| $I = 90^\circ$ | | a polar orbit |
| $90^\circ < I < 180^\circ$ | | a retrograde orbit |
| $I = 180^\circ$ | | a retrograde equatorial orbit |

Equation (167.19) shows that the ascending node of a direct orbit slowly drifts to the west. For a satellite at about 150 km above the Earth's surface, the right ascension of the ascending node decreases about 9° per day. The satellites belonging to the global positioning system have an inclination of about 55° . Their nodal regression rate is about -0.04187° per day.

167.5 The Global Positioning System (GPS)

The first U.S. navigation satellite was the Transit, "launched on April 13, 1960 into a 51° inclination orbit with an apogee of 745 and a perigee of 373 km. The spacecraft operated for 3 months. By 1968 there were 23 Transit satellites operating in circular orbits of 850km" [Graham, 1995]. The Transit system was intended to update the inertial navigation systems in the Polaris submarine.

Since Transit, several GPS satellite clusters have been put into operation or are proposed for operation in the near future. The Navstar GPS was conceived in 1973 as a replacement for the Transit system. The first Navstar satellite was launched in 1978. The Navstar GPS comprises a constellation of 24 satellites that orbit the Earth at an altitude of 20,200 km, constantly broadcasting GPS information. These satellites complete their orbits every 12 hours in six orbital planes.

The system is operated and controlled by the 50th Space Wing, located at Schriever Air Force Base, Colorado. The master control station crew sends updated navigation information to GPS satellites through ground antennas using an S-band signal. The ground antennas are also used to transmit commands to satellites and to receive state-of-health data (telemetry).

GPS receivers on Earth calculate their positions by making distance measurements to four or more satellites. Individual distance measurements to each satellite are determined by analyzing the time it takes for a signal to travel from a satellite to a GPS receiver. Using some relatively simple geometry, the receiver determines its position. This process is termed "trilateration."

The Russian Global'naya Navigatsionnaya Sputnikovaya Sistema (Global Navigation Satellite System, or GLONASS) was proposed in 1976 to provide navigational and time reference data for U.S.S.R. military use. As with the Navstar system, the GLONASS constellation was intended to include 24 satellites (21 on-line plus 3 spares in orbit), although in three orbital planes rather than Navstar's six planes. The GLONASS constellation orbited at an altitude of 19,100 km at an inclination of 64.8° and an orbit time of approximately 11 hours and 15 minutes. The GLONASS network was made available to civilian users in the early 1990s. Since that time, Russia and the United States have cooperated on integrating the GLONASS and Navstar GPS systems, so that users can use both networks. The capabilities of the GLONASS network were diminished during the 1990s, because Russia was unable to replace the aging GLONASS satellites on a regular schedule. Only six GLONASS satellites were functioning in orbit when this chapter was revised in 2003.

In 1999, the European Commission announced plans for another satellite navigation system, named Galileo. The rationale for a third satellite survey and navigation system was in part political (i.e., Europe had no control over the U.S. and Russian systems) and part economic (it was designed to allow the European Union's members to benefit from the projected demand for value-added services and equipment for navigation systems). The Galileo system also was intended to allow the European Union to develop its own integrated transport and navigation systems. Europe's first effort with satellite navigation will be EGNOS, a system intended to improve the reliability of Navstar GPS and GLONASS for certain critical applications that is scheduled to come on line in 2004. The Galileo constellation will comprise 30 satellites when complete. The satellites are scheduled to be in orbit by 2006 and the complete system, including ground infrastructure, is scheduled to be operational in 2008. It is the intention of the developers to be interoperable with the Navstar GPS and GLONASS systems.

Back on the ground, prices for GPS have dropped steadily over time. Several personal location GPS receivers intended for hiking, fishing, and other recreational uses are priced below \$100, while geodetic survey grade instruments can be purchased for less than \$10,000. GPS consumer markets have been rapidly expanding. In the areas of land, marine, and aviation navigation; precise surveying; electronic charting, and time transfer, the deployment of GPS equipment seems to have become indispensable. As events of recent years have demonstrated, this holds true for military users as well as civilian users.

Positioning

Two classes of positioning are recognized: standard positioning service (SPS) and precise positioning service (PPS). In terms of positional accuracies, one must distinguish between SPS with and without selective availability (SA) on the one hand and PPS on the other. SA deliberately introduced clock errors and ephemeris errors in the data being broadcast by the Navstar satellites. The accuracy of the (civil) signal without SA was approximately 20 m to 40 m. With SA implemented, SPS accuracy was degraded to 100 m. On May 1, 2000, President Clinton announced that the United States would stop the intentional degradation of Navstar GPS signals beginning at midnight of that date. This decision was based on a

recommendation by the Secretary of Defense in coordination with the Departments of State, Transportation and Commerce, the Central Intelligence Agency, and other executive branch departments and agencies, who realized that worldwide transportation safety, scientific, and commercial interests would best be served by discontinuation of SA.

In several applications, GPS receivers are interfaced with other positioning systems, such as inertial navigation systems (INS), hyperbolic systems, and even automatic braking systems in cars. GPS receivers operating in combination with other equipment can provide the answers to such general questions as [Wells and Kleusberg, 1990]:

Absolute positioning: Where am I? Where are you?

Relative positioning: Where am I with respect to you? Where are you with respect to me?

Orientation: Which way am I heading?

Timing: What time is it?

All these questions may refer to an observer either at rest (*static* positioning) or in motion (*kinematic* positioning). The questions may be answered immediately (*real-time* processing, often misnamed DGPS, which stands for differential GPS) or after the fact (*post-processing*).

Limiting Factors

The physics of the environment, instruments, broadcast ephemeris, and the relative geometry between orbits and networks are all limiting factors on the final accuracy of the results. Dilution of precision (DOP) is used as a scaling factor between the observational accuracy and positioning accuracy [Wells, 1986]. For reasons of safety and accuracy, one should avoid periods in which the DOP factor is larger than 5.

The atmosphere of the Earth changes the speed and the geometric path of the signals broadcast by GPS satellites. In the uppermost part of the atmosphere (the ionosphere), charged particles vary in number spatially as well as temporally. Ionospheric refraction errors may amount to several tens of meters. Because this effect is frequency dependent, the first-order effect can be eliminated for the most part by the use of dual-frequency receivers. The lower part of the atmosphere (the troposphere) causes refraction errors of several meters. Fortunately, the effect can be modeled rather well by measuring the atmospheric conditions at the measuring site.

GPS instruments are capable of measuring one or a combination of the following signals:

C/A code, with an accuracy of a few meters

P code, with an accuracy of a few decimeters

Carrier phase, with an accuracy of a few millimeters

In addition to this measurement noise, receiver clock errors must be modeled as to-be solved-for parameters. It is this synchronization parameter between satellite time and receiver time that makes it necessary to have at least four satellites in view to get a three-dimensional (3-D) fix.

Because of the high frequency of the GPS signals, multipath effects may hamper final accuracy; the signal arriving at the receiver through a reflected path may be stronger than the direct signal. By careful antenna design and positioning, multipath effects are reduced. The phase center of the antenna must be calibrated carefully with respect to a geometric reference point on the antenna assembly. However, because of the varying inclination angle of the incoming electromagnetic signals, effects of a moving phase center may be present at all times.

Information on the orbit of the satellite, as well as the orbital geometry relative to the network/receiver geometry, influences the overall positioning accuracy. The information that the satellite broadcasts on its position and velocity is necessarily the result of a process of prediction. Also, the on-board satellite clock is not free of errors. Orbital and satellite clock errors largely can be addressed by careful design of the functional model.

Differencing techniques are successfully used to eliminate a wide variety of errors, provided the receivers are not far apart. In essence, two close-by receivers are influenced almost equally by (delib-

erate) orbital errors and by part of the atmosphere error. Differencing of the measurements of both receivers will cancel a large portion of the first-order effects of these errors.

Modeling and the GPS Observables

Developing well-chosen functional models F , relating the GPS measurements L to the modeled parameters X , enables users to fit GPS to their needs. A wide class of applications, from monitoring the subsidence of oilrigs in the open sea to real-time navigation of vehicles collecting geospatial information, belongs to the range of possibilities opened up by the introduction of GPS.

In satellite geodesy, one traditionally modeled the state of the satellite — a vector combining the positional (X) and the velocity (\dot{X}) information. GPS provides geodesists, and geoscientists in general, with a tool by which the state of the observer, also in terms of position (x) and velocity (\dot{x}), can be determined with high accuracy and often in real time. The GPS satellite geodetic model has evolved to:

$$\mathbf{L} = F(X, \dot{X}, x, \dot{x}, \mathbf{p}, t) \quad (167.23)$$

where $L = C/A$ code, P code, or carrier phase observations, $i = 1, \dots, n$, $X = 3$ -D position of the satellite at epoch t , $\dot{X} = 3$ -D velocity of the satellite at epoch t , $x = 1$ -D, 2-D, or 3-D position of the observer at epoch t , $\dot{x} = 1$ -D, 2-D, or 3-D velocity of the observer at epoch t , $\mathbf{p} =$ vector of modeled (known or unknown) parameters, $j = 1, \dots, u$, and $t =$ epoch of measurement taking.

Various differencing operators D^k , up to order three, are applied to the original observations to take full benefit of the GPS measurements. The difference operator D^k may be applied in the observation space spanned by the vector L [Equation (167.24)], or the D^k operator may be applied in the parameter space x (Equation (167.25)):

$$D^k[\mathbf{L}] = D^k[F(X, \dot{X}, x, \dot{x}, \mathbf{p}, t)] \quad (167.24)$$

$$\mathbf{L} = F(X, \dot{X}, D^k(x, \dot{x}), \mathbf{p}, t) \quad (167.25)$$

The latter method is sometimes referred to as “delta positioning.” This is a difficult way of saying that one may either construct so-called derived observations from the original observations by differencing techniques, or model the original observations, compute parameters (e.g., coordinates) in this way, and subsequently start a differencing technique on the results obtained from the roving receiver and the base receiver.

Pseudo Range

We restrict the discussion to the C/A -code pseudo-range observables (pr). The ranges are called “pseudo” because they are calculated using time difference based on two independent clocks. The time offset δt_E^S between the satellite clock S and the receiver clock E yields one additional parameter to be solved for. Writing the observation equation in the Earth-fixed reference frame, we have:

$$pr = \sqrt{(x^S - x_E)^2 + (y^S - y_E)^2 + (z^S - z_E)^2} - c \cdot \delta t_E^S \quad (167.26)$$

Inspection of the partials,

$$\frac{\partial pr}{\partial x^S} = \frac{x^S - x_E}{pr} = -\frac{\partial pr}{\partial x_E} \quad (167.27)$$

$$\frac{\partial pr}{\partial y^S} = \frac{y^S - y_E}{pr} = -\frac{\partial pr}{\partial y_E} \quad (167.28)$$

$$\frac{\partial pr}{\partial z^S} = \frac{z^S - z_E}{pr} = -\frac{\partial pr}{\partial z_E} \quad (167.29)$$

$$\frac{\partial pr}{\partial(\delta t_E^S)} = -c \quad (167.30)$$

reveals the following:

- The coordinates of the stations are primarily obtained in a frame determined by the satellites or, better, by their broadcast ephemeris.
- Partial derivatives for neighboring stations are practically identical, so the coordinates of one station need to be adopted.

Carrier Phase

For precise engineering applications, the phase of the carrier wave is measured. Two wavelengths are available in principle:

$$L_1: \lambda_1 = \frac{c}{f_1} \quad \text{with } f_1 = 1.57542 \text{ GHz} \quad (167.31)$$

$$\cong 19.0 \text{ cm}$$

and

$$L_2: \lambda_2 = \frac{c}{f_2} \quad \text{with } f_2 = 1.22760 \text{ GHz} \quad (167.32)$$

$$\cong 24.4 \text{ cm}$$

For phase measurements the following observation equation can be set up:

$$\text{Range} = \phi + N \cdot \lambda_l, \quad l = 1, \dots, 2 \quad (167.33)$$

or

$$\Phi_E^S = \sqrt{(x^S - x_E)^2 + (y^S - y_E)^2 + (z^S - z_E)^2} - N_E^S \cdot \lambda_l \quad (167.34)$$

where Φ_E^S is the phase observable in a particular S-E combination, and N_E^S is the integer multiple of wavelengths in the range: the ambiguity. Phase measurements can be done with probable 1% accuracy. This yields an observational accuracy — in case the ambiguity N can be properly determined — in the millimeter range!

Various differencing operators on the phase measurements are used in GPS positioning:

- Single differences
 - Between receiver differences, $\Delta\Phi$, eliminating or reducing satellite-related errors
 - Between satellite differences, $\nabla\Phi$, eliminating or reducing receiver-related errors
 - Between epoch differences, $\delta\Phi$, eliminating phase ambiguities per satellite-receiver combination

TABLE 167.1 Accuracy Grades of Civilian/Commercial GPS Receivers

| | | |
|---------------------|---------------------------|-----------------------------------|
| Navigation grade | 15–100 m | C/A code, in stand-alone mode |
| Mapping (GIS) grade | 2–5 m | C/A code, in differenced mode |
| Surveying grade | 1–2 cm within 10 km | C/A code + phase, differenced |
| Geodesy grade | 5–15 mm over any distance | C/A + P code + phase, differenced |

- Double differences
 - Between receiver/satellite differences, $\nabla\Delta\Phi$, eliminating or reducing satellite-and receiver-related errors, and so forth
- Triple differences
 - Between epoch/receiver/satellite differences, $\delta\nabla\Delta\Phi$, eliminating or reducing satellite/receiver-related errors, and ambiguities

Receivers that use carrier wave observations have, in addition to the electronic components that do the phase measurements, a counter that counts the complete cycles between selected epochs. GPS analysis software uses the triple differences to detect and possibly repair cycle slips occurring during loss of lock.

Design specifications and receiver selection are dependent on the specific project accuracy requirements. In the United States, the Federal Geodetic Control Committee has adopted various specifications [FGCC, 1989].

GPS Receivers

A variety of receivers are on the market. Basically, they can be grouped in the four classes listed in Table 167.1. The observations of the first three types of receivers are subjected to models that can be characterized as *geometric* models. The position of the satellite is considered known, based primarily on the information taken from the broadcast ephemeris. The “known” positions are not without error for several reasons. First, the positions are predicted and thus contain errors because of an extrapolation process in time. Second, the positions being broadcast may be corrupted by intentional errors (e.g., by SA if reinstated). Differencing techniques are capable of eliminating most of the errors if the separation between the base station and the roving receiver is not too large.

Millimeter-accurate observations from geodesy-grade receivers often are subjected to analysis through models of the *dynamic* type. Software packages containing dynamic models are very elaborate and allow for an orbit improvement estimation process.

GPS Base Stations

For achieving better accuracy (couple meter or better), additional GPS receiver(s) at known location(s) are required to take measurements in order to correct and reduce errors. This implies that for most applications of GPS in geodesy (e.g., surveying, mapping, photogrammetry, and GIS), one must have access to at least two GPS receivers. If one of the receivers occupies a known location during an acceptable minimum period, one may obtain accurate coordinates for the second receiver *in the same time frame*. In surveying/geodesy applications, it is preferable to include three stations with known horizontal coordinates and at least four with known vertical (orthometric) heights. In most GIS applications, a receiver is left at one particular site. This station serves as a *base station*. There are also GPS correction services that are available. Some are free and some are required to be subscribed. Instead of setting up a base station, a differential GPS survey can be conducted using other available base correction services.

The National Geodetic Survey (NGS), an agency of the National Oceanic and Atmospheric Administration, defines and manages the National Spatial Reference System (NSRS). The NSRS is a consistent coordinate system that defines latitude, longitude, height, scale, gravity, and orientation throughout the United States. The accuracy and accessibility of NSRS depends in large and growing measure on use of GPS.

The High Accuracy Reference Network (HARN) was designed to provide the surveying community with a network of highly reliable positional coordinates to serve as control for surveys. A framework of

GPS stations were established across the country and verified on several occasions by the NGS. The coordinates of the HARN stations were determined by very long baseline interferometry (VLBI), which served as the control for an A-Order survey called the “Eastern Strain Network Project” observed in 1987 and 1990. ESNP became the foundation of the HARN.

The HARN, which is homogeneous across the country, serves as a standard reference to define position accuracy. Relative position accuracy with respect to this reference network may be considered absolute positional accuracy for practical surveying purposes. The accuracy of classical horizontal control was on the order of one part in 100,000 (1 cm over 1 km). GPS is a survey tool with an accuracy of one part per 1,000,000 (1 cm over 10 km). Even for GIS applications where 0.5-m accuracies are claimed for the roving receivers, one may speak of 1-ppm surveys whenever those rovers operate at a distance of 500 km from their base station.

To simplify the process of relative GPS positioning, many government agencies established automated, permanently configured GPS base station facilities to continuously collect and record GPS data. The NGS refers to these automated reference stations as continuously operating reference stations (CORS). The NGS defined a nationwide CORS initiative to support of its mission of providing an accurate and consistent national coordinate system, that is, the NSRS. In effect, the NSRS consists of this CORS network, a network of permanently marked points, and a set of models describing dynamic, geophysical processes that affect spatial measurements.

GPS ties between the HARN and CORS make it possible to evaluate the HARN relative to the CORS, and the NGS has adjusted the HARN to reflect CORS accuracy. Improvements to the reference system began with the High-Precision GPS Network (HPGN) adjusted by NGS in 1990. Subsequent surveys resulted in the current network. The acronym HPGN evolved into the name High-Accuracy Reference Networks (HARN). The HARN is comprised of the NGS-maintained Federal Base Network (FBN), which features 100-km station spacing, and the volunteer-densified Cooperative Base Network (CBN), which typically features 25-km to 50-km spacing. Given its source, the HARN is occasionally referred to as the FBN/CBN.

It should not be forgotten that GPS is a geometric survey tool yielding results in terms of Earth-fixed coordinate differences. From these coordinate differences expressed in curvilinear coordinates, we obtain at best somewhat reproducible ellipsoidal height differences. These height differences are *not* easily converted to orthometric height differences of equal accuracy. The latter height differences are of interest in engineering and GIS applications, as discussed in the next section.

167.6 Gravity Field and Related Issues

One-Dimensional Positioning: Heights and Vertical Control

Some of the most accurate measurements surveyors are able to make are the determinations of height differences by spirit leveling. Because a leveling instrument’s line of sight is tangent to the potential surface, one may say that leveling actually determines the height differences with respect to equipotential surfaces. If one singles out a particular equipotential surface at mean sea level (the so-called geoid), then the heights a surveyor determines are actually *orthometric heights* (Figure 167.3).

FIGURE 167.3 Orthometric heights.

Leveling in a closed loop is a check on the actual height differences, not in a metrical sense but in a potential sense: the distance between equipotential surfaces varies due to local gravity variations. In spherical approximation the potential at a point A is

$$V = -\frac{GM}{r} = -\frac{GM}{R+h} \tag{167.35}$$

The gravity is locally dependent on the change in the potential per height unit, or

$$\frac{dV}{dr} = g = \frac{GM}{r^2} \tag{167.36}$$

The potential difference dV between two equipotential surfaces is

$$dV = g \cdot dr \tag{167.37}$$

Consequently, if one levels in a loop, one has

$$\sum dV = \sum g \cdot dr = 0 \tag{167.38}$$

or

$$\oint dV = \oint g \cdot dr = 0 \tag{167.39}$$

This implies that for each metrically leveled height difference dr , one must multiply this difference by the local gravity. Depending on the behavior of the potential surfaces in a certain area and the diameter of one's project, one may require a gravimeter while leveling.

Variations in local gravity depend on the geology of the area. Variations on the order $10^{-7}g$ may yield errors as large as 10 mm for height differences in the order of several hundred meters. For precise leveling surveys (≤ 0.1 mm/km), gravity observations must be made with an interval of

- 2 to 3 km in relatively "flat" areas
- 1 to 2 km in hilly terrain
- 0.5 to 1.5 km in mountainous regions

For more design criteria on leveling and gravity surveys, see FGCC [1989] and Table 167.2.

GPS surveys yield at best ellipsoidal height differences. These are rather meaningless from the engineering point of view. Therefore, extreme caution should be exercised when GPS height information, even after correction for geoidal undulations, is to be merged with height information from leveling. For two different points i and j ,

$$h_i = H_i + N_i \tag{167.40}$$

$$h_j = H_j + N_j \tag{167.41}$$

TABLE 167.2 FGCC Vertical Control Accuracy Standards (Differential Leveling)

| First Order | |
|--------------|-------------|
| Class I | $b^a < 0.5$ |
| Class II | 0.7 |
| Second Order | |
| Class I | 1.0 |
| Class II | 1.3 |
| Third Order | |
| | 2.0 |

^a $b = S/\sqrt{d}$ (mm/ $\sqrt{\text{km}}$), where S = standard deviation of elevation difference between control points (mm), and d = approximate horizontal distance along leveled route (km).

Subtracting Equation (167.40) from (167.41), we find the ellipsoidal height differences h_{ij} (from GPS) in terms of the orthometric height differences H_{ij} (from leveling) and the geoidal height differences N_{ij} (from gravity surveys):

$$h_{ij} = H_{ij} + N_{ij} \quad (167.42)$$

where

$$h_{ij} = h_j - h_i \quad (167.43)$$

$$H_{ij} = H_j - H_i \quad (167.44)$$

$$N_{ij} = N_j - N_i \quad (167.45)$$

For instance, with the National Geodetic Survey's software program GEOID93, geoidal height differences are as accurate as 10 cm over 100 km for the conterminous U.S. For GPS leveling, this means that GPS may compete with third-order leveling as long as the stations are more than 5 km apart.

In principle, any equipotential surface can act as a vertical datum. The National Geodetic Vertical Datum of 1929 (NGVD29) is not a true mean sea-level datum. Problems may arise in merging GPS heights, gravity surveys and orthometric heights referring to NGVD29. Heights referring to the NGVD88 datum are more suitable for use with GPS surveys. More than 600,000 vertical control stations exist in the U.S.

Two-Dimensional Positioning: East/North and Horizontal Control

In classical geodesy, measurements of height were separated from the horizontal measurements (directions, angles, azimuths, and distances). To allow for the curvature of the Earth and the varying gravity field, the horizontal observations were reduced first to the geoid, taking into account the orthometric heights. Subsequently, it was desirable to take advantage of geometrical properties between the once-reduced horizontal observations, and the observations were reduced once more, from the geoid to the ellipsoid. An ellipsoid approximates the geoid up to 0.01%; variations of the geoid are not larger than 150 m. On the ellipsoid, which is a precise mathematical figure, one could check, for instance, whether the sum of the three angles equals a prescribed value.

In general, geodesists have relied on a biaxial ellipsoid of revolution. A semimajor axis a_e and a semiminor axis b_e define the dimensions of the ellipsoid. Rather than using this semiminor axis, one may specify the flattening of the ellipsoid:

$$f = \frac{a_e - b_e}{a_e} \approx \frac{1}{298.257\dots} \quad (167.46)$$

For a semimajor axis of about 6378.137 km, this implies that the semiminor axis is $6378.137/298.257 \approx 22$ kilometers shorter than a_e .

Distance measurements must be reduced to the ellipsoid. Angular measurements made with theodolites, total stations, and other instruments must be corrected for the following effects:

- The direction of local gravity does not coincide with the normal to the ellipsoid.
- The direction of the first axis of the instrument coincides with the direction of the local gravity vector. Notwithstanding this effect, the Earth's curvature causes nonparallelism of first axes of one arcsecond for each 30 m.
- The targets aimed at for distance calculations generally do not reside on the ellipsoid.

TABLE 167.3 FGCC Horizontal Control Accuracy Standards (Classical Techniques)

| Class I | 1:50 000 (20 mm/km) |
| Class II | 1:20 000 (50 mm/km) |
| Third Order | |
| Class I | 1:10 000 (100 mm/km) |
| Class II | 1:5 000 (200 mm/km) |

TABLE 167.4 Geographic (Spherical) Latitude as a Function of Geodetic Latitude

| Geodetic Latitude | | | Geographic Latitude | | | Geodetic Minus Geographic Latitude | | |
|-------------------|---------|---------|---------------------|---------|---------|------------------------------------|---------|---------|
| Degrees | Minutes | Seconds | Degrees | Minutes | Seconds | Degrees | Minutes | Seconds |
| 00 | 0 | 0.000 | 00 | 00 | 00.000 | 00 | 00 | 00.000 |
| 10 | 0 | 0.000 | 09 | 56 | 03.819 | 00 | 03 | 56.181 |
| 20 | 0 | 0.000 | 19 | 52 | 35.868 | 00 | 07 | 24.132 |
| 30 | 0 | 0.000 | 29 | 50 | 01.089 | 00 | 09 | 58.911 |
| 40 | 0 | 0.000 | 39 | 48 | 38.198 | 00 | 11 | 21.802 |
| 50 | 0 | 0.000 | 49 | 48 | 37.402 | 00 | 11 | 22.598 |
| 60 | 0 | 0.000 | 59 | 49 | 59.074 | 00 | 10 | 00.926 |
| 70 | 0 | 0.000 | 69 | 52 | 33.576 | 00 | 07 | 26.424 |
| 80 | 0 | 0.000 | 79 | 56 | 02.324 | 00 | 03 | 57.676 |
| 90 | 0 | 0.000 | 90 | 00 | 00.000 | 00 | 00 | 00.000 |

The noncoincidence of the gravity vector and the normal is called “deflection of the vertical.” Proper knowledge of the behavior of the local geopotential surfaces is needed for proper distance and angle reductions. Consult Vanicek and Krakiwsky [1982], for example, for the mathematical background of these reductions. The FGCC adopted the accuracy standards given in Table 167.3 for horizontal control using classical geodetic measurement techniques [FGCC, 1984]. In the U.S., over 270,000 horizontal control stations exist.

3-D Positioning: Geocentric Positions and Full 3-D Control

Modern 3-D survey techniques, most noticeably GPS, allow for immediate 3-D relative positioning. 3-D coordinates are equally accurately expressed in ellipsoidal, spherical, or Cartesian coordinates. Care should be exercised to properly label curvilinear coordinates as spherical (geographic) or ellipsoidal (geodetic). Table 167.4 shows the large discrepancies between the two. At the mid-latitudes they may differ by more than 11’. This could result in a north-south error of 20 km. When merging GIS data sets, one should be aware of the meaning “LAT/LONG” in any instance. Consult Stem [1991] for the use of U.S. state plane coordinates. Curvilinear coordinates and their transformations and their use are discussed in a variety of textbooks; see the section “Further Information” for articles such as Soler [1976], Leick and van Gelder [1975], Soler and Hothem [1988], and Soler and van Gelder [1987].

Despite their 3-D characteristics, networks generated by GPS are the weakest in the vertical component, not only because of the lack of physical significance of the GPS determined heights, as described in the preceding subsection, but also because of the geometric distribution of satellites with respect to the vertical: no satellite signals are received from “below the network.” This lopsidedness makes the vertical the worst determined component in 3-D.

Because of the inclination of the GPS satellites, there are places on Earth, most notoriously the mid-latitudes, where there is not an even distribution of satellites in the azimuth sense. For instance, in the

TABLE 167.5 Federal Geodetic Control Committee Three-Dimensional Accuracy Standards (Space System Techniques)

| | |
|---------------------|-----------------------------------|
| AA Order (global) | 3 mm + 1:100 000 00 (1 mm/100 km) |
| A Order (primary) | 5 mm + 1:10,000,000 (1 mm/10 km) |
| B Order (secondary) | 8 mm + 1:1 000 00 (1 mm/km) |
| C Order (dependent) | 10 mm + 1:100 000 (10 mm/km) |

northern mid-latitudes we never have as many satellites to the north as we have to the south (see, for example, Santerre [1991]). This makes latitude the second-best determined curvilinear coordinate.

168.5 GIS and Survey Specifications

Surveying and mapping has been transformed by the explosive growth of geospatial data and the software systems designed to manage, analyze, and map this data. Distinctions have eroded between *computer aided design and drafting* (CADD) and *geographic information systems* (GIS) because both systems are able to use data formats designed for one another. However, distinct differences still exist between CADD and GIS in terms of the types of spatial analysis that can be performed. Automated mapping and facility management (AM/FM) that relies on a database of attributes and spatial location has become widespread and is referred to as an AM/FM system. Even though the integration of GIS data sources into engineering design and mapping is commonplace, understanding the differences in source, resolution, and accuracy between data collected by field surveys and GIS data is crucial to the effective use of such data.

This chapter provides guidance on engineering surveying and mapping standards for geospatial data. It is intended to guide the engineer in the selection and specification of data for use in various project documents, architectural and engineering drawings, planning maps, construction plans, hydraulic and hydrologic studies, and related GIS, CADD, and AM/FM products.

Data collected by traditional survey means, satellite remote sensing, or aerial platforms provide the base mapping that may be assembled in a CADD/GIS system on separate layers. Other sources include digitizing paper maps or converting CADD drawings into GIS data sets. Integration of these diverse data types, sources, and formats into a common database or CADD/GIS system should explicitly recognize the widely differing accuracy and precision. Of fundamental importance is the coordinate system used to plot position of features or themes. Assembly of data from disparate sources often requires transformation of the data into a common coordinate system.

A concurrent step is to document information about the data known as *metadata*, which are data *about* the data. Knowing the origin, lineage, and other aspects of the data you are using is essential to understanding their limitations and getting the most usefulness from the data. The metadata include projection system, datum, and units (metrication) of the original data and derivative products such as reprojection or conversion from meters to U.S. customary units. Documentation for GIS data in the United States has been set forth in the Federal Geographic Data Committee (FGDC) *Content Standards*

for *Digital Geospatial Metadata* (FGDC, 1998). FGDC-compliant metadata files contain detailed descriptions of the data sets, and include narrative sections describing the procedures used to produce the data sets in digital form. Even if detailed FGDC procedures are not followed for a CADD/GIS engineering project, keeping metadata about essential characteristics and sources of the data saves critical project resources by avoiding confusion or over-reliance on inaccurate data.

168.1 GIS Fundamentals

A GIS can be generally described as a computer-based system that stores and manages information and data that are geographically located and graphically displayed in map form. Various CADD/GIS themes are arranged by placing them on separate data layers for convenience in accessing the database or for turning on and off the display of each theme. Decisions regarding data collection in CADD or GIS format rest on the type of analysis required during the project or with future applications. Two major GIS data types are raster and vector. A raster data set has a regular grid of cells with a single attribute assigned to that cell. A vector data set is composed of points, lines, and polylines/polygons that may be assigned multiple attributes within a database. Both data types can be used and displayed in CADD and GIS alike.

Query, selection, and display of georeferenced data are functions supported by both CADD and GIS. Unlike CADD, GIS formats and GIS software permit spatial analysis where new information is derived from the overlay and intersection of two or more features or themes. However, a GIS allows new information to be obtained as the result of analyzing spatial relationships called *topology*. For example, knowing which counties have land areas within a series of watersheds can easily be obtained by overlaying the two themes, counties and watersheds, and getting the spatial intersection. While a CADD system can display the overlay, a new layer will not be produced that shows the counties which have land in a certain watershed. [Figure 168.1](#) represents a simple GIS configuration where information of different types is stacked to form an organizational structure for the system itself. This graphic information is linked to one or more databases to form a relationship between the graphic information and supporting data. Within a GIS, every graphic element, together with its supporting data or attributes, has its own unique geographic coordinates. As such, a GIS can be used to query a database and find information on a geographic feature, element, or area. Many engineering, planning, and environmental projects can make use of both CADD and GIS formats.

Photogrammetric mapping for acquisition of features or topography is of particular importance to an engineering project. Photogrammetric mapping usage is generally divided into four categories: (1) topographic features, planimetric features, orthophotography, and land use. Topography acquisition requires stereo imagery with sufficient overlap, usually at least 60%, and stereo viewing equipment. Because increased precision is expensive, care should be taken to collect photogrammetric maps with appropriate precision and accuracy and with formats that can easily be assembled into CADD/GIS software packages. Orthophotography are aerial photographs that have been georeferenced and corrected for elevation differences, and generally referred to as *digital orthophoto quarter quadrangles* (DOQQs). One-meter resolution panchromatic photography is now available in most U.S. states. Both CADD and GIS software can readily use this data in common image formats such as the tagged image file format (TIFF). DOQQs provide an inexpensive background map for project mapping in CADD/GIS software packages.

Planimetric and topographic mapping most often forms the base data set in a CADD/GIS project. The accuracy of computations and queries made from these base mapping data sets is limited by the least accurate imagery or survey data collected. Collecting geospatial data from satellite or aerial sources involves several types of imagery for various purposes. [Table 168.1](#) lists general types of imagery and associated usage. “Small scale” refers to a ratio scale, meaning that features appear small. An example of a small-scale map would be at 1:100,000. Conversely, large-scale maps are at 1:20,000 or larger. Scales larger than 1:1000 are typical for site plans, whereas small-scale maps are generally used for planning or reconnaissance mapping.

CADD/GIS layers are arranged by theme, which offers convenience in accessing the database or for turning on and off the display of each theme. For this reason, individual layers must be georeferenced

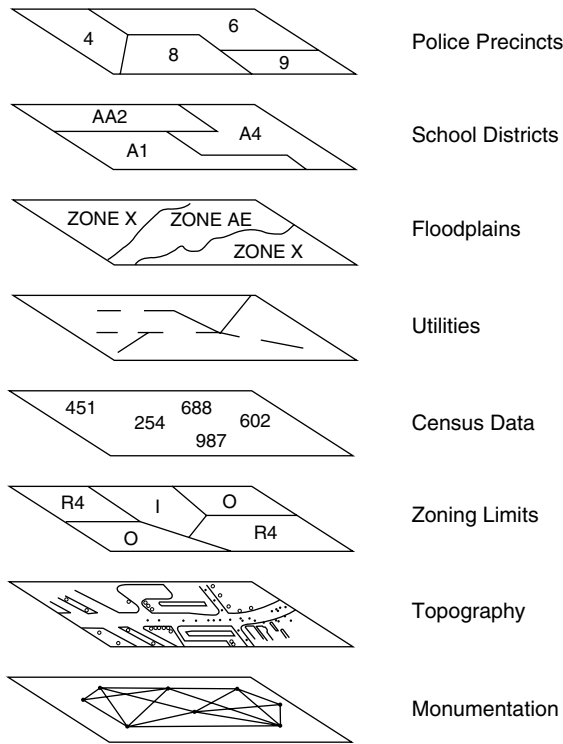

FIGURE 168.1 Simplified GIS layers.

TABLE 168.1 General Types of Imagery and Associated Usage

| Imagery Type | Usage |
|------------------------------------|--|
| Black and white aerial photography | Topographic and planimetric mapping |
| Natural color aerial photography | Topographic and planimetric mapping |
| Infrared aerial photography | Vegetation analysis, land use/land classification |
| Satellite imagery | Small-scale mapping, vegetation analysis, land use/land classification |

to a common ground reference (e.g., state plane, universal transverse mercator, latitude/longitude) so that data from various layers geographically match one another when overlaid. Features are assembled into a database separated into layers, but in a common coordinate system. Not all information is collected to the same degree of horizontal and vertical accuracy and scale. Enlarging a 1:24,000 (1 in = 2000 ft) topographic map to show features at 1 in = 100 ft can misplace features by as much as 0.5 in on the map or 100 ft on the ground. Similarly, for display of topographic relief, contours taken from 1:24,000 quadrangles are considered accurate to within one-half contour interval. These data can be used to create a topographic map showing 2-ft contour intervals far exceeding the accuracy of the source data.

The widespread adoption and availability of digital databases have had a dramatic impact on mapping and GIS/CADD applications. Because data can be manipulated at scales that are inconsistent with the scale at which the data was collected or compiled, care must be taken to fairly represent the data at appropriate scales and contour intervals without falsely conveying more accuracy and precision than is present. Because of the separation of planimetric features and topographic elevations into various layers, and depiction at any scale, problems arise when scales are increased beyond their original values. When merging data collected by traditional survey means, satellite remote sensing, or aerial platforms, maintaining the metadata for each layer in a CADD/GIS system or project becomes as important as the data set itself.

168.2 Monumentation or Control Surveying

This singular subject of establishing a monumentation network is one of the most important issues relating to the surveying applications for a GIS. Selecting the coordinate system and datum is the first step in building a geospatial database. Horizontal and vertical control for field surveys must ultimately be placed within the same coordinate system as other GIS data, or vice versa. Accuracy standards should set the level of accuracy of the monumentation network and remaining surveying information obtained. Most likely, the monumentation control network will be the most accurate data within the GIS. Conversely, the GIS data are most likely the least accurate data set in a CADD drawing containing survey information. In any case, the two data types, CADD and GIS, should not be treated as having equivalent accuracy.

A monumentation system for a GIS is a network of control points or monuments, established in the field, that are referenced not only to each other, but also to a common datum. In the U.S., this common datum is typically established by the National Geodetic Survey (NGS), an agency of the federal government. The NGS has established and maintains a network of first-order monuments with assigned horizontal coordinates across the country. In the past, first order was conventionally thought of as having an accuracy level of 1 part in 100,000; however, with the advancements in surveying equipment technology, first-order monuments commonly have a much higher level of accuracy. In addition, vertical elevation information is often available for many NGS monuments. It is important to understand that these NGS monuments provide a common thread that bonds geographic areas across the country.

Each state has its own coordinate system, as dependent on the map projection used, which is generally a result of the shape of the state or area to be projected. *Map projections* form the basis for planar mapping of geographic areas. A surveyor establishing the monumentation network for a given area must be knowledgeable of the projection and resultant *state plane coordinate system* used in the area.

When we establish a geodetic monumentation network for a GIS, we are typically densifying the existing NGS monumentation system in our area of interest. Often, many NGS monuments are recovered in the field and then used as reference points within the densified monumentation network. The result of the monumentation survey is a network of readily identifiable points throughout an area that can be easily used for land surveying and *aerial photogrammetry*. The fundamental issue at hand is that, once the monumentation network is established, a common datum will exist throughout an area that can be used to reference all subsequent surveying data. Even past surveying information can be moved to this newly established datum via a coordinate transformation.

The actual procedures for establishing a geodetic monumentation network can be divided into several stages that build upon each other:

1. Research existing NGS monuments and field recover the monuments.
2. Design a network layout as referenced to the recovered NGS monuments.
3. Plan the field survey activities to establish the monuments.
4. Execute the field survey activities.
5. Mathematically adjust the network and calculate the coordinates of the monuments.

Recovering the existing NGS monuments in the field can be very time consuming and, at times, frustrating. Many monuments have not been recovered or used for several years; thus, they are often difficult to find. Once recovered, these NGS monuments and their previously established coordinates will be used to reference and constrain the new monuments to be established.

Once the positions of the recovered NGS monuments are known in relation to the area of interest to serve as the geographic region supported by a GIS, a monumentation network is designed that provides the layout of the new monuments. This layout is composed of the existing NGS monuments, the new monuments to be established, and the baselines connecting all of the monuments. The strength and accuracy of a monumentation network is dependent on the design of the layout and, specifically, the baselines within the layout. Today, the most common means used to perform the survey for the establishment of a geodetic monumentation network is the *global positioning system* (GPS). GPS surveying is a method of using satellites and portable field receivers to accurately determine the coordinates of a point.

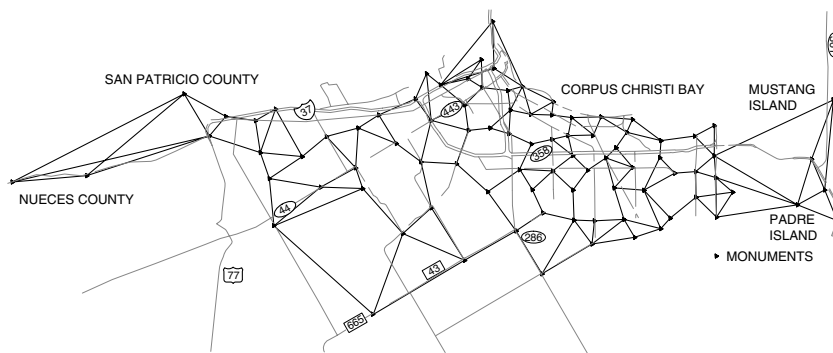

FIGURE 168.2 Baseline and monument layout for a municipal GIS application.

(GPS surveying is discussed in detail in [Chapter 167](#)) A baseline between two monuments is created when separate GPS receivers are set on both points and they receive credible satellite data simultaneously. Figure 168.2 illustrates a designed and successfully implemented baseline and monument layout for a municipal GIS application. In the design of the network layout, consideration must be given to the field procedures required to create the needed baselines throughout the monumentation network.

Once the desired monumentation layout is designed, the field activities themselves must be carefully planned. A poorly planned GPS field survey can result in no useful data collected. Assuming that all goes well during the GPS field surveys and that good data were received from the satellites, the resultant coordinates of the new monuments can be calculated. This entire process is often called *balancing*, *adjusting*, or *constraining* the network. During this process, the entire monumentation network is referenced to the NGS datum, and state plane coordinates are assigned to each monument. State plane coordinates differ from surface coordinates as would be needed for conventional plane table land surveying. Note that state plane coordinates are used in map projections to account for the curvature of the earth. Every point has a scale factor that must be applied to the state plane coordinates (northing and easting) of that point to convert the point's state plane coordinates to surface coordinates at sea level. To account for the difference of the terrain's elevation that normally differs from sea level, a sea level correction factor must be applied as well. The combination of a scale factor and a sea level correction factor is commonly termed a *combined scale factor*. The following equations are used to convert state plane coordinates to surface coordinates:

$$\text{Combined scale factor} = \text{Scale factor} \times \text{sea level correction factor}$$

$$\text{Surface coordinate} = \text{State plane coordinate} / \text{combined scale factor}$$

It is extremely important that the relationship between surface and state plane coordinates is understood. A conventional land surveyor does not measure distances, for example, along the map projection utilized, but, rather, along the true terrain surface being surveyed. Because of this, features must be scaled accordingly.

After the horizontal coordinates of the monuments are established, vertical elevations can be determined for the points, such as to support surveys that are in need of relational elevations. Once again, a similar method of balancing or adjusting the network is utilized as based upon the known elevations of points within the monumentation network. Much advancement has been made in accurately calculating vertical elevations using GPS surveying. This is mostly a result of the ability to more accurately account for the true shape of and anomalies in the earth's surface. The accuracy achieved by GPS surveying has resulted in reduced errors in location of features, both horizontally and vertically. Integration of these data into a CADD/GIS system requires proper coordinate transformations and adjustment with the combined scale factor.

168.3 Topographic Surveying

Much of the data and base mapping in a CADD/GIS system is supplied by topographic surveying. Besides collection of elevation X-Y-Z points (called mass points), other features are recorded, such as locations of telephone/utility poles, curb edges, fire hydrants, and many other objects relevant to the project. In a sense, the surveyor digitizes real objects for digital representation in a CADD/GIS system. What the surveyor includes in the survey in terms of topography, utilities, property corners, and so forth will dictate how much information and the accuracy available within the CADD/GIS database. The types of features, level of detail, and accuracy should be commensurate with project needs and requirements.

The methods used to perform topography surveying can vary tremendously. The most common method used is conventional land surveying, which has changed dramatically with advanced technology. Electronic data collectors using total stations are now standard procedure. Kinematic and differential GPS receivers are used routinely to gather elevation and other features for topographic surveys. In conjunction with conventional land surveys, aerial photogrammetry is a common means of obtaining contours for planning purposes. Although conventional land surveying and aerial photogrammetry are some of the most popular means of collecting topographic data for GIS applications. Other methods, such as *satellite imagery*, may be applied as well. Care must be taken to ensure that the vertical and horizontal resolution and accuracy are adequate for the intended purpose. While satellite-derived topographic information is useful for planning purposes over large spatial extents, the vertical accuracy may limit its use for site development, construction, or other purposes that require more accurate elevations. Similarly, the horizontal location of planimetric features from satellite imagery is less accurately known than data collected by photogrammetry, *Light detection and ranging* (LIDAR), electronic total station, GPS, or other field survey techniques. Evidence of misalignment becomes apparent when contours or other features such as stream channels derived from other sources of differing accuracy are overlaid on the imagery.

In performing a conventional topographic survey, a surveyor will traverse between the geodetic network monuments, obtaining as much topographic information as desired. Again, the information sought is dependent on the demands of the GIS that dictate the detail needed in terms of the survey data obtained. The traversed line of the survey between the monuments is balanced in terms of angles and distances as based upon the known coordinates of the monuments; this will ensure that coordinates of the obtained topographic features are properly determined in relation to the datum used for the GIS. [Figure 168.3](#) represents a series of points obtained for a GIS using conventional topographic surveying techniques. [Figure 168.4](#) illustrates the same data in their final form, as would be input graphically into the GIS. Every point has its own unique address and attribute. A fire hydrant, for example, will have its own specific coordinates. A relational database can be linked to the fire hydrant graphic element within the GIS, which would provide such information as when the hydrant was installed and when last checked to ensure its proper operating condition. Assigning codes in the field to represent features such as fire hydrants using an electronic data collector and total station simplifies the plotting and database development in the office.

When acquiring aerial photogrammetry for topographic mapping and other purposes, control points must be established within a coordinate system consistent with other mapped features. Linking the aerial photography to the monumentation network is achieved by referencing the aerial photographs to known points on the ground that can be clearly identified in the photographs. This is typically done by *painting*, that is, laying down of panels (or in many cases, taping) white or contrasting colored marks on the ground in the shape of an “X” or a “V” that can be clearly identified in the photograph. These marks are then tied to the monument system conventionally with ground surveys. The end result is an aerial photograph, or series of photographs, rectified to accurately illustrate the existing topography on the proper coordinate system. Once the aerial photographs are produced, they are digitized into graphic elements that are directly incorporated into a GIS. With the horizontal position of the topographic features, the elevation contours and many specific point elevations can be determined as well.

FIGURE 168.3 Series of points obtained using conventional topographic surveying techniques.

FIGURE 168.4 Points converted to topographic features to be input graphically into a GIS.

168.4 Digital Representation of Topography

Many GISs are being developed that store topographic information as the primary data for analyzing water resource and biological problems. Digital topography can be used to develop physically realistic models of terrain for land grading, project visualization, and hydraulic/hydrologic applications. A *digital elevation model* (DEM) is an ordered array of numbers that represents the spatial distribution of elevations above some arbitrary datum in a landscape. It usually consists of elevations sampled at discrete points on an irregular spacing over the landscape or on regular intervals. Field surveys may be used to collect elevations and then transform them into a DEM, also called a *digital terrain model* (DTM). When discussing the use of DEMs, it is important to consider the way in which the surface representation is to be used and how it was generated. The ideal data structure for a DEM depends on the project purpose. There are three principal ways of structuring digital elevation data: (1) grid based or raster; (2) triangular irregular network (TIN); and (3) contours.

Grid-based methods use regularly spaced elements or cells to represent the terrain. Grid DEMs are useful for automated watershed delineation. Preprocessing and quality control of the DEM are necessary to insure accurate results for applications such as hydrological modeling. No automatically produced drainage network is likely to be very accurate in flat areas because drainage directions assigned across flat areas are not assigned using information directly held in the DEM. This is particularly true where elevation differences are less than the contour interval of the original map used to create the DEM. A

FIGURE 168.5 Digital elevation map based on a raster data structure. (Courtesy Vieux & Associates, Inc., Norman, OK.)

river or stream vector map may be used to *burn in* the elevations forcing the drainage network to coincide with the vector map depicting the desired drainage network. In some cases, this procedure may introduce anomalies because of inaccuracies in the vector map of stream locations. Triangular networks are usually sample surfaces at specific points, such as peaks, ridges, and breaks in slope. The resulting *TIN* formed consists of points stored as x, y, and z coordinates together with pointers to their neighbors. The elemental area is the plane joining three adjacent points in the network and is known as a facet. TIN elevations are stored more efficiently because the facets in a TIN can be varied to represent highly variable terrain with many small triangles, and flat areas with fewer triangles. TIN data structures can provide striking visualizations of terrain. Hydrologic studies or determining the topographic attributes of the landscape may be more efficiently accomplished using a regular grid than contour-based or TIN DEMs. In the three images shown in Figure 168.5, Figure 168.6, and Figure 168.7, digital elevation data are portrayed as raster, TIN, and contours. The data contained in this 20-ft resolution DEM were developed from LIDAR data acquired in January through March 2001. Cell values in the DEM were derived from a TIN produced from the bare earth mass points measured by LIDAR. Individual cell values are based on an average of 25 points inside each 20-ft DEM cell. These data were collected and derived by the North Carolina Floodplain Mapping Program as part of its effort to modernize flood insurance rate maps statewide. Although created for specific use in the engineering aspects of floodplain delineation, the data were also developed to address the elevation data requirements of the broader geospatial data user community. The North Carolina Floodplain Mapping Program (NCFMP, 2003) was established in response to the extensive damage caused by Hurricane Floyd in 1999. The vertical accuracy of the elevation data is less than or equal to 25 cm root mean square error (RMSE). LIDAR DEMs are becoming standard means for topographic mapping at very high spatial resolutions. Because of the high resolution of measurement, automated and manual procedures are required to remove points that do not belong to the terrain surface, such as water, vegetation, buildings, and system noise.

FIGURE 168.6 Digital elevation model using the TIN data structure.

FIGURE 168.7 Digital elevation model using contours.

From the DEMs, the Tar River channel area is apparent in [Figure 168.5](#) with steep topography south and a flatter floodplain area to the north. Topographic relief is made more visible in [Figure 168.6](#) by using the TIN image data structure. Regardless of the data structure used to represent terrain, the analyst should realize that the DEM likely contains anomalies or artifacts resulting from data processing that can distort accurate representation of the surface. The contour lines in [Figure 168.7](#) were derived from the TIN at 2-ft contour intervals. The field checking of contours, breaklines, and derived drainage features such as stream locations and watershed boundaries is important just as it is with paper topographic maps.

168.5 GIS and Survey Specifications

Development of engineering plans often relies on spatial data collected from a variety of sources with mixed accuracies. Defining accuracy standards for mixed data makes metadata all the more important for a project. The purpose of the collected data defines the horizontal accuracy, target map scale, and vertical relief. Horizontal and vertical control survey accuracy should be selected that are consistent with the intended purpose of the map or analysis. Usually 1:5000 third-order control procedures (horizontal and vertical) will provide sufficient accuracy for most engineering work. In most small-scale or GIS mapping, third-order, class II methods and fourth-order topographic and construction control methods are adequate. Higher order control surveys may not be necessary. In some cases, the location of a feature is known more precisely than can be shown at the target map scale. [Table 168.2](#) provides a summary of planimetric feature coordinate accuracy requirements for well-defined points adapted from the American Society for Photogrammetry and Remote Sensing (ASPRS) *Standards for Large-Scale Mapping* (adapted from USACE, 1998). The ASPRS planimetric standard for horizontal accuracy is based on the RMSE between map coordinates at the specified map scale and field locations of well-defined features determined by an independent check survey of higher accuracy. The term “limiting RMSE” is the minimum error allowed for a percentage of points or confidence interval. The RMSE is the cumulative result of all errors originating from ground-control surveys, map compilation, and final extraction of ground dimensions at the target map scale. Vertical accuracy criteria are based on the required contour interval. [Table 168.3](#)

TABLE 168.2 ASPRS Planimetric Feature Coordinate Accuracy Requirements for Well-Defined Points

| Target Map Scale | | ASPRS Limiting RMSE in X or Y in Feet | | |
|------------------|-------------------|---------------------------------------|---------|---------|
| 1" = x ft | Ratio Scale ft/ft | Class 1 | Class 2 | Class 3 |
| 5 | 1:60 | 0.05 | 0.10 | 0.15 |
| 10 | 1:120 | 0.10 | 0.20 | 0.30 |
| 20 | 1:240 | 0.2 | 0.4 | 0.6 |
| 30 | 1:360 | 0.3 | 0.6 | 0.9 |
| 40 | 1:480 | 0.4 | 0.8 | 1.2 |
| 50 | 1:600 | 0.5 | 1.0 | 1.5 |
| 60 | 1:720 | 0.6 | 1.2 | 1.8 |

shows specifications for topographic elevation accuracy requirements (RMSE) for well-defined points. When a DTM is being generated, then an equivalent contour interval may be specified. The RMSE of vertical elevation of well-defined points are determined by differential leveling or other methods of higher accuracy. The equivalent contour interval of the DTM used in defining the accuracy standard is an important component of the metadata because contours at any interval may subsequently be derived in a GIS/CADD mapping system. Both tables are guides for selecting target map scale, contour interval, and vertical/horizontal accuracy for planimetric and topographic data acquisition.

The scale and accuracy of all data collected, whether by field survey instruments, photogrammetry, LIDAR, satellite remote sensing, or GPS should be consistent with project goals. *Over-specifying* the precision of data collection can lead to costly data acquisition that wastes project resources. *Under-specifying* precision can lead to erroneous planning and engineering design that results in costly construction modifications. Care should be exercised to meet project goals with *adequate* scale and accuracy, and to use metadata to document the source and processing of each data layer in a CADD/GIS system.

Defining Terms

Aerial photogrammetry — The surveying of surface features through the use of photographs, as taken from an aerial perspective (i.e., an airplane).

Combined scale factor — A factor that can be used to convert state plane coordinates to surface terrain coordinates, considering the map projection used and the relative elevation of the point of interest.

Digital elevation model (DEM) — An ordered array of numbers that represent the spatial distribution of elevations above some arbitrary datum in a landscape.

Digital terrain model (DTM) — An ordered array of numbers that represent attributes related to terrain that include, but not limited to, the spatial distribution of elevations above some arbitrary datum. Often used synonymously with a DEM.

Geographic information system (GIS) — A computer-based system that stores and manages information and data as related to a geographic area.

Global positioning system (GPS) — A method of surveying that uses transmitting satellites and portable field receivers to accurately determine the coordinates of a point.

Light detection and ranging (LIDAR) — An active sensory system that uses laser light to measure distances between an airborne platform and points on the ground, including trees, buildings, and other features, to collect and generate densely spaced and highly accurate elevation data.

Map projection — The projection of the Earth's surface to a two-dimensional plane (or map), considering the curvature of the Earth.

Metadata — Data *about* the data including origin, lineage, and other aspects of the data including documentation of its resolution, scale, accuracy, projection, and datum.

Monumentation surveying — The establishment or recovery of a horizontal and/or vertical coordinate control network as based upon a layout of monuments or control points.

Photogrammetric mapping — A method for acquiring topographic features, planimetric features, orthophotography, and land use by aerial photography using overlapping stereo imagery.

Raster data — A data set composed of regularly spaced grid cells with a single attribute assigned to each cell.

Satellite imagery — Images of the Earth's surface as obtained from orbiting satellites.

State plane coordinate system — A coordinate system used throughout the United States that is based on the map projection of one or more zones within each state.

Topographic surveying — The surveying of topographic features through conventional land surveying, aerial photogrammetry, or other means.

Vector data — A vector data set is composed of points, lines, and polylines/polygons that may be assigned multiple attributes within a database.

Further Information

One of the largest sources of information pertaining to surveying applications for geographic information systems is the American Congress of Surveying and Mapping (ACSM), 5410 Grosvenor Lane, Bethesda, MD 20814-2122. The ACSM publishes journals relating to surveying, mapping, and land information.

The NGS Information Center maintains a tremendous amount of valuable information on geodetic surveying, horizontal and vertical coordinate listings, and other applicable publications. This information may be obtained from NOAA, National Geodetic Survey, N/CG17, 1315 East-West Highway, Room 9202, Silver Spring, MD 20910-3282.

The "American Society for Photogrammetry and Remote Sensing (ASPRS) Standards for Large-Scale Mapping" (ASPRS, 1990) and the Federal Geographic Data Committee (FGDC), "Geospatial Positioning Accuracy Standards, Part 4: Standards for Architecture, Engineering, Construction (A/E/C) and Facility Management" (FGDC, 1998), provide accuracy standards for geospatial (CADD/GIS) data.

169.6 Digital Image Processing

Remote sensing involves the use of airborne and space-imaging systems to inventory and monitor Earth resources. Broadly defined, remote sensing is any methodology employed to study the characteristics of objects from a distance. Using various remote sensing devices, we remotely collect *data* that can be analyzed to obtain *information* about the objects, areas, or phenomena of interest. This chapter discusses sensor systems that record energy over a broad range of the *electromagnetic spectrum*, from ultraviolet to microwave wavelengths.

Remote sensing affords a practical means for frequent and accurate monitoring of the Earth's resources from a site-specific to global basis. This technology is aiding in assessing the impact of a range of human activities on our planet's air, water, and land. Data obtained from remote sensors have provided information necessary for making sound decisions and formulating policy in a host of resource development and land use applications. Remote sensing techniques have also been used in numerous special applications. Expediting petroleum and mineral exploration, locating forest fires, providing information for hydrologic modeling, aiding in global crop production estimates, monitoring population growth and distribution, and determining the location and extent of oil spills and other water pollutants are but a few of the many and varied applications of remote sensing that benefit humankind on a daily basis. It should be pointed out that these applications almost always involve some use of *ground truth* or on-the-ground observation. That is, remote sensing is typically a means of extrapolating from, not replacing, conventional field observation.

169.1 Electromagnetic Energy

The sun and various other sources radiate electromagnetic energy over a range of wavelengths. Light is a particular type of *electromagnetic radiation* that can be seen or sensed by the human eye. All electromagnetic energy, whether visible or invisible, travels in the form of sinusoidal waves. Wavelength ranges of special interest in remote sensing are shown in [Table 169.1](#).

When electromagnetic energy is incident upon an object on the Earth's surface, it can interact with the object in any or all of three distinct ways. The incident energy can be reflected, transmitted, or

TABLE 169.1 Components Electromagnetic Spectrum

| Wavelength | Spectral Region |
|--------------------------|--|
| 0.3 to 0.4 μm | Ultraviolet |
| 0.4 to 0.7 μm | Visible: 0.4 to 0.5 μm = blue 0.5 to 0.6 μm = green 0.6 to 0.7 μm = red |
| 0.7 to 1.3 μm | Near infrared |
| 1.3 to 3.0 μm | Mid-infrared |
| 3 to 14 μm | Thermal infrared |
| 1 mm to 1 m | Microwave |

absorbed. The absorbed component goes into heating the body and is subsequently re-emitted from the object. The particular mix of these three possible interactions is dependent on the physical nature of objects. For example, healthy vegetation normally appears green because the blue and red components of the incident light are absorbed by chlorophyll present in plant leaves. In contrast, concrete surfaces strongly reflect blue, green, and red wavelengths nearly equally and appear light gray. Remote sensors record such variations in energy interaction (both in visible and invisible wavelengths) in order to discriminate among Earth surface features and to assist in quantifying their condition.

All objects at a temperature greater than absolute zero radiate energy according to the formula

$$M = \sigma \epsilon T^4 \quad (169.1)$$

where M is the total radiant exitance (radiated energy) from the surface of a material (W m^{-2}), σ is the *Stefan-Boltzmann constant* ($5.6697 \cdot 10^{-8} \text{ W m}^{-2}\text{K}^{-4}$), ϵ is the emissivity (efficiency of radiation) of the material, and T is the absolute temperature (K) of the emitting material. The general shape of the resulting curves of *emitted energy* (radiant exitance) versus wavelength is shown in Figure 169.1(a). The wavelength at which the amount of emitted energy is a maximum is related to its temperature by *Wien's displacement law*, which states that

$$\lambda_m = \frac{A}{T} \quad (169.2)$$

where λ_m is the wavelength of maximum spectral radiant exitance (μm), $A = 2898 \mu\text{m K}$, and $T =$ temperature (K). Note that the sun's energy has a peak wavelength of 0.48 μm (in the visible part of the spectrum), whereas the Earth's energy has a peak wavelength of 9.67 μm (invisible to the human eye, but able to be sensed by a thermal scanner).

Reflected energy is recorded when objects are sensed in sunlight in the ultraviolet, visible, nearinfrared or midinfrared portions of the spectrum. Radiated energy is recorded in the thermal infrared portion of the electromagnetic spectrum using radiometers and thermal scanners. This allows, for example, the detection and recording of the heated effluent from a power plant as it flows into a lake at a cooler temperature.

Remote sensing systems can be active or passive systems. The examples cited earlier are passive systems in that they record reflected sunlight or emitted radiation. Radar systems are called *active systems* because they supply their own energy. Pulses of microwave energy are transmitted from radar systems toward objects on the ground, and the backscattered energy is then received by radar antennas and used to form images of the strength of the radar return from various objects. Lidar, like radar, is an active remote sensing technique. Such systems use pulses of laser energy directed toward the ground and measure the time of pulse return. The return time for each pulse back to the sensor is processed to calculate the variable distances between the sensor and the various surfaces present on (or above) the ground.

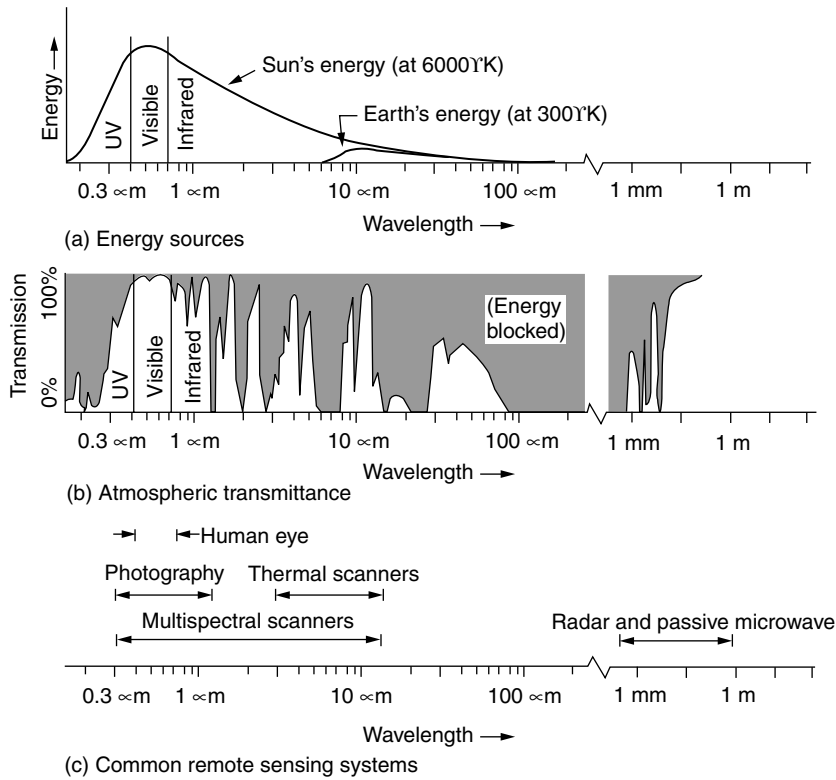

FIGURE 169.1 Spectral characteristics of (a) energy sources, (b) atmospheric effects, and (c) sensing systems. Note that the wavelength scale is logarithmic. (Source: Lillesand, T. M., Kiefer, R. W., and Chipman, J. W., *Remote Sensing and Image Interpretation*, 5th ed., John Wiley & Sons, New York, 2004. With permission.)

169.2 Atmospheric Effects

Because the atmosphere contains a wide variety of suspended particles, it offers energy interaction capabilities just as “ground” objects do. The extent to which the atmosphere transmits electromagnetic energy is dependent upon wavelength, as shown in Figure 169.1(b). The sensing systems typically used in various wavelength ranges are shown in Figure 169.1(c). Energy in the ultraviolet wavelengths is scattered greatly, which limits the use of ultraviolet wavelengths from aerial or space platforms. The atmosphere is transparent enough in the visible, nearinfrared, and midinfrared wavelengths to permit aerial photography and multispectral sensing in these wavelengths. In this region the blue wavelengths are scattered the most and the midinfrared wavelengths are scattered the least. In the thermal infrared region, there are two “windows” where the atmosphere is relatively transparent: 3–5 μm and 8–14 μm wavelength (most aerial thermal scanning is done in the 8–14 μm band). At microwave wavelengths, the atmosphere is extremely transparent, and many radar systems can be operated in virtually all weather conditions.

169.3 Remote Sensing Systems

Aerial Photography

Aerial photographs can be taken on any of several film types, from a variety of altitudes. Mapping cameras typically use an image size of 230 by 230 mm. Smaller-format cameras (70 mm and 35 mm) can be used where large-area coverage with great geometric fidelity is not required. The interpretability of aerial photographs is highly dependent on the selection of film type and image scale.

Principally because of cost considerations, the film most widely used for aerial photography is black and white (b/w). Panchromatic films are b/w films sensitive to the visible portion of the electromagnetic spectrum (0.4 to 0.7 μm). The sensitivity of b/w infrared films includes both the visible part of the spectrum and also the wavelengths 0.7 to 0.9 μm (near infrared). It is important to note that infrared energy of these wavelengths does not represent heat emitted from objects, but simply reflected infrared energy to which the human eye is insensitive.

Color and color infrared films are also widely used for aerial photography. Although the cost of using these films is greater than for b/w films, they provide greater information content due to the human eye's ability to discriminate substantially more colors than shades of gray. Normal color films have three separate emulsion layers sensitive to blue, green, and red wavelengths, respectively. Color infrared films have three similar emulsion layers, but they are sensitive to green, red, and near-infrared wavelengths, respectively. Again, as in the case of b/w infrared films, it is reflected sunlight, not emitted energy, that is photographed with color infrared film.

Digital cameras use a camera body and lens but record image data typically using an array of either CCD (charge-coupled device) or CMOS (complementary metal oxide semiconductor) detectors rather than film. In turn, the electrical signals generated by these detectors are stored digitally using various storage media. Although this process is not "photography" in the traditional sense (images are not recorded directly onto photographic film), it is often referred to as "digital photography." Of course, hardcopy photographs can also be converted into an array of digital picture elements (*pixels*) using some form of image scanner.

Video cameras are sometimes used as a substitute for small-format (70 mm and 35 mm) cameras. Video camera data are typically recorded on videotape or on CD or DVD media.

The scale of photographs affects the level of useful information they contain. Small-scale photographs (1:50,000 or smaller) are used for reconnaissance mapping, large-area resource assessment, and large-area planning. Medium-scale photographs (1:12,000 to 1:50,000) are used for the identification, classification, and mapping of such items as tree species, agricultural crop types, vegetation communities, and soil types. Large-scale photographs (larger than 1:12,000) are used for the intensive monitoring of specific items such as surveys of the damage caused by plant diseases, insects, or tree blow-downs. Applications such as hazardous waste site assessment often require very large-scale photographs.

The principles of *photogrammetry* can be used to obtain approximate distances and ground elevations from aerial photographs using relatively unsophisticated equipment and simple geometric concepts, as well as to obtain extremely precise maps and measurements using "softcopy" photogrammetric procedures. The latter approach involves the use of digital, rather than hardcopy, images. The digital images are either acquired by a digital camera designed for photogrammetric applications or by scanning airphotos taken with a precision mapping camera.

Softcopy photogrammetric procedures are implemented in an integrated hardware and software environment providing for end-to-end spatial data capture, manipulation, analysis, storage, display, and output of softcopy images. Such systems enable automated generation of digital elevation models (DEMs), and the capture of two-dimensional and three-dimensional data for direct entry into a geographic information system (GIS). They also enable the production of perspective views (singly or in a fly-through series) and *digital orthophotos*. Digital orthophotos are images that result from pixel-by-pixel mathematical correction for the various geometric distortions present in conventional aerial photographs.

Multispectral, Thermal, and Hyperspectral Scanners

Multispectral scanners are electro-optical devices that sense selectively in multiple spectral bands using electronic detectors rather than film. They sense one small area on the ground at a time and, through scanning, build up two-dimensional images of the terrain for a swath beneath an aircraft or spacecraft. Through this process, they collect rows and columns of image data that can be computer processed. As shown in [Figure 169.1](#), multispectral scanners can sense in a much broader spectral range than film.

Multispectral scanners are the sensing devices used in most Earth resource satellite systems operating in the optical portion of the electromagnetic spectrum (discussed later).

Thermal scanners are electro-optical devices that sense in the thermal infrared portion of the electromagnetic spectrum. They do not record the true internal temperature of objects (kinetic temperature), but rather their apparent temperature based on the radiation from their top surfaces (radiant temperature). Because they sense energy emitted (rather than reflected) from objects, thermal scanning systems can operate day or night. Multiple thermal bands can be sensed simultaneously, as in the case of the National Aeronautic and Space Administration's (NASA) *thermal infrared multispectral scanner*. Successful interpretations of thermal imagery have been made in such diverse tasks as determining rock type and structure, locating geological faults, mapping soil type and moisture conditions, determining the thermal characteristics of volcanoes, studying evapotranspiration from vegetation, locating cold water springs, determining the extent and characteristics of thermal plumes in lakes and rivers, delineating the extent of active forest fires, and locating underground coal mine fires.

Often, thermal scanners are designed and operated to acquire oblique views of the terrain ahead of an aircraft. These *forward-looking infrared (FLIR)* systems can be operated on a wide variety of fixed-wing aircraft and helicopters as well as from ground-based mobile platforms. FLIR systems have been used extensively in military applications. Civilian use includes such applications as fire fighting, electrical transmission line maintenance, law enforcement activities, and nighttime vision systems for automobiles.

Hyperspectral scanners acquire multispectral images in many very narrow, contiguous spectral bands throughout the visible, nearinfrared, and midinfrared portions of the electromagnetic spectrum. These systems typically collect 200 or more channels of data, which enables the construction of an effectively continuous reflectance spectrum for every pixel in the scene (as opposed to the four to six broad spectral bands commonly used by satellite systems). Research continues in the development of *ultraspectral scanners*, which employ channels numbering in the thousands.

Imaging Radar

An increasing amount of valuable environmental and resource information is being acquired by active radar systems that operate in the microwave portion of the spectrum. Microwaves are capable of penetrating the atmosphere under virtually all conditions. Depending on the specific wavelengths involved, microwave energy can penetrate clouds, fog, light rain, and smoke. Imaging radar uses an antenna pointed to the side of the aircraft or spacecraft. Because the sensor is mounted on a moving platform, it is able to produce continuous strips of imagery depicting very large ground areas located adjacent to the flight line.

Microwave reflections from Earth materials bear no direct relationship to their counterparts in the visible portion of the spectrum. For example, many surfaces that appear rough in the visible portion of the spectrum may appear smooth as seen by microwaves (e.g., a white sand beach). The appearance of various objects on radar images depends principally on the orientation of the terrain relative to the aircraft or spacecraft (important because this is a side-looking sensor), the object's surface roughness, its moisture content, and its metallic content.

Radar image interpretation has been successful in applications as varied as mapping major rock units and surficial materials, mapping geologic structure (folds, faults, and joints), discriminating vegetation types (natural vegetation and crops), determining sea ice type and condition, and mapping surface drainage patterns (streams and lakes). Imaging radar has also been used extensively as a means of topographic mapping. *Imaging radar interferometry* is the basis for this application. It is based on analysis of the phase difference of the radar signals as received by two antennas located at different positions during imaging. If the angle and distance between the two antennas is known with a high degree of accuracy, the phase difference associated with any point on the terrain can be used to determine the elevation of the point. The *Shuttle Radar Topography Mission*, conducted in 2000, used this procedure to map over 119 million km² of the Earth's surface, including over 99.9% of the land area between 60° N and 56° S latitude.

Radar images can also be used to study Earth surface changes that occur between two passes of a radar system. This procedure is known as *differential interferometry* and usually involves the acquisition of one interferometric image pair from the period before the surface change occurs and a third image after the change. The phase difference between the “before” and “after” images can be corrected to account for topography, with the residual phase differences then representing changes in the position of features on the surface (often measured to within 1 cm or better). This procedure has been used in such applications as monitoring ground uplift near volcanoes, measuring the displacements across faults after earthquakes, studying the movement of glaciers and ice sheets, and detecting land subsidence due to the pumping of groundwater, oil extraction, mining, and other activities.

Lidar

Lidar (which stands for *light detection and ranging*) is yet another very effective means for determining the elevation of objects on or above the Earth’s surface. Early lidar systems were profiling devices that obtained elevation data only directly under the path of an aircraft. The application of these systems was limited to such activities as bathymetric mapping.

Modern lidar systems are scanning devices that are typically operated in combination with an airborne global positioning system (GPS) for x , y , z sensor location and an inertial measurement unit (IMU) for measuring the angular orientation of the sensor with respect to the ground. This enables the determination of the three-dimensional position of all points “hit” by the lidar pulses.
