

THE

ENGINEERING

H A N D B O O K

SECOND EDITION

The Electrical Engineering Handbook Series

Series Editor

Richard C. Dorf

University of California, Davis

Titles Included in the Series

The Handbook of Ad Hoc Wireless Networks, Mohammad Ilyas

The Avionics Handbook, Cary R. Spitzer

The Biomedical Engineering Handbook, Second Edition, Joseph D. Bronzino

The Circuits and Filters Handbook, Second Edition, Wai-Kai Chen

The Communications Handbook, Second Edition, Jerry Gibson

The Computer Engineering Handbook, Vojin G. Oklobdzija

The Control Handbook, William S. Levine

The CRC Handbook of Engineering Tables, Richard C. Dorf

The Digital Signal Processing Handbook, Vijay K. Madisetti and Douglas Williams

The Electrical Engineering Handbook, Second Edition, Richard C. Dorf

The Electric Power Engineering Handbook, Leo L. Grigsby

The Electronics Handbook, Jerry C. Whitaker

The Engineering Handbook, Second Edition, Richard C. Dorf

The Handbook of Formulas and Tables for Signal Processing, Alexander D. Poularikas

The Handbook of Nanoscience, Engineering, and Technology, William A. Goddard, III,
Donald W. Brenner, Sergey E. Lyshevski, and Gerald J. Iafrate

The Handbook of Optical Communication Networks, Mohammad Ilyas and
Hussein T. Mouftah

The Industrial Electronics Handbook, J. David Irwin

The Measurement, Instrumentation, and Sensors Handbook, John G. Webster

The Mechanical Systems Design Handbook, Osita D.I. Nwokah and Yidirim Hurmuzlu

The Mechatronics Handbook, Robert H. Bishop

The Mobile Communications Handbook, Second Edition, Jerry D. Gibson

The Ocean Engineering Handbook, Ferial El-Hawary

The RF and Microwave Handbook, Mike Golio

The Technology Management Handbook, Richard C. Dorf

The Transforms and Applications Handbook, Second Edition, Alexander D. Poularikas

The VLSI Handbook, Wai-Kai Chen

Forthcoming Titles

The Electrical Engineering Handbook, Third Edition, Richard C. Dorf

The Electronics Handbook, Second Edition, Jerry C. Whitaker

Preface

Due to the success of the first edition of *The Engineering Handbook* published in 1995 I am pleased to provide the second edition ten years later fully updated and expanded.

Purpose

The purpose of *The Engineering Handbook, Second Edition* is to provide in a single volume a ready reference for the practicing engineer in industry, government, and academia. The book in its comprehensive format is divided into 30 sections which encompass the field of engineering and includes 19 brand new chapters and 131 fully updated contributions. The goal is to provide the most up-to-date information in the classical fields that comprise mechanical, electrical, civil, chemical, industrial, and aerospace engineering as well as the underlying fields of mathematics, materials, biomedical engineering, and nanotechnology. This book should serve the information needs of all professional engineers engaged in the practice of the profession whether in industry, education, or government. The goal of this comprehensive handbook is to replace a myriad of books with one highly informative, well-organized, definitive source of fundamental knowledge.

Organization

The fundamentals of engineering have evolved to include a wide range of knowledge, substantial empirical data, and a broad range of practice. The focus of the handbook is on the key concepts, models, and equations that enable the engineer to analyze, design, and predict the behavior of complex devices, circuits, instruments, systems, structures, plants, computers, fuels, and the environment. While data and formulae are summarized, the main focus is the provision of the underlying theories and concepts and the appropriate application of these theories to the field of engineering. Thus, the reader will find the key concepts defined, described, and illustrated in order to serve the needs of the engineer over many years.

With equal emphasis placed on materials, structures, mechanics, dynamics, fluids, thermodynamics, fuels and energy, transportation, environmental systems, circuits and systems, computers and instruments, manufacturing, aeronautical and aerospace, and economics and management as well as mathematics, the engineer should encounter a wide range of concepts and considerable depth of exploration of these concepts as they lead to application and design.

The level of conceptual development of each topic is challenging, but tutorial and relatively fundamental. Each of the more than 200 chapters is written to enlighten the expert, refresh the knowledge of the mature engineer, and educate the novice.

The information is organized into 30 major sections. The 30 sections encompass 232 chapters, and the Appendix summarizes the applicable mathematics, symbols, and physical constants.

Each chapter includes three important and useful categories: defining terms, references, and further information. *Defining terms* are key definitions, and the first occurrence of each term defined is indicated

in boldface in the text. The definitions of these terms are summarized as a list at the end of each chapter. The *references* provide a list of useful books and articles for follow-up reading. Finally, *further information* provides some general and useful sources of additional information on the topic.

Locating Your Topic

Numerous avenues of access to information contained in the handbook are provided. A complete table of contents is presented at the front of the book. In addition, an individual table of contents precedes each of the 30 sections. Finally, each chapter begins with its own table of contents. The reader should look over these tables of contents to become familiar with the structure, organization, and content of the book.

The index can also be used to locate key definitions. The page on which the definition appears for each key (defining) term is clearly identified in the index.

The Engineering Handbook, Second Edition is designed to provide answers to most inquiries and direct the inquirer to further sources and references. We hope that this handbook will be referred to often and that informational requirements will be satisfied effectively.

Acknowledgments

This handbook is testimony to the dedication of the associate editors, the publishers, and my editorial associates. I particularly wish to acknowledge at CRC Press Nora Konopka, Publisher; Helena Redshaw, Project Development Manager; Liz Spangenberg, Administrative Assistant; and Susan Fox, Project Editor.

Richard C. Dorf
Editor-in-Chief

Editor-in-Chief

Richard C. Dorf, professor of electrical and computer engineering at the University of California, Davis, teaches graduate and undergraduate courses in electrical engineering in the fields of circuits and control systems. He earned a Ph.D. in electrical engineering from the U.S. Naval Postgraduate School, an M.S. from the University of Colorado, and a B.S. from Clarkson University. Highly concerned with the discipline of engineering and its wide value to social and economic needs, he has written and lectured internationally on the contributions and advances in engineering and their value to society.

Professor Dorf has extensive experience with education and industry and is professionally active in the fields of robotics, automation, electric circuits, and communications. He has served as a visiting professor at the University of Edinburgh, Scotland; the Massachusetts Institute of Technology; Stanford University; and the University of California, Berkeley.

A Fellow of The Institute of Electrical and Electronics Engineers, Dr. Dorf is widely known to the profession for his *Modern Control Systems*, Tenth Edition (Prentice Hall, 2004) and *Introduction to Electric Circuits*, Sixth Edition (Wiley, 2004). He is the Editor-in-Chief of the *Technology Management Handbook* (CRC Press, 1999), the *Engineering Handbook*, Second Edition (CRC Press, 2004), and *CRC Handbook of Engineering Tables* (CRC Press, 2004).

Russell C. Hibbeler

University of Louisiana at Lafayette

Statics is a branch of mechanics that deals with the equilibrium of bodies, that is, those that are either at rest or move with constant velocity. In order to apply the laws of statics, it is first necessary to understand how to simplify force systems and compute the moment of a force. In this chapter these topics will be discussed, and some examples will be presented to show how the laws of statics are applied.

1.1 Force-System Resultants

Concurrent Force Systems

Force is a vector quantity that is characterized by its magnitude, direction, and point of application. When two forces \mathbf{F}_1 and \mathbf{F}_2 are **concurrent** they can be added together to form a resultant $\mathbf{F}_R = \mathbf{F}_1 + \mathbf{F}_2$ using the **parallelogram law**, [Figure 1.1](#). Here \mathbf{F}_1 and \mathbf{F}_2 are referred to as components of \mathbf{F}_R . Successive applications of the parallelogram law can also be applied when several concurrent forces are to be added; however, it is generally simpler to first determine the two components of each force along the axes of a coordinate system and then add the respective components. For example, the x , y , z (or Cartesian) components of \mathbf{F} are shown in [Figure 1.2](#). Here, \mathbf{i} , \mathbf{j} , \mathbf{k} are unit vectors used to define the direction of the positive x , y , z axes, and F_x , F_y , F_z are the magnitudes of each component. By vector addition, $\mathbf{F} = F_x\mathbf{i} + F_y\mathbf{j} + F_z\mathbf{k}$. When each force in a concurrent system of forces is expressed by its Cartesian components, the resultant force is therefore

$$\mathbf{F}_R = \sum F_x\mathbf{i} + \sum F_y\mathbf{j} + \sum F_z\mathbf{k} \quad (1.1)$$

where ΣF_x , ΣF_y , ΣF_z represent the scalar additions of the x , y , z components, respectively.

FIGURE 1.1 Addition of forces by parallelogram law.

FIGURE 1.2 Resolution of a vector into its x, y, z components.

Moment of a Force

When a force \mathbf{F} acts on a body, it will cause both external and internal effects on the body. These effects depend upon where the force is located. For example, if \mathbf{F} acts at point A on the body in Figure 1.3, it will cause a specific translation and rotation of the body. However, if \mathbf{F} is applied to some other point, B , which lies along the line of action of \mathbf{F} , then the external effects regarding the motion of the body remain unchanged, although the body's internal effects will be different. This effect of sliding a force along its line of action is called the **principle of transmissibility**. If the force acts at point C , which is not along the line of action AB , then both the external and internal effects on the body will change. The difference in external effects — notably the difference in the rotation of the body — occurs because of the distance d that separates the lines of action of the two positions of the force.

This tendency for the body to rotate about a specified point O or axis as caused by a force is a vector quantity called a *moment*. By definition, the magnitude of the moment is

$$M_O = Fd \quad (1.2)$$

where d is the moment arm or perpendicular distance from the point to the line of action of the force, as in Figure 1.4. The direction of the moment is defined by the right-hand rule, whereby the curl of the right-hand fingers follows the tendency for rotation caused by the force, and the thumb specifies the directional sense of the moment. In this case, \mathbf{M}_O is directed out of the page, since \mathbf{F} produces counter-clockwise rotation about O . It should be noted that the force can act at any point along its line of action and still produce the same moment about O .

FIGURE 1.3

FIGURE 1.4 Moment of a force.

FIGURE 1.5

FIGURE 1.6

FIGURE 1.7

Sometimes the moment arm d is geometrically hard to determine. To make the calculation easier, the force is first resolved into its Cartesian components and then the moment about point O is determined using **the principle of moments**, which states that the moment of the force about O is equal to the sum of the moments of the force's components about O . Thus, as shown in Figure 1.5, we have $M_O = Fd = F_y x + F_x y$.

The moment about point O can also be expressed as a vector cross product of the position vector \mathbf{r} , directed from O to any point on the line of action of the force and the force \mathbf{F} , as shown in Figure 1.6. Here,

$$\mathbf{M}_O = \mathbf{r} \times \mathbf{F} \quad (1.3)$$

If \mathbf{r} and \mathbf{F} are expressed in terms of their Cartesian components, then as in Figure 1.7 the Cartesian components for the moment about O are

$$\begin{aligned} \mathbf{M}_O = \mathbf{r} \times \mathbf{F} &= (x\mathbf{i} + y\mathbf{j} + z\mathbf{k}) \times (F_x\mathbf{i} + F_y\mathbf{j} + F_z\mathbf{k}) \\ &= (yF_z - zF_y)\mathbf{i} + (zF_x - xF_z)\mathbf{j} + (xF_y - yF_x)\mathbf{k} \end{aligned} \quad (1.4)$$

$$= \begin{vmatrix} \mathbf{i} & \mathbf{j} & \mathbf{k} \\ x & y & z \\ F_x & F_y & F_z \end{vmatrix}$$

Couple

A **couple** is defined as two parallel forces that have the same magnitude and opposite directions and are separated by a perpendicular distance d , as in Figure 1.8. The moment of a couple about the arbitrary point O is

FIGURE 1.8

$$\begin{aligned} \mathbf{M}_C &= \mathbf{r}_1 \times \mathbf{F} + \mathbf{r}_2 \times (-\mathbf{F}) = (\mathbf{r}_1 - \mathbf{r}_2) \times \mathbf{F} \\ &= \mathbf{r} \times \mathbf{F} \end{aligned} \quad (1.5)$$

Here the couple moment \mathbf{M}_C is independent of the location of the moment point O . Instead, it depends only on the distance between the forces; that is, \mathbf{r} in the above equation is directed from any point on the line of action of one of the forces ($-\mathbf{F}$) to any point on the line of action of the other force \mathbf{F} . The external effect of a couple causes rotation of the body with no translation, since the resultant force of a couple is zero.

Resultants of a Force and Couple System

A general force and couple-moment system can always be replaced by a single resultant force and couple moment acting at any point O . As shown in Figure 1.9(a) and Figure 1.9(b), these resultants are

$$\mathbf{F}_R = \sum \mathbf{F} \quad (1.6)$$

$$\mathbf{M}_{R_O} = \sum \mathbf{M}_O \quad (1.7)$$

where $\Sigma \mathbf{F} = \mathbf{F}_1 + \mathbf{F}_2 + \mathbf{F}_3$ is the vector addition of all the forces in the system, and $\Sigma \mathbf{M}_O = (\mathbf{r}_1 \times \mathbf{F}_1) + (\mathbf{r}_2 \times \mathbf{F}_2) + (\mathbf{r}_3 \times \mathbf{F}_3) + \mathbf{M}_1 + \mathbf{M}_2$ is the vector sum of the moments of all the forces about point O plus the sum of all the couple moments. This system may be further simplified by first resolving the couple moment \mathbf{M}_{R_O} into two components — one parallel and the other perpendicular to the force \mathbf{F}_R , as in Figure

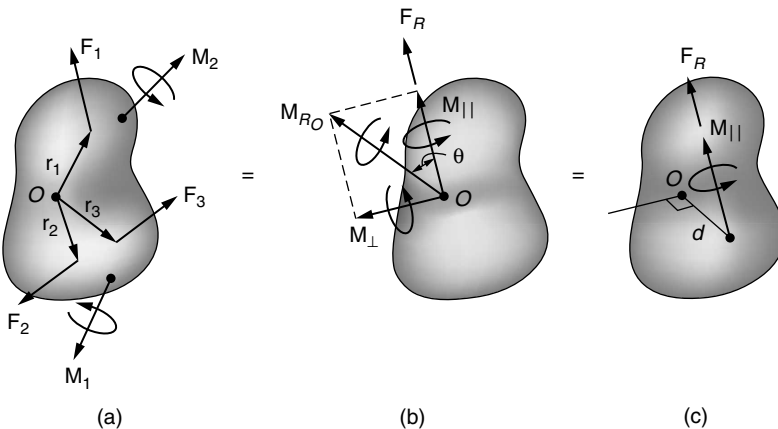

FIGURE 1.9

1.9(b). By moving the line of action of \mathbf{F}_R in the plane perpendicular to \mathbf{M}_\perp a distance $d = M_\perp/F_R$, so that \mathbf{F}_R creates the moment M_\perp about O , the system can then be represented by a **wrench**, that is, a single force \mathbf{F}_R and collinear moment \mathbf{M}_\parallel , Figure 1.9(c).

Note that in the special case of $\theta = 90^\circ$, Figure 1.9(b), $\mathbf{M}_\parallel = \mathbf{0}$ and the system then reduces to a single resultant force \mathbf{F}_R having a specified line of action. This will always be the case if the force system is either concurrent, parallel, or coplanar.

Distributed Loadings

When a body contacts another body, the loads produced are always distributed over the surface area of each body. If the area on one of the bodies is small compared to the entire surface area of the body, the loading can be represented by a single concentrated force acting at a point on the body. However, if the loading occurs over a large surface area — such as that caused by wind or a fluid — the distribution of load must be taken into account. The intensity of this surface loading at each point is represented as a pressure and its variation is defined by a load-intensity diagram. On a flat surface, the load intensity diagram is described by the loading function $p = p(x, y)$, which consists of an infinite number of parallel forces, as in Figure 1.10. Applying Equation (1.6) and Equation (1.7), the resultant of this loading and its point of application (\bar{x}, \bar{y}) can be determined from

$$F_R = \int p(x, y) dA \quad (1.8)$$

$$\bar{x} = \frac{\int x p(x, y) dA}{\int p(x, y) dA} \quad \bar{y} = \frac{\int y p(x, y) dA}{\int p(x, y) dA} \quad (1.9)$$

Geometrically, F_R is equivalent to the volume under the loading diagram, and its location passes through the centroid or geometric center of this volume. Often in engineering practice, the surface loading is symmetric about an axis, in which case the loading is a function of only one coordinate, $w = w(x)$. Here the resultant is geometrically equivalent to the area under the loading curve, and the line of action of the resultant passes through the centroid of this area.

Besides surface forces as discussed above, loadings can also be transmitted to another body without direct physical contact. These body forces are distributed throughout the volume of the body. A common

FIGURE 1.10

example is the force of gravity. The resultant of this force is termed the **weight**; it acts through the body's center of gravity and is directed towards the center of the earth.

1.2 Equilibrium

Equations of Equilibrium

A body is said to be in equilibrium when it either is at rest or moves with constant velocity. For purposes of analysis, it is assumed that the body is perfectly rigid, meaning that the particles composing the body remain at fixed distances from one another both before and after applying the load. Most engineering materials deform only slightly under load, so that moment arms and the orientation of the loading remain essentially constant. For these cases, therefore, the rigid-body model is appropriate for analysis. The necessary and sufficient conditions to maintain equilibrium of a rigid body require the resultant external force and moment acting on the body to be equal to zero. From Equation (1.6) and Equation (1.7), this can be expressed mathematically as

$$\sum \mathbf{F} = \mathbf{0} \quad (1.10)$$

$$\sum \mathbf{M}_O = \mathbf{0} \quad (1.11)$$

If the forces acting on the body are resolved into their x , y , z components, these equations can be written in the form of six scalar equations, namely,

$$\begin{aligned} \sum F_x &= 0 & \sum M_{Ox} &= 0 \\ \sum F_y &= 0 & \sum M_{Oy} &= 0 \\ \sum F_z &= 0 & \sum M_{Oz} &= 0 \end{aligned} \quad (1.12)$$

Actually, any set of three nonorthogonal, nonparallel axes will be suitable references for either of these force or moment summations.

If the forces on the body can be represented by a system of coplanar forces, then only three equations of equilibrium must be satisfied, namely,

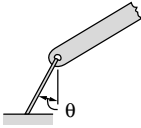

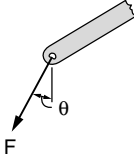

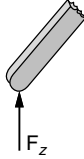

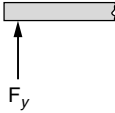

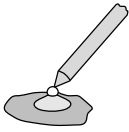

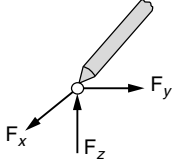

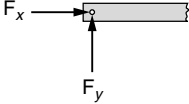

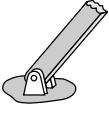

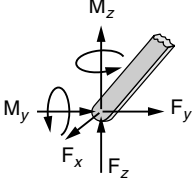

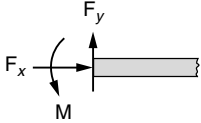

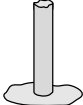

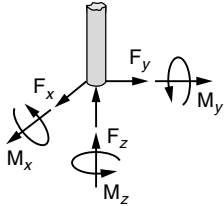

$$\begin{aligned} \sum F_x &= 0 \\ \sum F_y &= 0 \\ \sum M_O &= 0 \end{aligned} \quad (1.13)$$

Here the x and y axes lie in the plane of the forces and point O can be located either on or off the body.

Free-Body Diagram

Application of the equations of equilibrium requires accountability for *all* the forces that act on the body. The best way to do this is to draw the body's **free-body diagram**. This diagram is a sketch showing an outlined shape of the body and so represents it as being isolated or "free" from its surroundings. On this sketch it is necessary to show all the forces and couples that act on the body. Those generally encountered are due to applied loadings, reactions that occur at the supports and at points of contact with other bodies, and the weight of the body. Also one should indicate the dimensions of the body necessary for

TABLE 1.1 Force Systems

| Connection | Reaction | Connection | Reaction |
|--|--|--|--|
|  <p>cable</p> |  <p>F</p> |  <p>smooth surface</p> |  <p>F_z</p> |
|  <p>roller</p> |  <p>F_y</p> |  <p>ball and socket</p> |  <p>F_x F_y F_z</p> |
|  <p>pin</p> |  <p>F_x F_y</p> |  <p>single pin</p> |  <p>M_z F_y F_x F_z M_y</p> |
|  <p>fixed support</p> |  <p>F_y F_x M</p> |  <p>fixed support</p> |  <p>F_y F_x F_z M_x M_y M_z</p> |

computing the moments of forces. Once the free-body diagram has been drawn and the coordinate axes established, application of the equations of equilibrium becomes a straightforward procedure.

Support Reactions

Various types of supports can be used to prevent a body from moving. Table 1.1 shows some of the most common types, along with the reactions each exerts on the body at the connection. As a general rule, if a support prevents translation in a given direction, then a force is developed on the body in that direction, whereas if rotation is prevented, a couple moment is exerted on the body.

Friction

When a body is in contact with a rough surface, a force of resistance called **friction** is exerted on the body by the surface in order to prevent or retard slipping of the body. This force always acts tangent to the surface at points of contact with the surface and is directed so as to oppose the possible or existing motion of the body. If the surface is dry, the frictional force acting on the body must satisfy the equation

$$F < \mu_s N \tag{1.14}$$

TABLE 1.2 Typical Values for Coefficients of Static Friction

| Materials | μ_s |
|----------------------|--------------|
| Metal on ice | 0.03 to 0.05 |
| Wood on wood | 0.30 to 0.70 |
| Leather on wood | 0.20 to 0.50 |
| Leather on metal | 0.30 to 0.60 |
| Aluminum on aluminum | 1.10 to 1.70 |

The equality $F = \mu_s N$ applies only when motion between the contacting surfaces is impending. Here N is the resultant normal force on the body at the surface of contact, and μ_s is the coefficient of static friction, a dimensionless number that depends on the characteristics of the contacting surfaces. Typical values of μ_s are shown in Table 1.2. If the body is sliding, then $F = \mu_k N$, where μ_k is the coefficient of kinetic friction, a number that is approximately 25% smaller than those listed in Table 1.2.

Constraints

Equilibrium of a body is ensured not only by satisfying the equations of equilibrium, but also by its being properly held or constrained at its supports. If a body has more supports than are needed for equilibrium, it is referred to as *statically indeterminate*, since there will be more unknowns than equations of equilibrium. For example, the free-body diagram of the beam in Figure 1.11 shows four unknown support reactions, A_x , A_y , M_A , and B_y , but only three equations of equilibrium are available for solution [Equation (1.13)]. The additional equation needed requires knowledge of the physical properties of the body and deals with the mechanics of deformation, which is discussed in subjects such as mechanics of materials.

A body may be improperly constrained by its supports. When this occurs, the body becomes unstable and equilibrium cannot be maintained. Either of two conditions may cause this to occur — when the reactive forces are all parallel (Figure 1.12) or when they are concurrent (Figure 1.13).

In summary, then, if the number of reactive forces that restrain the body is a minimum — and these forces are not parallel or concurrent — the problem is statically determinate, and the equations of equilibrium are sufficient to determine all the reactive forces.

Internal Loadings

The equations of equilibrium can also be used to determine the internal resultant loadings in a member, provided the external loads are known. The calculation is performed using the **method of sections**, which

FIGURE 1.11

FIGURE 1.12

FIGURE 1.13

states that if a body is in equilibrium, then so is any segment of the body. For example, if an imaginary section is passed through the body in Figure 1.14(a), separating it into two parts, the free-body diagram of the left part is shown in Figure 1.14(b). Here the six internal resultant components are “exposed” and can be determined from the six equations of equilibrium given by Equation (1.12). These six components are referred to as the normal force, N_y , the shear-force components, V_x and V_z , the torque or twisting moment, T_y , and the bending-moment components, M_x and M_z .

If only coplanar loads act on the body [Figure 1.15(a)], then only three internal resultant loads occur [Figure 1.15(b)], namely, the normal force, N , the shear force, V , and the bending moment, M . Each of these loadings can be determined from Equation (1.13). Once these internal resultants have been computed, the actual load distribution over the sectioned surface, called stress, involves application of the theory related to mechanics of materials.

Numerical Applications

The following examples illustrate application of most of the principles discussed above. Solution of any problem generally requires first establishing a coordinate system, then representing the data on a diagram, and finally applying the necessary equations for solution.

FIGURE 1.14

FIGURE 1.15

FIGURE 1.16

Example 1.1

Simplify the system of three parallel forces acting on the plate in Figure 1.16 to a single resultant force and specify where the force acts on the plate.

Solution

First, Equation (1.6) and Equation (1.7) are applied in order to replace the force system by a single resultant force and couple moment at point O .

$$\mathbf{F}_R = \sum \mathbf{F} \quad \mathbf{F}_R = -300\mathbf{k} - 400\mathbf{k} - 200\mathbf{k} = \{-900\mathbf{k}\} \text{ N} \quad \text{Ans.}$$

$$\begin{aligned} \mathbf{M}_{R_O} &= \sum \mathbf{M}_O & \mathbf{M}_{R_O} &= \mathbf{r}_A \times (-300\mathbf{k}) + \mathbf{r}_B \times (-400\mathbf{k}) + \mathbf{r}_C \times (-200\mathbf{k}) \\ & & &= (2\mathbf{i} + 1.5\mathbf{j}) \times (-300\mathbf{j}) + (2.5\mathbf{j}) \times (-400\mathbf{k}) \\ & & &+ (-0.5\mathbf{i} + 2.5\mathbf{j}) \times (-200\mathbf{k}) \\ & & &= \{-1950\mathbf{i} + 500\mathbf{j}\} \text{ N} \cdot \text{m} \end{aligned}$$

Since the forces are parallel, note that as expected \mathbf{F}_R is perpendicular to \mathbf{M}_{R_O} .

The two components of \mathbf{M}_{R_O} can be eliminated by moving \mathbf{F}_R along the respective y and x axes an amount:

$$\bar{x} = M_{O_y} / F_R = 500 \text{ N} \cdot \text{m} / 900 \text{ N} = 0.556 \text{ m} \quad \text{Ans.}$$

$$\bar{y} = M_{O_x} / F_R = 1950 \text{ N} \cdot \text{m} / 900 \text{ N} = 2.17 \text{ m} \quad \text{Ans.}$$

Both coordinates are positive since \mathbf{F}_R , acting at $\mathbf{r} = \{0.556\mathbf{i} + 2.17\mathbf{j}\} \text{ m}$, will produce the required moment $\mathbf{M}_{R_O} = \mathbf{r} \times \mathbf{F}_R$.

Example 1.2

Determine the reactions at the supports for the beam shown in Figure 1.17(a).

Solution

Using Table 1.1, the free-body diagram for the beam is shown in Figure 1.17(b). The problem is statically determinate. The reaction N_B can be found by using the principle of moments and

FIGURE 1.17

summing moments about point A to eliminate A_x and A_y . Applying Equation (1.13) with reference to the coordinate system shown gives

$$\begin{aligned} \sum M_A = 0 \quad & -500 \text{ N}(3/5)(2 \text{ m}) + N_B \cos 60^\circ(4 \text{ m} + 2 \cos 60^\circ \text{ m}) \\ & + N_B \cos 60^\circ(2 \sin 60^\circ \text{ m}) = 0 \quad \text{Ans.} \\ N_B = & 150 \text{ N} \end{aligned}$$

$$\begin{aligned} \sum F_x = 0 \quad & A_x - 500 \text{ N}(4/5) - 150 \sin 60^\circ \text{ N} = 0 \quad \text{Ans.} \\ A_x = & 530 \text{ N} \end{aligned}$$

$$\begin{aligned} \sum F_y = 0 \quad & A_y - 500 \text{ N}(3/5) + 150 \cos 60^\circ \text{ N} = 0 \quad \text{Ans.} \\ A_y = & 225 \text{ N} \end{aligned}$$

Since the answers are all positive, the assumed sense of direction of the reactive forces is shown correctly on the free-body diagram.

Example 1.3

The compound beam shown in Figure 1.18(a) consists of two segments, AB and BC, which are pinned together at B. Determine the reactions on the beam at the supports.

Solution

The free-body diagrams of both segments of the beam are shown in Figure 1.18(b). Notice how the principle of action — equal but opposite reaction, Newton's third law — applies to the two force

FIGURE 1.18

components at B . Also, the distributed loading has been simplified to resultant forces, determined from the area under each loading diagram and passing through the centroid or geometric center of each area.

The six unknowns are determined by applying Equation (1.13) to each segment. For segment BC :

$$\sum F_x = 0 \quad B_x = 0 \quad \text{Ans.}$$

$$\sum M_B = 0 \quad -600 \text{ N}(1 \text{ m}) + C_y(3 \text{ m}) = 0$$

$$C_y = 200 \text{ N} \quad \text{Ans.}$$

$$\sum F_y = 0 \quad B_y - 600 \text{ N} + 200 \text{ N} = 0$$

$$B_y = 400 \text{ N} \quad \text{Ans.}$$

For segment AB :

$$\sum F_x = 0 \quad A_x = 0 \quad \text{Ans.}$$

$$\sum F_y = 0 \quad A_y - 1600 \text{ N} - 400 \text{ N} = 0$$

$$A_y = 2000 \text{ N} \quad \text{Ans.}$$

$$\sum M_A = 0 \quad M_A = 1600 \text{ N}(2 \text{ m}) - 400 \text{ N}(4 \text{ m}) = 0$$

$$M_A = 4800 \text{ N} \cdot \text{m} \quad \text{Ans.}$$

FIGURE 1.19

Example 1.4

The table in Figure 1.19(a) rests on a rough surface for which $\mu_s = 0.3$. If it supports a load of 500 N, determine the largest magnitude of force P that can be applied before it begins to move.

Solution

The free-body diagram is shown in Figure 1.19(b). Since the maximum force P is to be determined, slipping must impend at both A and B . Therefore, the friction equation $F = \mu_s N$ applies at these points. There are three unknowns. Applying the equations of equilibrium yields

$$\begin{aligned} \sum M_B = 0 & \quad -N_A(6 \text{ m}) + 500 \text{ N}(3 \text{ m}) + P \cos 30^\circ(2 \text{ m}) = 0 \\ \sum F_x = 0 & \quad 0.3N_A + 0.3N_B - P \cos 30^\circ = 0 \\ \sum F_y = 0 & \quad N_A + N_B - 500 \text{ N} - P \sin 30^\circ = 0 \end{aligned}$$

Solving,

$$P = 209 \text{ N}$$

$$N_A = 310 \text{ N}$$

$$N_B = 294 \text{ N}$$

Ans.

Since N_A and N_B are both positive, the forces of the floor push up on the table as shown on the free-body diagram, and the table remains in contact with the floor.

Defining Terms

Concurrent forces — Forces that act through the same point.

Couple — Two forces that have the same magnitude and opposite directions and do not have the same line of action. A couple produces rotation with no translation.

Free-body diagram — A diagram that shows the body “free” from its surroundings. All possible loads and relevant dimensions are labeled on it.

Friction — A force of resistance caused by one surface on another.

Method of sections — This method states that if a body is in equilibrium, any sectioned part of it is also in equilibrium. It is used for drawing the free-body diagram to determine the internal loadings in any region of a body.

Parallelogram law — The method of vector addition whereby two vectors, called *components*, are joined at their tails; parallel lines are then drawn from the head of each vector so that they intersect at a common point forming the adjacent sides of a parallelogram. The resultant vector is the diagonal that extends from the tails of the component vectors to the intersection of the lines.

Principle of moments — This concept states that the moment of the force about a point is equal to the sum of the moments of the force’s components about the point.

Principle of transmissibility — A property of a force that allows the force to act at any point along its line of action and produce the same external effects on a body.

Weight — The gravitational attraction of the earth on the mass of a body, usually measured at sea level and 45° latitude.

Wrench — A force and collinear moment. The effect is to produce both a push and simultaneous twist.

- 2.6 Determination of Centroids

2.1 Centroid of a Plane Area

Any set of forces acting on a rigid body is reducible to an equivalent force-couple system at any selected point O . This force-couple system, which consists of a force \mathbf{R} equal to the vector sum of the set of forces and a couple of moment equal to the moment \mathbf{M}_O of the forces about the point O , is equivalent to the original set of forces as far as the statics and dynamics of the entire rigid body are concerned. In particular, concurrent, coplanar, or parallel forces can always be reduced to a single equivalent force by an appropriate choice of the point O .

Consider, for example, a distributed load $p(x)$ acting on a straight beam (Figure 2.1). If $p(x)$ has units of force per length, the differential increment of force is $dR = p(x) dx$ and the total load R is found by integration:

$$R = \int p(x) dx \quad (2.1)$$

A point O is to be chosen such that the distributed load $p(x)$ is equivalent to a single resultant force of magnitude R acting at O . This requires that the moment of R about any point — say, point A — be the same as the moment of the load $p(x)$ about that point. Therefore the distance \bar{x} between A and O is given by

$$\bar{x}R = \int xp(x) dx = \int x dR \quad (2.2)$$

The line of action of the resultant force R is a vertical line drawn at a distance \bar{x} from point A . At any point on the line of action of R , the force-couple equivalent of the load $p(x)$ reduces to a single force.

FIGURE 2.1 Distributed load on a beam.

FIGURE 2.2 Centroid of an area.

This is a consequence of the *principle of transmissibility*, which states that moving a force along its line of action leaves the conditions of equilibrium or of motion of a rigid body unchanged.

Given a plane area A , the point with coordinates \bar{x} and \bar{y} defined by

$$\bar{x}A = \int_A x \, dA \quad \bar{y}A = \int_A y \, dA \quad (2.3)$$

is known as the *centroid* of the area A . In the calculation of the resultant force R on a beam, the increment of force $dR = p(x) \, dx$ is a differential element of area under the load curve $p(x)$, and the length \bar{x} given by Equation (2.2) is the x coordinate of the centroid of the area under the load curve. Thus, a distributed load on a beam can be replaced by a single force whose magnitude is equal to the area under the load curve $p(x)$ and whose line of action passes through the centroid of the area under $p(x)$.

Suppose that the homogeneous plate of uniform thickness t shown in Figure 2.2 is in a uniform and parallel field of force due to the earth's gravitational attraction in the negative y direction. The resultant of the gravitational forces is a single force in the same direction. The magnitude of this force is called the *weight*,

$$W = \gamma t A \quad (2.4)$$

where γ is the weight per unit volume of the material and A is the area of the plate. Since the gravitational forces and their single force equivalent must have the same moment about any point,

$$\int_A x \gamma t \, dA = M_O = \bar{x}W = \bar{x}\gamma t A \quad (2.5)$$

or, canceling the constant common factor γt on both sides,

$$\bar{x}A = \int_A x \, dA \quad (2.6)$$

Similarly, if the earth's attraction is assumed to be in the x direction, the line of action of the weight W , acting in the same direction, is specified by the coordinate \bar{y} , given by

$$\bar{y}A = \int_A y \, dA \quad (2.7)$$

The coordinates \bar{x} and \bar{y} locate the centroid of the area A of the plate. Thus, the centroid and the **center of gravity** of a homogeneous plate in a parallel and uniform gravitational field are coincident.

It can be shown that the coordinates \bar{x} and \bar{y} given by Equation (2.3) define the same geometric point regardless of the choice of coordinate axes. Thus, the location of the centroid is independent of

any particular choice of orientations for the axes and of the choice of origin. As a consequence, the centroid is a well-defined intrinsic geometric property of any object having a rigid shape. [Table 3.1](#) in [Chapter 3](#) lists the centroids of some common shapes.

2.2 Centroid of a Volume

If a rigid body of volume V is subjected to a distributed force of intensity \mathbf{f} (force per unit volume), the force-couple equivalent of this distributed force at an arbitrarily selected origin O of coordinates can be determined from

$$\mathbf{R} = \int_V \mathbf{f} dV \quad (2.8)$$

$$\mathbf{M}_O = \int_V \mathbf{r} \times \mathbf{f} dV \quad (2.9)$$

where \mathbf{r} is the position vector of volume elements dV measured from point O . In particular, if only one component of \mathbf{f} is nonzero, the resulting parallel system of distributed body forces acting on the body is reducible to a single equivalent force. For example, with $f_x = f_y = 0$ and f_z nonzero, the force-couple equivalent at O has the components

$$R_x = 0 \quad R_y = 0 \quad R_z = \int_V f_z dV \quad (2.10)$$

and

$$M_x = \int_V y f_z dV \quad M_y = - \int_V x f_z dV \quad M_z = 0 \quad (2.11)$$

The single force equivalent of this force-couple system is found by moving the force R_z from point O to a point in the xy plane such that the moment of R_z about O is equal to the moment of the force-couple system about O . The coordinates \bar{x} and \bar{y} of this point are therefore given by

$$\bar{x}R_z = \int_V x f_z dV \quad \bar{y}R_z = \int_V y f_z dV \quad (2.12)$$

The arbitrary choice of $z = 0$ for the point of application of the resultant R_z is permissible because R_z can be slid along its line of action according to the principle of transmissibility.

If the rigid body is homogeneous and f_z is its specific weight in a uniform gravitational field, $f_z dV$ is an incremental weight dW and R_z is the total weight W of the body. Equation (2.12) becomes

$$\bar{x}W = \int_V x dW \quad \bar{y}W = \int_V y dW \quad (2.13)$$

However, since the specific weight f_z is constant and

$$dW = f_z dV \quad W = f_z V \quad (2.14)$$

Equation (2.13) can be written as

$$\bar{x}V = \int_V x dV \quad \bar{y}V = \int_V y dV \quad (2.15)$$

Similarly, if the body is placed in a uniform gravitational field that exerts a force in the x direction only, then the line of action of the single equivalent force penetrates the yz plane at \bar{y} defined in Equation (2.15) and \bar{z} given by

$$\bar{z}V = \int_V z dV \quad (2.16)$$

The point with coordinates $\bar{x}, \bar{y}, \bar{z}$ defined in Equation (2.15) and Equation (2.16) is the centroid C of the volume V of the body. The centroid and the **center of gravity** of a homogeneous body in a uniform and parallel gravitational field are coincident points. If the body is not homogeneous, Equation (2.15) and Equation (2.16) cannot be used to find the center of gravity; however, they still define the centroid, which is an intrinsic geometric property of any rigid shape. The **center of mass** of a rigid body is defined by

$$\bar{\mathbf{r}}m = \int \mathbf{r} dm \quad (2.17)$$

where m is the mass. The center of mass depends solely on the mass distribution and is independent of the properties of the gravitational field in which the body may be placed. In a uniform and parallel gravitational field, however, $dW = g dm$ where g is the gravitational constant, so that the center of mass coincides with the center of gravity. If, in addition, the body is homogeneous, the x, y, z components of the vector $\bar{\mathbf{r}}$ given by Equation (2.17) are $\bar{x}, \bar{y}, \bar{z}$ defined in Eq. (2.15) and Equation (2.16). In this case, the centroid, the center of mass, and the center of gravity are coincident. The mass centers of some homogeneous solids are listed in [Table 3.2, Chapter 3](#).

2.3 Surface Forces

Suppose the distributed load is a force per unit area \mathbf{p} and let \mathbf{p} be a function of the position vector \mathbf{r} with respect to an origin O . For a surface of area A , the resultant of the distributed surface forces is

$$\mathbf{R} = \int_A \mathbf{p} dA \quad (2.18)$$

where dA is a differential surface element. The resultant moment of the distributed surface forces with respect to the reference point O is given by

$$\mathbf{M}_O = \int_A \mathbf{r} \times \mathbf{p} dA \quad (2.19)$$

The line of action of a single force equivalent for a parallel surface force distribution is determined as in the case of volume forces. For example, with a plane surface in the xy plane and with p_z as the only nonzero force, the line of action of the resultant force intersects the xy plane at the point whose coordinates are \bar{x}, \bar{y} given by

$$\bar{x} = \frac{\int_A x p_z dA}{\int_A p_z dA} \quad \bar{y} = \frac{\int_A y p_z dA}{\int_A p_z dA} \quad (2.20)$$

FIGURE 2.3 A surface with rotational symmetry.

2.4 Line Forces

In general, the formula for body forces can be employed for a line. For the special case of a plane curve of length l in the xy plane and distributed line force p_z (force/length) acting in the z direction, the force resultant is

$$R_z = \int_l p_z(s) ds \quad (2.21)$$

where s is the coordinate along the curve. The moment resultant about the reference point O is

$$\mathbf{M}_O = \int_l (y p_z \mathbf{i} - x p_z \mathbf{j}) ds \quad (2.22)$$

where \mathbf{i}, \mathbf{j} are unit vectors in the x, y directions, respectively. The coordinates where the line of action of the single force resultant intersects the xy plane are

$$\bar{x} = \frac{\int_l x(s) p_z(s) ds}{\int_l p_z(s) ds} \quad \bar{y} = \frac{\int_l y(s) p_z(s) ds}{\int_l p_z(s) ds} \quad (2.23)$$

2.5 Calculation of Surface Area and Volume of a Body with Rotational Symmetry

The two **Pappus–Guldin formulas**¹ take advantage of the definition of the centroid to assist in the calculation of the surface area and the volume of a body with rotational symmetry.

When a plane meridian curve (Figure 2.3) that does not intersect the y axis is rotated through ϕ radians about the y axis, a line element ds generates a surface of area

$$dS = x\phi ds \quad (2.24)$$

The total surface area generated by a meridian curve of length l is

¹Pappus of Alexandria was a 3rd-century Greek geometer. Of a collection of eight mathematical books, only a portion survived. This is an informative source on ancient Greek mathematics. Included in this collection is a method for the measurement of a surface area bounded by a spiral on a sphere.

Paul Habakuk Guldin (1577–1643) was a professor of mathematics in several Italian and Austrian Jesuit colleges. In 1635 he revealed a relationship between the volume and the area of a body of revolution.

FIGURE 2.4 A volume with rotational symmetry.

$$S = \phi \int_0^l x \, ds \tag{2.25}$$

Therefore

$$S = \phi \bar{x} l \tag{2.26}$$

where \bar{x} locates the centroid of the meridian curve. This is the first Pappus–Guldin formula.

If the meridian curve forms a shell of revolution, $\phi = 2\pi$ and

$$S = 2\pi \bar{x} l \tag{2.27}$$

When a plane area A (Figure 2.4) that is not cut by the y axis is rotated through an angle ϕ radians about the y axis, a volume element

$$dV = \phi x \, dA \tag{2.28}$$

is generated and the total volume is given by

$$V = \phi \bar{x} A \tag{2.29}$$

This is the second Pappus–Guldin formula.

For a solid of revolution, with $\phi = 2\pi$,

$$V = 2\pi \bar{x} A \tag{2.30}$$

If A and V are known, the centroid of A can be determined from

$$\bar{x} = \frac{V}{2\pi A} \tag{2.31}$$

2.6 Determination of Centroids

When an area or a line has an axis of symmetry, the centroid of the area or line is on that axis. If an area or line has two axes of symmetry, the centroid of the area or line is at the intersection of the axes of symmetry. Thus, the geometric centers of circles, ellipses, squares, rectangles, or lines in the shape of the perimeter of an equilateral triangle are also their centroids. When a volume has a plane of symmetry, the centroid of the volume lies on that plane. When a volume has two planes of symmetry, the centroid of the volume lies on the line of intersection of the planes of symmetry. When a volume has three planes of symmetry intersecting at a point, the point of intersection of the three planes is the centroid of the

FIGURE 2.5 Centroid of a triangle.

volume. Thus, the geometric centers of spheres, ellipsoids, cubes, or rectangular parallelepipeds are also their centroids.

Centroids of unsymmetrical areas, lines, or volumes can be determined by direct integration. The Pappus–Guldin formulas can be used to determine the centroid of a plane curve when the area of the surface generated by the curve is known or to determine the centroid of a plane area when the volume generated by the area is known.

If a body can be divided into n parts, for which the volumes V_i and the centroids $\bar{x}_i, \bar{y}_i, \bar{z}_i$ are known, the centroid of the entire body has coordinates $\bar{x}, \bar{y}, \bar{z}$, given by

$$\bar{x}V = \sum_{i=1}^n \bar{x}_i V_i \quad \bar{y}V = \sum_{i=1}^n \bar{y}_i V_i \quad \bar{z}V = \sum_{i=1}^n \bar{z}_i V_i \quad (2.32)$$

where V is the total volume of the body. The same equations are applicable for a body with cutouts, provided that the volumes of the cutouts are taken as negative numbers.

Example 2.1

Determine the location of the centroid for the triangle shown in Figure 2.5. The triangle is symmetric about the y axis. Hence the centroid lies on the y axis and $\bar{x} = 0$. To determine \bar{y} , select an element of area dA parallel to the x axis, thus making all points in the element an equal distance from the x axis. Then $dA = 2x dy$ and, with $A = bh/2$,

$$\bar{y} = \frac{\int_0^h y(2x dy)}{bh/2} = \frac{4 \int_0^h xy dy}{bh} \quad (2.33)$$

The expression for x in terms of y follows from the proportionality of the similar triangles ABC and DEC . This provides

$$\frac{x}{h-y} = \frac{b}{2h} \quad \text{or} \quad x = \frac{1}{2} \frac{b}{h}(h-y) \quad (2.34)$$

Finally,

$$\bar{y} = \frac{4 \int_0^h \frac{1}{2} \left(\frac{b}{h}\right)(h-y)y dy}{bh} = \frac{2}{h^2} \int_0^h (hy - y^2) dy = \frac{2}{h^2} \left(h \frac{h^2}{2} - \frac{h^3}{3} \right) = \frac{h}{3} \quad (2.35)$$

FIGURE 2.6 Centroid of a complicated area.

Thus, the centroid of the triangular area is on the y axis at a distance of one-third the altitude from the base of the triangle.

Example 2.2

Figure 2.6 shows a complicated shape that is made up of a semicircle, a rectangle, and a triangle. The areas and centroids of the semicircle, rectangle, and triangle are known:

$$A_1 = \frac{\pi r^2}{2} \quad A_2 = 8r^2 \quad A_3 = 2r^2 \quad (2.36)$$

$$C_1 = \left(0, -\frac{2(2+3\pi)r}{3\pi} \right) \quad C_2 = (0, 0) \quad C_3 = \left(\frac{r}{3}, \frac{8r}{3} \right) \quad (2.37)$$

The x coordinate \bar{x} of the centroid of the figure is given by

$$\bar{x}A = \sum_{i=1}^3 \bar{x}_i A_i = \frac{2r^3}{3} \quad (2.38)$$

where A is the total area

$$A = A_1 + A_2 + A_3 = \frac{(\pi+20)r^2}{2} \quad (2.39)$$

Therefore,

$$\bar{x} = \frac{4r}{3(\pi+20)} \quad (2.40)$$

FIGURE 2.7 Frustum of a cone.

Similarly, the y coordinate \bar{y} of the centroid is calculated from

$$\bar{y}A = \sum_{i=1}^3 \bar{y}_i A_i \quad (2.41)$$

which yields

$$\bar{y} = \frac{2(14 - 3\pi)r}{3(\pi + 20)} \quad (2.42)$$

Example 2.3

In this example, the y coordinate of the centroid of the frustum of the right circular cone shown in Figure 2.7 will be found by treating the frustum as a cone of height h with a cut-out cone of height $h/2$. From Table 3.2 of Chapter 3, the y coordinates of the centroids of these two cones are

$$y_1 = \frac{3h}{4} \quad y_2 = \frac{3h}{8} \quad (2.43)$$

The corresponding volumes are

$$V_1 = \frac{\pi r^2 h}{3} \quad V_2 = \frac{\pi r^2 h}{24} \quad (2.44)$$

and the y coordinate of the centroid of the frustum of the cone is

$$\bar{y} = \frac{y_1 V_1 - y_2 V_2}{V_1 - V_2} = \frac{45h}{56} \quad (2.45)$$

Example 2.4

The centroid of the area enclosed between the semicircles of radius R and r and part of the x axis (see Figure 2.8) can be found by an application of the second Pappus–Guldin formula. The volume generated by rotating this area through 2π is

$$V = \frac{4\pi}{3}(R^3 - r^3) \quad (2.46)$$

FIGURE 2.8 Plane area of Example 2.4.

FIGURE 2.9 Example 2.5.

Hence

$$\bar{y} = \frac{V}{2\pi(R^2 - r^2)/2} = \frac{4(r^2 + rR + R^2)}{3\pi(r + R)} \quad (2.47)$$

Example 2.5

Consider the problem of finding the centroid of the half torus in Table 3.2 of Chapter 3. The half torus is obtained by revolving a circle of a radius a through π radians about the z axis, and the second Pappus–Guldin formula gives its volume $V = \pi^2 a^2 R$. To calculate the x coordinate \bar{x} of the centroid, a volume element obtained by taking a horizontal slice of thickness dz (see Figure 2.9) can be used. The volume of this element is given by

$$dV = \frac{\pi}{2}(r_o^2 - r_i^2) dz \quad (2.48)$$

where

$$\begin{aligned} r_i &= R - a \cos \theta \\ r_o &= R + a \cos \theta \end{aligned} \quad (2.49)$$

Since $dz = a \cos \theta d\theta$, the expression for dV simplifies to

$$dV = 2\pi a^2 R \cos^2 \theta d\theta \quad (2.50)$$

It is known from Example 2.4 that the x coordinate of the centroid of the volume element is

$$x = \frac{4(r_i^2 + r_i r_o + r_o^2)}{3\pi(r_i + r_o)} = \frac{a^2(1 + \cos 2\theta) + 6R^2}{3\pi R} \quad (2.51)$$

Therefore, the x coordinate of the centroid of the half torus is

FIGURE 2.10 Semicircular cantilever beam.

$$\bar{x} = 2 \frac{\int_0^{\pi/2} x dV}{V} = \frac{4}{3\pi^2 R} \int_0^{\pi/2} (a^2(1 + \cos 2\theta) + 6R^2) \cos^2 \theta d\theta \quad (2.52)$$

in which the integration limits extend over the upper half of the volume so that the additional multiplicative factor of 2 is necessary. The result is

$$\bar{x} = \frac{a^2 + 4R^2}{2\pi R} \quad (2.53)$$

Example 2.6

Figure 2.10 shows a thin homogeneous semicircular cantilever beam of specific weight γ in a uniform gravitational field. Suppose that the only force acting on the beam is the gravitational force of attraction perpendicular to the plane of the figure. To determine the internal forces at any section E of the beam, the free-body diagram of the circular arc from B to E is used. The force distribution on this circular arc is a line force of constant intensity so that Equations (2.23), which give the coordinates of a point on the line of action of the single force resultant of a line force, show that the resultant passes through the centroid of the arc. The centroid C of the arc is at a distance \bar{r} from the center O :

$$\bar{r} = \frac{r \sin \theta / 2}{\theta / 2} \quad (2.54)$$

The single force equivalent of the gravitational forces acting on the arc BE is the weight $\gamma r \theta$ acting at the centroid C in the direction perpendicular to the plane of the figure. The moment arm for the twisting moment T at E is DE and the moment arm for the bending moment M at E is DC . Hence

$$T = \gamma r \theta \left(r - \bar{r} \cos \frac{\theta}{2} \right) \quad (2.55)$$

$$M = \gamma r \theta \bar{r} \sin \frac{\theta}{2} \quad (2.56)$$

These expressions may be rewritten as

$$T = \gamma r^2 (\theta - \sin \theta) \quad (2.57)$$

$$M = \gamma r^2 (1 - \cos \theta) \quad (2.58)$$

Defining Terms

Center of gravity — The point of application of the single force resultant of the distributed gravitational forces exerted by the earth on a rigid body.

Center of mass — A unique point of a rigid body determined by the mass distribution. It coincides with the center of gravity if the gravity field is parallel and uniform.

Centroid — A unique point of a rigid geometric shape, defined as the point with coordinates $\bar{x} = \int_V x dV/V$, $\bar{y} = \int_V y dV/V$, $\bar{z} = \int_V z dV/V$, for a three-dimensional solid of volume V .

Pappus–Guldin formulas — Two formulas that use the definition of the centroid to assist in the calculation of the area of a surface of revolution and the volume of a body of revolution.

Moments of Inertia

J. L. Meriam
University of California (Retired)

- 3.1 Area Moments of Inertia
Defining Relations • Radius of Gyration • Parallel-Axis
Theorem • Composite Areas
- 3.2 Mass Moments of Inertia
Defining Relations

The **mass moment of inertia**, I , of a body is a measure of the inertial resistance of the body to rotational acceleration and is expressed by the integral $I = \int r^2 dm$, where dm is the differential element of mass and r is the perpendicular distance from dm to the rotation axis. The **area moment of inertia** of a defined area about a given axis is expressed by the integral $I = \int s^2 dA$, where dA is the differential element of area and s is the perpendicular distance from dA to a defined axis either in or normal to the plane of the area. The mathematical similarity to mass moment of inertia gives rise to its name. A more fitting but less used term is the *second moment of area*.

The frequent occurrence of area and mass moments of inertia in mechanics justifies establishing and tabulating their properties for commonly encountered shapes, as given in [Table 3.1](#) and [Table 3.2](#).

3.1 Area Moments of Inertia

[Figure 3.1](#) illustrates the physical origin of the area moment-of-inertia integrals. In [Figure 3.1\(a\)](#) the surface area $ABCD$ is subject to a distributed pressure p whose intensity is proportional to the distance y from the axis AB . The moment about AB that is due to the pressure on the element of area dA is $y(p dA) = ky^2 dA$. Thus the integral in question appears when the total moment $M = k \int y^2 dA$ is evaluated.

[Figure 3.1\(b\)](#) shows the distribution of stress acting on a transverse section of a simple linear elastic beam bent by equal and opposite couples applied one to each end. At any section of the beam a linear distribution of force intensity or stress σ , given by $\sigma = ky$, is present, the stress being positive (tensile) below the axis $O-O$ and negative (compressive) above the axis. The elemental moment about axis $O-O$ is $dM = y(\sigma dA) = ky^2 dA$. Thus the same integral appears when the total moment $M = k \int y^2 dA$ is evaluated.

A third example is given in [Figure 3.1\(c\)](#), which shows a circular shaft subjected to a twist or torsional moment. Within the elastic limit of the material, this moment is resisted at each cross-section of the shaft by a distribution of tangential or shear stress τ that is proportional to the radial distance r from the center. Thus $\tau = kr$ and the total moment about the central axis becomes $M = \int r(\tau dA) = k \int r^2 dA$. Here the integral differs from that in the preceding two examples in that the area is normal instead of parallel to the moment axis and in that r is a radial coordinate instead of a rectangular one.

Defining Relations

Rectangular and Polar Moments of Inertia

For area A in the xy plane, Figure 3.2, the moments of inertia of the element dA about the x and y axes are, by definition, $dI_x = y^2 dA$ and $dI_y = x^2 dA$, respectively. The moments of inertia of A about the same axes become

$$I_x = \int y^2 dA \quad (3.1)$$

$$I_y = \int x^2 dA$$

where the integration is carried out over the entire area.

The moment of inertia of dA about the pole O (z axis) is, by definition, $dI_z = r^2 dA$, and the moment of inertia of the entire area about O is

$$I_z = \int r^2 dA \quad (3.2)$$

FIGURE 3.2 (Source: Meriam, J.L. and Kraige, L.G. 1992. *Engineering Mechanics*, 3rd ed. John Wiley & Sons, New York.)

The expressions defined by Equation (3.1) are known as *rectangular* moments of inertia, whereas the expression of Equation (3.2) is known as the *polar* moment of inertia. (In the literature the polar moment of inertia is sometimes denoted by the symbol J .) Because $x^2 + y^2 = r^2$, it follows that

$$I_z = I_x + I_y \tag{3.3}$$

A polar moment of inertia for an area whose boundaries are more simply described in rectangular coordinates than in polar coordinates is easily calculated using Equation (3.3).

Because the area moment of inertia involves distance squared, it is always a positive quantity for a positive area. (A hole or void may be considered a negative area.) In contrast, the first moment of area $\int y \, dA$ involves distance to the first power, so it can be positive, negative, or zero.

The dimensions of moments of inertia of areas are L^4 , where L stands for the dimension of length. The SI units for moments of inertia of areas are expressed in quartic meters (m^4) or quartic millimeters (mm^4). The U.S. customary units are quartic feet (ft^4) or quartic inches ($in.^4$).

Rectangular coordinates should be used for shapes whose boundaries are most easily expressed in these coordinates. Polar coordinates will usually simplify problems where the boundaries are expressed in r and θ . The choice of an element of area that simplifies the integration as much as possible is equally important.

Radius of Gyration

Consider the area A , Figure 3.3(a), which has rectangular moments of inertia I_x and I_y and a polar moment of inertia I_z about O . If the area is visualized as being concentrated into a long narrow strip of area A a distance k_x from the x axis, Figure 3.3(b), by definition the moment of inertia of the strip about the x axis will be the same as that of the original area if $k_x^2 A = I_x$. The distance k_x is known as the **radius of gyration** of the area about the x axis. A similar relation for the y axis is found by considering the area to be concentrated into a narrow strip parallel to the y axis as shown in Figure 3.3(c). Also, by visualizing the area to be concentrated into a narrow ring of radius k_z , as shown in Figure 3.3(d), the polar moment of inertia becomes $k_z^2 A = I_z$. Summarizing,

FIGURE 3.3 (Source: Meriam, J.L. and Kraige, L.G. 1992. *Engineering Mechanics*, 3rd ed. John Wiley & Sons, New York.)

FIGURE 3.4 (Source: Meriam, J.L. and Kraige, L.G. 1992. *Engineering Mechanics*, 3rd ed. John Wiley & Sons, New York.)

$$\begin{aligned}
 I_x &= k_x^2 A & k_x &= \sqrt{I_x / A} \\
 I_y &= k_y^2 A & k_y &= \sqrt{I_y / A} \\
 I_z &= k_z^2 A & k_z &= \sqrt{I_z / A}
 \end{aligned}
 \tag{3.4}$$

A rectangular or polar moment of inertia may be expressed by specifying its radius of gyration and its area. Substituting Equation (3.4) into Equation (3.3) gives

$$k_z^2 = k_x^2 + k_y^2 \tag{3.5}$$

Parallel-Axis Theorem

The moment of inertia of an area about a noncentroidal axis may be easily expressed in terms of the moment of inertia about a parallel centroidal axis. In Figure 3.4 the \$x_0\$ and \$y_0\$ axes pass through the centroid C of the area. By definition the moment of inertia of the element \$dA\$ about the \$x\$ axis is \$dI_x = (y_0 + d_x)^2 dA\$. Expanding and integrating give

$$I_x = \int y_0^2 dA + 2d_x \int y_0 dA + d_x^2 \int dA$$

The first integral is by definition the moment of inertia \$\bar{I}_x\$ about the centroidal \$x_0\$ axis. The second integral is zero because \$\int y_0 dA = A \bar{y}_0\$ where \$\bar{y}_0\$ is automatically zero because the centroid for the area lies on the \$x_0\$ axis. The third term is simply \$Ad_x^2\$. Thus, the expression for \$I_x\$ and the similar expression for \$I_y\$, become

$$\begin{aligned}
 I_x &= \bar{I}_x + Ad_x^2 \\
 I_y &= \bar{I}_y + Ad_y^2
 \end{aligned}
 \tag{3.6}$$

By Equation (3.3), the sum of these two equations gives

$$I_z = \bar{I}_z + Ad^2 \tag{3.6a}$$

Equation (3.6) and Equation (3.6a) are the so-called *parallel-axis theorems*. It is noted that the axes between which transfer is made *must be parallel* and that one of the axes *must pass through the centroid* of the area. The parallel-axis theorems also hold for radii of gyration. Substitution of the definition of \$k\$ into Equation (3.6) gives

$$k^2 = \bar{k}^2 + d^2 \quad (3.6b)$$

where \bar{k} is the radius of gyration about the centroidal axis parallel to the axis about which k applies and d is the distance between the two axes. The axes may be either in or normal to the plane of the area.

A summary of formulas for area moments of inertia for various commonly encountered plane areas is given in Table 3.1.

Composite Areas

When an area is the composite of a number of distinct parts, its moment of inertia is obtained by summing the results for each of the parts in terms of its area A , its centroidal moment of inertia \bar{I} , the perpendicular distance d from its centroidal axis to the axis about which the moment of inertia of the composite area is being computed, and the product Ad^2 . The results are easily tabulated in the form

| Part | Area, A | \bar{I}_x | \bar{I}_y | d_x | d_y | Ad_x^2 | Ad_y^2 |
|------|-----------|------------------|------------------|-------|-------|---------------|---------------|
| Sums | | $\sum \bar{I}_x$ | $\sum \bar{I}_y$ | | | $\sum Ad_x^2$ | $\sum Ad_y^2$ |

The final results are simply

$$I_x = \sum \bar{I}_x + \sum Ad_x^2 \quad I_y = \sum \bar{I}_y + \sum Ad_y^2$$

Products of Inertia

In certain problems involving unsymmetrical cross-sections, an expression of the form $dI_{xy} = xy \, dA$ occurs, and its integral

$$I_{xy} = \int xy \, dA \quad (3.7)$$

is known as the **product of inertia**. Unlike moments of inertia, which are always positive for positive areas, the product of inertia may be positive, negative, or zero, depending on the signs of x and y .

Rotation of Axes

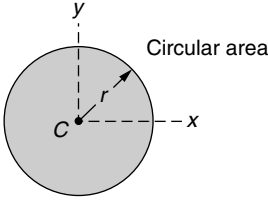

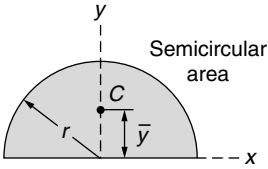

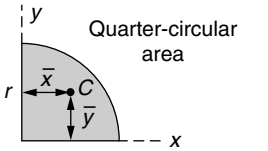

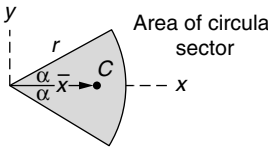

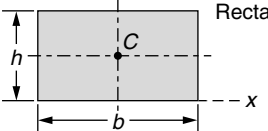

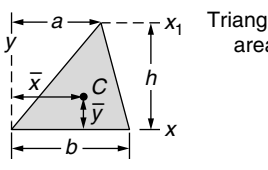

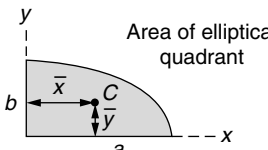

It may be shown that the moments and products of inertia for the area of [Figure 3.5](#) about the rotated axes $x'-y'$ are given by

$$\begin{aligned} I_{x'} &= \frac{I_x + I_y}{2} + \frac{I_x - I_y}{2} \cos 2\theta - I_{xy} \sin 2\theta \\ I_{y'} &= \frac{I_x + I_y}{2} - \frac{I_x - I_y}{2} \cos 2\theta + I_{xy} \sin 2\theta \\ I_{x'y'} &= \frac{I_x - I_y}{2} \sin 2\theta + I_{xy} \cos 2\theta \end{aligned} \quad (3.8)$$

The angle that makes $I_{x'}$ and $I_{y'}$ a maximum or a minimum is determined by setting the derivative of $I_{x'}$ and $I_{y'}$ with respect to θ equal to zero. Denoting this critical angle by α gives

$$\tan 2\alpha = \frac{2I_{xy}}{I_y - I_x} \quad (3.9)$$

TABLE 3.1 Properties of Plane Areas

| Figure | Centroid | Area Moments of Inertia |

|  <p>Circular area</p> | — | $I_x = I_y = \frac{\pi r^4}{4}$ $I_z = \frac{\pi r^4}{2}$ |
|  <p>Semicircular area</p> | $\bar{y} = \frac{4r}{3\pi}$ | $I_x = I_y = \frac{\pi r^4}{8}$ $\bar{I}_x = \left(\frac{\pi}{8} - \frac{8}{9\pi} \right) r^4$ $I_z = \frac{\pi r^4}{4}$ |
|  <p>Quarter-circular area</p> | $\bar{x} = \bar{y} = \frac{4r}{3\pi}$ | $I_x = I_y = \frac{\pi r^4}{16}$ $\bar{I}_x = \bar{I}_y = \left(\frac{\pi}{16} - \frac{4}{9\pi} \right) r^4$ $I_z = \frac{\pi r^4}{8}$ |
|  <p>Area of circular sector</p> | $\bar{x} = \frac{2 r \sin \alpha}{3 \alpha}$ | $I_x = \frac{r^4}{4} \left(\alpha - \frac{1}{2} \sin 2\alpha \right)$ $I_y = \frac{r^4}{4} \left(\alpha + \frac{1}{2} \sin 2\alpha \right)$ $I_z = \frac{1}{2} r^4 \alpha$ |
|  <p>Rectangular area</p> | — | $I_x = \frac{bh^3}{3}$ $\bar{I}_x = \frac{bh^3}{12}$ $\bar{I}_z = \frac{bh}{12} (b^2 + h^2)$ |
|  <p>Triangular area</p> | $\bar{x} = \frac{a+b}{3}$ $\bar{y} = \frac{h}{3}$ | $I_x = \frac{bh^3}{12}$ $\bar{I}_x = \frac{bh^3}{36}$ $\bar{I}_{x_1} = \frac{bh^3}{4}$ |
|  <p>Area of elliptical quadrant</p> | $\bar{x} = \frac{4a}{3\pi}$ $\bar{y} = \frac{4b}{3\pi}$ | $I_x = \frac{\pi ab^3}{16}, \quad \bar{I}_x = \left(\frac{\pi}{16} - \frac{4}{9\pi} \right) ab^3$ $I_y = \frac{\pi a^3 b}{16}, \quad \bar{I}_y = \left(\frac{\pi}{16} - \frac{4}{9\pi} \right) a^3 b$ $I_z = \frac{\pi ab}{16} (a^2 + b^2)$ |

Source: Meriam, J.L. and Kraige, L.G. 1992. *Engineering Mechanics*, 3rd ed. John Wiley & Sons, New York.

Substitution of Equation (3.9) for 2θ in Equation (3.8) gives $I_{x'y'} = 0$ and

$$I_{\max} = \frac{1}{2} \left\{ I_x + I_y + \sqrt{(I_x - I_y)^2 + 4I_{xy}^2} \right\}$$

$$I_{\min} = \frac{1}{2} \left\{ I_x + I_y - \sqrt{(I_x - I_y)^2 + 4I_{xy}^2} \right\}$$
(3.10)

3.2 Mass Moments of Inertia

The dynamics of bodies that rotate with angular acceleration calls for a knowledge of mass moments of inertia and is treated in the chapter on Dynamics and Vibration.

Defining Relations

Fixed Axis

The moment of inertia of the body of mass m in Figure 3.6 about the fixed axis $O-O$ is given by

$$I_o = \int r^2 dm$$
(3.11)

The dimensions are (mass)(length)², which are kg·m² in SI units and lb·ft·sec² in U.S. customary units. If the density ρ of the body is constant, then $dm = \rho dV$ and the integral becomes

$$I_o = \rho \int r^2 dV$$
(3.12)

where dV is the differential volume of the mass element. To facilitate integration, coordinates that best suit the boundaries of the body should be utilized.

Radius of Gyration

The **radius of gyration** k of a mass m about an axis for which the moment of inertia is I is defined as

$$k = \sqrt{I/m} \quad \text{or} \quad I = k^2 m$$
(3.13)

Thus k is a measure of the distribution of mass about the axis in question, and its definition is analogous to the similar definition of radius of gyration for area moments of inertia.

FIGURE 3.5 (Source: Meriam, J.L. and Kraige, L.G. 1992. *Engineering Mechanics*, 3rd ed. John Wiley & Sons, New York.)

FIGURE 3.6 (Source: Meriam, J.L. and Kraige, L.G. 1992. *Engineering Mechanics*, 3rd ed. John Wiley & Sons, New York.)

FIGURE 3.7 (Source: Meriam, J.L. and Kraige, L.G. 1992. *Engineering Mechanics*, 3rd ed. John Wiley & Sons, New York.)

Parallel-Axis Theorem

If the moment of inertia of a body of mass m about an axis through the mass center is known, it may easily be determined about any parallel axis by the expression

$$I = \bar{I} + md^2 \quad (3.14)$$

where \bar{I} is the moment of inertia about the parallel axis through the mass center and d is the perpendicular distance between the axes. This *parallel-axis theorem* is analogous to that for area moments of inertia, Equation (3.6). It applies *only* if transfer is made to or from a parallel axis through the mass center. From the definition of Equation (3.13), it follows that

$$k^2 = \bar{k}^2 + d^2 \quad (3.15)$$

where k is the radius of gyration about an axis a distance d from the parallel axis through the mass center for which the radius of gyration is \bar{k} .

Flat Plates

The moments of inertia of a flat plate, Figure 3.7, about axes in the plane of and normal to the plate are frequently encountered. The elemental mass is $\rho(t dA)$, where ρ is the plate density, t is its thickness, and $dA = dx dy$ is the face area of dm . If ρ and t are constant, the moment of inertia about each of the axes becomes

$$\begin{aligned} I_{xx} &= \int y^2 dm = \rho t \int y^2 dA = \rho t I_x \\ I_{yy} &= \int x^2 dm = \rho t \int x^2 dA = \rho t I_y \\ I_{zz} &= \int r^2 dm = \rho t \int r^2 dA = \rho t I_z \end{aligned} \quad (3.16)$$

where the double subscript designates mass moment of inertia and the single subscript designates the moment of inertia of the plate area. Inasmuch as $I_z = I_x + I_y$ for area moments of inertia, it follows that

$$I_{zz} = I_{xx} + I_{yy} \quad (3.16a)$$

FIGURE 3.8 (Source: Meriam, J.L. and Kraige, L.G. 1992. *Engineering Mechanics*, 3rd ed. John Wiley & Sons, New York.)

This relation holds *only* if t is small compared with the other plate dimensions.

Composite Bodies

The mass moment of inertia of a composite body about a given axis is simply the sum of the moments of inertia of its individual components about the same axis.

A summary of formulas for mass moments of inertia for various bodies of common shape is given in Table 3.2.

General Rotation

For three-dimensional rotation of a rigid body the moments and products of inertia assume a more general form from Figure 3.8, as follows:

$$\begin{aligned}
 I_{xx} &= \int r_x^2 dm = \int (y^2 + z^2) dm & I_{xy} &= I_{yx} = \int xy dm \\
 I_{yy} &= \int r_y^2 dm = \int (z^2 + x^2) dm & I_{xz} &= I_{zx} = \int xz dm \\
 I_{zz} &= \int r_z^2 dm = \int (x^2 + y^2) dm & I_{yz} &= I_{zy} = \int yz dm
 \end{aligned}
 \tag{3.17}$$

Whereas the moments of inertia are always positive, the products of inertia may be positive, negative, or zero. Parallel-axis theorems for products of inertia are

$$\begin{aligned}
 I_{xy} &= \bar{I}_{xy} + m\bar{x}\bar{y} \\
 I_{xz} &= \bar{I}_{xz} + m\bar{x}\bar{z} \\
 I_{yz} &= \bar{I}_{yz} + m\bar{y}\bar{z}
 \end{aligned}
 \tag{3.18}$$

where the bar represents the product of inertia with respect to axes through the mass center and \bar{x} , \bar{y} , and \bar{z} represent the coordinates of the mass center.

Defining Terms

Area moment of inertia — Defined as $\int (\text{distance})^2 d(\text{area})$.

Mass moment of inertia — A measure of the inertial resistance to angular acceleration.

Product of inertia — Defined as $\int xy dA$ for areas (xy plane) and $\int xy dm$, $\int xz dm$, and $\int yz dm$ for masses.

Radius of gyration — Defined as $\sqrt{I/A}$ for areas and $\sqrt{I/m}$ for masses.

TABLE 3.2 Moments of Inertia of Homogeneous Solids ($m =$ Mass of Body Shown)

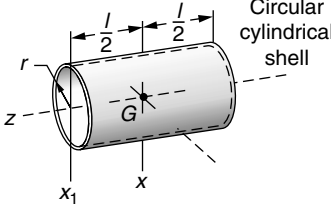

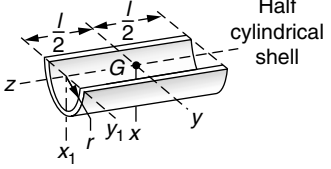

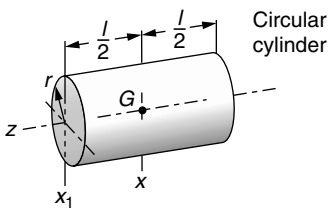

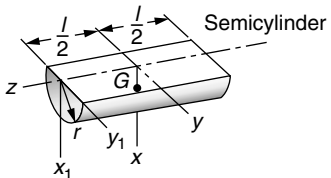

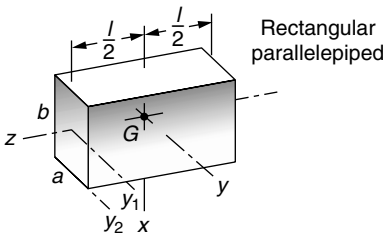

| Body | Mass Center | Mass Moments of Inertia |
|---|-----------------------------|---|
|  <p>Circular cylindrical shell</p> | — | $I_{xx} = \frac{1}{2}mr^2 + \frac{1}{12}ml^2$ $I_{x_1x_1} = \frac{1}{2}mr^2 + \frac{1}{3}ml^2$ $I_{zz} = mr^2$ |

- 4.1 Types of Supports
- 4.2 Actual versus Idealized Support Conditions
- 4.3 Static Determinacy and Indeterminacy
- 4.4 Computation of Reactions

For purposes of analysis, forces and moments acting on a structure or structural element can be grouped into two categories: loads and reactions. The loads acting on a structure include gravitational forces, inertial forces, friction, wind, lift, drag, hydrostatic pressure, soil pressure, and impacts. Supports are used to prevent a body from moving when subjected to these loads. **Reactions** are those moments and forces that act on the body as a consequence of the restraint provided by the supports. The magnitudes of reactions are controlled by the magnitudes of the applied loads. It should be understood that a reaction does not necessarily occur as a consequence of attaching a structure to the ground. Each structural element can have reactions due to its being connected to or supported by another structure or structural element. The type of reaction depends on the physical characteristics of the support. In order for a structure or structural element to be **stable**, there must be a sufficient number of supports to prevent it from undergoing unrestrained displacements.

4.1 Types of Supports

A variety of supports are available for restraining a structure. The type of support selected by the designer often depends on the type of structure, the material being used, the configuration of the structure, and the anticipated loads. A reaction occurs when the structure or structural element is prevented by a support from moving in a particular direction. For example, consider the fixed support shown in [Table 4.1](#). This support prevents vertical and horizontal translation as well as rotation about an axis perpendicular to the page; thus the reactions are a vertical force, a horizontal force, and a moment.

A body at rest or moving at constant velocity is said to be in *equilibrium*. In accord with Newton's second law, equilibrium will exist if all of the forces and moments acting on the body sum to zero. To analyze the equilibrium of a structure or structural element, a free-body diagram must be drawn, on which all loads are shown and all supports have been replaced by the reactions they produce. For purposes of analysis and design many structures (but not all) subjected to two-dimensional systems of loads can be accurately modeled as **planar structures**. For these planar structures, models of support conditions can be greatly simplified. The idealized models of structural supports for planar structures are presented in [Table 4.1](#). [Table 4.2](#) summarizes supports and their accompanying reaction components for **space structures**. Space structures are those structures for which the members and/or the load systems are three-dimensional.

TABLE 4.1 Supports for Planar Structures

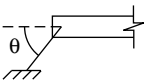

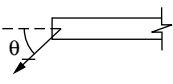

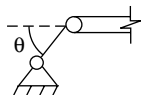

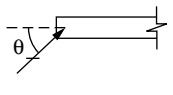

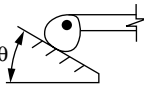

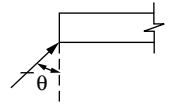

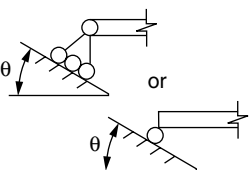

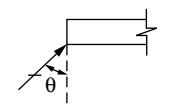

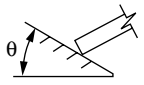

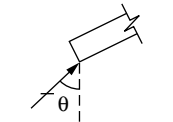

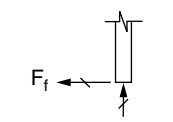

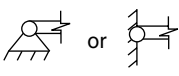

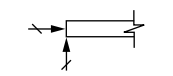

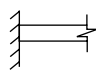

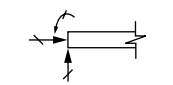

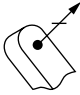

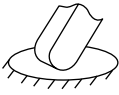

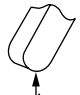

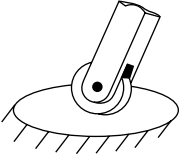

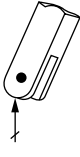

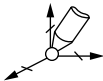

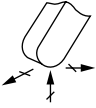

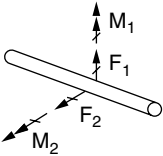

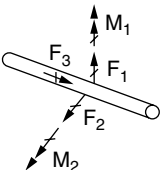

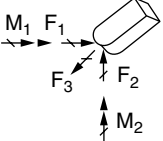

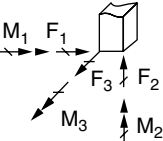

| Support | Symbol | Reaction Components | Description of Support and Reactions |
|---------------------------|---|---|--|
| Cable |  |  | A cable can prevent translation only along its axis and can only exert tension. The unknown reaction is a tension force that acts away from the body in the direction of the cable. |
| Link |  |  | A link can prevent translation only along its axis. A link can exert tension or compression. The unknown reaction is a force that acts along the axis of the link either toward or away from the body. |
| Rocker |  |  | A rocker is capable only of applying a compressive force perpendicular to the surface on which it sits, and thus motion is only restrained perpendicular to that surface. The unknown reaction is a force that acts perpendicular to the surface at the point of contact. |
| Roller |  |  | A roller is capable only of applying force (tension or compression) perpendicular to the surface on which it sits, and thus motion is only restrained perpendicular to the support surface. The body can translate parallel to the surface and can rotate. The unknown reaction is a force that acts perpendicular to the surface (in either direction) at the point of contact. |
| Smooth contacting surface |  |  | A smooth (frictionless) contacting surface is capable only of applying a compressive force and cannot provide any restraint parallel to the surface. The unknown reaction is a force that acts perpendicular to the surface at the point of contact. |
| Rough contacting surface |  |  | A rough contacting surface provides a frictional force (F_f) parallel to the surface. The two unknown reactions are a frictional force parallel to the surface and a compressive force that acts on the body perpendicular to the surface at the point of contact. |
| Frictionless pin or hinge |  |  | A frictionless pinned support allows a member to rotate freely but does not permit translation. The two unknown reactions are two perpendicular components of force. |
| Fixed support |  |  | A fixed support does not permit translation or rotation. The three unknown reactions are two perpendicular force components and a moment. |

TABLE 4.2 Supports for Space Structures

| Support | Symbol | Reaction Components | Description of Support and Reactions |
|---------------------------|---|---|--|
| Cable |  |  | A cable can prevent translation only along its axis and can only exert tension. The unknown reaction is a tension force that acts away from the body in the direction of the cable. |
| Smooth contacting surface |  |  | A smooth (frictionless) contacting surface cannot provide any restraint parallel to the surface. The unknown reaction is a compressive force that acts perpendicular to the surface at the point of contact. |
| Roller |  |  | A roller is capable only of applying force (tension or compression) perpendicular to the surface on which it sits, and thus motion is only restrained perpendicular to the support surface. The body can translate parallel to the surface and can rotate. The unknown reaction is a force that acts perpendicular to the surface at the point of contact. |
| Ball-and-socket joint |  |  | A frictionless ball-and-socket joint allows a member to rotate freely but does not permit translation. The unknown reactions are three mutually perpendicular force components. |
| Rough contacting surface |  |  | A rough contacting surface provides a frictional force parallel to the surface. The three unknown reactions are two perpendicular frictional forces parallel to the surface and a compressive force that acts perpendicular to the surface at the point of contact. |
| Journal bearing |  |  | A journal bearing allows the shaft to spin freely and to translate parallel to itself. The four unknown reactions are two force components that act perpendicular to the shaft and two moments about axes perpendicular to the shaft. |
| Thrust bearing |  |  | A thrust bearing allows the shaft to spin freely but does not permit any other translation or rotation. The five unknown reactions are three mutually perpendicular forces and two moments about axes perpendicular to the shaft. |
| Frictionless pin |  |  | A frictionless pin permits rotation only about the axis of the pin. The five unknown reactions are three mutually perpendicular forces and two moments about axes perpendicular to the pin. |
| Fixed support |  |  | A fixed support does not permit translation or rotation. The six unknown reactions are three mutually perpendicular forces and moments about three mutually perpendicular axes. |

FIGURE 4.1 Connection between column and beam that is modeled as a pin support for the beam. (a) Actual connection; (b) idealized support for the beam.

4.2 Actual versus Idealized Support Conditions

The idealized models of supports presented in [Table 4.1](#) and [Table 4.2](#) are based on a variety of assumptions. For example, in the cases of pinned, hinged, and ball-and-socket supports, it is assumed that no friction occurs. If friction were present, rotation would be hampered and moments would result. Similarly, as shown in [Figure 4.1](#) and [Figure 4.2](#), a so-called pin support may not actually consist of two bodies connected by a frictionless pin. It is even possible that the connection in [Figure 4.1](#) would be better represented by a torsional spring to account for the stiffness of the connection against rotation.

Another idealization is that hinged and roller supports are modeled by reaction forces acting at a point (see [Figure 4.2](#)). However, actual structures consist of members with finite depth or width. Thus, if a beam is resting on a wall, the actual reaction consists of a distributed force or pressure acting over the area of contact. However, if the width of the supporting wall is small compared with the length of the member, the assumption of a knife-edge support may be sufficiently accurate. In the example shown in [Figure 4.2](#), for modeling purposes, the engineer may want to place the roller support at the center of the bearing plate. When selecting from the idealized models in [Table 4.1](#) and [Table 4.2](#) to represent actual supports, the engineer must be aware of what the assumptions are, how well these assumptions correspond to the actual situation, and how the idealization of the supports affects the accuracy of the analysis.

4.3 Static Determinacy and Indeterminacy

The first step in analyzing the reactions acting on any structure or structural element is to isolate the object of interest and construct a free-body diagram. Equilibrium of a body requires that the sum of the forces in any direction and the sum of the moments about any axis be zero. For a three-dimensional body, these equilibrium conditions can be expressed by the following set of equations:

$$\begin{aligned} \sum F_x = 0 & \quad \sum F_y = 0 & \quad \sum F_z = 0 \\ \sum M_{x \text{ axis}} = 0 & \quad \sum M_{y \text{ axis}} = 0 & \quad \sum M_{z \text{ axis}} = 0 \end{aligned} \quad (4.1)$$

FIGURE 4.2 (a) Actual beam; (b) idealized beam.

If the body and all of the loads are in one plane (for example, the xy plane) the equilibrium equations reduce to

$$\sum F_x = 0 \quad \sum F_y = 0 \quad \sum M_{z \text{ axis}} = 0 \quad (4.2)$$

From Equations (4.1) and Equations (4.2), it can be seen that for a three-dimensional free body a maximum of six unknowns can be determined using equations of equilibrium, and for a planar free body a maximum of three unknowns. Thus, looking at an entire structure as a free body, it can be classified depending on the number and arrangement of unknown reactions. A structure for which equilibrium equations are sufficient to determine all of the unknown forces and moments is classified as **statically determinate**. If the number of unknowns exceeds the number of available equilibrium equations it is **statically indeterminate**. The number of excess unknowns defines the degree of static indeterminacy.

Examples of statically determinate planar structures are shown in Figure 4.3. The simply supported and cantilevered beams in Figure 4.3(a) and Figure 4.3(b) each have three unknown reactions. These reactions can be determined by summing forces in the vertical and horizontal directions and summing moments about an axis perpendicular to the plane of the structure [see Equations (4.2)]. The same is true for the frame shown in Figure 4.3(c). However, in this case the reaction R_3 would likely be resolved into vertical and horizontal components to simplify writing of the equilibrium equations.

A compound structure such as the one shown in Figure 4.3(d) may be made up of several rigid elements connected by pins. The procedure for analyzing a compound structure is to break it apart at the pins and draw a free-body diagram of each element. Each pin can then be replaced by the forces it applies to the element. Since no rotation can be transferred from one member to the other by a frictionless pin, the moment at a pin connection is zero. This condition provides an additional equation at each pin that can be used to solve for unknowns. Thus, while the structure in Figure 4.3(d) may at first appear to be statically indeterminate because there are four unknown reactions, it is not. The equation of condition at the pin can be combined with the three equilibrium equations to solve for all four reactions. Similarly,

FIGURE 4.3 Statically determinate structures.

the four reactive forces on the three-hinged arch in Figure 4.3(e) can be determined by breaking the structure apart at the hinge (where the moment is zero) and applying equilibrium equations to each of the resulting free bodies.

Figure 4.4(a) and Figure 4.4(b) give examples of first-degree statically indeterminate structures. For each of these planar structures, only three equilibrium equations are available and only three reactions can be determined. The additional unknown that cannot be determined using equilibrium equations is called the *redundant*. The frame in Figure 4.4(c) has six unknown reactions and is third-degree statically indeterminate. It has three redundant reactions. The frame in Figure 4.4(d) appears to be third-degree statically indeterminate, but due to the two equations of condition provided by the two pins, it is only first-degree statically indeterminate.

A planar structure such as the one shown in Figure 4.5(a) with fewer than three reactions is **statically unstable** because there are fewer reactions than equilibrium equations. Statically unstable structures are incapable of preventing rigid body movement. It is possible, however, that while a structure has an adequate number of supports to potentially satisfy equilibrium, they can be arranged in such a way that the structure is still capable of moving. For example, in Figure 4.5(b) the beam has three reactions, but they are all parallel, so the beam can move horizontally. The reactions on the frame in Figure 4.5(c) are concurrent at point *C* and thus under certain loading conditions the frame will rotate. Structures such as these are classified as **geometrically unstable**. The reactions for a geometrically unstable structure cannot be completely determined using equations of equilibrium.

4.4 Computation of Reactions

For statically determinate structures, solving for the unknown reactions involves applying the appropriate equilibrium equations. Determination of reactions for statically indeterminate structures requires the use of additional relationships such as compatibility equations and constitutive equations involving the structural and material properties of the members. For example, either the *stiffness method* or the *flexibility method* can be used.

The procedure for determining the reactions on a statically determinate compound structure is illustrated in the following example. This requires only the use of free-body diagrams and equations of equilibrium. Example 1.2, Example 1.3, and Example 1.4 (Chapter 1) provide additional illustrations of how to determine reactions for statically determinate planar structures.

Example

The compound frame shown in Figure 4.6(a) consists of two members connected by a frictionless pin at *B*. Using the loads and dimensions shown in the figure, determine the reactions for this frame.

Solution

The unknown reactions for this frame are shown in Figure 4.6(b). The equilibrium equations [Equations (4.2)] can be combined with the equation of condition at the pin to solve for all four reactions. The frame must be separated into its two members in order to solve for the reactions. The corresponding free-body diagrams are shown in Figure 4.6(c). Starting with member *AB* because it has only three unknowns, apply Equations (4.2) with respect to the coordinate system shown.

$$\begin{aligned} \sum F_x &= 0 & B_x &= 0 \\ \sum M_A &= 0 & -(20 \text{ k} \times 5 \text{ ft}) + (B_y \times 10 \text{ ft}) &= 0 & B_y &= 10 \text{ k} \\ \sum F_y &= 0 & R_{Ay} + B_y - 20 \text{ k} &= 0 & R_{Ay} &= 10 \text{ k} \end{aligned}$$

Having determined the unknown forces for member *AB*, apply Equations (4.2) to member *CBD*.

(a) 1st degree statically indeterminate

(b) 1st degree statically indeterminate

(c) 3rd degree statically indeterminate

(d) 1st degree statically indeterminate

(a)

(b)

(c)

FIGURE 4.4 Statically indeterminate structures.

FIGURE 4.5 Examples of unstable structures: (a) statically unstable; (b) geometrically unstable; (c) geometrically unstable.

FIGURE 4.6 Calculation of reactions for a statically determinate structure.

$$\begin{aligned}
 \sum F_x = 0 & \quad R_{Cx} - (2 \text{ k/ft} \times 15 \text{ ft}) - B_x = 0 & \quad R_{Cx} = 30 \text{ k} \\
 \sum F_y = 0 & \quad R_{Cy} - B_y = 0 & \quad R_{Cy} = 10 \text{ k} \\
 \sum M_C = 0 & \quad (2 \text{ k/ft} \times 15 \text{ ft} \times 7.5 \text{ ft}) + (B_x \times 12 \text{ ft}) + M_C = 0 \\
 & \quad M_C = -225 \text{ k-ft} - 12B_x & \quad M_C = -225 \text{ k-ft}
 \end{aligned}$$

Since the value of the reaction moment at C, M_C , is negative, it is in the opposite direction to that assumed in Figure 4.6(b).

Defining Terms

Geometrically unstable — A structure is geometrically unstable if, even though it has sufficient restraints (reactions) to potentially satisfy equilibrium, it can undergo rigid-body movements due to the arrangement of the reactions.

Planar structure — A structure for which all members and loads are in one plane.

Reactions — Those moments and forces that are induced by the supports as they restrain a body from moving.

Space structure — A structure for which members and/or loads are three-dimensional.

Stable structure — A stable structure has sufficient reactions and members in the proper configuration to prevent rigid-body motion.

Statically determinate — A structure is statically determinate if all of the unknown forces and moments can be determined using equations of equilibrium.

Statically indeterminate — A structure is statically indeterminate if there are more unknown forces and moments than equations of equilibrium.

Statically unstable — A structure is statically unstable if it has fewer reactions than equilibrium equations.

Further Information

Extensive discussions and examples of how to determine reactions for statically determinate structures can be found in textbooks on statics and structural analysis. These textbooks also provide illustrations and photographs of actual supports and discuss how these supports vary from the idealized models. Textbooks on structural analysis, such as those listed in the References, usually cover analysis techniques for both statically determinate and statically indeterminate structures. More in-depth discussions of the analysis of statically indeterminate structures using techniques such as the flexibility and stiffness methods can be found in textbooks on matrix analysis of structures and finite-element analysis.

Bending Stresses in Beams

James M. Gere
Stanford University

- 5.1 Longitudinal Strains in Beams
- 5.2 Normal Stresses in Beams (Linearly Elastic Materials)

A *beam* is a slender structural member subjected to lateral loads. In this chapter we consider the bending stresses (i.e., normal stresses) in beams having initially straight longitudinal axes, such as the cantilever beam of [Figure 5.1\(a\)](#). For reference, we direct the positive x axis to the right along the longitudinal axis of the beam and the positive y axis downward (because the deflections of most beams are downward). The z axis, which is not shown in the figure, is directed away from the viewer, so that the three axes form a right-handed coordinate system. All cross-sections of the beam are assumed to be symmetric about the xy plane, and all loads are assumed to act in this plane. Consequently, the beam will deflect in this same plane [[Figure 5.1\(b\)](#)], which is called the **plane of bending**.

Pure bending refers to bending of a beam under a constant bending moment M , which means that the shear force V is zero (because $V = dM/dx$). **Nonuniform bending** refers to bending in the presence of shear forces, in which case the bending moment varies along the axis of the beam. The sign convention for bending moments is shown in [Figure 5.2](#); note that positive bending moment produces tension in the lower part of the beam and compression in the upper part.

The stresses and strains in a beam are directly related to the *curvature* κ of the deflection curve. Because the x axis is positive to the right and the y axis is positive downward, the curvature is positive when the beam is bent concave downward and negative when the beam is bent concave upward ([Figure 5.2](#)).

5.1 Longitudinal Strains in Beams

Consider a segment DE of a beam subjected to pure bending by positive bending moments M [[Figure 5.3\(a\)](#)]. The cross-section of the beam at section mn is of arbitrary shape except that it must be symmetrical about the y axis [[Figure 5.3\(b\)](#)]. All cross-sections of the beam (such as mn) that were plane before bending remain plane after bending, a fact that can be proven theoretically using arguments based on symmetry. Therefore, *plane sections remain plane regardless of the material properties, whether elastic or inelastic, linear or nonlinear*. (Of course, the material properties, like the dimensions, must be symmetric about the plane of bending.)¹

With positive bending moments, the lower part of the beam is in tension and the upper part is in compression. Therefore, longitudinal lines (i.e., line segments parallel to the x axis) in the lower part of

¹This chapter contains selected material (text and figures) from Gere, J. M. and Timoshenko, S. P. 1990. *Mechanics of Materials*, 3rd ed. PWS, Boston. With permission.

FIGURE 5.1 Bending of a cantilever beam.

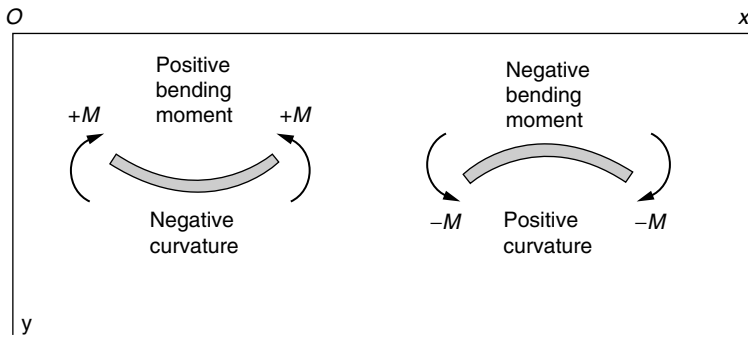

FIGURE 5.2 Sign conventions for bending moment and curvature.

FIGURE 5.3 Beam in pure bending. (a) Side view of segment of beam showing bending moments M and typical section mn . (b) Cross-section of beam at section mn .

the beam are elongated and those in the upper part are shortened. The intermediate surface in which longitudinal lines do not change in length is called the **neutral surface** of the beam. We place the origin O of coordinates in this plane, so that the xz plane becomes the neutral surface. The intersection of this surface with any cross-sectional plane is called the **neutral axis of the cross-section**, for instance, the z axis in Figure 5.3(b).

Because plane sections remain plane, the longitudinal strains ϵ_x in the beam vary linearly with the distance y from the neutral surface, regardless of the material properties. It can also be shown that the strains are proportional to the curvature κ . Thus, the strains are given by the equation

$$\epsilon_x = -\kappa y \quad (5.1)$$

The sign convention for ϵ_x is positive for elongation and negative for shortening. Note that when the curvature is positive (Figure 5.2) and y is positive (Figure 5.3), the strain is negative.

5.2 Normal Stresses in Beams (Linearly Elastic Materials)

Since longitudinal line elements in the beam are subjected only to tension or compression (elongation or shortening), they are in a state of uniaxial stress. Therefore, we can use the stress–strain diagram of the material to obtain the normal stresses σ_x from the normal strains ϵ_x . If the shape of the stress–strain curve can be expressed analytically, a formula can be derived for the stresses in the beam; otherwise, they must be calculated numerically.

The simplest and most common stress–strain relationship is for a linearly elastic material, in which case we can combine Hooke’s law for uniaxial stress ($\sigma = E\epsilon$) with Equation (5.1) and obtain

$$\sigma_x = E\epsilon_x = -E\kappa y \quad (5.2)$$

in which E is the modulus of elasticity of the material. Equation (5.2) shows that the normal stresses acting on a cross-section vary linearly with the distance y from the neutral surface when the material follows Hooke’s law.

Since the beam is in pure bending (Figure 5.3), the resultant of the stresses σ_x acting over the cross-section must equal the bending moment M . This observation provides two equations of statics — the first expressing that the resultant force in the x direction is equal to zero and the second expressing that the resultant moment is equal to M . The first equation of statics leads to the equation

$$\int y \, dA = 0 \quad (5.3)$$

which shows that the first moment of the cross-sectional area with respect to the z axis is zero. Therefore, the z axis must pass through the *centroid* of the cross-section. Since the z axis is also the neutral axis, we arrive at the following conclusion: The neutral axis passes through the centroid C of the cross-section provided the material follows Hooke’s law and no axial force acts on the cross-section.

Since the y axis is an axis of symmetry, the y axis also passes through the centroid. Therefore, the origin of coordinates O is located at the centroid C of the cross-section. Furthermore, the symmetry of the cross-section about the y axis means that the y axis is a *principal axis*. The z axis is also a principal axis since it is perpendicular to the y axis. Therefore, when a beam of linearly elastic material is subjected to pure bending, the y and z axes are principal centroidal axes.

The second equation of statics leads to the *moment-curvature equation*

$$M = -\kappa EI \quad (5.4)$$

in which

$$I = \int y^2 \, dA \quad (5.5)$$

is the moment of inertia of the cross-sectional area with respect to the z axis (that is, with respect to the neutral axis). Moments of inertia have dimensions of length to the fourth power, and typical units are in.⁴, mm⁴, and m⁴ for beam calculations. The quantity EI is a measure of the resistance of the beam to bending and is called the *flexural rigidity* of the beam.

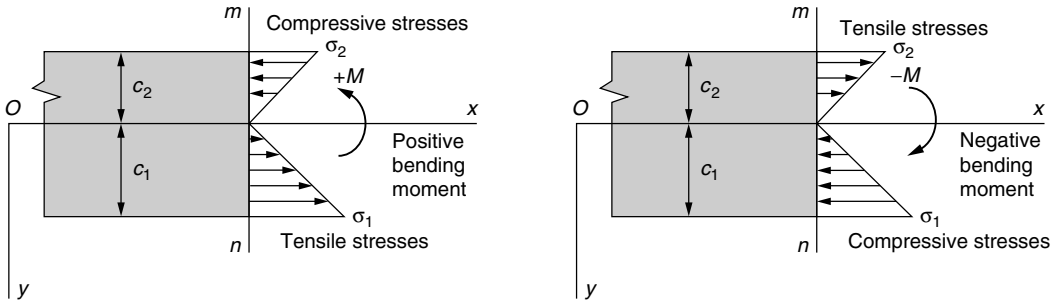

FIGURE 5.4 Bending stresses obtained from the flexure formula.

The minus sign in the moment-curvature equation is a consequence of the sign conventions we have adopted for bending moments and coordinate axes (Figure 5.2). We see that a positive bending moment produces negative curvature and a negative bending moment produces positive curvature. If the opposite sign convention for bending moments is used, or if the y axis is positive upward, then the minus sign is omitted in Equation (5.4) but a minus sign must be inserted in the flexure formula [Equation (5.6)] that follows.

The normal stresses in the beam can be related to the bending moment M by eliminating the curvature κ between Equation (5.2) and Equation (5.4), yielding

$$\sigma_x = \frac{My}{I} \quad (5.6)$$

This equation, called the **flexure formula**, shows that the stresses are directly proportional to the bending moment M and inversely proportional to the moment of inertia I of the cross-section. Furthermore, the stresses vary linearly with the distance y from the neutral axis, as shown in Figure 5.4. Stresses calculated from the flexure formula are called **bending stresses**.

The maximum tensile and compressive bending stresses occur at points located farthest from the neutral axis. Let us denote by c_1 and c_2 the distances from the neutral axis to the extreme elements in the positive and negative y directions, respectively (see Figure 5.3 and Figure 5.4). Then the corresponding maximum normal stresses σ_1 and σ_2 are

$$\sigma_1 = \frac{Mc_1}{I} = \frac{M}{S_1} \quad \sigma_2 = -\frac{Mc_2}{I} = -\frac{M}{S_2} \quad (5.7)$$

in which

$$S_1 = \frac{I}{c_1} \quad S_2 = \frac{I}{c_2} \quad (5.8)$$

The quantities S_1 and S_2 are known as the *section moduli* of the cross-sectional area. From Equation (5.8) we see that a section modulus has dimensions of length to the third power (for example, in^3 , mm^3 , or m^3).

If the cross-section is symmetric with respect to the z axis, which means that it is a *doubly symmetric cross-section*, then $c_1 = c_2 = c$, and the maximum tensile and compressive stresses are equal numerically:

$$\sigma_1 = -\sigma_2 = \frac{Mc}{I} = \frac{M}{S} \quad (5.9)$$

in which

FIGURE 5.5 Doubly symmetric cross-sectional shapes.

$$S = \frac{I}{c} \quad (5.10)$$

is the section modulus. For a beam of *rectangular cross-section* with width b and height h [Figure 5.5(a)], the moment of inertia and section modulus are

$$I = \frac{bh^3}{12} \quad S = \frac{bh^2}{6} \quad (5.11)$$

For a *circular cross-section* of diameter d [Figure 5.5(b)], these properties are

$$I = \frac{\pi d^4}{64} \quad S = \frac{\pi d^3}{32} \quad (5.12)$$

The properties of many other plane figures are listed in textbooks and handbooks.

The preceding equations for the normal stresses apply rigorously only for pure bending, which means that no shear forces act on the cross-sections. The presence of shear forces produces warping, or out-of-plane distortion, of the cross-sections, and a cross-section that is plane before bending is no longer plane after bending. Warping due to shear greatly complicates the behavior of the beam, but detailed investigations show that the normal stresses calculated from the flexure formula are not significantly altered by the presence of the shear stresses and the associated warping. Thus, under ordinary conditions we may use the flexure formula for calculating normal stresses even when we have nonuniform bending.

The flexure formula gives results that are accurate only in regions of the beam where the stress distribution is not disrupted by abrupt changes in the shape of the beam or by discontinuities in loading. For instance, the flexure formula is not applicable at or very near the supports of a beam, where the stress distribution is irregular. Such irregularities produce localized stresses, or *stress concentrations*, that are much greater than the stresses obtained from the flexure formula. With ductile materials and static loads, we may usually disregard the effects of stress concentrations. However, they cannot be ignored when the materials are brittle or when the loads are dynamic in character.

Example

The beam ABC shown in Figure 5.6 has simple supports at A and B and an overhang from B to C . A uniform load of intensity $q = 3.0$ kN/m acts throughout the length of the beam. The beam is constructed of steel plates (12 mm thick) welded to form a channel section, the dimensions of which are shown in Figure 5.7(a). Calculate the maximum tensile and compressive stresses in the beam due to the uniform load.

FIGURE 5.6 Beam dimensions.

FIGURE 5.7 Cross-section of beam.

Solution

The maximum tensile and compressive stresses occur at the cross-sections where the bending moments have their maximum numerical values. Therefore, we construct the bending-moment diagram for the beam (Figure 5.6) and note that the maximum positive and negative moments equal $1.898 \text{ kN} \cdot \text{m}$ and $-3.375 \text{ kN} \cdot \text{m}$, respectively.

Next, we determine the position of the neutral axis by locating the centroid of the cross-sectional area shown in Figure 5.7(a). The results are as follows:

$$c_1 = 61.52 \text{ mm}; c_2 = 18.48 \text{ mm}$$

The moment of inertia of the cross-sectional area about the neutral axis (the z axis) is calculated with the aid of the parallel-axis theorem for moments of inertia; the result is

$$I = 2.469 \cdot 10^6 \text{ mm}^4$$

Also, the section moduli for the bottom and top of the beam, respectively, are

$$S_1 = \frac{I}{c_1} = 40\,100 \text{ mm}^3 \quad S_2 = \frac{I}{c_2} = 133\,600 \text{ mm}^3$$

At the cross-section of maximum positive bending moment, the largest tensile stress occurs at the bottom of the beam (σ_1), and the largest compressive stress occurs at the top (σ_2):

$$\sigma_t = \sigma_1 = \frac{M}{S_1} = \frac{1.898 \text{ kN} \cdot \text{m}}{40\,100 \text{ mm}^3} = 47.3 \text{ MPa}$$

$$\sigma_c = \sigma_2 = -\frac{M}{S_2} = -\frac{1.898 \text{ kN} \cdot \text{m}}{133\,600 \text{ mm}^3} = -14.2 \text{ MPa}$$

Similarly, the largest stresses at the section of maximum negative moment are

$$\sigma_t = \sigma_2 = -\frac{M}{S_2} = -\frac{-3.375 \text{ kN} \cdot \text{m}}{133\,600 \text{ mm}^3} = 25.3 \text{ MPa}$$

$$\sigma_c = \sigma_1 = \frac{M}{S_1} = \frac{-3.375 \text{ kN} \cdot \text{m}}{40\,100 \text{ mm}^3} = -84.2 \text{ MPa}$$

A comparison of these four stresses shows that the maximum tensile stress due to the uniform load q is 47.3 MPa and occurs at the bottom of the beam at the section of maximum positive bending moment. The maximum compressive stress is -84.2 MPa and occurs at the bottom of the beam at the section of maximum negative moment.

Defining Terms

Bending stresses — Longitudinal normal stresses σ_x in a beam due to bending moments.

Flexure formula — The formula $\sigma_x = My/I$ for the bending stresses in a beam (linearly elastic materials only).

Neutral axis of the cross-section — The intersection of the neutral surface with a cross-sectional plane; that is, the line in the cross-section about which the beam bends and where the bending stresses are zero.

Neutral surface — The surface perpendicular to the plane of bending in which longitudinal lines in the beam do not change in length (no longitudinal strains).

Nonuniform bending — Bending in the presence of shear forces (which means that the bending moment varies along the axis of the beam).

Plane of bending — The plane of symmetry in which a beam bends and deflects.

Pure bending — Bending of a beam under a constant bending moment (no shear forces).

Section modulus — A property of the cross-section of a beam, equal to I/c [see Equation (5.8)].

Shear Stresses in Beams

James M. Gere
Stanford University

- 6.1 Shear Stresses in Rectangular Beams
- 6.2 Shear Stresses in Circular Beams
- 6.3 Shear Stresses in the Webs of Beams with Flanges

The loads acting on a beam [Figure 6.1(a)] usually produce both bending moments M and shear forces V at cross-sections such as ab [Figure 6.1(b)]. The longitudinal normal stresses σ_x associated with the bending moments can be calculated from the flexure formula (see Chapter 5). The transverse shear stresses τ associated with the shear forces are described in this chapter.

Since the formulas for shear stresses are derived from the flexure formula, they are subject to the same limitations:

1. The beam is symmetric about the xy plane and all loads act in this plane (the *plane of bending*).
2. The beam is constructed of a linearly elastic material.
3. The stress distribution is not disrupted by abrupt changes in the shape of the beam or by discontinuities in loading (*stress concentrations*).

6.1 Shear Stresses in Rectangular Beams

A segment of a beam of rectangular cross-section (width b and height h) subjected to a vertical shear force V is shown in Figure 6.2(a). We assume that the shear stresses τ acting on the cross-section are parallel to the sides of the beam and uniformly distributed across the width (although they vary as we move up or down on the cross-section). A small element of the beam cut out between two adjacent cross-sections and between two planes that are parallel to the neutral surface is shown in Figure 6.2(a) as element $m n$. Shear stresses acting on one face of an element are always accompanied by complementary shear stresses of equal magnitude acting on perpendicular faces of the element, as shown in Figure 6.2(b) and Figure 6.2(c). Thus, there are horizontal shear stresses acting between horizontal layers of the beam as well as transverse shear stresses acting on the vertical cross-sections.

The equality of the horizontal and vertical shear stresses acting on element $m n$ leads to an interesting conclusion regarding the shear stresses at the top and bottom of the beam. If we imagine that the element $m n$ is located at either the top or the bottom, we see that the horizontal shear stresses vanish because there are no stresses on the outer surfaces of the beam. It follows that the vertical shear stresses also vanish at those locations; thus, $\tau = 0$ where $y = \pm h/2$. (Note that the origin of coordinates is at the centroid of the cross-section and the z axis is the neutral axis.)

FIGURE 6.1 Beam with bending moment M and shear force V acting at cross-section ab .

FIGURE 6.2 Shear stresses in a beam of rectangular cross-section.

The magnitude of the shear stresses can be determined by a lengthy derivation that involves only the flexure formula and static equilibrium (see References). The result is the following¹ formula for the shear stress:

$$\tau = \frac{V}{Ib} \int y dA \tag{6.1}$$

in which V is the shear force acting on the cross-section, I is the moment of inertia of the cross-sectional area about the neutral axis, and b is the width of the beam. The integral in Equation (6.1) is the first moment of the part of the cross-sectional area below (or above) the level at which the stress is being evaluated. Denoting this first moment by Q , that is,

$$Q = \int y dA \tag{6.2}$$

we can write Equation (6.1) in the simpler form

¹Selected material (text and figures) from Chapter 5 of Gere, J. M. and Timoshenko, S. P. 1990. *Mechanics of Materials*, 3rd ed. PWS, Boston. With permission.

FIGURE 6.3 Distribution of shear stresses in a beam of rectangular cross-section. (a) Side view of beam showing the shear force V and bending moment M acting at a cross-section. (b) Cross-section of beam showing shear stresses τ acting at distance y_1 from the neutral axis. (c) Diagram showing the parabolic distribution of shear stresses.

$$\tau = \frac{VQ}{Ib} \quad (6.3)$$

This equation, known as the **shear formula**, can be used to determine the shear stress τ at any point in the cross-section of a rectangular beam. Note that for a specific cross-section, the shear force V , moment of inertia I , and width b are constants. However, the first moment Q (and hence the shear stress τ) varies depending upon where the stress is to be found.

To evaluate the shear stress at distance y_1 below the neutral axis (Figure 6.3), we must determine the first moment Q of the area in the cross-section below the level $y = y_1$. We can obtain this first moment by multiplying the partial area A_1 by the distance \bar{y}_1 from its centroid to the neutral axis:

$$Q = A_1 \bar{y}_1 = b \left(\frac{h}{2} - y_1 \right) \left(y_1 + \frac{h/2 - y_1}{2} \right) = \frac{b}{2} \left(\frac{h^2}{4} - y_1^2 \right) \quad (6.4)$$

Of course, this same result can be obtained by integration using Equation (6.2):

$$Q = \int y \, dA = \int_{y_1}^{h/2} yb \, dy = \frac{b}{2} \left(\frac{h^2}{4} - y_1^2 \right) \quad (6.5)$$

Substituting this expression for Q into the shear formula [Equation (6.3)], we get

$$\tau = \frac{V}{2I} \left(\frac{h^2}{4} - y_1^2 \right) \quad (6.6)$$

This equation shows that the shear stresses in a rectangular beam vary quadratically with the distance y_1 from the neutral axis. Thus, when plotted over the height of the beam, τ varies in the manner shown by the parabolic diagram of Figure 6.3(c). Note that the shear stresses are zero when $y_1 = \pm h/2$.

The maximum value of the shear stress occurs at the neutral axis, where the first moment Q has its maximum value. Substituting $y_1 = 0$ into Equation (6.6), we get

$$\tau_{\max} = \frac{Vh^2}{8I} = \frac{3V}{2A} \quad (6.7)$$

FIGURE 6.4 Shear stresses in a beam of circular cross section.

in which $A = bh$ is the cross-sectional area. Thus, the maximum shear stress is 50% larger than the average shear stress (equal to V/A). Note that the preceding equations for the shear stresses can be used to calculate either vertical shear stresses acting on a cross-section or horizontal shear stresses acting between horizontal layers of the beam.

The shear formula is valid for rectangular beams of ordinary proportions; it is exact for very narrow beams (width b much less than height h) but less accurate as b increases relative to h . For instance, when $b = h$, the true maximum shear stress is about 13% larger than the value given by Equation (6.7).

A common error is to apply the shear formula to cross-sectional shapes, such as a triangle, for which it is not applicable. The reasons it does not apply to a triangle are:

1. We assumed the cross-section had sides parallel to the y axis (so that the shear stresses acted parallel to the y axis).
2. We assumed that the shear stresses were uniform across the width of the cross-section.

These assumptions hold only in particular cases, including beams of narrow rectangular cross-section.

6.2 Shear Stresses in Circular Beams

When a beam has a circular cross-section (Figure 6.4), we can no longer assume that all of the shear stresses act parallel to the y axis. For instance, we can easily demonstrate that at a point on the boundary of the cross-section, such as point m , the shear stress τ acts tangent to the boundary. This conclusion follows from the fact that the outer surface of the beam is free of stress, and therefore the shear stress acting on the cross-section can have no component in the radial direction (because shear stresses acting on perpendicular planes must be equal in magnitude).

Although there is no simple way to find the shear stresses throughout the entire cross-section, we can readily determine the stresses at the neutral axis (where the stresses are the largest) by making some reasonable assumptions about the stress distribution. We assume that the stresses act parallel to the y axis and have constant intensity across the width of the beam (from point p to point q in Figure 6.4). Inasmuch as these assumptions are the same as those used in deriving the shear formula [Equation (6.3)], we can use that formula to calculate the shear stresses at the neutral axis. For a cross section of radius r , we obtain

$$I = \frac{\pi r^4}{4} \quad b = 2r$$

$$Q = A_1 \bar{y}_1 = \left(\frac{\pi r^2}{2} \right) \left(\frac{4r}{3\pi} \right) = \frac{2r^3}{3} \quad (6.8)$$

in which Q is the first moment of a semicircle. Substituting these expressions for I , b , and Q in the shear formula, we obtain

FIGURE 6.5 Shear stresses in a beam of hollow circular cross-section.

$$\tau_{\max} = \frac{VQ}{Ib} = \frac{V(2r^3/3)}{(\pi r^4/4)(2r)} = \frac{4V}{3\pi r^2} = \frac{4V}{3A} \quad (6.9)$$

in which A is the area of the cross-section. This equation shows that the maximum shear stress in a circular beam is equal to $4/3$ times the average shear stress V/A .

Although the preceding theory for the maximum shear stress in a circular beam is approximate, it gives results that differ by only a few percent from those obtained by more exact theories.

If a beam has a *hollow circular cross-section* (Figure 6.5), we may again assume with good accuracy that the shear stresses along the neutral axis are parallel to the y axis and uniformly distributed. Then, as before, we may use the shear formula to find the maximum shear stress. The properties of the hollow section are

$$I = \frac{\pi}{4}(r_2^4 - r_1^4) \quad b = 2(r_2 - r_1) \quad Q = \frac{2}{3}(r_2^3 - r_1^3) \quad (6.10)$$

and the maximum stress is

$$\tau_{\max} = \frac{VQ}{Ib} = \frac{4V}{3A} \left(\frac{r_2^2 + r_2 r_1 + r_1^2}{r_2^2 + r_1^2} \right) \quad (6.11)$$

in which $A = \pi(r_2^2 - r_1^2)$ is the area of the cross-section. Note that if $r_1 = 0$, this equation reduces to Equation (6.9) for a solid circular beam.

6.3 Shear Stresses in the Webs of Beams with Flanges

When a beam of wide-flange shape [Figure 6.6(a)] is subjected to a vertical shear force, the distribution of shear stresses is more complicated than in the case of a rectangular beam. For instance, in the flanges of the beam, shear stresses act in both the vertical and horizontal directions (the y and z directions). Fortunately, the largest shear stresses occur in the web, and we can determine those stresses using the same techniques we used for rectangular beams.

Consider the shear stresses at level ef in the web of the beam [Figure 6.6(a)]. We assume that the shear stresses act parallel to the y axis and are uniformly distributed across the thickness of the web. Then the shear formula will still apply. However, the width b is now the thickness t of the web, and the area used in calculating the first moment Q is the area between ef and the bottom edge of the cross-section [that is, the shaded area of Figure 6.6(a)]. This area consists of two rectangles — the area of the flange (that is, the area below the line $abcd$) and the area $efcb$ (note that we disregard the effects of the small fillets

FIGURE 6.6 Shear stresses in the web of a wide-flange beam. (a) Cross-section of beam. (b) Graph showing distribution of vertical shear stresses in the web.

at the juncture of the web and flange). After evaluating the first moments of these areas and substituting into the shear formula, we get the following formula for the shear stress in the web of the beam at distance y_1 from the neutral axis:

$$\tau = \frac{VQ}{It} = \frac{V}{8It} [b(h^2 - h_1^2) + t(h_1^2 - 4y_1^2)] \quad (6.12)$$

in which I is the moment of inertia of the entire cross section, t is the thickness of the web, b is the flange width, h is the height, and h_1 is the distance between the insides of the flanges. The expression for the moment of inertia is

$$I = \frac{bh^3}{12} - \frac{(b-t)h_1^3}{12} = \frac{1}{12}(bh^3 - bh_1^3 + th_1^3) \quad (6.13)$$

Equation (6.12) is plotted in Figure 6.6(b), and we see that τ varies quadratically throughout the height of the web (from $y_1 = 0$ to $y_1 = \pm h_1/2$).

The maximum shear stress in the beam occurs in the web at the neutral axis ($y_1 = 0$), and the minimum shear stress in the web occurs where the web meets the flanges ($y_1 = \pm h_1/2$). Thus, we find

$$\tau_{\max} = \frac{V}{8It} (bh^2 - bh_1^2 + th_1^2) \quad \tau_{\min} = \frac{Vb}{8It} (h^2 - h_1^2) \quad (6.14)$$

For wide-flange beams having typical cross-sectional dimensions, the maximum stress is 10 to 60% greater than the minimum stress. Also, the shear stresses in the web typically account for 90 to 98% of the total shear force; the remainder is carried by shear in the flanges.

When designing wide-flange beams, it is common practice to calculate an approximation of the maximum shear stress by dividing the total shear force by the area of the web. The result is an average shear stress in the web:

$$\tau_{\text{ave}} = \left(\frac{V}{th_1} \right) \quad (6.15)$$

For typical beams, the average stress is within 10% (plus or minus) of the actual maximum shear stress.

FIGURE 6.7 Example.

The elementary theory presented in the preceding paragraphs is quite satisfactory for determining shear stresses in the web. However, when investigating shear stresses in the flanges, we can no longer assume that the shear stresses are constant across the width of the section, that is, across the width b of the flanges [Figure 6.6(a)]. For instance, at the junction of the web and lower flange ($y_1 = h_1/2$), the width of the section changes abruptly from t to b . The shear stress at the free surfaces ab and cd [Figure 6.6(a)] must be zero, whereas across the web at bc the stress is τ_{\min} . These observations indicate that at the junction of the web and either flange the distribution of shear stresses is more complex and cannot be investigated by an elementary analysis. The stress analysis is further complicated by the use of fillets at the reentrant corners, such as corners b and c . Without fillets, the stresses would become dangerously large. Thus, we conclude that the shear formula cannot be used to determine the vertical shear stresses in the flanges. (Further discussion of shear stresses in thin-walled beams can be found in the references.)

The method used above to find the shear stresses in the webs of wide-flange beams can also be used for certain other sections having thin webs, such as T-beams.

Example

A beam having a T-shaped cross section (Figure 6.7) is subjected to a vertical shear force $V = 10,000$ lb. The cross-sectional dimensions are $b = 4$ in., $t = 1$ in., $h = 8$ in., and $h_1 = 7$ in. Determine the shear stress τ_1 at the top of the web (level mn) and the maximum shear stress τ_{\max} . (Disregard the areas of the fillets.)

Solution

The neutral axis is located by calculating the distance c from the top of the beam to the centroid of the cross-section. The result is

$$c = 3.045 \text{ in.}$$

The moment of inertia I of the cross-sectional area about the neutral axis (calculated with the aid of the parallel-axis theorem) is

$$I = 69.66 \text{ in.}^4$$

To find the shear stress at the top of the web we need the first moment Q_1 of the area above level mn . Thus, Q_1 is equal to the area of the flange times the distance from the neutral axis to the centroid of the flange:

$$Q_1 = A_1 \bar{y}_1 = (4 \text{ in.}) (1 \text{ in.}) (c - 0.5 \text{ in.}) = 10.18 \text{ in.}^3$$

Substituting into the shear formula, we find

$$\tau_1 = \frac{VQ_1}{It} = \frac{(10\,000 \text{ lb}) (10.18 \text{ in.}^3)}{(69.66 \text{ in.}^4) (1 \text{ in.})} = 1460 \text{ psi}$$

Like all shear stresses in beams, this stress exists both as a vertical shear stress and as a horizontal shear stress. The vertical stress acts on the cross section at level mn and the horizontal stress acts on the horizontal plane between the flange and the web.

The maximum shear stress occurs in the web at the neutral axis. The first moment Q_2 of the area below the neutral axis is

$$Q_2 = A_2 \bar{y}_2 = (1 \text{ in.}) (8 \text{ in.} - c) \left(\frac{8 \text{ in.} - c}{2} \right) = 12.28 \text{ in.}^3$$

Substituting into the shear formula, we obtain

$$\tau_{\max} = \frac{VQ_2}{It} = \frac{(10\,000 \text{ lb}) (12.28 \text{ in.}^3)}{(69.66 \text{ in.}^4) (1 \text{ in.})} = 1760 \text{ psi}$$

which is the maximum shear stress in the T-beam.

Defining Terms

Shear formula — The formula $\tau = VQ/Ib$ giving the shear stresses in a rectangular beam of linearly elastic material [Equation (6.3)].

(See also Defining Terms for Chapter 5.)

7

Shear and Moment Diagrams

George R. Buchanan

Tennessee Technological University

[7.1 Sign Convention](#)

[7.2 Shear and Moment Diagrams](#)

[7.3 Shear and Moment Equations](#)

Computations for shear force and bending moment are absolutely necessary for the successful application of the theory and concepts presented in the previous chapters. The discussion presented here is an extension of [Chapter 4](#), and the reader should already be familiar with computations for reactions. This chapter will concentrate on **statically determinate** beams. Statically indeterminate beams and frames constitute an advanced topic, and the reader is referred to the end of the chapter for further information in this area. Even though the problems that illustrate shear and moment concepts appear as structural beams, the reader should be aware that the same concepts apply to structural machine parts. A distinction should not be drawn between civil engineering and mechanical engineering problems because the methods of analysis are the same.

7.1 Sign Convention

The sign convention for moment in a beam is based on the behavior of the loaded beam. The sign convention for shear in a beam is dictated by the convenience of constructing a shear diagram using a load diagram. The sign convention is illustrated in [Figure 7.1](#). The x axis corresponds to the longitudinal axis of the beam and must be directed from left to right. This convention dictates that shear and moment diagrams should be drawn from left to right. The direction of the positive y axis will be assumed upward, and loads that act downward on the beam will be negative. Note that it is not mandatory in shear and moment computations for positive y to be directed upward or even defined since the sign convention is independent of the vertical axis. However, for the more advanced topic of **beam deflections** positive y must be defined [Buchanan, 1988]. Positive bending moment causes compression at the top of the beam and negative bending moment causes compression at the bottom of the beam. Positive shear forces act downward on the positive face of the **free body** as shown in [Figure 7.1](#).

7.2 Shear and Moment Diagrams

Two elementary differential equations govern the construction of shear and moment diagrams and can be derived using a free-body diagram similar to [Figure 7.1](#), with w corresponding to a continuous load acting along the length of the beam.

FIGURE 7.1 Beam element showing positive shear force V and positive bending moment M .

$$dV = w dx \quad \text{or} \quad \int_{V_1}^{V_2} dV = \int_{x_1}^{x_2} w dx \quad (7.1)$$

$$dM = V dx \quad \text{or} \quad \int_{M_1}^{M_2} dM = \int_{x_1}^{x_2} V dx \quad (7.2)$$

The differential equations show that the change in shear V between any two points x_1 and x_2 on a beam is equal to the area of the load diagram between those same two points and, similarly, that the change in bending moment M is equal to the area of the shear diagram. It follows that the slope of a tangent drawn at any point on the moment diagram is given by dM/dx and corresponds to the magnitude of V at that point. When the tangent has zero slope, $dM/dx = 0$, that corresponds to a **maximum or minimum moment** and can be located by examining the shear diagram for a point (x location) where $V = 0$. Locating the largest positive or negative bending moment is important for properly designing beam structures when using the equations of the previous chapters.

Shear and moment diagrams (as opposed to shear and moment equations) offer the most efficient method for analyzing beam structures for shear and moment when the beam loading can be represented as **concentrated loads** or **uniform continuous loads**. An elementary example will serve to illustrate the concept. Consider the **simply supported beam** of Figure 7.2. There is a single concentrated load with reactions as shown. The shear is obtained by directly plotting the load; the sign convention of Figure 7.1 specifically allows for this. The reaction on the left is plotted upward as the change in the shear at a point, $x = 0$. The area of the load diagram between $x = 0$ and $x = a$ is zero since the load is zero; it follows that the change in shear is zero and the shear diagram is a straight horizontal line extending from the left end of the beam to the concentrated load P . The load changes abruptly by an amount P downward and a corresponding change is noted on the shear diagram. Positive shear is above the axis of the shear diagram. There is no change in load between $x = a$ and $x = L$ and the shear remains constant. The reaction at the right end of the beam is upward and the shear is plotted upward to return to zero. The beam is simply supported, indicating that the moment must be zero at the supports. The change in moment between the left support and the point where the load is applied, $x = a$, is equal to the area of the shear diagram or a positive Pab/L . The variation in moment appears as a straight line (a line with constant slope) connecting $M = 0$ at $x = 0$ with $M = Pab/L$ at $x = a$. The area of the remaining portion of the shear diagram is $-Pab/L$ and, when plotted on the moment diagram, returns the moment to zero and satisfies the simply supported boundary condition.

Equation (7.1) and Equation (7.2) indicate that the load function is integrated to give the shear function, and similarly the shear function is integrated to give the moment function. The diagrams are a graphical illustration of the integration. An important point is that the order (power) of each function increases by one as the analyst moves from load to shear to moment. In Figure 7.2, note that when the load function is zero (1) the corresponding shear function is a constant and (2) the corresponding moment function is linear in x and is plus or minus corresponding to the sign of the area of the shear diagram.

Consider, as a second example, the beam of Figure 7.3, where a series of uniform loads and concentrated loads is applied to a beam with an overhang. The reactions are computed and shown in the figure. The shear diagram is plotted starting at the left end of the beam. Shear and moment diagrams are always

FIGURE 7.2 Shear and moment diagrams for a simple beam with a concentrated load.

constructed from left to right because Equation (7.1) and Equation (7.2) were derived in a coordinate system that is positive from left to right. The area of the load between $x = 0$ and $x = 1$ m is -4 kN; this value is the change in shear, which is plotted as a sloping line. The corresponding change in bending moment equals the area of the shear diagram, $(-4 \text{ kN})(1 \text{ m})/2 = 2 \text{ kN} \cdot \text{m}$. A curve with continually changing negative slope between $x = 0$ and $x = 1$ m is shown in Figure 7.3. The point of zero shear occurs in the beam section, $2 \text{ m} \leq x \leq 4 \text{ m}$, and is located using similar triangles as shown in the space between the shear and moment diagrams. For practice the reader can verify the construction of the shear and moment diagrams of Figure 7.3. A textbook on mechanics of materials or structural analysis should have a complete discussion of the topic. Again, refer to “Further Information.”

Concentrated loads and uniform loads lead to shear diagrams with areas that will always be rectangles or triangles; the change in moment is easily computed. The uniformly varying load shown in Figure 7.4(e) sometimes occurs in practice; locating the point of maximum moment (point of zero shear) for some boundary conditions is not so elementary when using geometrical relationships. In such cases the use of shear and moment equations becomes a valuable analysis tool.

7.3 Shear and Moment Equations

Shear and moment equations are equations that represent the functions shown in Figure 7.2 and Figure 7.3. As with any mathematical function, they must be referenced to a coordinate origin, usually the left end of the beam. Shear and moment equations are piecewise continuous functions. Note that two separate equations are required to describe the shear diagram of Figure 7.2 and, similarly, four equations are required to describe the shear diagram of Figure 7.3. The same is true for the moment diagram.

The following procedure can be used to write shear and moment equations for almost any beam loading:

1. Choose a coordinate origin for the equation, usually, but not limited to, the left end of the beam.
2. Pass a free-body cut through the beam section where the shear and moment equations are to be written.

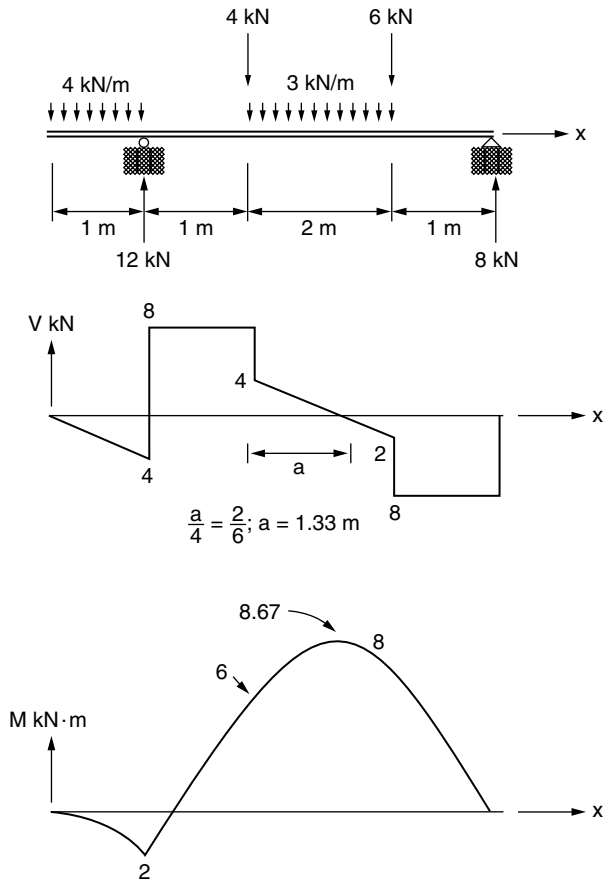

FIGURE 7.3 Shear and moment diagrams for a beam with an overhang. The concentrated loads and uniform loads illustrate the concept of maximum moment and corresponding zero shear.

3. Choose the free body that contains the coordinate origin.
4. Assume positive unknown shear and moment at the free-body cut using the sign convention defined by Figure 7.1.
5. View the free body as a **free-fixed beam** with the fixed end being at the free-body cut and the beam extending toward the coordinate origin.
6. Statically solve for the unknown shear and moment as if they were the reactions at the fixed end of any beam, that is, $\sum F = 0$ and $\sum M = 0$.
7. Always sum moments at the free-body cut such that the unknown shear passes through that point. An example should illustrate the concept.

A complete description of the beam of Figure 7.3 would require four shear and moment equations. Consider a free body of the first section — the uniformly loaded overhang. The free body is shown in Figure 7.5(a). Compare Figure 7.4(b) with Figure 7.5(a); L is merely replaced with x , the length of the free-body section. The seven steps outlined above have been followed to give

$$V_x = -wx = -4x \text{ kN}, \quad M_x = -wx^2 / 2 = -4x^2 / 2 \text{ kN} \cdot \text{m}, \quad 0 \leq x \leq 1 \text{ m} \quad (7.3)$$

The second segment ($1 \text{ m} \leq x \leq 2 \text{ m}$) is shown in Figure 7.5(b) and can be compared with Figure 7.4(c) and Figure 7.4(a): merely replace L with an x , a with 1 m, P with 12 kN, and w with 4 kN.

FIGURE 7.4 Shear and moment reactions for free-fixed beams.

FIGURE 7.5 Free-body diagrams for the beam shown in Figure 7.3.

$$V_x = -wa + P = -(4 \text{ kN/m})(1 \text{ m}) + 12 \text{ kN}, \quad (7.4)$$

$$\begin{aligned} M_x &= -wa(x-a/2) + P(x-a) \\ &= -(4)(1)(x-1/2) \text{ kN} \cdot \text{m} + 12(x-1) \text{ kN} \cdot \text{m} \end{aligned} \quad (7.5)$$

The general idea is that any shear or moment equation can be broken down into a series of individual problems that always correspond to computing the reactions at the fixed end of a free-fixed beam. Continuing with the shear and moment equations for the beam of Figure 7.3, the third section ($2 \text{ m} \leq x \leq 4 \text{ m}$) is shown in Figure 7.5(c) and should be compared with Figure 7.4(a), Figure 7.4(c), and Figure 7.4(d). Each equation has four terms since there are four separate loadings on the free body.

$$V_x = -(4 \text{ kN/m})(1 \text{ m}) + 12 \text{ kN} - 4 \text{ kN} - (3 \text{ kN/m})(x - 2 \text{ m}), \quad (7.6)$$

$$M_x = -(4 \text{ kN/m})(1 \text{ m})(x - 1 \text{ m}/2) + (12 \text{ kN})(x - 1 \text{ m}) - (4 \text{ kN})(x - 2 \text{ m}) - (3 \text{ kN/m})(x - 2 \text{ m})^2 / 2 \quad (7.7)$$

The last beam section ($4 \text{ m} \leq x \leq 5 \text{ m}$) is shown in Figure 7.5(d). There are five separate loadings on the beam. The shear and moment equations are written again by merely summing forces and moments on the free-body section.

$$V_x = -(4 \text{ kN/m})(1 \text{ m}) + 12 \text{ kN} - 4 \text{ kN} - (3 \text{ kN/m})(2 \text{ m}) - 6 \text{ kN}, \quad (7.8)$$

$$M_x = -(4 \text{ kN/m})(1 \text{ m})(x - 1 \text{ m}/2) + (12 \text{ kN})(x - 1 \text{ m}) - (4 \text{ kN})(x - 2 \text{ m}) - (3 \text{ kN/m})(2 \text{ m})(x - 3 \text{ m}) - (6 \text{ kN})(x - 4 \text{ m}) \quad (7.9)$$

The point of maximum moment corresponds to the point of zero shear in the third beam section. The shear equation, Equation (7.6), becomes $V_x = 10 - 3x$. Setting V_x to zero and solving for x gives $x = 3.33 \text{ m}$. Substituting into the corresponding moment equation, Equation (7.7), gives the maximum moment as $8.67 \text{ kN} \cdot \text{m}$.

Defining Terms

Beam deflections — A theory that is primarily based upon the moment behavior for a beam and leads to a second-order differential equation that can be solved to give a mathematical equation describing the deflection of the beam.

Concentrated load — A single load, with units of force, that can be assumed to act at a point on a beam.

Free body — A section that is removed from a primary structural system and is assumed to be in equilibrium mathematically.

Free-fixed beam — A beam that is free to rotate and deflect at one end but is completely clamped or rigid at the other end (also known as a *cantilever beam*).

Maximum or minimum moment — The bending moment that usually governs the design and analysis of beam structures.

Simply supported beam — A beam that is supported using a pin (hinge) at one end and a surface at the other end, with freedom to move along the surface

Statically determinate beam — A beam that can be analyzed for external reactions using only the equations of engineering mechanics and statics.

Uniform continuous load — A distributed beam loading of constant magnitude, with units of force per length, that acts continuously along a beam segment.

8.1 Fundamentals

[Buckling of Long Straight Columns • Effective Lengths • Compression Blocks and Intermediate Lengths](#)

8.2 Examples

8.3 Other Forms of Instability

A column is an initially straight load-carrying member that is subjected to a compressive axial load. The failure of a column in compression is different from one loaded in tension. Under compression, a column can deform laterally or buckle, and this deflection can become excessive. The buckling of columns is a major cause of failure. To illustrate the fundamental aspects of the buckling of long, straight, prismatic bars, consider a thin meter stick. If a tensile axial load is applied to the meter stick, the stable equilibrium position is that of a straight line. If the stick is given a momentary side load to cause a lateral deflection, upon its release the stick immediately returns to the straight line configuration. If a compressive axial load is applied, a different result may occur. At small axial loads, the meter stick will again return to a straight line configuration after being displaced laterally. At larger loads the meter stick will remain in the displaced position. With an attempt to increase the axial load acting on the buckled column, the lateral deformations become excessive and failure occurs.

In theory, a column that is long and perfectly straight is in stable equilibrium for small loads up to a specific **critical buckling load**. At this critical buckling load, the beam will remain straight unless it is perturbed and displays large lateral deformations. This is a bifurcation point since the column can be in equilibrium with two different shapes — laterally displaced or perfectly straight. The load in this neutral equilibrium state is the critical buckling load and, for long slender columns, is referred to as the **Euler buckling load**. At loads higher than the critical load the beam is in unstable equilibrium.

8.1 Fundamentals

Buckling of Long Straight Columns

In 1757, Leonhard Euler published the solution to the problem of long slender columns buckling under compressive loads. [Figure 8.1\(a\)](#) shows a column that is deflected in the lateral direction. The load P_{cr} is the smallest load that will just hold the column in the laterally deflected shape. The ends of the beam are free to rotate and are commonly referred to as being *pinned*, *hinged*, or simply *supported*. The following assumptions are used in determining P_{cr} :

1. The beam is initially straight with a constant cross-section along its length.
 2. The material is linearly elastic, isotropic, and homogeneous.
 3. The load is applied axially through the centroidal axis.
-

FIGURE 8.1 Effective column lengths.

4. The ends are pinned–pinned (pinned end condition at both ends).
5. No residual stresses exist in the column prior to loading.
6. No distortion or twisting of the cross-section occurs during loading.
7. The classical differential equation for the elastic curve can be used since the deflections are small.

Standard mechanics of materials textbooks [Riley and Zachary, 1989] and structural stability textbooks [Chajes, 1974] contain the derivation of the following formula:

$$\sqrt{\frac{P_{cr}}{EI}} L = n\pi, \quad n = 1, 2, 3, \dots \quad (8.1)$$

The smallest value for P_{cr} occurs when $n = 1$. Larger values of n give magnitudes of P_{cr} that will never be reached in practice.

$$P_{cr} = \frac{\pi^2 EI}{L^2} \quad (8.2)$$

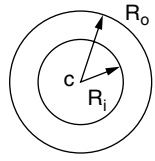

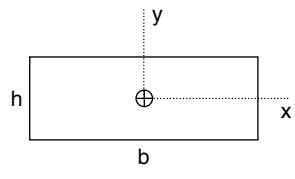

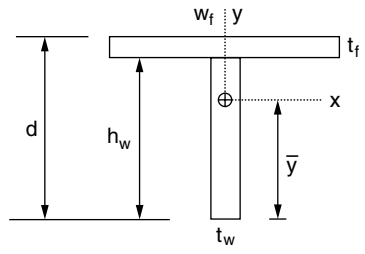

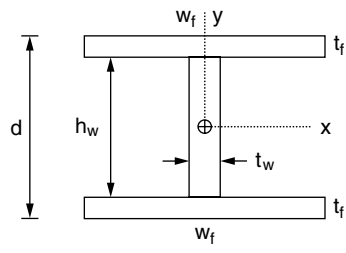

The Euler buckling load, P_{cr} , is calculated using the moment of inertia I of the column cross-section about which axis buckling (bending) occurs. The moment of inertia can also be written in terms of the radius of gyration about the same axis:

$$I = Ar^2 \quad (8.3)$$

Table 8.1 gives some formulas that are helpful in determining the radius of gyration and moment of inertia. Using Equation (8.2) and Equation (8.3), the Euler buckling stress, σ_{cr} , in terms of the **slenderness ratio** L/r , is

$$\sigma_{cr} = \frac{P_{cr}}{A} = \frac{\pi^2 E}{(L/r)^2} \quad (8.4)$$

Table 8.1 Properties of Selected Areas

| | |

Effective Lengths

The development given above is for a beam with simple supports at both ends. Other boundary conditions give equations similar to Equation (8.4) if the physical length of the beam, L , is replaced by the effective length L_{eff} .

$$\sigma_{cr} = \frac{\pi^2 E}{(L_{\text{eff}} / r)^2} \quad (8.5)$$

FIGURE 8.2 Effect of slenderness ratio on compressive failure stress.

Figure 8.1 gives the effective lengths for four classic end condition cases. The effective lengths are all measured between the inflection points of the elastic curves. The moments at the inflection points, $y'' = 0$, are zero. This observation can be used to estimate the effective length of other boundary condition cases. If one can estimate the elastic curve and visualize the location of the inflection points, a rough estimate of the effective length can be obtained.

Compression Blocks and Intermediate Lengths

A plot of Equation (8.5), using a generic steel with a Young’s modulus, E , of 200 GPa for illustration purposes, is shown as the solid curved line in Figure 8.2. For columns that are very short and stocky where L/r approaches zero, Equation (8.5) predicts that the column will support a very large load or normal stress. However, the mechanism of failure changes when the column becomes a short compression block. The compressive yield strength limits the compressive normal load that can be carried by the column. The horizontal dotted line in Figure 8.2 represents the yield stress limit that the column can sustain due to compressive block failure.

Critical buckling loads for large values of L/r are predicted with a high degree of confidence using Euler’s column equation. Failure loads for small values of L/r are reliably predicted from compressive yield strength criteria for the compression block. Columns that have effective lengths in the region near the yield strength magnitude on the Euler curve may behave either as an Euler column or a compressive block. Experiments using the particular material in question establish the shape of the curve between the compression block values and the Euler column values. Standard mechanics of materials textbooks [Riley and Zachary, 1989] give empirical formulas for this range. Using a horizontal line to cover the complete compression block and intermediate ranges usually predicts a higher critical buckling load than is found experimentally.

8.2 Examples

The following examples illustrate the procedure for determining the critical buckling load and stress for columns of several different cross-sections and effective lengths. Initially, the slenderness ratio for the two principal directions of possible buckling must be calculated to determine which direction controls. The direction with the largest slenderness ratio will give the smallest buckling load.

FIGURE 8.3 Cross-section used in Example 8.1.

Example 8.1: Checking Both Directions for Buckling

Consider the rectangular cross-section shown in Figure 8.3. Both ends of the column are pinned for the pinned–pinned condition in Figure 8.1(a). The physical length of the column is 1.5 m. Determine the Euler buckling load if the column is made of steel ($E = 200$ GPa). Using Table 8.1,

$$A = (20 \text{ mm})(35 \text{ mm}) = 700 \text{ mm}^2$$

$$r_y = \frac{h}{\sqrt{12}} = \frac{20 \text{ mm}}{\sqrt{12}} = 5.77 \text{ mm}$$

$$r_z = \frac{b}{\sqrt{12}} = \frac{32 \text{ mm}}{\sqrt{12}} = 10.10 \text{ mm}$$

The column tends to bend (buckle) about the y axis since r_y is smaller than r_z , producing the maximum L/r and the smallest P_{cr} and σ_{cr} for the 1.5-m length.

If the ends of the column are later restrained or fixed with respect to buckling about one of the axes — say the y axis — this changes the boundary conditions for buckling to the fixed–fixed condition [Figure 8.1(c)] for that direction. The effective length of the beam is then half the physical length or 750 mm for buckling about the y axis.

$$\frac{L_y}{r_y} = \frac{L/2}{r_y} = \frac{750 \text{ mm}}{5.77 \text{ mm}} = 130$$

$$\frac{L_z}{r_z} = \frac{L}{r_z} = \frac{1500 \text{ mm}}{10.10 \text{ mm}} = 149$$

The column will now buckle about the z axis before the load can become large enough to cause buckling about the y axis. Although the moment of inertia and radius of gyration about the y axis are smaller than about the z axis, the end conditions significantly influence the slenderness ratio and the axis about which buckling occurs.

$$P_{cr} = \frac{\pi^2 EA}{(L_z/r_z)^2} = \frac{\pi^2 200(10)^9 \text{ N/m}^2 \times 700(10)^{-6} \text{ m}^2}{(149)^2} = 62.2 \text{ kN}$$

Ans.

$$\sigma_{cr} = \frac{P_{cr}}{A} = \frac{62.2(10)^3 \text{ N}}{700(10)^{-6} \text{ m}^2} = 88.9 \text{ MPa}$$

Ans.

According to the Euler buckling formula, any load below 62.2 kN will not cause the column to buckle. No factor of safety is included in the calculations. In practice, however, such a factor should

FIGURE 8.4 Cross-sections used in Example 8.2a and Example 8.2b.

be used, since real columns are never ideally straight nor is column loading purely axial. Some inadvertent bending moment or load eccentricity is always possible. The σ_{cr} calculated above is the axial compressive stress in the beam just before the beam deforms laterally. This stress is relatively small when compared to a yield strength for structural steel of approximately 250 MPa. The compressive stress in long slender beams at or below the critical buckling stress σ_{cr} can be much less than the yield strength of the material. It is imperative that failure due to buckling be checked for compressive loads.

Example 8.2a: Built-Up Section

A single 20-mm solid steel rod is being used in compression. It has been determined that the rod will buckle. It has been decided that two rods will be welded together — Figure 8.4(a) — in order to increase the buckling load. Does this increase the Euler buckling load?

The parallel axis theorem can be used to determine the combined moments of inertia and radii of gyration. The term d in the following equation is the transfer distance from the centroid of the component area to the centroid of the entire cross-section.

$$I = \sum (I_c + Ad^2)$$

$$r_z = \sqrt{I_z / A} = \sqrt{\frac{2Ar_{cz}^2 + 2Ad_z^2}{2A}} = \sqrt{r_{cz}^2 + d_z^2} = \sqrt{(R/2)^2 + R^2} = \sqrt{5} \frac{R}{2}$$

$$r_y = \sqrt{I_y / A} = \sqrt{\frac{2Ar_{cy}^2 + 2Ad_y^2}{2A}} = \sqrt{r_{cy}^2 + d_y^2} = \sqrt{(R/2)^2 + 0} = \frac{R}{2}$$

The radius of gyration is not increased for bending about the y axis compared to the single rod value of $R/2$. The buckling load will remain the same even though the column has been stiffened in one direction.

Example 8.2b: Built-Up Section

Consider the composite aluminum ($E = 70$ GPa) section in Figure 8.4(b). Determine the maximum compressive stress that can be applied. The end conditions are as follows: about the y axis, the ends

are fixed–pinned [see Figure 8.1(d)], and about the z axis, the ends are fixed–fixed [see Figure 8.1(d)]. The column length is 2 m.

Compared to Example 8.2a, the radius of gyration about the y axis has the same basic definition, but the details are slightly different.

$$A_{\text{rect}} = (8 \text{ mm})(50 \text{ mm}) = 400 \text{ mm}^2$$

$$A_{\text{rod}} = \pi(12.5 \text{ mm})^2 = 490.9 \text{ mm}^2$$

$$\bar{y} = \frac{\sum A\bar{y}}{\sum A} = \frac{(400 \text{ mm}^2)50 \text{ mm} + (490.9 \text{ mm})12.5 \text{ mm}}{400 \text{ mm}^2 + 490.9 \text{ mm}^2} = 29.34 \text{ mm}$$

$$r_y = \sqrt{\frac{\sum I_y}{\sum A}} = \sqrt{\frac{\sum A(r_y^2 + d_y^2)}{\sum A}}$$

$$= \sqrt{\frac{400 \left(\left(\frac{50}{\sqrt{12}} \right)^2 + (50 - 29.34)^2 \right) + 490.9 \left(\left(\frac{12.5}{2} \right)^2 + (29.34 - 12.5)^2 \right)}{890.9}}$$

$$= 21.52 \text{ mm}$$

$$r_z = \sqrt{\frac{\sum I_z}{\sum A}} = \sqrt{\frac{\sum A(r_z^2 + d_z^2)}{\sum A}}$$

$$= \sqrt{\frac{400 \left(\left(\frac{8}{\sqrt{12}} \right)^2 + 490.9 \left(\frac{12.5}{2} \right)^2 \right)}{890.9}} = 4.891 \text{ mm}$$

The slenderness ratio for buckling about the z axis controls since r_z is less than one-fourth of the value about the y axis:

$$\frac{L_y}{r_y} = \frac{0.7L}{r_y} = \frac{0.7(2000 \text{ mm})}{21.52 \text{ mm}} = 65.1$$

For many materials a slenderness ratio of 65.1 places the beam in the intermediate length range.

$$\frac{L_z}{r_z} = \frac{L/2}{r_z} = \frac{1000 \text{ mm}}{4.891 \text{ mm}} = 204.5$$

The beam acts as an Euler beam for buckling about the z axis:

$$\sigma_{cr} = \frac{\pi^2 E}{(L_z / r_z)^2} = \frac{\pi^2 70(10^9) \text{ N/m}^2}{(204.5)^2} = 16.52 \text{ MPa} \quad \text{Ans.}$$

8.3 Other Forms of Instability

Beams can also fail due to local instabilities. There can be a crushing type of failure that is familiar in the crushing of thin-walled soda pop cans. The above formulas do not apply in such instances [Young, 1989]. Hollow rods subjected to torsion can buckle locally due to the compressive principal stress acting at a 45° angle to the longitudinal axis of the rod. Beams can fail in a combined bending and torsion fashion. An I-beam, with a pure moment applied, can have the flanges on the compression side buckle. When lateral loads are present in conjunction with an axial compressive load, the beam acts as a beam-column [Chen and Atsuta, 1976].

Defining Terms

Critical buckling load — The smallest compressive load at which a column will remain in the laterally displaced, buckled shape.

Critical buckling stress — The smallest compressive stress at which a column will remain in the laterally displaced, buckled shape.

E — Young's modulus of elasticity, which is the slope of the stress versus strain diagram in the initial linear region.

Euler buckling load — Same as the critical buckling load if the column is long and slender.

Euler buckling stress — Same as the critical buckling stress if the column is long and slender.

Pressure Vessels

- 9.1 Design Criteria
Design Loads • Materials • Allowable Stress
- 9.2 Design Formulas
- 9.3 Opening Reinforcement

The **pressure vessels** used in industry are leak-tight pressure containers, usually cylindrical or spherical in shape, with various head configurations. They are usually made from carbon steel or stainless steel and assembled by welding. The early operation of pressure vessels and boilers resulted in numerous explosions, causing loss of life and considerable property damage. In the early 1920s, the American Society of Mechanical Engineers formed a committee for the purpose of establishing minimum safety rules for boiler construction. In 1925, the committee issued a set of rules for the design and construction of unfired pressure vessels. Most states have laws mandating that these **Code** rules be met. Enforcement of these rules is accomplished via a third party employed by the state or an insurance company. These Codes are living documents in that they are constantly being revised and updated by committees comprised of individuals knowledgeable on the subject. Keeping current requires that revised Codes be published every 3 years with addenda issued every year. This chapter covers a generalized approach to pressure vessel design based on the ASME Boiler and Pressure Vessel Code, Section VIII, Division 1: Pressure Vessels.

9.1 Design Criteria

The Code design criteria consist of basic rules specifying the design method, design load, allowable stress, acceptable materials, and fabrication–inspection certification requirements for vessel **construction**. The design method, known as “design by rule,” uses design pressure, allowable stress, and a design formula compatible with the geometry of the part to calculate the minimum required thickness of the part. This procedure minimizes the amount of analysis required to ensure that the vessel will not rupture or undergo excessive distortion. In conjunction with specifying the vessel thickness, the Code includes many construction details that must be followed. Where vessels are subject to complex loadings such as thermal or localized loads, and where significant discontinuities exist, the Code requires a more rigorous analysis to be performed. This method is known as the “design by analysis” method. A more complete background of both methods may be found in Chattopadhyay, 2004.

The ASME Code is included as a standard by the American National Standards Institute (ANSI). The American Petroleum Institute (API) has also developed codes for low-pressure storage tanks, and these are also part of the ANSI standards. The ASME Boiler and Pressure Vessel Code has worldwide applications, but many other industrialized countries have also developed their own boiler and pressure vessel codes. Differences in these codes sometimes cause difficulty in international trade.

TABLE 9.1 Acceptable Pressure Vessel Materials

| Temperature Use Limit (°F) | Plate Material | Pipe Material | Forging Material |
|----------------------------|---|----------------------------|----------------------------|
| Down to -50 | SA-516 ^a All grades | SA 333 Gr. 1 | SA 350 GR. LF1, LF2 |
| +33 to +775 | SA-285 Gr. C SA-515 Gr. 55, 60, 65 SA-516 All grades | SA-53 SA-106 | SA-181 Gr. I, II |
| +776 to +1000 | SA-204 Gr. B, C SA-387 Gr. 11, 12 Class 1 | SA-335 Gr. P1, P11, P12 | SA-182 Gr. F1, F11, F12 |

^a Impact testing required.

Note: SA is a classification of steel used in the ASME Boiler and Pressure Vessel Code.

Design Loads

The forces that influence pressure vessel design are internal/external pressure; dead loads due to the weight of the vessel and contents; external loads from piping and attachments; wind, snow, and earthquakes; operating-type loads such as vibration and sloshing of the contents; and startup and shutdown loads. The Code considers design pressure, design temperature, and, to some extent, the influence of other loads that impact the circumferential (or hoop) and **longitudinal stresses** in shells. It is left to the designer to address the effects of the remaining loads on the vessel. Various national and local building codes must be consulted for handling wind, snow, and earthquake loadings.

Materials

The materials to be used in a pressure vessel must be selected from Code-approved material specifications. This requirement is generally not a problem, since a large database of acceptable materials is available. The factors that need to be considered in selecting a suitable material are:

- Cost
- Fabricability
- Service condition (wear, corrosion, operating temperature)
- Availability
- Strength requirements

Several typical pressure vessel materials for a noncorrosive environment and for service temperatures between -50 and 1000°F are shown in [Table 9.1](#).

Allowable Stress

The allowable stress used to determine the minimum vessel thickness is based on the tensile and yield strengths of the material at room and design temperatures. When the vessel operates at an elevated temperature (typically above 800°F), the creep properties of the material must be considered. These properties are adjusted by design factors that limit the **hoop membrane stress** to a value that precludes tensile rupture, excessive elastic and plastic deformations, and creep rupture. [Table 9.2](#) shows typical allowable stresses for several carbon steels commonly used for unfired pressure vessels.

TABLE 9.2 Typical Allowable Stresses for Use in Pressure Vessel Design

| Material Specification | Temperature Use Limit (°F) | Allowable Stress (psi) |
|------------------------|----------------------------|------------------------|
| SA-515 Gr. 60 | 700 | 14 400 |
| | 800 | 10 800 |
| | 900 | 6 500 |
| SA 516-Gr. 70 | 700 | 16 600 |
| | 800 | 14 500 |
| | 900 | 12 000 |
| SA-53 Gr. A | 700 | 11 7000 |
| | 800 | 9 300 |
| | 900 | 6 500 |
| SA-106 Gr. B | 700 | 14 400 |
| | 800 | 10 800 |
| | 900 | 6 500 |
| SA-181 Gr. 1 | 700 | 16 600 |
| | 800 | 12 000 |
| | 900 | 6 500 |

9.2 Design Formulas

The design formulas used in the “design by rule” method are based on the so-called maximum principal stress theory of failure involving the average hoop stress. The maximum principal stress theory of failure states that failure occurs when the greatest of the three principal stresses reaches the material yield strength. Ignoring the radial stress, the other two principal stresses can be determined by simplified engineering mechanics formulas.

The Code recognizes that the shell thickness may be such that the radial stresses may not be ignored; accordingly, adjustments have been made in the appropriate formulas. These formulas include a parameter, the **weld joint efficiency factor**, to address the nature of the examination performed at the welded joints during the fabrication of the vessel. [Table 9.3](#) shows various formulas used to calculate the wall thickness for a number of pressure vessel configurations.

9.3 Opening Reinforcement

Vessel components are weakened when material is removed to provide openings for nozzles or access. High **stress concentrations** exist at the opening edge and decrease radially outward from the opening, becoming negligibly small beyond distances twice the diameter of the opening. To avoid failure in the opening region, compensation or reinforcement is required. Some ways in which this can be accomplished are:

1. Increase the vessel wall thickness.
2. Increase the nozzle wall thickness.
3. Use a combination of additional shell and nozzle thicknesses.

The Code procedure is to relocate the removed material to an area within the effective boundary around the opening. [Figure 9.1](#) shows the steps necessary to reinforce an opening in a pressure vessel. Numerous assumptions have been made with the intent of simplifying the general approach.

The example shown in [Figure 9.2](#) uses the design approach indicated by the Code to perform a simple sizing calculation for a typical welded carbon steel vessel. [Figure 9.3](#) shows typical nozzle-shell and head-shell junctures that meet the Code requirements. Design specifications for the many associated vessel parts, such as bolted flanges, external attachments, and vessel supports, can be found in Chattopadhyay, 2004.

TABLE 9.3 Code Formulas for Calculation of Vessel Component Thickness

| | |
|---------------------------------------|---------------------------------|
| Cylindrical shell | $t = \frac{PR}{SE - 0.6P}$ |
| Hemispherical head or spherical shell | $t = \frac{PR}{2SE - 0.2P}$ |
| 2:1 ellipsoidal head | $t = \frac{PD}{2SE - 0.2P}$ |
| Flanged and dished head | $t = \frac{1.77PL}{2SE - 0.2P}$ |
| Flat head | $t = d\sqrt{CP/SE}$ |

where

t = Minimum required thickness (in.)
 P = Design pressure (psi)
 R = Inside radius (in.)
 S = Allowable stress (psi)
 D = Inside diameter (in.)
 L = Inside spherical crown radius (in.)
 E = Weld joint efficiency factor, determined by joint location and degree of examination
 C = Factor depending upon method of head-to-shell attachment

Defining Terms

Code — The complete rules for the construction of pressure vessels as identified in the ASME Boiler and Pressure Vessel Code, Section VIII, Division 1, Pressure Vessels.

Construction — The complete manufacturing process, including design, fabrication, inspection, examination, hydrostatic test, and certification. This applies to new construction only.

Hoop membrane stress — The average stress in a ring subjected to radial loads uniformly distributed along its circumference.

Longitudinal stress — The average stress acting on a cross-section of a vessel in the axial (lengthwise) direction.

Pressure vessel — A leak-tight pressure container, usually cylindrical or spherical in shape, subjected to internal pressure.

Stress concentration — Local high stress in the vicinity of a geometrical discontinuity such as a change in thickness or an opening in a shell.

Weld efficiency factor — A factor intended to reduce the allowable stress for welded connections, dependent on the degree of weld examination performed during the construction of the vessel.

Further Information

Each summer, usually in July, the Pressure Vessel and Piping Division of the American Society of Mechanical Engineers organizes an annual meeting devoted to pressure vessel technology. Over 500

x = Larger of d or $R_n + t_n + T_n$

y = Smaller of $2\frac{1}{2}T_s$ or $2\frac{1}{2}T_n$

d = Diameter of circular opening (in.)

D = Inside diameter of shell (in.)

t_s = Required thickness of shell (in.)

T_s = Actual thickness of shell (in.)

t_n = Required thickness of nozzle (in.)

T_n = Actual thickness of nozzle (in.)

R_n = Inside radius of nozzle = $d/2$ (in.)

A_r = Area of required reinforcement (in.²)

A_s = Area available in the shell (in.²)

A_n = Area available in the nozzle (in.²)

$A_r = (d)(t_s)$

A_s = Larger of: $d(T_s - t_s) - 2T_n(T_s - t_s)$ or

$2(T_s + t_n)(T_s - t_s) - 2t_n(T_s - t_s)$

A_n = Smaller of: $2[2\frac{1}{2}(T_s)(T_n - t_n)$ or

$2[2\frac{1}{2}(T_n)(T_n - t_n)]$

$A_r < (A_s + A_n)$: Acceptable configuration

FIGURE 9.1 Opening reinforcement requirements.

papers are presented, many of which are published as ASME special publications in book form. Archival papers are also published in the *Journal of Pressure Vessel Technology*.

Research programs for the ASME Boiler and Pressure Vessel Code are often conducted by the Pressure Vessel Research Council (PVRC). This research is normally published in Welding Research Council (WRC) bulletins. These bulletins provide excellent documentation of major research contributions in the field of pressure vessel technology. The Electric Power Research Institute (EPRI) also conducts extensive research for the electric power industry, and this work includes some research on pressure vessels.

DESIGN SPECIFICATION

Design pressure = 700 psi
 Design temperature = 700°F

Material:

Shell SA-516 Gr. 70

Head SA-181 Class 70

Nozzle SA-106 Gr. B

Weld efficiency factor = 1.0 = *E*
 (full radiographic examination)

Shell Thickness

$$t_s = \frac{PR}{SE - 0.6P}$$

$$= \frac{700(30)}{16\,600(1.0) - 0.6(700)}$$

$$= 1.30 \text{ in. Use } 1\frac{1}{2}'' = T_s$$

P = 700 psi

R = 30 in.

E = 1.0

S = 16 600 psi (SA-516 Gr. 70, Table 9.2)

Hemispherical Head Thickness

$$t_h = \frac{PR}{2SE - 0.2P}$$

$$= \frac{700(30)}{2(16\,600)(1.0) - 0.2(200)}$$

$$= 0.64 \text{ in. Use } 1'' = T_h$$

Nozzle Thickness

$$t_n = \frac{PR}{SE - 0.6P}$$

$$= \frac{700(4)}{16\,600(1.0) - 0.6(700)}$$

$$= 0.17 \text{ in. Use } 1\frac{3}{4}'' = T_n$$

P = 700 psi

R = 4 in.

E = 1.0

S = 16 600 psi (SA-106 Gr. B, Table 9.2)

Opening Reinforcement Calculation (see Fig. 9.1)*

$$A_{req'd} = (d)(t_s) = (8)(1.3) = 10.4 \text{ in.}^2$$

$$A_n = \text{Smaller of: } 2[2\frac{1}{2}(T_s)(T_n - t_n)] \text{ or}$$

$$2[2\frac{1}{2}(T_n)(T_n - t_n)]$$

$$T_s < T_n \text{ Use } T_s$$

$$2[2\frac{1}{2}(1\frac{1}{2})(1\frac{3}{4} - 0.17)] = 11.7 \text{ in.}^2$$

$$d = 8 \text{ in.}$$

$$t_s = 1.3 \text{ in.}$$

$$T_s = 1\frac{1}{2} \text{ in.}$$

$$T_n = 1\frac{3}{4} \text{ in.}$$

$$t_n = 0.17 \text{ in.}$$

*This example places all the required reinforcement in the nozzle wall since it is more economical than increasing the shell thickness.

$$A_n = 11.7 \text{ in.}^2 > A_{req'd} = 10.4 \text{ in.}^2 \text{ — OK}$$

10.1 Axially Loaded Bars

A bar is said to be axially loaded if the action lines of all the applied forces coincide with the axis of the bar. The **bar axis** is defined as the locus of the centroids of the cross-sectional areas along the length of the bar. This locus of centroids must form a straight line, and the action lines of the applied forces must coincide with it in order for the theory of this section to apply.

Axial Strain

The axial strain in an axially loaded bar is based on the geometric assumptions that plane cross-sections in the unloaded bar, such as sections mn and pq in Figure 10.1(a), remain plane in the loaded bar as shown in Figure 10.1(b), and that they displace only axially.

The axial strain of a **line element** such as rs in Figure 10.1(a) is defined as the limit of the ratio of its change in length to its original length as its original length approaches zero. Thus, the axial strain ϵ at an arbitrary cross-section x is

$$\epsilon(x) = \lim_{\Delta x \rightarrow 0} (\Delta x^* - \Delta x) / \Delta x = \lim_{\Delta x \rightarrow 0} [u(x + \Delta x) - u(x)] / \Delta x = du / dx \quad (10.1)$$

where $u(x)$ and $u(x + \Delta x)$ are axial displacements of the cross sections at x and $x + \Delta x$. Common units for axial strain are in./in. or mm/mm. Because axial strain is the ratio of two lengths, units for axial strain are frequently not recorded.

Axial Stress

The axial stress σ at cross-section x of an axially loaded bar is

$$\sigma(x) = N(x) / A(x) \quad (10.2)$$

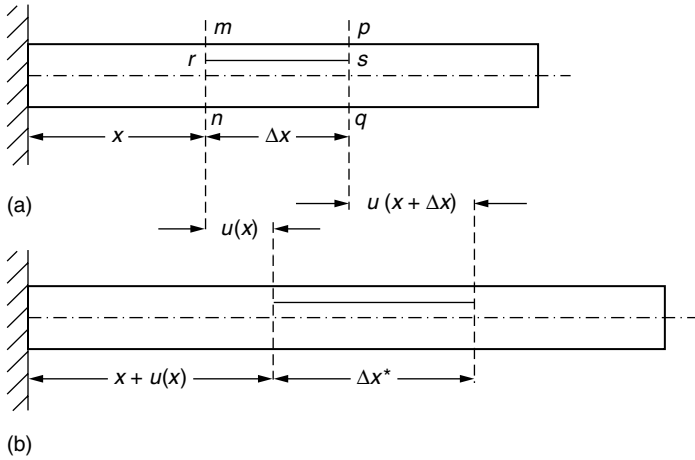

FIGURE 10.1 Axial displacements of an axially loaded bar.

where $N(x)$ is the internal force and $A(x)$ is the cross-sectional area, each at section x . Common units for axial stress are pounds per square inch (psi) or megapascals (MPa). Equation (10.2) is valid at cross-sections that satisfy the geometric assumptions stated previously. It ceases to be valid at abrupt changes in cross section and at points of load application. Cross-sections at such locations distort and therefore violate the plane cross-section assumption. Also, Equation (10.2) requires that the material at cross-section x be homogeneous; that is, the cross section cannot be made of two or more different materials.

Axial Stress-Strain Relation

The allowable stress for axially loaded bars used in most engineering structures falls within the proportional limit of the material from which they are made. Consequently, material behavior considered in this section is confined to the linearly elastic range and is given by

$$\sigma(x) = E(x) \epsilon(x) \tag{10.3}$$

where $E(x)$ is the modulus of elasticity for the material at section x . Common units for the modulus of elasticity are pounds per square inch (psi) or gigapascals (GPa).

Relative Displacement of Cross-Sections

The relative displacement $e_{B/A}$ of a cross-section at x_B with respect to a cross-section at x_A is obtained by combining Equation (10.1) through Equation (10.3) and integrating from section x_A to x_B . Using Figure 10.2,

FIGURE 10.2

FIGURE 10.3 Uniform bar.

$$e_{B/A} = u(x_B) - u(x_A) = \int_{x_A}^{x_B} N(x) / [A(x)E(x)] dx \quad (10.4)$$

where $e_{B/A}$ denotes the change in length between the cross-sections at x_A and x_B .

Equation (10.4) must be interpreted as the sum of several integrals for a bar for which the integrand exhibits discontinuities. Discontinuities occur for cross-sections where either N , A , E , or combinations thereof change abruptly and can usually be detected by inspection.

Uniform Bar

A bar for which the internal force $N(x)$, the cross-sectional area $A(x)$, and the modulus of elasticity $E(x)$ do not change over its length is referred to as a **uniform bar**. If P denotes equilibrating forces applied to the ends of the bar and L its length, as shown in Figure 10.3, then Equation (10.4) gives the change in length of the bar as

$$e = PL/AE \quad (10.5)$$

Nonuniform Bars

A **nonuniform bar** is one for which either A , E , N , or combinations thereof change abruptly along the length of the bar. Three important methods are available to analyze axially loaded bars for which the integrand in Equation (10.4) contains discontinuities. They are as follows.

Direct Integration

Equation (10.4) is integrated directly. The internal force $N(x)$ is obtained in terms of the applied forces via the axial equilibrium equation, $A(x)$ from geometric considerations, and $E(x)$ by observing the type of material at a given section.

Discrete Elements

The bar is divided into a finite number of segments, for each of which N/AE is constant. Each segment is a uniform bar for which its change in length is given by Equation (10.5). The change in length of the nonuniform bar is the sum of the changes in length of the various segments. Accordingly, if e_i denotes the change in length of the i th segment, then the change in length e of the nonuniform bar is

$$e = \sum e_i \quad (10.6)$$

Superposition

The superposition principle applied to axially loaded bars asserts that the change in length between two cross-sections caused by several applied forces acting simultaneously is equal to the algebraic sum of the changes in length between the same two cross-sections caused by each applied force acting separately. Thus, letting $e_{B/A}$ represent the change in length caused by several applied forces acting simultaneously, and $e'_{B/A}$, $e''_{B/A}$, ... represent the changes in length caused by each applied force acting separately,

$$e_{B/A} = e'_{B/A} + e''_{B/A} + \dots \quad (10.7)$$

Superposition of displacements requires that the axial forces be linearly related to the displacements they cause, and this implies that the stress at every cross-section cannot exceed the proportional limit stress of the material of the bar. This requirement must be satisfied for each separate loading as well as for the combined loading.

Statically Indeterminate Bars

The internal force $N(x)$ in statically determinate axially loaded bars is determined via axial equilibrium alone. Subsequently, axial stress, axial strain, and axial displacements can be determined via the foregoing equations.

The internal force $N(x)$ in statically indeterminate axially loaded bars cannot be determined via axial equilibrium alone. Thus, it is necessary to augment the axial equilibrium equation with an equation (geometric compatibility equation) that accounts for any geometric constraints imposed on the bar — that is, that takes into account how the supports affect the deformation of the bar.

Three basic mechanics concepts are required to analyze statically indeterminate axially loaded bars: axial equilibrium, geometric compatibility of axial deformations, and material behavior (stress–strain relation).

Example 10.1

Determine the stresses in the aluminum and steel segments of the composite bar of [Figure 10.4\(a\)](#) when $P = 7000$ lb. The cross-sectional areas of the steel and aluminum segments are 2 and 4 in.², respectively, and the moduli of elasticity are $30 \cdot 10^6$ and $10 \cdot 10^6$ psi, respectively.

Solution

The bar is statically indeterminate; therefore, the solution requires the use of the three mechanics concepts discussed in the previous paragraph.

Equilibrium. The axial equilibrium equation is obtained from the free-body diagram of [Figure 10.4\(b\)](#) as

$$-P_{ST} + P_{AL} - 7000 = 0 \tag{10.8}$$

FIGURE 10.4 Statically indeterminate composite step-bar.

Geometric compatibility. The compatibility equation is obtained by noting that the total elongation of the bar is zero. Accordingly,

$$e = e_{ST} + e_{AL} = 0 \quad (10.9)$$

Material behavior. The steel and aluminum segments are assumed to behave in a linearly elastic manner, so their elongations are given by

$$e_{ST} = P_{ST} L_{ST} / (A_{ST} E_{ST}) \text{ and } e_{AL} = P_{AL} L_{AL} / (A_{AL} E_{AL}) \quad (10.10)$$

Combining Equation (10.9) and Equation (10.10) yields

$$\begin{aligned} P_{ST} &= -(L_{AL} / L_{ST})(E_{ST} / E_{AL})(A_{ST} / A_{AL})P_{AL} \\ &= -(10/20)(30/10)(2/4)P_{AL} = -3/4P_{AL} \end{aligned} \quad (10.11)$$

Solving Equation (10.8) and Equation (10.11) simultaneously yields

$$P_{ST} = -3000 \text{ lb} \quad \text{and} \quad P_{AL} = 4000 \text{ lb} \quad (10.12)$$

from which the stresses in the steel and aluminum are found as follows:

$$\sigma_{ST} = -3000 / 2 = -1500 \text{ psi} = 1500 \text{ psi (compression)}$$

$$\sigma_{AL} = 4000 / 4 = 1000 \text{ psi (tension)}$$

Example 10.2

Assuming that $P = 0$ in [Figure 10.4\(a\)](#), determine the stress in the steel and aluminum segments of the bar due to a temperature increase of 10°F . The *thermal expansion coefficients* for steel and aluminum are $\alpha_{ST} = 6.5 \cdot 10^{-6}$ and $\alpha_{AL} = 13 \cdot 10^{-6}$ inches per inch per degree Fahrenheit (in./in./ $^\circ\text{F}$), respectively.

Solution

Because free thermal expansion of the bar is prevented by the supports, internal stresses are induced in the two segments.

Equilibrium. The axial equilibrium equation is obtained from the free-body diagram of [Figure 10.4\(b\)](#). Thus,

$$-P_{ST} + P_{AL} = 0 \quad (10.13)$$

Compatibility. The compatibility equation is obtained by noting that if the bar could expand freely, its total elongation Δ would be

$$\Delta = \Delta_{ST} + \Delta_{AL} \quad (10.14)$$

where Δ_{ST} and Δ_{AL} denote the free thermal expansions of the separate segments. Because the net change in length of the bar is zero, internal strains are induced in the steel and aluminum such that the sum of the changes in lengths of the steel and aluminum segments must be equal to Δ . Therefore, the compatibility equation becomes

$$e_{ST} + e_{AL} - \Delta = 0 \quad (10.15)$$

Material behavior. Assuming linear elastic behavior for both materials

$$e_{ST} = P_{ST} L_{ST} / (A_{ST} E_{ST}) \quad \text{and} \quad e_{AL} = P_{AL} L_{AL} / (A_{AL} E_{AL}) \quad (10.16)$$

Also, because

$$\Delta_{ST} = \alpha_{ST} L_{ST} \Delta T \quad \text{and} \quad \Delta_{AL} = \alpha_{AL} L_{AL} \Delta T \quad (10.17)$$

it follows that

$$\Delta = (6.5 \cdot 10^{-6})(20)(10) + (13 \cdot 10^{-6})(10)(10) = 0.0026 \text{ in.} \quad (10.18)$$

Equation (10.13), Equation (10.15), Equation (10.16), and Equation (10.18) yield

$$P_{ST} \{1 + (E_{ST} / E_{AL})(A_{ST} / A_{AL})(L_{AL} / L_{ST})\} = (E_{ST} A_{ST} / L_{ST}) \Delta$$

or

$$P_{ST} \{1 + (30/10)(2/4)(10/20)\} = \{(30 \cdot 10^6)(2)\} / 20 \{0.0026\}$$

Thus

$$P_{ST} = P_{AL} = 4457 \text{ lb} \quad (10.19)$$

The corresponding stresses in the steel and aluminum are compression and equal to

$$\sigma_{ST} = 4457 / 2 = 2228 \text{ psi} \quad \text{and} \quad \sigma_{AL} = 4457 / 4 = 1114 \text{ psi}$$

10.2 Torsion

Torsionally loaded bars occur frequently in industrial applications such as shafts connecting motor–pump and motor–generator sets; propeller shafts in airplanes, helicopters, and ships; and torsion bars in automobile suspension systems. Many tools or tool components, such as screwdrivers and drill and router bits, possess a dominant torsional component. These tools also rely on an axial force component for their effectiveness.

Power Transmission

The specifications for a motor customarily list the power it transmits in horsepower (hp) and its angular speed in either revolutions per minute (rpm) or in cycles per second (Hz). To design or analyze a shaft, the *torque* that it is to transmit is required. Therefore, a relationship between horsepower, angular speed, and torque is required. In U.S. customary units and in the International System of Units (SI units) these relationships are

$$\text{hp} = \begin{cases} 2\pi n T / [550(12)60] = n T / 63\,000 \text{ (U.S. customary units)} \\ 2\pi f T / 745.7 = f T / 119 \text{ (SI units)} \end{cases} \quad (10.20)$$

FIGURE 10.5

where f and n denote the angular speed in cycles per second and revolutions per minute, respectively, and T denotes the torque transmitted in Newton-meters ($\text{N} \cdot \text{m}$) or inch-pounds ($\text{in.} \cdot \text{lb}$), depending on the system of units used.

Kinematics of Circular Shafts

The theory of circular shafts is based on the geometric assumption that a plane cross-section simply rotates about the axis of the shaft and can be visualized as being composed of a series of *thin rigid disks* that rotate about the axis of the shaft.

To obtain a formula that expresses the rotation of one cross-section relative to another infinitesimally close to it, consider a shaft of radius c and examine the angular deformations of an interior segment of radius r and length Δx . This portion of the bar is indicated in Figure 10.5(a). Before twisting, line element AB is parallel to the shaft axis, and line element AC lies along a cross-sectional circle of radius r . The angle between these elements is 90 degrees. Due to twisting, AC merely moves to a new location on the circumference, but AB becomes A^*B^* , which is no longer parallel to the shaft axis, as in indicated in Figure 10.5(b). The shearing deformation e_r at radius r is

$$e_r = r\Delta\phi = \gamma_r \Delta x \quad (10.21)$$

where γ_r denotes the shearing strain between line elements A^*B^* and A^*C^* , and $\Delta\phi$ represents the angular rotation of the cross-section at B relative to the cross-section at A . In the limit, as Δx becomes infinitesimal, Equation (10.21) becomes

$$\gamma_r = r d\phi / dx \quad (10.22)$$

Because a cross-section is considered rigid, Equation (10.22) indicates that the shearing strain varies linearly with distance from the center of the shaft. Consequently, because c denotes the outside radius of the shaft, the shearing strain at radius r is

$$\gamma_r = (r/c)\gamma_c \quad (10.23)$$

Equilibrium

The shearing stress τ_r that acts on a differential element of cross-sectional area da is shown in [Figure 10.6](#). A concentrated torque T that is equivalent to the torque produced by the distributed shearing stress τ_r is

$$T = \int_{\text{area}} (\tau_r da)r \quad (10.24)$$

Elastic Twisting of Circular Shafts

Explicit formulas for the angle of twist per unit length and for the shearing stress at any point r in a cross-section of a circular shaft made from a linearly elastic material are obtained from Equation (10.22) and Equation (10.24) and the stress–strain relation

$$\tau_r = G\gamma_r \quad (10.25)$$

in which G is the shearing modulus of elasticity. Common units for G are pounds per square inch (psi) or gigapascals (GPa). Accordingly,

$$T = \int_{\text{area}} (G\gamma_r/r)r^2 da = G d\phi/dx \int_{\text{area}} r^2 da$$

or

$$d\phi/dx = T/JG \quad (10.26)$$

in which J is the polar moment of inertia of the cross-sectional area of the bar. Common units for J are inches to the fourth power (in.⁴) or meters to the fourth power (m⁴), depending on the system of units used.

FIGURE 10.6

The shearing stress at radius r is obtained by combining Equation (10.22), Equation (10.25), and Equation (10.26). Thus,

$$\tau_r = Tr / J \quad (10.27)$$

Equation (10.26) and Equation (10.27) provide the means needed to analyze the strength and stiffness of linearly elastic shafts with circular cross-sections. These formulas remain valid for annular shafts for which the hollow and solid portions are concentric. Formulas for the polar moments of inertia J are

$$J = \begin{cases} \pi / 32 d^4 & \text{(solid cross-section)} \\ \pi / 32 (d_o^4 - d_i^4) & \text{(annular cross-section)} \end{cases} \quad (10.28)$$

where d_o and d_i denote external and internal diameters.

Uniform Shaft

A *uniform shaft* is one for which the cross-sectional area, the shearing modulus of elasticity, and the applied torque do not change along its length. Because J , G , and T are constants over the length L , Equation (10.26) integrates to give the angle of twist of one end relative to the other end as

$$\phi = TL / JG \quad (10.29)$$

The shearing stress on any cross-section at radial distance r is

$$\tau_r = Tr / J \quad (10.30)$$

Nonuniform Shaft

A *nonuniform shaft* is one for which either J , G , T , or a combination thereof changes abruptly along the length of the shaft. Three procedures are available to determine the angle of twist for circular shafts made from linearly elastic materials.

Direct Integration

Equation (10.26) is integrated directly. Because the integrand T/JG can possess discontinuities at cross-sections for which J , G , or T changes abruptly, the integration must be interpreted as a sum of several integrations. Discontinuities in J , G , and T can usually be detected by inspection. The polar moment of inertia J is discontinuous at abrupt changes in cross-sectional area, G is discontinuous at cross-sections where the material changes abruptly, and the internal torque T is discontinuous at points where concentrated torques are applied.

Discrete Elements

The shaft is divided into a finite number of segments for each of which T/JG is constant. Consequently, the shaft is perceived to be a series of connected uniform shafts for each of which Equation (10.29) applies. Thus, if ϕ_i denotes the angle of twist of the i th segment, then the angle of twist for the shaft is

$$\phi = \sum \phi_i \quad (10.31)$$

Superposition

The superposition principle applied to the twisting of circular shafts stipulates that the relative rotation of one cross section with respect to another cross section due to several torques applied simultaneously

FIGURE 10.7

is equal to the algebraic sum of the relative rotations of the same cross sections due to each torque applied separately. If $\phi'_{B/A}$, $\phi''_{B/A}$, ... denote relative angles of twist for each torque applied separately, then

$$\phi_{B/A} = \phi'_{B/A} + \phi''_{B/A} + \dots \quad (10.32)$$

Superposition of angles of twist requires that the torques be linearly related to the angles of twist that they produce, which in turn implies that the shearing stress must not exceed the proportional limit stress for the material involved. This requirement must be satisfied for each separate loading, as well as for the combined loading.

Statically Indeterminate Circular Shafts

A shaft is statically indeterminate if the internal torque at a cross-section cannot be determined from moment equilibrium about the axis of the shaft. In such cases an additional equation is obtained by requiring that angles of twist be compatible with the geometric constraints imposed on the shaft. As with axially loaded bars, three basic concepts of mechanics are involved in the solution of statically indeterminate shafts: equilibrium, geometric compatibility, and material behavior.

Example 10.3

The diameters of the aluminum and steel segments of the statically indeterminate step-shaft of Figure 10.7(a) are 50 and 25 mm, respectively. Knowing that $G_{AL} = 28$ GPa, $G_{ST} = 84$ GPa, and $T_0 = 200\pi$ N · m, determine the maximum shearing stresses in the aluminum and in the steel.

Solution

Equilibrium. From Figure 10.7(b), moment equilibrium about the axis of the shaft gives

$$T_A + T_B - T_0 = 0 \quad (10.33)$$

Compatibility. The supports at the ends of the shaft prevent the cross-sections at A and B from rotating; hence, the required compatibility equation is

$$\phi_{B/A} = 0 \quad (10.34)$$

and, with the aid of the superposition principle, it can be written as

$$\phi_{B/A} = \phi'_{B/A} + \phi''_{B/A} = 0 \quad (10.35)$$

Here $\phi'_{B/A}$ and $\phi''_{B/A}$, denote the relative angular rotations of the cross-section at B with respect to the cross-section at A due to the torques T_B and T_0 acting separately.

To convert Equation (10.35) into an algebraic equation involving the torques T_B and T_0 , the discrete element procedure is used. First calculate the polar moments of inertia for the two segments:

$$\begin{aligned} J_{AL} &= \pi/32(0.050)^4 = 0.613 \cdot 10^{-6} \text{ m}^4 \\ J_{ST} &= \pi/32(0.025)^4 = 0.038 \cdot 10^{-6} \text{ m}^4 \end{aligned} \quad (10.36)$$

Using Equation (10.29) for a uniform shaft, determine that

$$\begin{aligned} \phi'_{B/A} &= 0.3T_B / \{J_{AL} 28 \cdot 10^9\} + 0.3T_B / \{J_{ST} 84 \cdot 10^9\} = 111.47 \cdot 10^{-6} T_B \text{ m}^4 \\ \phi''_{B/A} &= 0.3T_0 / \{J_{AL} 28 \cdot 10^9\} = 11.65 \cdot 10^{-6} T_0 \text{ m}^4 \end{aligned} \quad (10.37)$$

Consequently,

$$\phi_{B/A} = \{111.47T_B - 11.65T_0\} \cdot 10^{-6} = 0 \quad (10.38)$$

Equation (10.38) gives T_B and Equation (10.33) gives T_A . Thus,

$$T_A = 179\pi \text{ N} \cdot \text{m} \quad \text{and} \quad T_B = 21\pi \text{ N} \cdot \text{m} \quad (10.39)$$

The maximum shearing stress in each material occurs at the most remote point on a cross-section. Thus,

$$\begin{aligned} (\tau_{AL})_{\max} &= T_{AL} c / J_{AL} = 179\pi(0.025) / 0.613 \cdot 10^{-6} = 22.9 \text{ MPa} \\ (\tau_{ST})_{\max} &= T_{ST} c / J_{ST} = 21\pi(0.0125) / 0.038 \cdot 10^{-6} = 21.7 \text{ MPa} \end{aligned} \quad (10.40)$$

Defining Terms

Bar axis — Straight line locus of centroids of cross-sections along the length of a bar.

Line element — Imaginary fiber of material along a specific direction.

Nonuniform bar — A bar for which the cross-sectional area or the material composition changes abruptly along its length, or external forces are applied intermediate to its ends.

Nonuniform shaft — A bar of circular cross-section for which the diameter or material composition changes abruptly along its length, or external twisting moments are applied intermediate to its ends.

Thin rigid disk — Imaginary circular cross-section of infinitesimal thickness that is assumed to undergo no deformations in its plane.

Torque — Twisting moment.

Uniform bar — A bar of uniform cross-sectional area that is made of one material and is subjected to axial forces only at its ends.

Uniform shaft — A bar of uniform, circular cross-sectional area that is made of one material and is subjected to twisting moments only at its ends.

Structural Reliability Technology

- 11.1 Introduction
- 11.2 Fundamental Concepts
 - The Energy Criterion • The Stress Intensity Approach • Time-Dependent Crack Growth and Damage Tolerance • Effect of Material Properties on Fracture
- 11.3 Concluding Remarks

11.1 Introduction

Since the advent of iron and steel structures during the Industrial Revolution, a significant number of brittle fractures have occurred at stresses well below the tensile strength of the material. One of the most famous of these failures was the rupture of a molasses tank in Boston in January 1919 [Shank, 1953]. Over 2 million gallons of molasses were spilled, resulting in 12 deaths, 40 injuries, massive property damage, and several drowned horses.

The traditional strength-of-materials approach cannot explain events such as the molasses tank failure. In the first edition of his elasticity text published in 1892, Love remarked that “the conditions of rupture are but vaguely understood.” Designers typically applied safety factors of 10 or more (based on the tensile strength) in an effort to avoid these seemingly random failures.

Several centuries earlier, Leonardo da Vinci had performed a series of experiments on iron wires that shed some light on the subject of brittle fracture. He found that the strength of the wires varied inversely with length. These data implied that flaws in the material controlled the strength; a longer wire corresponded to a larger sample volume and a higher probability of sampling a region containing a flaw. These results were only qualitative, however, and formal mathematical relationships between flaw size and failure stress were not developed until recently.

During World War II, a large number of Liberty ships and T2 tankers sustained brittle fractures [Bannerman and Young, 1946]. The need to understand the cause of these failures led to extensive research in the 1950s, which resulted in the engineering discipline known as **fracture mechanics**.

The field of fracture mechanics attempts to quantify the relationship between failure stress, flaw size, and material properties. Today, many segments of industry, including aerospace, oil and gas, and electric utilities, apply fracture mechanics principles in order to prevent catastrophic failures.

11.2 Fundamental Concepts

Figure 11.1 contrasts the fracture mechanics approach with the traditional approach to structural design and material selection. In the latter case, the anticipated design stress is compared to the tensile properties of candidate materials; a material is assumed to be adequate if its strength is greater than the expected applied stress. Such an approach may attempt to guard against brittle fracture by imposing a safety factor

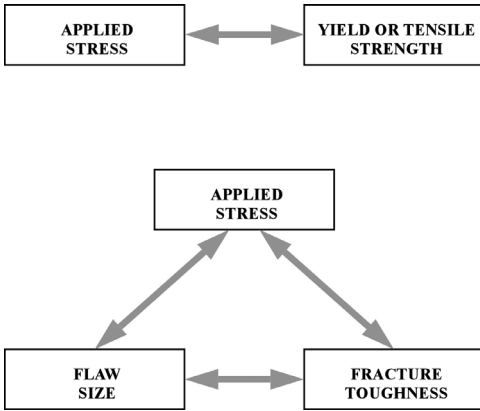

FIGURE 11.1 Comparison of the fracture mechanics approach to design with the traditional strength of materials approach. (a) The strength of materials approach. (b) The fracture mechanics approach.

FIGURE 11.2 Through-thickness crack in an infinite plate subject to a remote tensile stress. In practical terms, “infinite” means that the width of the plate is $\gg 2a$.

on stress, combined with minimum tensile elongation requirements on the material. The fracture mechanics approach [Figure 11.1(b)] has three important variables, rather than two as in Figure 11.1(a). The additional structural variable is flaw size, and **fracture toughness** replaces strength as the relevant material property. Fracture mechanics quantifies the critical combinations of these three variables.

Most fracture mechanics methodologies assume linear elastic behavior, although more advanced approaches incorporate nonlinear material behavior such as yielding. Two alternative approaches to linear elastic fracture analysis (LEFM) exist: the energy criterion and the stress intensity approaches, both of which are described below.

In addition to predicting the conditions for ultimate failure, fracture mechanics methodologies can also characterize time-dependent cracking mechanisms such as fatigue.

The Energy Criterion

The energy approach states that crack extension (i.e., fracture) occurs when the energy available for crack growth is sufficient to overcome the resistance of the material. The material resistance may include the surface energy, plastic work, or other type of energy dissipation associated with a propagating crack.

Griffith [1920] was the first to propose the energy criterion for fracture, but Irwin [1956] is primarily responsible for developing the present version of this approach: the **energy release rate**, G , which is defined as the rate of change in potential energy with crack area for a linear elastic material. At the moment of fracture, $G = G_c$, the critical energy release rate, which is a measure of fracture toughness.

For a crack of length $2a$ in an infinite plate subject to a remote tensile stress (Figure 11.2), the energy release rate is given by

$$G = \frac{\pi\sigma^2 a}{E} \quad (11.1)$$

where E is Young’s modulus, σ is the remotely applied stress, and a is the half crack length. At fracture, $G = G_c$, and Equation (11.2) describes the critical combinations of stress and crack size for failure:

$$G_c = \frac{\pi\sigma_f^2 a_c}{E} \quad (11.2)$$

Note that for a constant G_c value, failure stress, σ_f , varies with $1/\sqrt{a}$. The energy release rate, G , is the driving force for fracture, while G_c is the material's resistance to fracture. To draw an analogy to the strength of materials approach of Figure 11.1(a), the applied stress can be viewed as the driving force for plastic deformation, while the yield strength is a measure of the material's resistance to deformation.

The tensile stress analogy is also useful for illustrating the concept of similitude. A yield strength value measured with a laboratory specimen should be applicable to a large structure; yield strength does not depend on specimen size, provided the material is reasonably homogeneous. One of the fundamental assumptions of fracture mechanics is that fracture toughness (G_c in this case) is independent of the size and geometry of the cracked body; a fracture toughness measurement on a laboratory specimen should be applicable to a structure. As long as this assumption is valid, all configuration effects are taken into account by the driving force, G . The similitude assumption is valid as long as the material behavior is predominantly linear elastic.

The Stress Intensity Approach

Figure 11.3 schematically shows an element near the tip of a crack in an elastic material, together with the in-plane stresses on this element. Note that each stress component is proportional to a single constant, K_I . If this constant is known, the entire stress distribution at the crack tip can be computed with the equations in Figure 11.3. This constant, which is called the **stress intensity factor**, completely characterizes the crack tip conditions in a linear elastic material [Irwin, 1957]. If one assumes that the material fails locally at some critical combination of stress and strain, then it follows that fracture must occur at a critical stress intensity, K_{IC} . Thus, K_{IC} is an alternate measure of fracture toughness.

For the plate illustrated in Figure 11.2, the stress intensity factor is given by

$$K_I = \sigma\sqrt{\pi a} \tag{11.3}$$

Failure occurs when $K_I = K_{IC}$. In this case, K_I is the driving force for fracture and K_{IC} is a measure of material resistance. As with G_c , the property of similitude should apply to K_{IC} . That is, K_{IC} is assumed to be a size-independent material property.

Comparing Equation (11.1) and Equation (11.3) results in a relationship between K_I and G :

$$G = \frac{K_I^2}{E} \tag{11.4}$$

This same relationship obviously holds for G_c and K_{IC} . Thus, the energy and stress intensity approaches to fracture mechanics are essentially equivalent for linear elastic materials.

FIGURE 11.3 Stresses near the tip of a crack in an elastic material.

FIGURE 11.4 The damage tolerance approach to design.

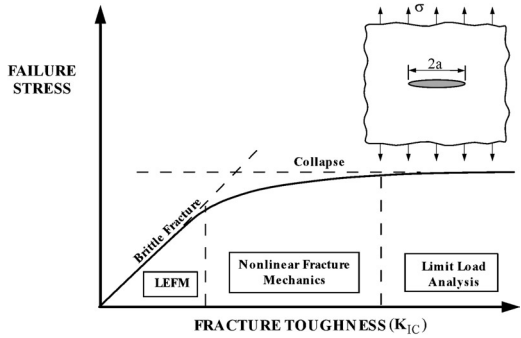

FIGURE 11.5 Effect of fracture toughness on the governing failure mechanism.

Time-Dependent Crack Growth and Damage Tolerance

Fracture mechanics often plays a role in life prediction of components that are subject to time-dependent crack growth mechanisms such as fatigue or stress corrosion cracking. The *rate* of cracking can be correlated with fracture mechanics parameters such as the stress intensity factor, and the critical crack size for failure can be computed if the fracture toughness is known. For example, Paris and Erdogan [1960] showed that the fatigue crack growth rate in metals could be described by the following empirical relationship:

$$\frac{da}{dN} = C(\Delta K)^m \quad (11.5)$$

where da/dN is the crack growth per cycle, ΔK is the stress intensity range, and C and m are material constants.

Damage tolerance, as its name suggests, entails allowing subcritical flaws to remain in a structure. Repairing flawed material or scrapping a flawed structure is expensive and is often unnecessary. Fracture mechanics provides a rational basis for establishing flaw tolerance limits.

Consider a flaw in a structure that grows with time (e.g., a fatigue crack or a stress corrosion crack) as illustrated schematically in Figure 11.4. The *initial* crack size is inferred from **nondestructive examination** (NDE), and the *critical* crack size is computed from the applied stress and fracture toughness. Normally, an *allowable* flaw size would be defined by dividing the critical size by a safety factor. The predicted service life of the structure can then be inferred by calculating the time required for the flaw to grow from its initial size to the maximum allowable size.

Effect of Material Properties on Fracture

Most early work was applicable only to linear elastic materials under quasistatic conditions, while subsequent advances in fracture research incorporated other types of material behavior. Elastic-plastic fracture mechanics considers plastic deformation under quasistatic conditions, while dynamic, viscoelastic, and viscoplastic fracture mechanics include time as a variable. Elastic-plastic, viscoelastic, and viscoplastic fracture behavior are sometimes included under the more general heading of **nonlinear fracture mechanics**. The branch of fracture mechanics one should apply to a particular problem obviously depends on material behavior.

Consider a cracked plate (Figure 11.2) that is loaded to failure. Figure 11.5 is a schematic plot of failure stress versus fracture toughness (K_{IC}). For low toughness materials, brittle fracture is the governing failure mechanism, and critical stress varies linearly with K_{IC} , as predicted by Equation (11.3). At very high toughness values, LEFM is no longer valid, and failure is governed by the flow properties of the material.

TABLE 11.1 Typical Fracture Behavior of Selected Materials

| Material | Typical Fracture Behavior |
|--------------------------------------|-------------------------------|
| High strength steel | Linear elastic |
| Low- and medium-strength steel | Elastic-plastic/fully plastic |
| Austenitic stainless steel | Fully plastic |
| Precipitation-hardened aluminum | Linear elastic |
| Metals at high temperatures | Viscoplastic |
| Metals at high strain rates | Dynamic-viscoplastic |
| Polymers (below T_g) ^a | Linear elastic/viscoelastic |
| Polymers (above T_g) ^a | Viscoelastic |
| Monolithic ceramics | Linear elastic |
| Ceramic composites | Linear elastic |
| Ceramics at high temperatures | Viscoplastic |

Note: Temperature is ambient unless otherwise specified.

^a T_g , Glass transition temperature.

At intermediate toughness levels, there is a transition between brittle fracture under linear elastic conditions and ductile overload. Nonlinear fracture mechanics bridges the gap between LEFM and collapse. If toughness is low, LEFM is applicable to the problem, but if toughness is sufficiently high, fracture mechanics ceases to be relevant to the problem because failure stress is insensitive to toughness; a simple limit load analysis is all that is required to predict failure stress in a material with very high fracture toughness.

Table 11.1 lists various materials, together with the typical fracture regime for each material.

11.3 Concluding Remarks

Fracture is a problem that society has faced for as long as there have been manmade structures. The problem may actually be worse today than in previous centuries, because more can go wrong in our complex technological society. Major airline crashes, for instance, would not be possible without modern aerospace technology.

Fortunately, advances in the field of fracture mechanics have helped to offset some of the potential dangers posed by increasing technological complexity. Our understanding of how materials fail and our ability to prevent such failures have increased considerably since World War II. Much remains to be learned, however, and existing knowledge of fracture mechanics is not always applied when appropriate.

While catastrophic failures provide income for attorneys and consulting engineers, such events are detrimental to the economy as a whole. An economic study [Duga et al., 1983] estimated the cost of fracture in the United States in 1978 at \$119 billion (in 1982 dollars), about 4% of the gross national product. Furthermore, this study estimated that the annual cost could be reduced by \$35 billion if current technology were applied, and that further fracture mechanics research could reduce this figure by an additional \$28 billion.

Defining Terms

Damage tolerance — A methodology that seeks to prevent catastrophic failures in components that experience time-dependent cracking. Fracture mechanics analyses are used in conjunction with nondestructive examination (NDE) to ensure that any flaws that may be present will not grow to a critical size prior to the next inspection.

Energy release rate — The rate of change in stored energy with respect to an increase in crack area. Energy release rate is a measure of the driving force for fracture. A crack will grow when the energy available for crack extension is greater than or equal to the energy required for crack extension. The latter quantity is a property of the material.

Fracture mechanics — An engineering discipline that quantifies the effect of cracks and crack-like flaws on material performance. Fracture mechanics analyses can predict both catastrophic failure and subcritical crack growth.

Fracture toughness — A measure of the ability of a material to resist crack propagation. The fracture toughness of a material can be quantified by various parameters, including a critical stress intensity factor, K_{IC} , and a critical energy release rate, G_c .

Linear elastic fracture mechanics (LEFM) — A branch of fracture mechanics that applies to materials that obey Hooke's law. LEFM is not valid when the material experiences extensive nonlinear deformation such as yielding.

Nondestructive examination (NDE) — A technology that can be used to characterize a material without altering its properties or destroying a sample. It is an indispensable tool for fracture mechanics analysis because NDE is capable of detecting and sizing crack-like flaws.

Nonlinear fracture mechanics — An extension of fracture mechanics theory to materials that experience nonlinear behavior such as yielding.

12.1 Dynamics of Particles

The dynamics of particles consists of five main parts:

1. **Kinematics** of a point (the geometry of a point moving through space)
2. Newton's second law
3. Moment of momentum equation
4. Momentum integrals of Newton's second law
5. Work-energy integral of Newton's second law

The concept of a **particle** is an abstraction or model of the actual physical situation. The moon in motion about the earth might be modeled as a mass point. In fact, the motion of any finite body in which the rotation effects are not important can properly be described as a particle or point mass.

Although it is possible to derive all the fundamental equations in a purely vector format, in order to describe any particular problem in dynamics, it is crucial that a specific coordinate system be employed. The coordinate systems that will be considered in this chapter are the following:

1. Cartesian coordinates
 2. Natural (path) coordinates
 3. Cylindrical coordinates
 4. Spherical coordinates
 5. Relative motion
-

FIGURE 12.1 Cartesian coordinates.

FIGURE 12.2 Natural coordinates.

The fundamental equation that is encountered in dynamics is Newton's second law, $\mathbf{F} = m\mathbf{a}$, where \mathbf{F} is the total force acting on a particle and \mathbf{a} is the resulting acceleration. Thus the geometric problem of dynamics consists of finding the **position**, \mathbf{r} , the **velocity**, \mathbf{v} , and the **acceleration**, \mathbf{a} , of a point mass.

In order to use any coordinate system, the equations for the position \mathbf{r} , the velocity \mathbf{v} , and the acceleration \mathbf{a} as expressed in that coordinate system must be known. In order to achieve these results, the derivatives of the unit vectors of the coordinate system must be determined.

Cartesian Coordinates

Consider the path of point P with respect to the Cartesian coordinate system shown in Figure 12.1. The position, velocity, and acceleration are expressed in [Table 12.1](#).

Natural (Path) Coordinates

Natural or path coordinates are useful to understand the intrinsic nature of the velocity and acceleration vectors. Natural coordinates are defined by the actual trajectory of the point P as it moves through space. Consider the trajectory as shown in Figure 12.2.

The distance or arc length along the path (from some convenient starting position) is denoted by s . The velocity and acceleration of P are defined in terms of the path characteristics: the unit vector \mathbf{e}_t tangent to the path, the unit vector \mathbf{e}_n normal to the path, the radius of curvature, R , and the derivatives of the arc length with respect to time, \dot{s} and \ddot{s} . The quantity R is the radius of curvature, and τ is the torsion of the curve. Table 12.2 lists the natural coordinate equations. Struik [1961] contains a proof of the derivatives of the unit vectors.

TABLE 12.1 Equations of Cartesian Coordinates

$$\begin{aligned}\mathbf{r} &= x\mathbf{i} + y\mathbf{j} + z\mathbf{k} \\ \mathbf{v} &= \dot{x}\mathbf{i} + \dot{y}\mathbf{j} + \dot{z}\mathbf{k} \\ \mathbf{a} &= \ddot{x}\mathbf{i} + \ddot{y}\mathbf{j} + \ddot{z}\mathbf{k}\end{aligned}$$

TABLE 12.2 Equations of Natural Coordinates

| $\mathbf{a} = (\ddot{r} - r\dot{\vartheta}^2)\mathbf{e}_r + (r\ddot{\vartheta} + 2\dot{r}\dot{\vartheta})\mathbf{e}_\vartheta + \ddot{z}\mathbf{k}$ | $\dot{\mathbf{k}} = 0$ |

Cylindrical Coordinates

Cylindrical coordinates are used when there is some symmetry about a line. If this line is taken to be the z axis, the coordinates appear as in Figure 12.3. The parameters of cylindrical coordinates are introduced by dropping a line from the point P to the xy plane. The distance from the origin O to the intersection in the xy plane is denoted by the scalar r . Finally, the angle between the x axis and the line from O to the intersection is ϑ . Thus the parameters that define cylindrical coordinates are $\{r, \vartheta, z\}$, and the unit vectors are $\{\mathbf{e}_r, \mathbf{e}_\vartheta, \mathbf{k}\}$. See Table 12.3.

Spherical Coordinates

Spherical coordinates are particularly useful in problems with symmetry about a point. The coordinates are defined by the three parameters $\rho, \phi,$ and ϑ and the corresponding unit vectors $\mathbf{e}_\rho, \mathbf{e}_\phi,$ and \mathbf{e}_ϑ . Refer to Figure 12.4 and Table 12.4.

Kinematics of Relative Motion

The equations of relative motion are used when it is convenient to refer the motion to a coordinate system that is in motion. In general, such a coordinate system cannot be used to write the equations of

TABLE 12.4 Equations of Spherical Coordinates

| $\mathbf{r} = \rho\mathbf{e}_\rho$ | $\dot{\mathbf{e}}_\rho = \dot{\phi}\mathbf{e}_\phi + \dot{\vartheta}\sin\phi\mathbf{e}_\vartheta$ |
| $\mathbf{v} = \dot{\rho}\mathbf{e}_\rho + \rho\dot{\phi}\mathbf{e}_\phi + \rho\dot{\vartheta}\sin\phi\mathbf{e}_\vartheta$ | $\dot{\mathbf{e}}_\phi = -\dot{\phi}\mathbf{e}_\rho + \dot{\vartheta}\cos\phi\mathbf{e}_\vartheta$ |
| $\mathbf{a} = (\ddot{\rho} - \rho\dot{\phi}^2 - \rho\dot{\vartheta}^2\sin^2\phi)\mathbf{e}_\rho$ $+ (2\dot{\rho}\dot{\phi} + \rho\ddot{\phi} - \rho\dot{\vartheta}^2\sin\phi\cos\phi)\mathbf{e}_\phi$ $+ (2\dot{\rho}\dot{\vartheta}\sin\phi + 2\rho\dot{\phi}\dot{\vartheta}\cos\phi + \rho\ddot{\vartheta}\sin\phi)\mathbf{e}_\vartheta$ | $\dot{\mathbf{e}}_\vartheta = -\dot{\vartheta}\sin\phi\mathbf{e}_\rho - \dot{\vartheta}\cos\phi\mathbf{e}_\phi$ |

FIGURE 12.5 Angular velocity.

FIGURE 12.6 Relative motion.

dynamics since it will not be an inertial reference frame. The crucial concept in this regard is the **angular velocity** vector, $\boldsymbol{\omega}$. Consider Figure 12.5.

The angular velocity vector $\boldsymbol{\omega}$ is introduced through the equation

$$\mathbf{v} = \boldsymbol{\omega} \times \mathbf{r} \tag{12.1}$$

for any point P that is embedded in the moving frame $\{x_1, y_1, z_1\}$. Then

$$\frac{d\boldsymbol{\rho}}{dt} = \frac{dx}{dt}\mathbf{i} + \frac{dy}{dt}\mathbf{j} + \frac{dz}{dt}\mathbf{k} + x\boldsymbol{\omega} \times \mathbf{i} + y\boldsymbol{\omega} \times \mathbf{j} + z\boldsymbol{\omega} \times \mathbf{k}$$

or

$$\frac{d\boldsymbol{\rho}}{dt} = \underbrace{\frac{dx}{dt}\mathbf{i} + \frac{dy}{dt}\mathbf{j} + \frac{dz}{dt}\mathbf{k}}_{\mathbf{v}_0} + \underbrace{\boldsymbol{\omega} \times (xi + yj + zk)}_{\boldsymbol{\omega} \times \boldsymbol{\rho}}$$

The first block of terms is the velocity as seen from the moving frame — that is, the velocity as it would appear to an observer whose feet are firmly planted in the moving frame $\{x, y, z\}$. It is convenient to denote this as $\delta\boldsymbol{\rho}/\delta t$. The second block of terms is just $\boldsymbol{\omega} \times \boldsymbol{\rho}$. Thus,

$$\frac{d\boldsymbol{\rho}}{dt} = \frac{\delta\boldsymbol{\rho}}{\delta t} + \boldsymbol{\omega} \times \boldsymbol{\rho} \tag{12.2}$$

Equation (12.2) gives an operator equation for computing time derivatives with respect to a fixed or moving frame:

$$\frac{d}{dt} = \frac{\delta}{\delta t} + \boldsymbol{\omega} \times \tag{12.3}$$

Now suppose the origin of the moving frame has a motion. Then if \mathbf{v}_o is the velocity of the moving origin (see Figure 12.6),

$$\mathbf{v} = \mathbf{v}_o + \frac{\delta\boldsymbol{\rho}}{\delta t} + \boldsymbol{\omega} \times \boldsymbol{\rho} \tag{12.4}$$

In order to interpret this, it is instructive to rearrange the terms:

TABLE 12.5 Equations of Relative Motion

$$\mathbf{r} = \mathbf{r}_o + \boldsymbol{\rho}$$

$$\mathbf{v} = (\mathbf{v}_o + \boldsymbol{\omega} \times \boldsymbol{\rho}) + \frac{\delta \boldsymbol{\rho}}{\delta t}$$

$$\mathbf{a} = [\mathbf{a}_o + \boldsymbol{\omega} \times (\boldsymbol{\omega} \times \boldsymbol{\rho}) + \dot{\boldsymbol{\omega}} \times \boldsymbol{\rho}] + \frac{\delta^2 \boldsymbol{\rho}}{\delta t^2} + 2\boldsymbol{\omega} \times \frac{\delta \boldsymbol{\rho}}{\delta t}$$

$$\mathbf{v} = \underbrace{(\mathbf{v}_o + \boldsymbol{\omega} \times \boldsymbol{\rho})}_{\text{Convective velocity}} + \underbrace{\frac{\delta \boldsymbol{\rho}}{\delta t}}_{\text{Relative velocity}}$$

The *relative velocity* is that which is seen by an observer fixed to the moving frame. The *convective velocity* is the velocity of a fixed point that instantaneously shares the position of the moving point.

This process is repeated to determine the acceleration. That is, the operator of Equation (12.3) is applied to Equation (12.4) to get $\mathbf{a} = d\mathbf{v}/dt$. The result is arranged as follows:

$$\mathbf{a} = \underbrace{[\mathbf{a}_o + \boldsymbol{\omega} \times (\boldsymbol{\omega} \times \boldsymbol{\rho}) + \dot{\boldsymbol{\omega}} \times \boldsymbol{\rho}]}_{\text{Convective acceleration}} + \underbrace{\frac{\delta^2 \boldsymbol{\rho}}{\delta t^2}}_{\text{Relative acceleration}} + \underbrace{2\boldsymbol{\omega} \times \frac{\delta \boldsymbol{\rho}}{\delta t}}_{\text{Coriolis acceleration}} \quad (12.5)$$

Again, the *relative acceleration* is that which a moving observer in $\{x, y, z\}$ would see. The *convective acceleration* is the acceleration of the fixed point of $\{x, y, z\}$ that shares the instantaneous position of the moving point under consideration.

The equations of position, velocity, and acceleration are summarized in [Table 12.5](#).

12.2 Newton's Second Law

In order to write Newton's second law for a particle, m ,

$$\mathbf{F} = m\mathbf{a} \quad (12.6)$$

the terms of the equation must be evaluated:

1. The force, \mathbf{F} , is obtained from a free-body diagram of the particle. It should be noted that the free-body diagram will appear unbalanced because the particle is not in static equilibrium.
2. The mass, m , can be obtained from the weight of the particle:

$$\text{Weight} = mg \quad (12.7)$$

3. The acceleration is written in some convenient nonaccelerating coordinate system (from the equations in Section 12.1).

Any equation must ultimately be expressed in some unit system. The fundamental units of dynamics are force, mass, length, and time. The units for these quantities are shown in [Table 12.6](#). Conversion of units is shown in [Table 12.7](#).

TABLE 12.6 Unit Systems Used in Dynamics

| Unit System | Type | Force | Mass | Length | Time |
|-----------------|---------------|---------------|---------------------------------|-----------------|--------------|
| English (large) | Gravitational | Pound (lb) | Slug lb · s ² /ft | Foot (ft) | Second (sec) |
| English (small) | Gravitational | Pound (lb) | lb · s ² /in. | Inch (in.) | Second (sec) |

| | 1.0 ft | = 0.3048 m |
| Mass units | 1.0 lb · s ² /ft | = 12 lb · s ² /ft |
| | 1.0 lb · s ² /ft | = 1.2162 kg |
| | 1.0 lb · s ² /ft | = 1.2162 · 10 ³ g |
| | 1.0 slug = | 1.0 lb · s ² /ft = 0.08333 lb · s ² /in. |
| | 1.0 lb · s ² /ft | = 14.594 kg |
| | 1.0 lb · s ² /ft | = 1.4594 · 10 ⁴ g |

FIGURE 12.7 Moment of momentum and moment of force.

12.3 Moment of Momentum Relations

The moment of a force is determined by the (vector) *cross product*:

$$\mathbf{M}_o = \mathbf{r} \times \mathbf{F} \quad (12.8)$$

See Figure 12.7.

The *linear momentum* of m is

$$\mathbf{p} = m\mathbf{v} \quad (12.9)$$

and the *moment of momentum* (sometimes called the *angular momentum*) is

$$\mathbf{h}_o = \mathbf{r} \times \mathbf{p} = \mathbf{r} \times m\mathbf{v} \quad (12.10)$$

Computing the time derivative of \mathbf{h} gives

$$\frac{d\mathbf{h}_o}{dt} = \frac{d\mathbf{r}}{dt} \times m\mathbf{v} + \mathbf{r} \times m\mathbf{a}$$

The first term is $\mathbf{v} \times m\mathbf{v}$. This is the cross product of two vectors in the same direction. Thus this term is zero. From Equation (12.6) and Equation (12.8), the remaining term is the moment of the force, \mathbf{F} , about the point O . Thus:

$$M_o = \frac{d\mathbf{h}_o}{dt} \quad (12.11)$$

12.4 Momentum Integrals of Newton's Second Law

Newton's second law, Equation (12.6), can be integrated over time or space. When the former is done, the result is called an *impulse* or an *angular impulse*. When the integration is performed over space, the result is the *work*. This will be demonstrated later.

Impulse-Momentum and Angular Impulse-Moment of Momentum Relations

Recall Newton's second law, $\mathbf{F} = m\mathbf{a}$. Suppose we write $\mathbf{a} = d\mathbf{v}/dt$. Then

$$\int_{t_o}^{t_1} \mathbf{F} dt = m \int_{t_o}^{t_1} \frac{d\mathbf{v}}{dt} dt = m[\mathbf{v}(t_1) - \mathbf{v}(t_o)] \quad (12.12)$$

Equation (12.12) is called the *impulse change of linear momentum theorem*.

Similarly, taking Equation (12.11) as the basis of the time integration gives

$$\int_{r_o}^{r_1} \mathbf{M}_o dr = m \int_{t_o}^{t_1} \frac{d\mathbf{h}_o}{dt} dt = \mathbf{h}_o(t_1) - \mathbf{h}_o(t_o) \quad (12.13)$$

Equation (12.13) is called the *angular impulse change of angular momentum theorem*. Equation (12.12) and Equation (12.13) are particularly interesting when the left-hand side is zero. Then we say that linear momentum is conserved or that the moment of momentum (angular momentum) is conserved.

Two important examples that utilize these conservation laws are collision problems [Karnopp, 1974] and central force motion problems [Goldstein, 1959].

12.5 Work-Energy Integral of Newton's Second Law

In deriving the momentum laws, Newton's second law is integrated over time. In the work-energy relation, the integration takes place over space. Recall Newton's second law, $\mathbf{F} = m\mathbf{a} = m(d\mathbf{v}/dt)$. An instantaneous quantity is the *power* of the force \mathbf{F} :

$$P = \mathbf{F} \cdot \mathbf{v} \quad (12.14)$$

The **power**, P , is a scalar quantity. The units of power are listed in Table 12.8.

TABLE 12.8 Units of Power

| | |
|------------|--|
| English | ft · lb/s |
| | in. · lb/s |
| | 1.0 horsepower = 550 ft · lb/s |
| Metric | N · m/sec |
| | 1.0 watt = 1.0 N · m/sec |
| Conversion | 1.0 N · m/sec = 0.7376 ft · lb/s |
| | 1.0 ft · lb/s = 1.3557 N · m/sec |
| | 1.0 horsepower = 746 watts |
| | 1.0 watt = 1.34048 · 10 ⁻³ hp |

FIGURE 12.8 Work of a force.

The *work* of a force is the time integral of the power of the force. Work is also a scalar quantity:

$$W = \int_{t_0}^{t_1} P dt \quad (12.15)$$

With Equation (12.14), and recalling that $\mathbf{v} = d\mathbf{r}/dt$ the work W (see Figure 12.8) becomes

$$W = \int_{\mathbf{r}_0}^{\mathbf{r}_1} \mathbf{F} \cdot d\mathbf{r} \quad (12.16)$$

Equation (12.16) is what is called a *path* or *line integral*. That is, the value of the work is dependent, in general, on the particular path that is traversed between positions \mathbf{r}_0 and \mathbf{r}_1 .

Recall from Equation (12.6) and Equation (12.14) that $\mathbf{F} = m\mathbf{a} = m(d\mathbf{v}/dt)$ and $P = \mathbf{F} \cdot \mathbf{v}$. Inserting Equation (12.13) into Equation (12.14) gives

$$P = m \frac{d\mathbf{v}}{dt} \cdot \mathbf{v} \quad (12.16a)$$

Now consider that

$$\frac{1}{2} \frac{d}{dt} (m\mathbf{v} \cdot \mathbf{v}) = \frac{1}{2} \left[m \frac{d\mathbf{v}}{dt} \cdot \mathbf{v} + m\mathbf{v} \cdot \frac{d\mathbf{v}}{dt} \right] = m \frac{d\mathbf{v}}{dt} \cdot \mathbf{v} \quad (12.16b)$$

Defining the *kinetic energy* of a particle to be

$$T = \frac{1}{2} m\mathbf{v} \cdot \mathbf{v} = \frac{1}{2} m\mathbf{v}^2 \quad (12.17)$$

Equation (12.16a) and Equation (12.16b) give

$$P = \frac{d}{dt} T \quad (12.18)$$

That is, the power of the force \mathbf{F} equals the time rate of change of the kinetic energy T .

Finally, from Equation (12.18), the work of \mathbf{F} in moving the particle from \mathbf{r}_0 to \mathbf{r}_1 , equals the change in kinetic energy between \mathbf{r}_0 and \mathbf{r}_1 . The work–energy theorem is derived in [Table 12.9](#).

While Equation (12.16) gives a way to compute the work of a force, there is a very special and important class of forces that give a very simple way of computing work. These are called *conservative forces*. A force is conservative if it can be derived from a *potential energy function* through differentiation.

TABLE 12.9 The Work–Energy Theorem

The work of a force \mathbf{F} is

$$W = \int_{\mathbf{r}_o}^{\mathbf{r}_1} \mathbf{F} \cdot d\mathbf{r}$$

The kinetic energy of a particle is

$$T = \frac{1}{2} m \mathbf{v} \cdot \mathbf{v} = \frac{1}{2} m v^2$$

And the work–energy relation is

$$W_{\mathbf{r}_o}^{\mathbf{r}_1} = T(\mathbf{r}_1) - T(\mathbf{r}_o)$$

TABLE 12.10 Conservative Forces

| | Force | Potential Energy |
|------------------------------------|--|-----------------------------|
| Gravity | $\mathbf{F} = -mg\mathbf{k}$ | $V = mgz$ |
| Universal gravitation ^a | $\mathbf{F} = -\frac{\gamma Mm}{r^2} \mathbf{e}_r$ | $V = -\frac{\gamma Mm}{r}$ |
| Spring force | $\mathbf{F} = -k\delta$ | $V = \frac{1}{2} k\delta^2$ |

^a For motion about the earth $\gamma M_e = 1.255 \cdot 10^3 \text{ mi}^3 / \text{h}^2 = 5.2277 \cdot 10^3 \text{ km}^3 / \text{h}^2$.

$$\mathbf{F} = -\nabla V \tag{12.19}$$

where V is the potential energy function for \mathbf{F} and ∇ is the del operator. In Cartesian coordinates, Equation (12.18) becomes

$$\mathbf{F} = -\frac{\partial V}{\partial x} \mathbf{i} - \frac{\partial V}{\partial y} \mathbf{j} - \frac{\partial V}{\partial z} \mathbf{k}$$

The general form for conservative forces, Equation (12.19), is usually overly complex. Conservative forces are listed in Table 12.10.

The Work–Energy Relation for a Conservative Force

Recall the equation for the work of a force, $W = \int_{\mathbf{r}_o}^{\mathbf{r}_1} \mathbf{F} \cdot d\mathbf{r}$. Suppose \mathbf{F} is conservative. Then, by Equation (12.19), $\mathbf{F} = -\nabla V$. And, finally, recall the equations of natural coordinates to write the expression for $d\mathbf{r}$: $\mathbf{v} = (d\mathbf{r}/ds)(ds/dt) = (ds/dt)\mathbf{e}_t$. Thus,

$$d\mathbf{r} = \frac{d\mathbf{r}}{ds} ds = \mathbf{e}_t ds$$

Finally, the work, by Equation (12.16), becomes

$$W = \int_{\mathbf{r}_o}^{\mathbf{r}_1} -(\nabla V \cdot \mathbf{e}_t) ds$$

The term inside the parentheses is just the *directional derivative* dV/ds — that is, the derivative that is taken tangent to the path. Thus the work becomes

TABLE 12.11 Units of Energy

| | | |
|-------------|---------------------------------|--|
| English | ft · lb in. · lb | |
| Metric | N · m = joule dyn · cm = erg | |
| Conversion | | |
| 1.0 joule = | 1.0 N · m | = 10 ⁷ dyn · cm = 10 ⁷ erg |
| 1.0 joule = | 1.0 N · m | = 0.07376 ft · lb |
| 1.0 joule = | 1.0 N · m | = 0.88512 in. · lb |
| 1.0 erg = | 1.0 dyn · cm | = 7.376 · 10 ⁻⁹ ft · lb |
| 1.0 erg = | 1.0 dyn · cm | = 8.8512 · 10 ⁻⁸ in. · lb |
| | 1.0 ft · lb | = 1.3557 N · m |
| | 1.0 ft · lb | = 1.3557 · 10 ⁷ dyn · cm |
| | 1.0 in. · lb | = 0.11298 N · m |
| | 1.0 in. · lb | = 0.11298 · 10 ⁷ dyn · cm |

$$W = \int_{\mathbf{r}_o}^{\mathbf{r}_1} -\left(\frac{dV}{ds}\right) ds = \int_{\mathbf{r}_o}^{\mathbf{r}_1} -dV = -V(\mathbf{r}_1) + V(\mathbf{r}_o) \quad (12.20)$$

The crucial thing to note in Equation (12.20) is that the work of a conservative force depends *only* on the end positions of the path. Thus the work–energy relation derived in Table 12.9 becomes, in the case of conservative forces:

$$T(\mathbf{r}_1) + V(\mathbf{r}_1) = T(\mathbf{r}_o) + V(\mathbf{r}_o) = \text{constant}$$

For conservative and nonconservative forces:

$$[T(\mathbf{r}_o) + V(\mathbf{r}_o)] + W_{\mathbf{r}_o}^{\mathbf{r}_1} = [T(\mathbf{r}_1) + V(\mathbf{r}_1)]$$

where $W_{\mathbf{r}_o}^{\mathbf{r}_1}$ is the work of the nonconservative forces.

Units of energy are shown in Table 12.11.

The work–energy theorem is used when what is sought is the speed of a particle as a function of *position in space*. The impulse momentum theorems, on the other hand, will give the velocity as a function of *time*. Both relations are derived from Newton’s second law and are called *first integrals*.

The work–energy problem solving method presented has five advantages for solving dynamics problems:

1. Coordinate system origins are arbitrary, so the problem can be simplified by choosing them carefully.
2. Accelerations do not need to be calculated.
3. Problem modifications or updates are easily made; parameterizing the dynamics problem for system layouts and case studies is also easy.
4. Scalar quantities are summed, even though the paths of motion may be complex.
5. Forces that do no work are ignored.

The main disadvantage to the energy method approach is the recognition that accelerations and work cannot be calculated for forces that do no work. In these cases, Newton’s second law must be used.

12.6 Conclusion

The notion of a mass point or particle forms the basis of Newtonian mechanics. Although many systems can be modeled as a point mass, others cannot. Rigid configurations of systems, deformable systems,

and so forth all require more elaborate geometrical (kinematic) description. The kinetic equations (Newton's law, momentum, moment of momentum, etc.) must be expanded in these cases. Still, the equations for particle dynamics form the basis of these discussions.

Defining Terms

Acceleration — The (vector) rate of change of velocity.

Angular velocity — The rate of change of orientation of a coordinate system.

Kinematics — The geometry of motion.

Particle — A point mass.

Position — The location of a point in space.

Power — The dot product of the force and the velocity.

Velocity — The (vector) rate of change of position.

Forces and Acceleration • Work and Energy

13.1 Kinematics of Rigid Bodies

Kinematics is the study of the geometry of rigid body motion without reference to what causes the motion. **Kinematic analyses** are conducted to establish relationships between the position, **velocity**, and **acceleration** of rigid bodies or points on a rigid body.

The position and orientation of a body can be described by their distance from a perpendicular set of fixed axes called a *coordinate system*. The minimum number of independent or generalized coordinates needed to completely describe the position and orientation of a system of rigid bodies is equal to the number of *degrees of freedom* for the system. The number of degrees of freedom equals the number of nonindependent coordinates used to describe the position and orientation of each body of the system minus the number of constraints equations governing the system's motion. Therefore, the maximum number of independent coordinates needed to completely describe the position and orientation of a rigid body in space is six. Three independent equations are required to locate and describe the rigid body in translation with respect to time; the other three independent equations of motion are required to define its orientation and rotation in space with respect to time.

In general, the equations of motion of a rigid body are created relative to an inertial reference frame. The inertial reference frame is usually the rectangular set of Cartesian coordinate axes x, y, z with corresponding unit vectors i, j, k , as described previously.

A rigid body is in *rectilinear translation* when a line that joins any two points on the body does not rotate during motion. A rigid body is in *curvilinear translation* when all points of the body move on congruent curves. A *fixed-axis rotation* occurs when the line that connects any point on the body to the center of rotation rotates without any translation. When all points in a body move in parallel planes, the rigid body is in *general plane motion*. If no restriction is placed on the motion of the rigid body, it will move in *general space motion*. If the body is in general space motion and one of its points is pivoted, the body is in a *fixed-point rotation*.

FIGURE 13.1 Rectilinear translation.

FIGURE 13.2 Curvilinear translation.

Translation

All points on a rigid body in pure translation will have the same velocity and the same acceleration at any given instant. Figure 13.1 and Figure 13.2 show examples of two different types of translational motion and a possible choice of a fixed reference frame whose axes are denoted as x and y with corresponding unit vectors i and j , respectively.

When a body is undergoing rectilinear translation, as shown in Figure 13.1, the velocities and accelerations of all points are identical in both magnitude and direction for all time.

$$\left. \begin{aligned} v_A &= v_B \\ a_A &= a_B \end{aligned} \right|_{\text{for all } t} \quad (13.1)$$

where $\{A, B, \dots\}$ are arbitrary points on the body. In Figure 13.2, the velocities of any two points A and B on the body are identical and parallel at any instant of time; however, unlike in rectilinear translation, the velocity and acceleration directions are not constant. For curvilinear translation, the velocity equation holds at any instant of time but not necessarily throughout the entire motion:

FIGURE 13.3 A body in pure rotation.

$$\left. \begin{aligned} v_A &= v_B \\ a_A &= a_B \end{aligned} \right|_{t_1 \neq t_2} \quad (13.2)$$

Rotation

The angular position of a body in pure rotation is completely defined by the angle between an arbitrary fixed reference line that passes through the center of rotation and any arbitrary line fixed to the body and passing also through the center of rotation, as shown in Figure 13.3. The rotation angle θ may be measured in degrees or radians, where

$$1 \text{ revolution} = 360 \text{ degrees} = 2\pi \text{ radians} \quad (13.3)$$

The rotation angular velocity ω is defined as the rate of change of the angular position angle θ with respect to time. It is expressed in radians per second (rps) or in revolutions per minute (rpm), as follows:

$$\omega = \frac{d\theta}{dt} \quad (13.4)$$

The rotational angular acceleration α is the time rate of change of the angular velocity resulting in the following relationship:

$$\alpha = \frac{d\omega}{dt} = \frac{d^2\theta}{dt^2} = \frac{d\omega}{d\theta} \frac{d\theta}{dt} = \omega \frac{d\omega}{d\theta} \quad (13.5)$$

In pure rotational motion, the relation between the *rotational position, velocity, and acceleration* are similar to pure translation. The angular velocity is the integral of the angular acceleration plus the initial velocity; the angular displacement is equal to the initial displacement added to the integral of the velocity. That is,

$$\begin{aligned}\omega &= \omega_0 + \alpha t \\ \theta &= \theta_0 + \omega t = \theta_0 + \omega_0 t + \frac{1}{2} \alpha t^2\end{aligned}\tag{13.6}$$

In general, the angular velocity and angular acceleration are three-dimensional vectors whose three components are normally projected on a coordinate system fixed to the body that is translating and rotating in space, which is the general behavior of rigid bodies as discussed in later sections. For planar motion, two of the components of the angular velocity vector are equal to zero and the third component points always outward from the plane of motion.

Therefore, the position of any point B on a body in pure planar rotation is determined by the distance $r_{B/A}$ of that point from the center of rotation A times the magnitude of the angle of rotation expressed in radians θ . Thus the distance s that a point fixed on a rigid body travels during a rotation θ is given by:

$$s = r_{B/A} \theta\tag{13.7}$$

Similarly, the linear velocity of that point will depend on the distance $r_{B/A}$ and on the angular velocity ω and will have a direction perpendicular to the line between the center of rotation and the point, as follows:

$$\vec{v} = \vec{\omega} \times \vec{r}_{B/A}\tag{13.8}$$

where \times indicates cross product. The angular acceleration of a point on a rigid body can be decomposed into a tangential and a normal component. The tangential component is the time rate of change of the linear velocity v and is in the direction of the linear velocity, namely, along the line perpendicular to the radius of rotation $r_{B/A}$.

$$\vec{a}_t = \frac{d\vec{v}}{dt} = \vec{\alpha} \times \vec{r}_{B/A}\tag{13.9}$$

The normal acceleration depends on the time rate of change of the velocity in the tangential direction and on the angle of displacement, which gives the equation

$$\vec{a}_n = \vec{\omega} \times \vec{\omega} \times \vec{r}_{B/A}\tag{13.10}$$

General Plane Motion: Euler Theorem

General plane motion can be separated into a pure translation followed by a pure rotation about a point called the *center of rotation*. If we attach a coordinate system at point A , as shown in [Figure 13.4](#), the position of any point on the body can be described by the position vector of point A — namely, r_A — added to the relative position of that point with respect to A — namely, the vector $r_{B/A}$ — all measured in the fixed coordinate system.

$$\vec{r}_B = \vec{r}_A + \vec{r}_{B/A}\tag{13.11}$$

Similarly, the velocity of a rigid body in general plane motion can be separated into a velocity due to pure translation v_A together with a velocity due to pure rotation $v_{A/B}$.

$$\vec{v}_B = \vec{v}_A + \vec{v}_{B/A}\tag{13.12}$$

where $\vec{v}_{B/A} = \omega \times \vec{r}_{B/A}$ and \vec{v}_A is the velocity vector of point A . The velocity vector $\vec{v}_{B/A}$ is called the *relative velocity vector* of point B with respect to point A .

FIGURE 13.4 General motion of a rigid body in plane.

Instantaneous Center of Rotation in Plane Motion

At any instant in time, a body in general plane motion has a point — which may be either outside or on the body — around which all points of the body appear to be rotating in pure rotation. This point, called *instantaneous center of rotation*, can be found if the velocity vector of any point on the body together with the angular velocity of the body are known. The instantaneous center of rotation will lie on a line perpendicular to the velocity vector and at a distance from that point that is equal to the magnitude of the velocity of the point divided by angular velocity ω of the body.

Once the instantaneous center of rotation is found, the velocity of any point B on the body can be determined from the vector from that center to the point B , \vec{r}_B , as follows:

$$\vec{v}_B = \vec{\omega} \times \vec{r}_B$$

The direction of the velocity vector will be perpendicular to the vector \vec{r}_B .

Absolute and Relative Acceleration in Plane Motion

The angular acceleration of a point on a rigid body in plane motion also has a component due to translation and a component due to rotation; the latter component consists of a normal and a tangential component.

$$\begin{aligned} \vec{a}_B &= \vec{a}_A + \vec{a}_{B/A} \\ \vec{a}_{B/A} &= (\vec{a}_{B/A})_n + (\vec{a}_{B/A})_t \\ (\vec{a}_{B/A})_n &= \omega \times \omega \times \vec{r}_{B/A} \\ (\vec{a}_{B/A})_t &= \alpha \times \vec{r}_{B/A} \end{aligned} \tag{13.13}$$

FIGURE 13.5 Coordinate transformation in rotation.

The acceleration of a point located by variable vector $\vec{r}_{B/A}$ on a moving rigid body is given by the following relation:

$$\vec{a}_{B/A} = \vec{a}_A + \omega \times \omega \times \vec{r}_{B/A} + \alpha \times \vec{r}_{B/A} + 2\omega \times \frac{d\vec{r}_{B/A}}{dt} + \frac{d^2\vec{r}_{B/A}}{dt^2} \quad (13.14)$$

where the vector $\vec{r}_{B/A}$ and its time derivative are measured in a fixed reference frame — namely, its components are $[X_r, Y_r]$ as shown in Figure 13.5. If the vector $\vec{r}_{B/A}$ is known by its components in a body-fixed coordinate $[x_r, y_r]$, then they can be transformed to the inertial coordinates as follows:

$$\begin{aligned} X_r &= x_r \cos\theta - y_r \sin\theta \\ Y_r &= x_r \sin\theta + y_r \cos\theta \end{aligned} \quad (13.15)$$

This is a coordinate transformation and is orthogonal, that is, its transpose is equal to its inverse. In matrix form the transformation of coordinates in Equation (13.15) can be written as follows:

$$\begin{bmatrix} X_r \\ Y_r \end{bmatrix} = \begin{bmatrix} \cos\theta & -\sin\theta \\ \sin\theta & \cos\theta \end{bmatrix} \begin{bmatrix} x_r \\ y_r \end{bmatrix} \quad \text{and} \quad \begin{bmatrix} x_r \\ y_r \end{bmatrix} = \begin{bmatrix} \cos\theta & \sin\theta \\ -\sin\theta & \cos\theta \end{bmatrix} \begin{bmatrix} X_r \\ Y_r \end{bmatrix} \quad (13.16)$$

If we use the prime symbol to denote that the vector components are measured in a body-fixed coordinate, then Equation (13.16) can be written in a more compact form as follows:

$$\vec{r}_{B/A} = T_z^T r'_{B/A} \quad \text{and} \quad r'_{B/A} = T_z^T r_{B/A} \quad (13.17)$$

where T_z^T is the transpose of the rotation matrix around the z axis (which would point outward from the page).

Space Motion

Three angles, called *Euler angles*, may be used to describe the orientation of a rigid body in space. These angles describe three consecutive rotations around the three coordinates of the frame fixed in a moving body with respect to an inertial fixed frame. Twelve combinations of rotation sequences can be chosen; here we choose the rotation around the z axis, ψ , followed by a rotation around the body-fixed y axis, θ , and finally a rotation around the body-fixed x axis, ϕ .

FIGURE 13.6 Three consecutive rotations of a body-fixed coordinate system (x, y, z) around the inertial-fixed axis (X, Y, Z) .

Figure 13.6(c) shows the final position of a body which has a fixed coordinate system $[x, y, z]$. Originally, the body was oriented such that its fixed coordinate $[x, y, z]$ corresponded to the inertial fixed coordinate system $[X, Y, Z]$. The body was then rotated by an angle ψ around z , as shown in Figure 13.6(a), followed by a rotation of an angle θ around y , as shown in Figure 13.6(b), and finally by a rotation through an angle ϕ around z .

If the components of a vector are known in the body-fixed coordinate system, then the components of that vector can be obtained in the inertial reference frame by multiplying the vector by a transformation matrix. This transformation is obtained from the sequential product of the three successive rotation matrices around axis z , then y , and then x , respectively. As an example, the transformation matrix for the rotation in the order shown in Figure 13.6 is as follows:

$$T_{z,y,x} = \begin{bmatrix} \cos\theta\cos\psi & \cos\theta\sin\psi & -\sin\theta \\ -\cos\phi\sin\psi + \sin\phi\sin\theta\cos\psi & \cos\phi\cos\psi + \sin\phi\sin\theta\sin\psi & \sin\psi\cos\theta \\ \sin\phi\sin\psi + \cos\phi\sin\theta\cos\psi & -\sin\phi\cos\psi + \cos\phi\sin\theta\sin\psi & \cos\phi\cos\theta \end{bmatrix} \quad (13.18)$$

In order to transform any vector $r'_{B/A}$ known by its components in a body-fixed coordinate system into the corresponding vector whose components are given in inertial fixed coordinates, $r_{B/A}$, and vice versa, the vector would be multiplied by the transformation matrix as follows:

$$r_{B/A} = T_{z,y,x} r'_{B/A} \quad \text{and} \quad r'_{B/A} = T_{z,y,x}^T r_{B/A} \quad (13.19)$$

where the superscript T denotes the transpose of the matrix. Because the transformation matrix is orthogonal, its transpose is equal to its inverse, as shown by Equation (13.19).

The time derivatives of the Euler angles can be obtained from the components of the angular rotation matrix ω expressed in body coordinates. For the sequence of rotations shown in Figure 13.6, the angular

velocity vector can be expressed in terms of the rate of change of the Euler angles as follows. In [Figure 13.6\(a\)](#) we have

$$\begin{aligned}\omega_x &= 0 \\ \omega_y &= 0 \\ \omega_z &= \frac{d\Psi}{dt}\end{aligned}$$

In [Figure 13.6\(b\)](#) we have

$$\begin{aligned}\omega_x &= -\frac{d\Psi}{dt} \sin\theta \\ \omega_y &= \frac{d\theta}{dt} \\ \omega_z &= \frac{d\Psi}{dt} \cos\theta\end{aligned}$$

Finally, in [Figure 13.6\(c\)](#) we have

$$\begin{aligned}\omega_x &= -\frac{d\Psi}{dt} \sin\theta + \frac{d\phi}{dt} \\ \omega_y &= \frac{d\Psi}{dt} \cos\theta \sin\phi + \frac{d\theta}{dt} \cos\phi \\ \omega_z &= \frac{d\Psi}{dt} \cos\theta \cos\phi - \frac{d\theta}{dt} \sin\phi\end{aligned}\tag{13.20}$$

$$\frac{d\Psi}{dt} = (\omega_y \sin\phi + \omega_z \cos\phi) / \cos\theta$$

$$\frac{d\theta}{dt} = \omega_y \cos\phi - \omega_z \sin\phi$$

$$\frac{d\phi}{dt} = \omega_x + (\omega_y \sin\phi - \omega_z \cos\phi) \tan\theta$$

In vector form the above equation may be written as follows:

$$\omega = E \frac{d\Sigma}{dt} \quad \text{or} \quad \frac{d\Sigma}{dt} = E^{-1} \omega\tag{13.21}$$

where the matrix E is given by:

$$E = \begin{bmatrix} -\sin\theta & 0 & 1 \\ \cos\theta \sin\phi & \cos\phi & 0 \\ \cos\theta \cos\phi & -\sin\phi & 0 \end{bmatrix}, \quad \bar{\omega} = \begin{bmatrix} \omega_x \\ \omega_y \\ \omega_z \end{bmatrix},$$

and

$$E^{-1} = \begin{bmatrix} 0 & \frac{\sin \phi}{\cos \theta} & \frac{\cos \phi}{\cos \theta} \\ 0 & \cos \phi & -\sin \phi \\ 1 & \frac{\sin \phi \sin \theta}{\cos \theta} & \frac{\cos \phi \sin \theta}{\cos \theta} \end{bmatrix} \quad (13.22)$$

Note that the matrix E is not orthogonal, so its transpose is not equal to its inverse.

13.2 Kinetics of Rigid Bodies

Forces and Acceleration

Kinetics is the study of the relation between the forces that act on a rigid body and the resulting acceleration, velocity, and motion as a function of the body mass and geometric shape. The acceleration of a rigid body is related to its mass and to the applied forces by D'Alembert's principle, which states that the external forces acting on a rigid body are equivalent to the effective forces of the various particles of the body.

In the case of a rigid body moving in a plane motion, the D'Alembert principle amounts to the vector equation $\vec{F} = m\vec{a}$ together with the scalar equation of the moments $M = I\alpha$. In the particular case when a symmetric body is rotating around an axis that passes through its mass center — namely, centroidal rotation — the angular acceleration vector relates to the sum of moments by the equation $M = I\alpha$.

In general plane motion, the x and y components for the force vector, together with the moment equation, should be included in calculating the motion.

The **free-body diagram** is one of the essential tools for setting up the equations of motion that describe the kinetics of rigid bodies. It depicts the fundamental relation between the force vectors and the acceleration of a body by sketching the body together with all applied, reaction, and **D'Alembert force** and moment vectors drawn at the point where they are applied.

Systems of Rigid Bodies in Planar Motion

Free-body diagrams can be used to set up, and in some cases to solve, problems that involve several rigid bodies interconnected by elements forcing them to a prescribed motion — for example, a motion that follows a curve or a surface. Such elements, called *kinematical joints*, can be rigid links with negligible masses or wires in tension, such as the ones used in pulley systems.

For planar motion three equations of motion are obtained by writing down the x and y components of the forces and acceleration with the equation of moments and the angular acceleration.

For a rigid body moving under a constraint, the free-body diagram is supplemented by a *kinematical analysis*, which provides the tangential and normal component of the acceleration. Rolling of a disc on a surface, which is a noncentroidal rotation, is an example of a constrained plane motion that belongs to this class of problems. The rolling can be with no sliding, with impeding sliding, and with sliding. Rotation of a gear pair and a pulley also belong to this class of problems.

Rotation of a Three-Dimensional Body about a Fixed Axis

If several bodies each rotating in its own plane are connected by a rigid shaft then each will exert a D'Alembert force, $m\vec{a}$, on the shaft. Their combined effect will be a vector force and a couple equal to the inertia I of the body times the angular acceleration α .

If the body that rotates about a fixed axis is at rest and if the moments of the weights about the center of the rotating shaft are zero, we say that the system is *statically balanced*. When the body starts rotating, the moment due to D'Alembert forces, $m\vec{a}$, around the center of gravity of the system may not sum to zero; the system is *not dynamically balanced*. Rotating machinery strives to have its systems dynamically balanced to reduce the reaction forces at the bearings and consequently their wearing. Counterweights are added such that the total D'Alembert forces of the original bodies and the weights sum to zero.

In its most general case, the motion of a rigid body in space can be solved only through numerical integration, except for very few simple problems, such as *gyroscopic motion*.

Work and Energy

The **kinetic energy** of a particle in translation is a scalar quantity measured in joules or ft-lb and can be simply defined as $\frac{1}{2}mv^2$.

The infinitesimal element of work, Δw , is defined as the product of the projection of the force vector on the path s of the body and the infinitesimal length ds of that path: $(F \cos \beta) ds$, where β is the angle that the force vector makes with the path ds .

The principle of work and energy states that the energy of a body is equal to the sum, over a certain displacement path, of the work done by all external forces that acted on the body and caused that displacement plus any initial kinetic energy that the body had at the beginning of the path.

For bodies in pure rotation the work of a couple is the product of the couple and the infinitesimal angle moved due to that couple. The summation of the work over all the angular displacement caused by that couple is the rotational energy and is also defined as $\frac{1}{2}I\omega^2$, where ω is the angular velocity of the body.

The kinetic energy of a rigid body in general plane motion T is equal to the sum of kinetic energy in translation and the kinetic energy in rotation:

$$T = \frac{1}{2}(m\bar{v}^2 + \bar{I}\omega^2)$$

where \bar{v} is the velocity of the mass center G of the body and \bar{I} is the moment of inertia of the body about an axis through its mass center. This energy is identical to the kinetic rotational energy of the body if it is considered to be in pure rotation around its instantaneous center of rotation. In this case I would be the moment of inertia of the body around an axis that passes through the instantaneous center of rotation.

The principle of conservation of energy states that the sum of the potential and kinetic energy of a body acted upon by conservative forces — that is, nondissipative forces of friction or damping — remains constant during the time when these forces are applied.

Power is the product of the projection of the force vector on the velocity that resulted from this force. Power is measured in watt and horsepower units. The summation of power over a certain time interval is equal to the total energy stored in the body during that time.

Kinetics of Rigid Bodies in Plane Motion: Impulse and Momentum for a Rigid Body

The principle of impulse and momentum for a rigid body states that the momenta of all the particles of a rigid body at time t_1 , added to the impulses of external forces acting during the time interval from time t_1 to time t_2 , are equal to the system momenta at time t_2 .

Momentum of a Rigid Body in Plane Motion

Translation, Rotation, and General Motion

The momenta vector of a body in plane translation motion is the product of the mass and the velocity vector. For a rigid body in plane centroidal rotation, the linear momenta vector is equal to 0 since the mass center does not have any linear velocity. The sum of the couples of forces acting on the particle of that body gives the angular momentum, which is $H_G = \bar{I}\omega$.

In a general plane motion, the momentum is a vector with components along the x , y , and ω directions. The dynamic equations of motion of a rigid body in plane motion can be obtained from D'Alembert's principle as follows:

$$\begin{aligned}
\frac{dm\bar{v}_x}{dt} &= (F_1)_x + (F_2)_x + \dots \\
\frac{dm\bar{v}_y}{dt} &= (F_1)_y + (F_2)_y + \dots \\
\frac{dI\alpha}{dt} &= M_1 + M_2 + \dots + r_1 \times F_1 + r_2 \times F_2 + \dots
\end{aligned}
\tag{13.23}$$

For a system of rigid bodies, the linear momentum vector does not change in the absence of a resultant linear impulse. Similarly, the angular momentum vector does not change in the absence of an angular impulse.

Space Motion

The momentum vector of a rigid body moving in space has a linear component G and an angular component H . The linear component represents the D'Alembert principle as described by the following equations:

$$\begin{aligned}
\frac{dm\bar{v}_x}{dt} &= (F_1)_x + (F_2)_x + \dots \\
\frac{dm\bar{v}_y}{dt} &= (F_1)_y + (F_2)_y + \dots \\
\frac{dm\bar{v}_z}{dt} &= (F_1)_z + (F_2)_z + \dots
\end{aligned}
\tag{13.24}$$

where the velocity and the force vectors are expressed in their inertial $[X, Y, Z]$ components. If these vectors are expressed in a body-fixed coordinate system, the time derivative should include the effect of the rotation vector, as in the case of the angular momentum. The angular momentum vector H is defined as follows:

$$\vec{H} = I\vec{\omega}
\tag{13.25}$$

where H and ω are expressed by their components in the body coordinate $[x, y, z]$. When a vector is expressed in a body coordinate, its time derivative should include the effect of angular rotation. For this reason — and because normally the position vector of the point of application of a force F_i from a center of rotation A , denoted by $\vec{r}_{Bi/A}$, is known by its components in a body coordinate system — the equation stating that the time rate of change of the angular momentum is equal to the sum of the moments would be written as follows:

$$\frac{dI\omega}{dt} + \omega \times I\omega = T_{z,y,x}^T M_1 + T_{z,y,x}^T M_2 + \dots + r'_{B1/A} \times T_{z,y,x}^T F_1 + r'_{B2/A} \times T_{z,y,x}^T F_2 + \dots
\tag{13.26}$$

where I is the matrix of inertia relative to a coordinate system fixed in the body and moving with it and the center of the coordinate system is located at point A . The forces and the moments are assumed to be known by their components in an inertial fixed coordinate system, and ω is the angular velocity of the body given by its components in the body-fixed coordinates.

If the body-fixed coordinate system is chosen along the principal axis of the body, then the term $\omega \times I\omega$ can be written in matrix form as follows:

$$\omega \times I\omega = \begin{bmatrix} 0 & -\omega_z & \omega_y \\ \omega_z & 0 & -\omega_x \\ -\omega_y & \omega_x & 0 \end{bmatrix} \begin{bmatrix} I_{xx} & 0 & 0 \\ 0 & I_{yy} & 0 \\ 0 & 0 & I_{zz} \end{bmatrix} \begin{bmatrix} \omega_x \\ \omega_y \\ \omega_z \end{bmatrix} = - \begin{bmatrix} (I_{yy} - I_{zz})\omega_y\omega_z \\ (I_{zz} - I_{xx})\omega_z\omega_x \\ (I_{xx} - I_{yy})\omega_x\omega_y \end{bmatrix}$$

and the equation of motion can be reduced to the Euler's equations as follows:

$$\begin{aligned} I_{xx}\dot{\omega}_x &= (I_{yy} - I_{zz})\omega_y\omega_z + \sum M_x \\ I_{yy}\dot{\omega}_y &= (I_{zz} - I_{xx})\omega_z\omega_x + \sum M_y \\ I_{zz}\dot{\omega}_z &= (I_{xx} - I_{yy})\omega_x\omega_y + \sum M_z \end{aligned} \quad (13.27)$$

In general, Equation (13.25) and Equation (13.26) are solved by numerical integration, except for the cases where they are simplified, for example in gyroscopic motion. The Euler angles used in the transformation matrix T are obtained from the numerical integration of Equation (13.20).

Impulsive Motion and Eccentric Impact

The principle of conservation of momentum is useful in solving the problem of impacting bodies. If the colliding of two bodies is such that the collision point is on a line that joins their mass centers, then the collision is centroidal, the two bodies can be considered particles, and impulsive motion of particle dynamics can be used.

If the collision is noncentroidal, rotational motion will occur. In this case the projection of the velocity differential of the bodies' point of contact on the line normal to the contact surface after collision is equal to the same projection of the differential velocity prior to collision times the coefficient of restitution. This vector relation can be used to find the velocity after impact.

Rotation Around a Fixed Point and Gyroscopic Motion

When a rigid body spins at a rate ω about its axis of symmetry and is subjected to a couple of moment M about an axis perpendicular to the spin axis, then the body will precess at a rate Ω about an axis that is perpendicular to both the spin and the couple axis. The rate of precession Ω is equal to $M = \bar{I}\omega\Omega$.

A well-known example of gyroscopic motion is the motion of a top (see [Figure 13.7](#)), in which the couple moment M — due to gravity — is expected to force the top to fall. However, the top does not fall and rather precesses around the y axis.

Defining Terms

Acceleration — The rate of change of the velocity vector. Absolute acceleration of a rigid body is the rate of change of the velocity vector of the mass center of the body. Relative acceleration is the acceleration of a point on a body due to the angular velocity of that body only.

D'Alembert forces — Force and moment vectors due to the linear and angular accelerations of the body.

Free-body diagram — An essential sketch used to solve kinetics problems that involves sketching the rigid body together with all internal, reaction, and external force vectors.

Gyroscopic motion — Describes the motion of a rigid body that is spinning with a very large angular velocity around one axis when the couple of a moment is applied on the second axis. The resultant motion, called *precession*, is an angular velocity around the third axis.

Kinematic analysis — Starts from the geometry of constraints and uses differentiation to find the velocity and acceleration of the constrained points on a rigid body.

Kinetic energy — The accumulation of work of forces on a rigid body between two instants of time; includes kinetic energy due to translation and kinetic energy due to rotation.

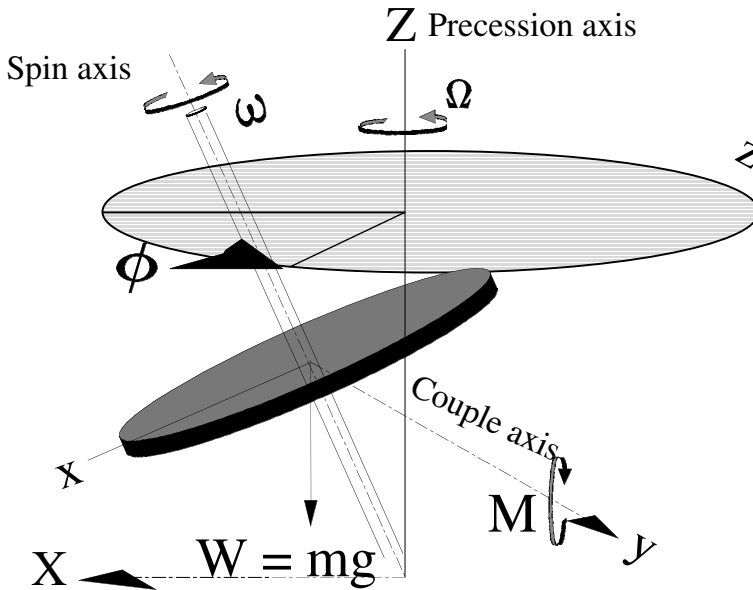

FIGURE 13.7 Gyroscopic motion.

Rotation — Centroidal rotation is the motion of a rigid body around an axis that passes through its mass center. In noncentroidal rotation the body rotates around an axis that passes through a point not corresponding to its mass center and which may not be on the body; this point is called the instantaneous center of rotation.

Translation — Rectilinear translation occurs when the velocities of any two points on the body remain equal in direction and magnitude throughout the entire duration of the motion. Curvilinear translation occurs when the velocity vectors of any two points are equal at any instant of time but change from one instant to another.

Velocity — Absolute velocity is the rate of change of the position vector of a point on a body measured from a fixed reference coordinate. Relative velocity is the rate of change of the position vector of a point on a rigid body measured from a moving reference frame.

14.1 Basic Principles

In its simplest form, mechanical vibration is the process of a mass traveling back and forth through its position of static equilibrium under the action of a *restoring force* or *moment* that tends to return the mass to its equilibrium position. The most common restoring mechanism is a spring or elastic member that exerts a force proportional to the displacement of the mass. Gravity may also provide the restoring action, as in the case of a pendulum. The restoring mechanism of structural members is provided by the elasticity of the material of which the member is made. **Free vibration** is a condition in which there are no external forces on the system.

Cyclic or *periodic* motion in time is described by the property $x(t + \tau) = x(t)$, where t is time and τ is the *period*, that is, the time to complete one cycle of motion. The **cyclic frequency** of the motion is $f = 1/\tau$, usually measured in cycles per second (Hz). The special case of periodic motion shown in [Figure 14.1](#) is *harmonic motion*,

$$x(t) = A \sin(\omega t) + B \cos(\omega t) \quad (14.1a)$$

$$= X \sin(\omega t + \phi) \quad (14.1b)$$

where $\omega = 2\pi f$ is the **circular frequency**, typically measured in radians (rad)/sec, $X = (A^2 + B^2)^{1/2}$ is the *amplitude* of the motion, and $\phi = \tan^{-1}(B/A)$ is the *phase angle*. Many systems exhibit harmonic motion when in free vibration but do so only at discrete **natural frequencies**. A vibrating system with n **degrees of freedom** (DOF) has n natural frequencies, and for each natural frequency there is a relationship between the amplitudes of the n independent motions, known as the **mode shape**. A structural elastic member has an infinite number of discrete natural frequencies and corresponding mode shapes. The **fundamental frequency** and associated mode shape refer to the smallest natural frequency and associated

FIGURE 14.1 Time history of undamped periodic or cyclic motion.

mode shape. The study of free vibrations consists of the determination of the natural frequencies and mode shapes of a vibrating system as a function of geometry, boundary conditions, mass (density) of the components, and the strength of the restoring forces or moments. Although the natural frequencies and mode shapes are valuable to know by themselves, they have perhaps their greatest value in the analysis of forced vibrations, as discussed in detail in the following chapter.

14.2 Single-Degree-of-Freedom Systems

Equation of Motion and Fundamental Frequency

The system shown in Figure 14.2(a) consists of a mass, m , that rolls smoothly on a rigid floor and is attached to a linear spring of stiffness k . Throughout this chapter all linear (or longitudinal) springs have stiffnesses of dimension force per unit change in length from equilibrium, and all rotational (or torsional) springs have stiffnesses of dimension moment per radian of rotation from equilibrium (i.e., force times length). The distance of the mass from its equilibrium position, defined by zero stretch in the spring, is denoted by x . Applying Newton's second law to the mass in Figure 14.3(a) gives the equation of motion:

$$-kx = m \frac{d^2x}{dt^2} \Rightarrow m \frac{d^2x}{dt^2} + kx = 0 \quad (14.2)$$

Alternatively, Lagrange's equation (with only one generalized coordinate, x) may be used to find the equation of motion:

$$\frac{d}{dt} \left(\frac{\partial L}{\partial (dx/dt)} \right) - \frac{\partial L}{\partial x} = 0 \quad (14.3)$$

The Lagrangian, L , is the difference between the *kinetic energy*, T , and the *potential energy*, U , of the system. The Lagrangian for the system in Figure 14.2(a) is

$$L \equiv T - U = \frac{1}{2} m \left(\frac{dx}{dt} \right)^2 - \frac{1}{2} kx^2 \quad (14.4)$$

FIGURE 14.2 Typical one-degree-of-freedom system: (a) without damping, (b) with viscous damping, and (c) with frictional damping.

FIGURE 14.3 Free-body diagrams of the single-degree-of-freedom systems in Figure 14.2.

Substituting Equation (14.4) into Equation (14.3) gives the same equation of motion as in Equation (14.2). Using the harmonic form in Equation (14.1) for x , Equation (14.2) is satisfied if ω takes on the value

$$\omega = \sqrt{k/m} \quad (14.5)$$

which is therefore the natural frequency of the system. If the displacement and velocity are known at some time (say, $t = 0$), then the constants in Equation (14.1) may also be evaluated,

$$A = \frac{1}{\omega_0} \frac{dx}{dt}(0); \quad B = x(0) \quad (14.6)$$

and the corresponding displacement history is shown in Figure 14.1.

The natural frequency for conservative systems can also be found by the *energy method*. As the mass passes through equilibrium, $U = 0$ and $T = T_{\max}$, while at its maximum displacement where the mass has zero velocity, $T = 0$ and $U = U_{\max}$. Since the total energy is constant, ω is the frequency for which $T_{\max} = U_{\max}$. Using Equation (14.1a) and the system in Figure 14.2(a), this principle gives

$$T_{\max} = \frac{1}{2} m(\omega X)^2 = \frac{1}{2} kX^2 = U_{\max} \quad (14.7)$$

which in turn gives the same result for ω as in Equation (14.5).

Table 14.1 contains the equation of motion and natural frequency for some single-DOF systems. Gravity acts down, and displacements or rotations are with respect to static equilibrium. The mode shapes are of the form in Equation (14.1) with ω given in Table 14.1.

Linear Damping

Figure 14.2(b) and Figure 14.3(b) show an example of viscous damping caused by a dashpot of strength c (force per unit velocity) that acts opposite the velocity. Newton's second law then gives

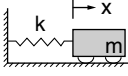

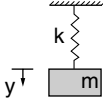

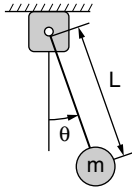

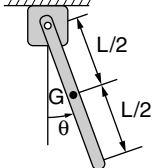

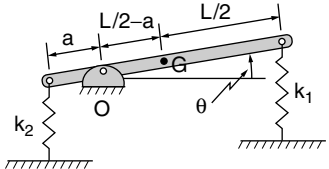

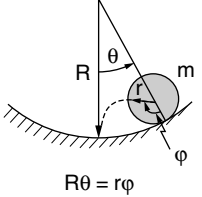

$$-kx - c \frac{dx}{dt} = m \frac{d^2x}{dt^2} \Rightarrow m \frac{d^2x}{dt^2} + c \frac{dx}{dt} + kx = 0 \quad (14.8)$$

which has the solution

$$\begin{aligned} x(t) &= e^{-\zeta\omega_0 t} [A \sin(\omega_d t) + B \cos(\omega_d t)] \\ &= X e^{-\zeta\omega_0 t} \sin(\omega_d t + \phi) \end{aligned} \quad (14.9)$$

where the *damped natural frequency*, ω_d , *damping factor*, ζ , and *critical damping coefficient*, c_c , are given by

TABLE 14.1 Equations of Motion and Natural Frequencies for some Single-DOF Systems

| System | Equation of Motion | Natural Frequency |
|--|---|---|
|  | $m \frac{d^2x}{dt^2} + kx = 0$ | $\sqrt{\frac{k}{m}}$ |
|  | $m \frac{d^2y}{dt^2} + ky = 0$ | $\sqrt{\frac{k}{m}}$ |
|  | $(mL^2) \frac{d^2\theta}{dt^2} + (mgL)\theta = 0$ | $\sqrt{\frac{g}{L}}$ |
|  <p>bar has mass m, center of gravity G</p> | $\left(\frac{1}{2} mL^2\right) \frac{d^2\theta}{dt^2} + \left(mg \frac{L}{2}\right)\theta = 0$ | $\sqrt{\frac{3}{2} \frac{g}{L}}$ |
|  | $I_0 \frac{d^2\theta}{dt^2} + [k_1 a^2 + k_2 (L-a)^2]\theta = 0$ $I_0 = \frac{1}{12} mL^2 + m \left(\frac{L}{2} - a\right)^2$ | $\sqrt{\frac{k_1 a^2 + \left(\frac{k_2}{k_1}\right)^2 (L-a)^2}{m \left[\frac{1}{3} L^2 - aL + a^2\right]}}$ |
|  <p>$R\theta = r\phi$</p> | $\frac{3}{2} mr^2 \left(\frac{R}{r} - 1\right) \frac{d^2\theta}{dt^2} + (mgr)\theta = 0$ <p>$r = \text{radius of mass } m$</p> | $\sqrt{\frac{2}{3} \frac{g}{(R-r)}}$ |

$$\omega_d \equiv \omega \sqrt{1 - \zeta^2}; \quad \zeta \equiv \frac{c}{c_c}; \quad c_c \equiv 2m\omega = 2\sqrt{mk} \quad (14.10)$$

respectively. If $c < c_c$, then ω_d is real and Equation (14.9) represents exponentially damped oscillation, as shown in Figure 14.4. If $c \geq c_c$, then the system is *supercritically damped* and decaying motion but no vibration occurs.

The frictional effects in Figure 14.2(c) and Figure 14.3(c) are characterized by a Coulomb frictional force $F = \mu N = \mu mg$, where μ is the coefficient of sliding friction. The equation of motion is then

FIGURE 14.4 Time history of viscously damped vibration.

FIGURE 14.5 Time history of frictionally damped vibration.

$$m \frac{d^2 x}{dt^2} + (\mu mg) \operatorname{sgn} \left(\frac{dx}{dt} \right) + kx = 0 \quad (14.11)$$

where $\operatorname{sgn}(dx/dt)$ is equal to +1 or -1 for positive or negative values of dx/dt , respectively. This equation must be solved separately for each n th half period of the oscillation of frequency, ω ,

$$x(t) = [x_0 - (2n-1)\gamma] \cos(\omega t) - \operatorname{sgn} \left(\frac{dx}{dt} \right) \gamma \quad (14.12)$$

where $\gamma = (\mu mg/k)$ is the minimum initial displacement to allow motion, and ω is the undamped natural frequency, Equation (14.5). Figure 14.5 shows $x(t)$ for an initial displacement of $x_0 = 20\gamma$.

14.3 Multiple-Degree-of-Freedom Systems

For each DOF in an n -DOF system there is a *coordinate*, $x_i (i = 1, 2, \dots, n)$, which is a measure of one of the independent components of motion. The motion of the system is governed by n , generally coupled, equations of motion, which may be obtained by a Newtonian approach requiring complete free-body and acceleration diagrams for each mass. For systems with many DOFs, this approach becomes very tedious. Alternatively, applying Lagrange's equations, with no damping present,

$$\frac{d}{dt} \left(\frac{\partial L}{\partial \dot{x}_i} \right) - \frac{\partial L}{\partial x_i} = 0, \quad (i = 1, 2, \dots, n) \quad (14.13)$$

to the particular system yields the n equations of motion in the n unknown coordinates x_i ,

$$[M] \left\{ \frac{d^2 x}{dt^2} \right\} + [K] \{x\} = \{0\} \quad (14.14)$$

As stated before, the Lagrangian, $L = T - U$, is the difference between the kinetic and potential energies of the system. $[M]$ and $[K]$ are the $n \times n$ *mass* and *stiffness matrices*, with elements m_{ij} and k_{ij} , which multiply the acceleration and displacement vectors of the masses, respectively. Writing x_i in the form of Equation (14.1), Equation (14.14) yields n homogeneous equations, $[A] \{X\} = \{0\}$, in the n amplitudes X_i . The elements of $[A]$ are $a_{ij} = k_{ij} - m_{ij} \omega^2$. If a solution exists, the determinant of $[A]$, an n th order polynomial in ω^2 , must be zero. This yields the *frequency* or *characteristic equation*, whose n roots are the natural frequencies squared, $(\omega_i)^2$. Each mode shape may be written as a vector of $n - 1$ amplitude ratios:

$$\left\{ \frac{X_2}{X_1}, \frac{X_3}{X_1}, \dots, \frac{X_n}{X_1} \right\}_{(i)}, \quad (i = 1, 2, \dots, n) \quad (14.15)$$

The ratios are found by eliminating one equation of $[A]\{X\} = \{0\}$, dividing the remaining $n - 1$ equations by X_1 , and solving. Then setting $\omega = \omega_i$ gives the i th mode shape. Equations of motion, natural frequencies, and mode shapes for some two-DOF systems undergoing small amplitude vibrations are in [Table 14.2](#). Gravity acts down, and displacements and rotations are taken with respect to the position of static equilibrium.

14.4 Continuous Systems (Infinite DOF)

The equations of motion of structural members made up of continuously distributed elastic or flexible materials are most easily obtained by a Newtonian analysis of a representative volume element. As an example, consider the longitudinal vibration of an elastic rod (Young's modulus E , density ρ) of cross-sectional area A . A free-body diagram of a volume element $A \, dx$, with normal stresses $[\sigma_x](x)$ and $[\sigma_x + (\partial\sigma_x/\partial x)dx](x)$ acting on the cross-sections is shown in [Figure 14.6\(a\)](#). A circular section is shown but the analysis applies to any shape of cross-section. If $u(x)$ is the displacement in the x direction of the cross-section at x , then Newton's second law gives

$$-\sigma_x A + \left(\sigma_x + \frac{\partial\sigma_x}{\partial x} dx \right) A = (\rho A dx) \frac{\partial^2 u}{\partial t^2} \quad (14.16)$$

Simplifying, letting dx go to zero, and noting uniaxial Hooke's law and the definition of the strain, ϵ_x ,

$$\sigma_x = E\epsilon_x = E \frac{\partial u}{\partial x} \quad (14.17)$$

Equation (14.16) can be written as

$$\frac{\partial^2 u}{\partial x^2} = \left(\frac{\rho}{E} \right) \frac{\partial^2 u}{\partial t^2} \quad (14.18)$$

which is the equation of motion for standing modes of free vibration and for wave propagation along the rod at velocity $c = \sqrt{E/\rho}$. If $u(x, t) = U(x)[A \sin(\omega t) + B \cos(\omega t)]$, then Equation (14.18) gives

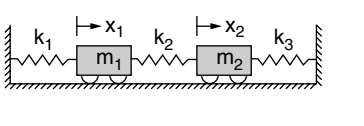

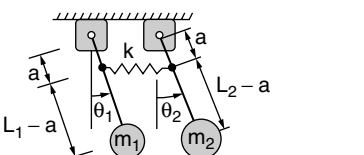

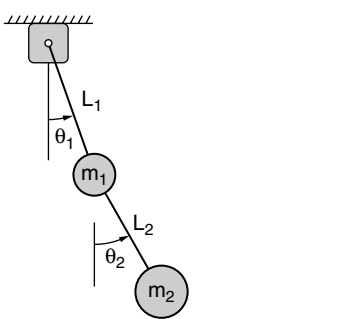

$$\frac{d^2 U}{dx^2} - \lambda^2 U = 0, \quad \lambda^2 = \frac{\rho \omega^2}{E} \quad (14.19)$$

which has solution $U(x) = C \sin(\lambda x) + D \cos(\lambda x)$. Now as an example, consider the fixed-fixed bar of length L shown in [Figure 14.6\(b\)](#) that has boundary conditions (BCs) $U(0) = 0$ and $U(L) = 0$, which give, respectively, $D = 0$ and either $C = 0$, which is not of interest, or

$$\sin(\lambda L) = 0 \Rightarrow \lambda = \lambda_n = \frac{n\pi}{L} \Rightarrow \omega_n = \frac{n\pi}{L} \sqrt{\frac{E}{\rho}} \quad (n = 1, 2, 3, \dots) \quad (14.20)$$

This is the frequency equation and the resulting infinite set of discrete natural frequencies for the fixed-fixed beam of length L . The mode shapes are $U_n(x) = \sin(\lambda_n x)$.

TABLE 14.2 Equations of Motion, Natural Frequencies, and Mode Shapes for some Two-DOF Systems

| Symbol | Equation of Motion | Natural Frequencies and Mode Shapes |

FIGURE 14.6 Longitudinal vibration of a rod of circular cross-section: (a) free-body diagram of representative volume element and (b) a clamped-clamped rod of length L .

The transverse motion $y(x, t)$ of a taut flexible string (tension T and mass per unit length ρ), the longitudinal motion $u(x, t)$ of a rod (Young's modulus E), and the torsional rotation $\phi(x, t)$ of a rod of circular or annular cross-section (shear modulus G) all share the same governing equations — Equation (14.18) and Equation (14.19) — but with different λ values: $\lambda^2 = \rho\omega^2/T$, $\rho\omega^2/E$, and $\rho\omega^2/G$, respectively. Table 14.3 and Table 14.4 contain frequency equations, nondimensional natural frequencies, and mode shapes for various combinations of BCs for a rod of length L . Only the fixed-fixed conditions apply to the string.

TABLE 14.3 Longitudinal and Torsional Vibration of a Rod

| System | Frequency Equation | Natural Frequencies | Normalized Mode Shape |
|--------|---|---------------------------------|------------------------------|
| | $\sin(\lambda_n L) = 0$ | $(\lambda_n L) = n\pi$ | $U_n(x) = \sin(\lambda_n x)$ |
| | $\sin(\lambda_n L) = 0$ | $(\lambda_n L) = (2n - 1)\pi/2$ | $U_n(x) = \sin(\lambda_n x)$ |
| | $\tan(\lambda_n L) = -\gamma(\lambda_n L)^1$ | See Table 14.4 | $U_n(x) = \sin(\lambda_n x)$ |
| | $(\lambda_n L) \tan(\lambda_n L) = \gamma^2$ | See Table 14.4 | $U_n(x) = \sin(\lambda_n x)$ |
| | $\sin(\lambda_n L) = 0$ | $(\lambda_n L) = n\pi$ | $U_n(x) = \cos(\lambda_n x)$ |
| | $(\lambda_n L) \tan(\lambda_n L) = -\gamma^3$ | See Table 14.4 | $U_n(x) = \cos(\lambda_n x)$ |
| | $\tan(\lambda_n L) = -\gamma(\lambda_n L)^4$ | See Table 14.4 | $U_n(x) = \cos(\lambda_n x)$ |

$$^1 \gamma_{\text{long}} = \frac{AE}{kL}; \quad \gamma_{\text{tor}} = \frac{I_p G}{kL}$$

$$^2 \gamma_{\text{long}} = \frac{\rho AL}{m}; \quad \gamma_{\text{tor}} = \frac{I_p \rho L}{I_0}$$

$$^3 \gamma_{\text{long}} = \frac{kL}{AE}; \quad \gamma_{\text{tor}} = \frac{kL}{I_p G}$$

$$^4 \gamma_{\text{long}} = \frac{m}{\rho AL}; \quad \gamma_{\text{tor}} = \frac{I_0}{I_p \rho L}$$

Note: “long” denotes longitudinal vibration and “tor” denotes torsional vibration; A = cross-sectional area, L = rod length, E = Young's modulus, G = shear modulus, k = force per length (long) or moment per radian (tor), ρ = mass per unit volume, I_p = polar moment of inertia of A about rod axis, I_0 = mass moment of inertia of attached mass; the definition of λ_n is in the text.

^d See Table 14.3, case 3.

The transverse deflection of a beam, $w(x, t)$, is governed by the equation of motion,

$$\frac{\partial^4 w}{\partial x^4} = \left(\frac{\rho A}{EI} \right) \frac{\partial^2 w}{\partial t^2} \quad (14.21)$$

which, upon substitution of $w(x, t) = W(x)[A \sin(\omega t) + B \cos(\omega t)]$, leads to

$$\frac{d^4 W}{dx^4} - \lambda^4 W = 0, \quad \lambda^4 = \frac{\rho A \omega^2}{EI} \quad (14.22)$$

This equation has the general solution $W(x) = c_1 \sin(\lambda x) + c_2 \cos(\lambda x) + c_3 \sinh(\lambda x) + c_4 \cosh(\lambda x)$. The frequency equation, natural frequencies, and normalized mode shapes are found by applying the BCs in the same manner as above. The results for various combinations of simply supported (SS: $W = W'' = 0$), clamped (C: $W = W' = 0$), and free (F: $W''' = W'''' = 0$) BCs for a beam of length L and flexural rigidity EI are given in Table 14.5.

Defining Terms

Cyclic and circular frequency — The cyclic frequency of any cyclic or periodic motion is the number of cycles of motion per second. One cycle per second is called a hertz (Hz). The circular frequency of the motion is 2π times the cyclic frequency and converts one cycle of motion into 2π radians of angular motion. The circular frequency is measured in radians per second.

Degree of freedom (DOF) — An independent motion of a moving system. A single mass rolling on a surface has one DOF, a system of two masses rolling on a surface has two DOFs, and a continuous elastic structure has an infinite number of DOFs.

Free vibration — The act of a system of masses or a structure vibrating back and forth about its position of static equilibrium in the absence of any external forces. The vibration is caused by the action of restoring forces internal to the system or by gravity.

TABLE 14.5 Transverse Vibrations of a Beam

| BCs | Frequency Equation | β_1 | β_2 | Asymptotic to | Normalized Mode Shape |
|-------|--------------------------------|-----------|-----------|---------------|---|
| C-F | $1 + \cos\beta \cosh\beta = 0$ | 1.875 | 4.694 | $(2n+1)\pi/2$ | $(\cosh\lambda_n x - \cos\lambda_n x) - \gamma_n(\sinh\lambda_n x - \sin\lambda_n x), \quad \gamma_n = \frac{\cosh\beta_n + \cos\beta}{\sinh\beta_n + \sin\beta}$ |

| F-F | $1 - \cos\beta \cosh\beta = 0$ | 4.730 | 7.853 | $(2n+1)\pi/2$ | $(\cosh\lambda_n + \cos\lambda_n x) - \gamma_n(\sinh\lambda_n x + \sin\lambda_n x), \quad \gamma_n = \frac{\sinh\beta_n + \sin\beta}{\cosh\beta_n - \cos\beta}$ |

SS: 

F: 

C: 

Fundamental frequency — The smallest natural frequency in a system with more than one DOF.

Mode shape — The relationship between the amplitudes (one per DOF) of the independent motions of a system in free vibration. There is one mode shape for each natural frequency, and it depends on the value of that natural frequency. For a continuous elastic structure, the mode shapes are the shapes of the structure at its maximum deformation during a cycle of vibration.

Natural frequency — The frequency or frequencies at which a system will undergo free vibration. There is one natural frequency per DOF of the system. Natural frequencies depend on the geometry, the boundary conditions (method of support or attachment), the masses of the components, and the strength of the restoring forces or moments.

Further Information

Several excellent texts discuss the free vibrations of discrete systems (finite number of DOFs). In particular, the books by Den Hartog [1956], Timoshenko et al. [1974], and Thomson [1988] are recommended.

Extensive data for the natural frequencies of beams that have elastic supports (translational or rotational), end masses, multiple spans, discontinuities in cross-sections, axial tension or compression, variable thickness, or elastic foundations may be found in the monograph by Gorman.

Other important structural elements are plates and shells. Plates are flat, whereas shells have curvature (e.g., circular cylindrical, elliptic cylindrical, conical, spherical, ellipsoidal, hyperboloidal). A summary of natural frequencies for plates obtained from 500 other references is available in the book on plate vibrations by Leissa [1993a]. Extensive frequency data for various shells taken from 1000 references is also available in the book on shell vibrations by Leissa [1993b].

15.1 Single-Degree-of-Freedom Systems
15.2 Multiple-Degree-of-Freedom Systems

Consider a mechanical system that is subjected to external forces (or moments) that are periodic in time. The forces may arise in various ways. For example, forces may be applied directly to the system (mechanical connections, fluid pressure, electromechanical), or indirectly through a foundation (which may be represented by springs and dampers). Such exciting forces always occur in rotating bodies (e.g., electric motors, internal combustion engines, gas turbines), but can also have other sources (e.g., earthquake motions, wind gusts, acoustic excitations).

The frequency (Ω) of an exciting force is typically different from the natural frequencies ($\omega_1, \omega_2, \omega_3, \dots$) of the system. However, if Ω is close to *any* of the natural frequencies, the amplitude of the resulting motion may be very large. If Ω *equals* one of the ω_i , **resonance** exists. In this situation, if no damping were present, the amplitude would grow with time until the system failed due to excessive motion or stress. All physical systems have at least some damping, but the damping may be very small. In this situation, the amplitude of motion at resonance would remain finite, but could become very large — even excessive. When a system is excited, the responsive displacements are a combination (superposition) of all the mode shapes of free vibration. However, if Ω is close to one of the ω_i , the response is dominated by the mode shape corresponding to the ω_i .

The most important reason to know the natural frequencies of free vibration is to avoid resonant situations. One seeks to change the mass or stiffness of the system to shift the natural frequencies away from the exciting frequencies. In typical situations, the largest resonant amplitudes occur at the lowest natural frequencies. Therefore, it is particularly important to know the smallest ω_i . Free vibration mode shapes are also important because they enable one to determine *how* the system vibrates at or near resonance.

15.1 Single-Degree-of-Freedom Systems

Take the spring-mass system shown in [Figure 14.2\(a\)](#) of [Chapter 14](#) and add a horizontal exciting force $F_o \sin \Omega t$ to the mass, where Ω is the *exciting frequency*. From the free-body diagram of [Figure 14.3\(a\)](#), the equation of motion is

$$m\ddot{x} + kx = F_o \sin \Omega t \quad (15.1)$$

The solution of Equation (15.1) consists of the sum of two parts. One part is the *complementary* solution obtained by setting $F_o = 0$. This is the free, undamped vibration discussed in [Chapter 14](#). The second part is the *particular* solution, due to $F_o \sin \Omega t$. This is

$$x = \frac{F_o/k}{1 - (\Omega/\omega)^2} \sin \Omega t \quad (15.2)$$

where $\omega = \sqrt{k/m}$ is the *natural frequency*. Observing the amplitude of this motion in Equation (15.2), one sees that if excitation begins with a small frequency ($\Omega/\omega \ll 1$) and increases, the amplitude grows until, at $\Omega/\omega = 1$, it becomes (theoretically) infinite. This is resonance. As Ω/ω increases further, the amplitude diminishes. For large Ω/ω , it becomes very small.

If viscous damping is present, as represented in Figure 14.2(b) of Chapter 14, the equation of motion is

$$m\ddot{x} + c\dot{x} + kx = F_o \sin \Omega t \quad (15.3)$$

Again the solution has two parts, one part being the free, damped vibration, and the other part being the forced motion. The free vibration part is given by Equation (14.9) of Chapter 14. It decays with increasing time and eventually vanishes (i.e., it is *transient*). The forced vibration part is

$$x = A \sin \Omega t - B \cos \Omega t = C \sin(\Omega t - \phi) \quad (15.4a)$$

$$C = \sqrt{A^2 + B^2}, \quad \phi = \tan^{-1}(B/A) \quad (15.4b)$$

$$C = \frac{F_o/k}{[1 - (\Omega/\omega)^2]^2 + [2\zeta(\Omega/\omega)]^2} \quad (15.4c)$$

where $\zeta = c/c_c$, $c_c = 2\sqrt{mk}$ as in Chapter 14. This forced vibration is called the **steady state** vibration because it remains indefinitely, even after the transient free vibration vanishes.

A graph of steady state amplitude versus forcing frequency is shown in Figure 15.1. This graph is worthy of considerable study because it shows clearly what vibratory amplitudes exist at different forcing frequencies. The *non-dimensional amplitude* C/δ_{st} is used, where $\delta_{st} = F_o/k$ is the **static deflection** that the mass would have if F_o were applied. For small Ω/ω , Figure 15.1 shows that $C/\delta_{st} = 1$, regardless of the damping. The case discussed earlier with *no damping* ($\zeta = 0$) is shown, although C/δ_{st} is plotted positive for $\Omega/\omega > 1$. It is positive for all nonzero ζ (and for all Ω/ω), no matter how small. For no damping, the infinite amplitude at resonance is implied in Figure 15.1. For small damping (e.g., $\zeta = 0.1$), the peak amplitude is several times the static deflection. If ζ were only 0.01, the peak amplitude would be 50 times the static deflection.

Figure 15.1 also shows the **phase angle**, ϕ ; that is, the angle by which the motion *lags* the exciting force. For small Ω/ω , it is seen that the motion is essentially **in-phase** (ϕ is nearly zero), whereas, for $\Omega/\omega \gg 1$, the motion is essentially **out-of-phase** (ϕ is nearly 180°). In the vicinity of resonance ($\Omega/\omega = 1$), ϕ changes rapidly as Ω is varied, especially if the damping is small.

Suppose that, instead of applying an exciting force $F_o \sin \Omega t$ directly to the mass in Figure 14.2(b) of Chapter 14, the wall (or foundation) on the left side is given the vibratory displacement $\delta_w \sin \Omega t$. This motion causes forces to be transmitted through the spring and damper to the mass. One finds that the equation of motion is again Equation (15.3), with F_o replaced by $k\delta$. Thus, Figure 15.1 again describes the steady state vibratory amplitude of the mass, except that δ_{st} is replaced by δ_w . Now consider the *relative* displacement $x_R = x - \delta_w \sin \Omega t$ between the mass and the wall. A free-body diagram yields the equation of motion:

$$m\ddot{x}_R + c\dot{x}_R + kx_R = m\Omega^2 \delta_w \sin \Omega t \quad (15.5)$$

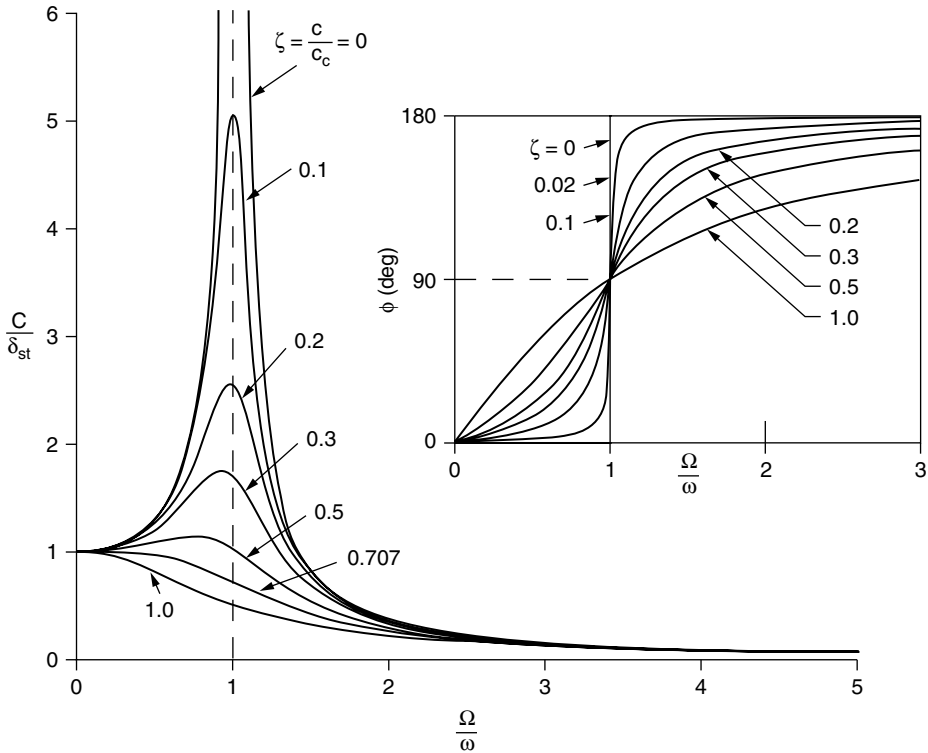

FIGURE 15.1 Displacement amplitude and phase angle resulting from an applied force versus exciting frequency for various amounts of damping (one DOF).

which has a steady state solution in the form of Equation (15.4a). The amplitude of the *relative* motion is found to be:

$$C_R = \frac{\delta_w (\Omega/\omega)^2}{[1 - (\Omega/\omega)^2]^2 + [2\zeta(\Omega/\omega)]^2} \quad (15.6)$$

A graph of the ratio of the amplitudes of relative displacement and wall displacement (C_R/δ_w) is shown in [Figure 15.2](#). The phase angle lag is the same as in Figure 15.1. In Figure 15.2, it is seen that at small excitation frequencies (Ω/ω almost zero), the relative displacement is nearly zero. But, at resonance ($\Omega/\omega = 1$), large relative motion may occur, especially for small damping (small ζ). For $\Omega/\omega \gg 1$, C_R/δ_w is nearly unity, and the relative motion is 180° out of phase. This means that although the wall is shaking at a high frequency, the mass barely moves at all. This behavior is important in design when isolation from ground vibration is desired.

Other types of damping will exist in a typical mechanical system. These include:

1. Dry friction (e.g., the mass slides on a floor against opposing frictional forces)
2. Structural (or material) damping (e.g., the spring material is not perfectly elastic, but dissipates energy during each cycle of vibratory motion)
3. Aerodynamic damping (e.g., the mass vibrates in air, instead of in a vacuum as the previously described models do)

These other forms of damping may be approximated by an **equivalent viscous damping** with reasonable accuracy for many of the vibratory characteristics.

FIGURE 15.2 Relative displacement resulting from foundation excitation (one DOF).

15.2 Multiple-Degree-of-Freedom Systems

The characteristics described above (vibratory displacement and phase angle) behave similarly for systems having two or more degrees of freedom (DOF). That is, with small damping in the vicinity of a resonant frequency, the steady state displacement amplitude is large and the phase angle changes rapidly with changing Ω . The primary difference is that, instead of having a single region of resonance, there are as many regions as there are DOF. A **continuous system** (e.g., string, rod, beam, membrane, plate, shell) has infinite DOF, with an infinite number of free vibration frequencies. Thus, with small damping, large amplitudes can occur in many ranges of exciting frequency for a given exciting force or moment. Fortunately, practical applications show that, typically, only the excitations near the lowest few natural frequencies are significant (although exceptions to this can be shown).

A *two-DOF system* is depicted in Figure 15.3. The two equal masses are separated by equal springs (stiffnesses k) and equal viscous dampers (damping coefficients c). A force $F_o \sin \Omega t$ is applied to one of the masses *only*. From free-body diagrams of each mass, one may obtain two differential equations of motion in the displacements x_1 and x_2 . The equations are coupled because of the spring and mass in the middle. Their steady state solution is found to be sinusoidal in time, with a common frequency Ω , but

FIGURE 15.3 Two-DOF mechanical system.

FIGURE 15.4 Displacement amplitude versus exciting frequency (two DOF).

different phase angles for each of the masses. A plot of the amplitude (C_1) for the vibratory displacement (x_1) of the mass to which the force is applied is seen in Figure 15.4 for damping ratios $\zeta = c/2\sqrt{mk} = 0, 0.1, 0.3,$ and 0.5 . With no damping, the amplitude is seen to become infinite at the two resonances ($\Omega/\omega_1=1$ and $\sqrt{3}=1.732$, where $\omega_1 = \sqrt{k/m}$ is the smallest *natural frequency* of the system). Interestingly, for $\zeta = 0$ and $\Omega/\omega_1 = \sqrt{2} = 1.414$, there is *no* motion of the mass to which the force is applied (although the other mass vibrates). This is an example of *vibration isolation*. By adding a second mass to a single-DOF system, the vibratory motion of the first mass may be eliminated at a certain exciting frequency. The added mass need not be equal. With small damping ($\zeta = 0.1$), a large amplitude is observed in Figure 15.4 at the first resonance, but a smaller one at the second resonance. For larger damping ($\zeta = 0.3$), the second resonant peak essentially vanishes.

As an example of a **continuous system**, consider a string (or wire) of length l stretched with a tensile force (T) between two rigid walls. It has uniform thickness and mass density (ρ , mass/length), and negligible bending stiffness. Let the string be subjected to a uniformly distributed loading (p , force/length) which varies sinusoidally in time ($p = p_o \sin \Omega t$), as shown in Figure 15.5. Considering only small amplitude transverse vibrations, the equation of motion is found to be a linear, second-order, *partial*

FIGURE 15.5 A string stretched between two walls (continuous system).

FIGURE 15.6 Displacement amplitude versus exciting frequency for the vibrating string.

differential equation. This may be solved exactly either in closed form or by taking the infinite sum of the displacement responses of the free vibration modes of the system (eigenfunction superposition). The amplitude of the transverse vibration of the center of the string (W_c) is observed in Figure 15.6. It is plotted in the nondimensional form W_c/δ_{st} , where δ_{st} would be the displacement if the pressure were static ($\delta_{st} = p_0 l^2 / 8T$). The abscissa is the frequency ratio (Ω/ω_1 , where ω_1 is the first natural frequency of the system). If there is no damping ($c = 0$), then infinite amplitudes (resonances) occur at the first, third, fifth, seventh, and so on natural frequencies. The natural frequencies are $\omega_m = m\pi/l$, where $m = 1, 2, 3, \dots$. The free vibration mode shapes are symmetric with respect to the center of the string for $m = 1, 3, 5, \dots$, and these are the modes that are excited by the symmetric loading. The antisymmetric modes ($m = 2, 4, 6, \dots$) are not excited by it. In the vicinity of each resonance, the mode shape (a sine function along the length) for that natural frequency dominates. Away from resonances (e.g., $\Omega/\omega_1 = 2$), all symmetric modes are present. The width of each region of resonance decreases as the order of natural frequencies increases. Thus, for example, if W_c/δ_{st} is to be less than 3, the range of unacceptable operating frequencies (Ω/ω_1) is seen to be much smaller at the second resonance than at the first, and smaller yet at the third resonance. For small, uniformly distributed, viscous damping (e.g., $c/c_c = 0.1$, where $c_c = 2\pi\sqrt{Tp/l^2}$ is the critical damping coefficient for the *first* mode), the amplitudes at the first three resonances are found to be $W_c/\delta_{st} = 5.18, 0.59$, and 0.21 .

Defining Terms

Continuous system — A system with continuously varying physical parameters (e.g., mass, stiffness, damping), having infinite degrees of freedom; as opposed to a discrete system, which has discontinuous parameters and finite degrees of freedom.

Equivalent viscous damping — Viscous damping which would yield a forced vibratory response the same as another form of damping.

In-phase — Vibratory displacement which follows in time an exciting force (or displacement).

Out-of-phase — Vibratory displacement which is opposite to the direction of excitation.

Phase angle — The angle in a cycle of motion by which a displacement lags behind the exciting force (or displacement).

Resonance — Large amplitude motion that occurs when a forcing frequency is in the vicinity of a natural frequency of a system.

Static deflection — The limiting case of a forced vibratory displacement, when the exciting frequency is very small, so that dynamic (inertia) effects are negligible.

Steady state — The vibratory motion that persists after the transient effects die away or are neglected.

University of Louisiana at Lafayette

The lumped, consistent, and distributed (or continuous) mass methods are the main methods for dynamics and vibration analyses of structures. In the continuous mass method the equations of motion are satisfied at every point of the structure. In the consistent and lumped mass methods they are satisfied only at the joints of the structures. In consistent mass the displacements within members are assumed as static displacements. The lumped mass method considers the members as massless springs. The lumped and consistent mass methods are simple and fast; they are fairly approximate, but their accuracy decreases for structures subjected to the effects of the shear and rotatory inertia, member axial force, elastic medium, and so on. The continuous mass method provides accurate results under the assumptions made.

16.1 Procedure of Analysis

For frames, the general formulation is based on the vector of displacement $\{a_o(y, t)\}$ at a time t and at a point y on the center line of its constitutive members. The same formulation is valid for the above mentioned three methods, only the vector of center line displacement $\{a_o(y, t)\}$ depends on the assumptions made for each method.

For materially and geometrically linear frames, the vector $\{a_o(y, t)\}$ is made of four independent components,

$$\{a_o(y, t)\}^T = [u(y, t) \ v(y, t) \ w(y, t) \ \vartheta(\rho_\Theta, t)] \quad (16.1)$$

where $u(y, t)$, $v(y, t)$, and $w(y, t)$ are the displacements along the member axes x , y , z ; $\vartheta(\rho_\Theta, t)$ is the twist rotation about the y axis, and $\rho_\Theta = (x^2 + y^2)^{1/2}$. It is assumed that the material properties are independent of time, and that the external disturbances applied to a structure are proportional to a same-time variable function. Thus, the displacement function $\{a_o(y, t)\}$ can be written in separable variable form. The integration of the differential equations and elimination of the integration constants gives

$$\{a_o(y, t)\} = [N(y)]\{d(t)\} = [N(y)]\{d\}f(t) \quad (16.2)$$

where $\{d(t)\} = \{d\}f(t)$, $[N(y)]$, and $\{d\}$ are time-independent matrix-of-shape functions and vector-of-member displacements, and $f(t)$ is a time-variable function of external disturbances. See [Figure 16.1](#).

The strains $\{\varepsilon\}$ at a point within the cross-section of a member can be obtained from the center line displacements $\{a_o(y, t)\}$ [Przemieniecki, 1968] as

$$\{\varepsilon\} = [\partial]\{a_o(y, t)\} = [B(y)]\{d\}f(t) \quad (16.3)$$

where $[B(y)] = [\partial][N(y)]$, and $[\partial]$ is the matrix of differential operators.

The stresses $\{\sigma\}$ are determined from the stress-strain relationship as

$$\{\sigma\} = [E]\{\varepsilon\} = [E][B(y)]\{d\}f(t) \quad (16.4)$$

The expressions of the **strain energy**, U_p , and **kinetic energy**, \mathcal{K} , as well as the work done by damping forces, W_D , and by externally applied loads, W_e , are written as

$$\begin{aligned} U_i &= \frac{1}{2} \int_v \{\varepsilon\}^T \{\sigma\} dV = \frac{1}{2} (f(t))^2 \{d\}^T \left(\int_v [B(y)]^T [E] [B(y)] dV \right) \{d\} \\ W_D &= - \int_v c \{\dot{a}_o\}^T \{a_o\} dV = -c \dot{f}(t) f(t) \{d\}^T \left(\int_v [N(y)]^T [N(y)] dV \right) \{d\} \\ \mathcal{K} &= \frac{1}{2} \int_v m \{\dot{a}_o\}^T \{\dot{a}_o\} dV = \frac{1}{2} (\dot{f}(t))^2 \{d\}^T \left(m \int_v [N(y)]^T [N(y)] dV \right) \{d\} \\ W_e &= f_e(t) \int_y \{P_o\}^T \{a_o\} dy = f_e(t) \left(\int_y \{P_o\}^T [N(y)] dy \right) \{d\} \end{aligned} \quad (16.5)$$

where $f_e(t)$ and $\{P_o\}$ are the time-dependent and -independent parts of the vector of externally applied joint forces.

For a member, stiffness $[k]$, mass $[m]$, and damping $[c]$ matrices are determined by substituting the strain energy U_p , **damping energy** W_D , kinetic energy \mathcal{K} , and **external energy** W_e into the Lagrangian dynamic equation [Ovunc, 1974],

$$\frac{\partial U_i}{\partial d_j} - \frac{\partial W_D}{\partial d_j} + \frac{d}{dt} \left(\frac{\partial \mathcal{K}}{\partial \dot{d}_j} \right) = \frac{\partial W_e}{\partial d_j} \quad (16.6)$$

which provides the equation of forced vibration for a member as

$$[k]\{d\}f(t) - 2v_o[m]\{d\}\dot{f}(t) + [m]\{d\}\ddot{f}(t) = \{P_o\}f_e(t) \quad (16.7)$$

where the damping matrix $[c]$ is assumed to be proportional to mass matrix $[m]$ and v_o is the damping coefficient.

FIGURE 16.1 Coordinate axes systems.

For the free vibration, $\{P\} = 0$, the equation of motion is divided into two parts — time-independent and time-dependent:

$$([k] - \omega^2[m])\{d\} = 0 \quad (16.8)$$

$$\frac{d^2 f(t)}{dt^2} + 2v\omega \frac{df(t)}{dt} + \omega^2 f(t) = 0 \quad (16.9)$$

The time-dependent part, $f(t)$, Equation (16.9), is the same for all four independent cases, and $v = v_o\omega$ [Paz, 1993].

Although the lumped mass method was developed long before the continuous mass method, the continuous mass method is herein explained first. The consistent and lumped mass methods are presented as particular cases of the continuous mass method.

16.2 Continuous Mass Matrix Method

For the materially and geometrically linear frame, an arbitrary vibration of its member is obtained by combining the four independent components: axial displacement, torsional rotation, and bending in two orthogonal planes.

Member under Axial Displacement

For members with constant section, the time-independent part of the differential equation of free vibration has been given [Ovunc, 1985]. (See Figure 16.2.)

$$\frac{d^2 Y(y)}{dy^2} + \alpha^2 Y(y) = 0 \quad (16.10)$$

where $\alpha^2 = (\omega^2 m - C_p p)/EA$; and where $m = (A\rho + q)/g$, p , and $cf.$ are the mass, the peripheral area, and the friction coefficient of the elastic medium per unit length of the member, respectively.

The time-dependent part, $f(t)$, is the same for all four independent cases.

FIGURE 16.2 Axial force member.

FIGURE 16.3 Bending member.

The time-independent part of axial displacement function $Y(y)$ is obtained by integrating Equation (16.10), through the elimination of the integration constants $\{C\}$, by the boundary conditions; thus one has

$$Y(y) = \{\phi_{ax}(y)\}^T [L]^{-1} \{d_{ax}\} = \{N_{ax}(y)\}^T \{d_{ax}\} \quad (16.11)$$

The nature of the shape function $\{N_{ax}(y)\}$ depends on the sign of parameter α^2 .

$$\{N_{ax}(y)\}^T = (1/\sin \alpha \ell) \{(\sin \alpha \ell \cos \alpha y - \cos \alpha \ell \sin \alpha y) \quad \sin \alpha y\} \text{ for } \alpha^2 > 0$$

$$\{N_{ax}(y)\}^T = (1/\sinh \alpha \ell) \{(\sinh \alpha \ell \cosh \alpha y - \cosh \alpha \ell \sinh \alpha y) \quad \sinh \alpha y\} \text{ for } \alpha^2 > 0$$

Member under Bending along Its Major Moment of Inertia Axes

For members with constant section, the time-independent part of the differential equation of free vibration (see Figure 16.3) has been given by Ovunc [1985] as

$$\frac{d^4 Z}{dy^4} + 2k^2 \frac{d^2 Z}{dy^2} - \beta^4 Z = 0 \quad (16.12)$$

where $2k^2 = P/EI$, $\beta^4 = (\omega^2 m - C_s P')/EI$; and where I , C_s , and where p' are the moment inertia of the cross-section, the subgrade coefficient of the elastic medium, and the projected area of the cross-section, respectively.

The shape function $\{N_{bd}(y)\}$ due to deflection,

$$Z(y) = \{\phi_{bd}(y)\}^T [L]^{-1} \{d_{bd}\} = \{N_{bd}(y)\}^T \{d_{bd}\} \quad (16.13)$$

is obtained in a similar manner as in the case of axial displacement, Equation (16.11). The nature of the shape function $\{N_{bd}(y)\}$ and its component $\{\phi_{bd}(y)\}^T$ depend on the parameters α_1^2 and α_2^2 , which are expressed in terms of k^2 and β^4 :

$$\alpha_1 = [(\beta^4 + k^4)^{1/2} + k^2]^{1/2}, \quad \alpha_2 = [(\beta^4 + k^4)^{1/2} - k^2]^{1/2}$$

Thus, for $\beta^4 > 0$ and $P > 0$ (compression is positive),

$$\{\phi_{bd}(y)\}^T = (\sin \alpha_1 y \cos \alpha_1 y \sinh \alpha_2 y \cosh \alpha_2 y) \quad (16.14)$$

The above expression remains the same when the axial force P is tension, except α_1 and α_2 must be interchanged. For the combination of $\beta^4 < 0$ and $P < 0$ or $P > 0$, the expression of $\{\phi_{bd}(y)\}$ can be determined in a similar manner.

The member stiffness matrices for the twist rotation and the bending in the Oxy plane are obtained by following similar steps as in the previous cases. The stiffness matrix for the space frame is determined by combining the stiffness matrices of all four independent cases.

Dynamic Member Stiffness Matrix for Plane and Space Frames

The dynamic member stiffness matrix $\{k_{dy}\}$ for either a plane frame or a space frame is obtained by substituting either the shape functions for axial displacement and bending in Oyz plane [Equation (16.11) and Equation (16.13)] or the shape functions of all the four independent cases, in the Lagrangian dynamic equation [Equation (16.6)]. Integrating [Equation (16.7)] one has

$$[k_{dyn}] = [k] - \omega^2[m] \quad (16.15)$$

The continuous mass method has also been extended to frames with tapered members [Ovunc, 1990].

16.3 Consistent Mass Matrix Method

In the consistent mass matrix method, the deformations within a member are static deformations. The shape function for each independent component $\{N(y)\}$ is a static displacement due to its corresponding independent cases. Thus, the shape functions for axial displacement, $\{N_{ax}(y)\}$, and for bending in the Oyz plane, $\{N_{bn}(y)\}$, are given as

$$\{N_{ax}(y)\}^T = ((1 - \eta) \eta) \quad (16.16)$$

$$\{N_{bn}(y)\}^T = ((1 - 3\eta^2 + 2\eta^3) (\eta - 2\eta^2 + \eta^3)\ell \quad (3\eta^2 - 2\eta^3) \quad (-\eta^2 + \eta^3)\ell) \quad (16.17)$$

where $\eta = y/\ell$. The shape functions for twist rotation and bending in the Oxy plane are obtained in similar manner.

The member stiffness $[k]$ and mass $[m]$ matrices are evaluated by substituting the shape functions in the Lagrangian dynamic equation [Equation (16.6)]. Herein, the stiffness matrix $[k]$ is a static stiffness matrix and the mass matrix $[m]$ is a full matrix [Przemieniecki, 1968; Paz, 1993].

Moreover, the member stiffness matrix $[k]$ and the mass matrix $[m]$ for the consistent mass matrix method can be obtained as the first three terms of the power series expansion of the dynamic member stiffness matrix $[k_{dyn}]$ for the continuous mass matrix [Paz, 1993].

16.4 Lumped Mass Matrix Method

The lumped mass method is obtained from the continuous mass matrix method by considering the limit when the mass of the members tends to zero. Thus, the shape functions [Equation (16.17)] and the member stiffness matrix $[k]$ are the same as in the consistent mass method. But the mass matrix $[m]$ is diagonal [Paz, 1993].

16.5 Free Vibration of Frames

The **stiffness coefficients** for the frames are evaluated from those of its members as

$$K_{i,j} = \sum k_{r,s}, \quad M_{i,j} = \sum m_{r,s}, \quad P_i = \sum P_r$$

where r and s are the member freedom numbers corresponding to the i and j of the structure freedoms.

The equation of free vibration is obtained from those of members [Equation (16.8)]

$$([K] - \omega^2[M])\{D\} = \{0\} \quad (16.18)$$

where $\{D\}$ is the vector of the structure displacements.

The natural circular frequencies, ω_n , and the corresponding modal shapes, $\{D_n\}$, are calculated from the equation of free vibration [Equation (16.18)], also called the *frequency equation*.

16.6 Forced Vibration

The second-order differential (n simultaneous equations with n unknowns)

$$[M]\{\ddot{D}(t)\} + 2v_o[M]\{\dot{D}(t)\} + [K]\{D(t)\} = \{P(t)\} = \{P_o\}f_e(t) \quad (16.19)$$

is converted to n separate, second-order, single-variable differential equations through the two orthogonality conditions, which proves that each modal shape vector $\{D_i\}$ is independent of the others. The i th participation factor \mathcal{A}_i is defined as the component of given forced vibration on the i th modal shape vector $\{D_i\}$. Thus, any arbitrary motion can be determined by considering the summation of its components \mathcal{A}_i on each modal shape vector $\{D_i\}$ [Clough and Penzien, 1993; Paz, 1993; Ovunc, 1974].

If the time variable factor $f_e(t)$ of the external disturbance [Equation (16.2)] is periodic (pulsating), the forced vibration can be directly determined without the calculation of participation factors \mathcal{A}_i [Paz, 1993].

16.7 Practical Applications

For any structure, the natural circular frequency ω can be expressed in terms of a parameter C as [Paz, 1993]

$$\omega = C \sqrt{\frac{EI_j}{m_j \ell_j^4}} \quad (16.20)$$

where E is the Young's modulus, and I_j , m_j , and ℓ_j are the moment of inertia, mass, and span length of a selected member j .

Substituting the natural circular frequency ω (its expression in terms of C) into the frequency equation [Equation (16.18)] gives

$$[-C^2[M] + [K]] = 0 \quad (16.21)$$

where the general terms M_{rs} and K_{rs} of the mass and the stiffness matrix are constant and expressed as

$$M_{rs} = M_{rs} / m_j \ell_j \quad \text{and} \quad K_{rs} = K_{rs} \ell_j / EI_j \quad (16.22)$$

It can be easily seen that the determinant of the frequency equation [Equation (16.21)] is independent of the member characteristics (E , m , ℓ , I) but depends on the parameter C . If, in a frame, the same characteristics of the members are multiplied by the same factor, the magnitude of the parameter C remains unchanged. However, a natural circular frequency ω_i corresponding to C_i changes [Equation (16.20)]. If the characteristics of some members change and those of the others remain constant, the parameter C_i is affected.

The advantages of one method over the others and the limits on their accuracy depend on the number and type of the members in the structures and whether the structure is subjected to additional effects.

The type of member depends on the ratio of the thickness t (of its cross-section) to its span length ℓ : $\gamma = t/\ell$.

- If the ratio $\gamma = O(1/100)$ (in the order of $1/100$), the effect of bending is negligible. The member is a very thin member, called *cable*.
- If the ratio $\gamma = O(1/10)$, axial force, torsion, and bending are affecting the member. The member is a *thin member*.
- If the ratio $\gamma = O(1)$, the member is considered a *deep beam*.

The inclusion of the variation of the width or the thickness of the member, the effect of member axial force, shear, rotatory inertia, vibration of the member within an elastic medium, and so on constitutes the additional effects.

The dynamic responses of beams and frames are evaluated with or without the additional effects by lumped and consistent mass methods. The results are compared with those evaluated by continuous mass.

16.8 Linear Structures without Additional Effects

The behavior of a structure is linear when its stresses are within their elastic limits and its deformations are infinitesimal. The first one constitutes the *geometrical linearity*, the second is the *material linearity*.

Single Beams

The data related to a cantilever beam, considered as an example, composed of a single element or with two, three, or five subelements, are given in Figure 16.4. The dynamic responses of each beam have been determined by the lumped mass and the consistent mass matrix methods. The first two natural circular frequencies, ω_1 and ω_2 , and the vertical displacement d_{v11} , rotation d_{r11} , and shearing force V_{11} at the free end 1 as well as the bending moment M_{21} at the fixed end 2 due to the first mode ω_1 are furnished in Table 16.1 for the lumped mass method, for the consistent mass method, and for the continuous mass method.

In the lumped mass method, increasing the number of subelements improves the accuracies of the natural circular frequencies ω_1 , ω_2 , and ω_i and those of the vertical displacements, d_{v11} , and rotations, d_{r11} , when their magnitudes are compared to their magnitudes obtained by the continuous mass method. For the consistent mass method, the beam has better approximations when it is subdivided into two subelements.

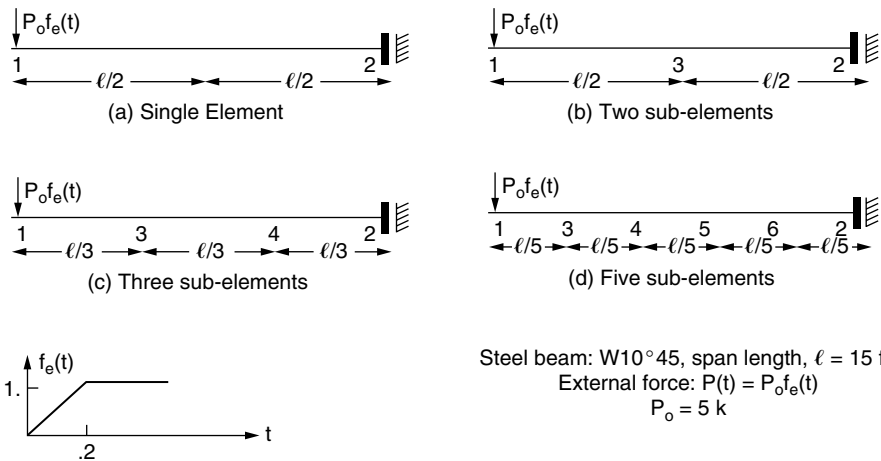

FIGURE 16.4 Cantilever beam formed by (a) a single member or (b) two, (c) three, or (d) five subelements and subjected to a force $P(t) = P_o(t)f_e(t)$.

FIGURE 16.5 Three-story steel frame.

Frames

Three-story frames have been selected as an example to compare responses obtained by lumped, consistent, and continuous mass methods [Ovunc, 1980]. The data for the three-story frames are given in Figure 16.5.

The dynamic responses of the three-story frame for three different ratios of $\alpha = I_b/I_{bo}$ are selected, where I_b and I_{bo} are new and actual moments of inertia of the beams. The moments of inertia I_{bo} are for thin members with a depth-to-span ratio γ in the order of 1/10. Only the sizes of the beams have been varied.

The frame's first two natural circular frequencies (ω_1, ω_2), horizontal displacements (d_{h71}, d_{h72}) at joint 7, and bending moments (M_{11}, M_{12}) at joint 1 are given in Table 16.2.

The responses obtained by the lumped mass and consistent mass methods are close to each other for any magnitude of α (or γ). However, they are roughly approximate compared to those obtained by the continuous mass method for low order of the ratio $\alpha = O(.01)$ (or γ) — that is, when the beams are very thin. The responses obtained by lumped mass, consistent mass, and continuous mass are very close for the actual or higher order of the ratio $\alpha \leq O(1)$ (or γ) — that is, for thin and deep beams.

16.9 Linear Structures with Additional Effects

The additional effects included in the analysis of structures with linear behavior are the member axial force, soil structure interaction, and the additional mass of the members [Ovunc, 1992]. The parameters related to the member axial forces, soil-structure interaction, and additional masses of the members are

TABLE 16.2 Dynamic Responses of a Three-Story Frame

| Method | $\alpha = I_b/I_{bo}$ | ω_1 | ω_2 | d_{h71} (ft) | d_{h72} (ft) | M_{11} (k/ft) | M_{12} (k/ft) |

FIGURE 16.6 Axial force element.

introduced in the differential equations of motion. The stability of the structures, including the additional effects, is also analyzed by means of the continuous mass matrix method. It is assumed that the material is linear elastic and the member axial forces are static. The compaction of the soil is due to deformations and the effect of pore pressure is neglected.

Depending on the type of soil, the variation of the soil subgrade reaction is given as (Figure 16.6) [APJ RP-2A]:

- For cohesive soils,

$$C_s = k_L (y/L)^n \text{ k/ft}^3$$

- For cohesionless soils,

$$C_s = k (y/d) \text{ k/ft}^3$$

where k_L is the value of C_s at the tip of the pile ($y = L$), n and k are empirical constants that depend on the type of soil, and d is the diameter of the pile.

Under the axial displacements, the equation of motion of an infinitesimal element of the member can be written as (Figure 16.7)

$$\frac{\partial P}{\partial y} - \frac{C dv}{dt} - \frac{m d^2 v}{dt^2} - p \left(C_{fb} + \frac{C_{ft} - C_{fb} y}{1} \right) \quad (16.23)$$

where C and p are the damping coefficient and unit peripheral area of the pile and C_{ft} and C_{fb} are the skin frictions at the top and the bottom of the pile. The mass per unit length of the pile is $m = (ap + q)/g$.

By expressing the axial force P in terms of displacement $v(y, t)$, and assuming the displacement $v(y, t)$ can be written in separable variable form,

FIGURE 16.7 Bending element.

$$v(y, t) = Y(y)f(t)$$

then substituting them in Equation (16.23), one has the temporal part,

$$\frac{d^2 f}{dt^2} + 2v\omega \frac{df}{dt} + \omega^2 f = 0 \quad (16.24)$$

$$\frac{d^2 Y}{dy^2} + (\alpha^2 - \gamma Y)Y = 0 \quad (16.25)$$

where $v = C/2\omega m$, $\alpha^2 = (m\omega^2 - pC_{fb})/AE$, $\gamma = p(C_{ft} - C_{fb})/AEI$, and ω is the natural frequency of the vibration.

The integration of the differential equation [Equation (16.25)], for the spatial part of can be written as

$$Y(y) = \{(t)\}^T \{C\} \quad (16.26)$$

The vector of the integration constants $\{C\}$ is determined from the boundary conditions. The dynamic member stiffness matrix can be determined either by writing the relations among the member end forces $\{f\}$ and the member end displacements $\{d\}$, or by using the Lagrangian Dynamic Equation. Thus one has,

$$\{f\} = [k_A] \{d\} \quad (16.27)$$

where $[k_A]$, is the dynamic, axial displacement member stiffness matrix.

Noticing the similarity between the twist rotation and axial displacement functions, and the similarity between the stress-strain relationships in both cases, the dynamic member stiffness matrix for torsion can be written by analogy from that of the axial force member by simply substituting the axial force rigidity EA by the torsional rigidity GJ and the parameters α , by their expression for torsion

$$\alpha^2 = (m\omega^2/GA - pR^2 C_{fb}/GJ)$$

$$\gamma = p R^2 (C_{ft} - C_{fb})/GJ$$

where R is the mean radius of the cross-section.

The vibration of a member under the bending in the Oyz plane is obtained from the differential of motion as follows (Figure 16.7)

$$EI_x \frac{\partial^4 w}{\partial y^4} + C \frac{dw}{dt} + P \frac{d^2 w}{dy^2} + m \frac{d^2 w}{dt^2} + p' \left(C_{sb} - \frac{C_{sb} - C_{st}}{1} y \right) = 0 \quad (16.28)$$

where P is the member axial force, positive when it is in compression; p is the projection of the cross-section per unit length of the member on the plane subjected to soil pressure; and since the variation of the soil modulus is assumed to be linear, C_{st} and C_{sb} are the soil subgrade modulus at the top and at the bottom of the pile.

Assuming that the deflection function $w(y, t)$ can be written in separable variable form:

$$w(y, t) = Z(y) f(t)$$

and substituting them into the differential equation of motion (Equation 16.28), for the spatial part one has

$$\frac{d^4 Z}{dy^4} + 2k^2 \frac{d^2 Z}{dy^2} - (\beta^4 + \gamma^2)Z = 0 \quad (16.29)$$

where $k^2 = P/2EI_x$, $\beta^4 = (m\omega^2 - p C_{sb})/EI_x$, and $\gamma^2 = p (C_{sb} - C_{st})/EI_x$. The time-dependent part $f(t)$ is the same for all four independent vibrations [Equation (16.24)].

By using the Lagrangian Dynamic Equation, the member stiffness matrix $[k_{B,Oyz}]$ subjected to bending in the Oyz plane can be obtained as

$$\{f\} = [k_{B,Oyz}]\{d\} \quad (16.30)$$

The nature of the shape function and the stiffness matrix depend on the values of the parameters β and γ and the member axial force P , whether it is in tension or compression [Ovunc, 1985].

The dynamic member stiffness matrix for the bending in the Oxy plane is obtained following the same steps mentioned for bending in the Oyz plane.

The dynamic stiffness matrices for all four independent cases are combined, according to the type of structure: either truss or frames in planes or in space. The dynamic stiffness matrix $[K]$ for the structure is obtained from the dynamic stiffness matrices of its constituent members as

$$\{F\} = [K]\{D\} \quad (16.31)$$

The dynamic stiffness matrix $[K]$ is a transcendental function of the natural circular frequency ω of the structure.

Single Beams

The cantilever beam subdivided into three subelements is subjected to a static axial force f_{ax} at its free end 1 (Figure 16.6). The effect of member axial force f_{ax} appears in the equations of free vibration as an additional matrix — $[N_{LM}]$ and $[N_{CS}]$ for the lumped and consistent mass methods [Equation (16.18)]:

$$([K] + [N_{LM}] - \omega^2[M_{LM}])\{D\} = \{0\} \quad (16.32)$$

$$([K] + [N_{CS}] - \omega^2[M_{CS}])\{D\} = \{0\} \quad (16.33)$$

In the continuous mass method, the member axial force f_{ax} appears in the argument of the trigonometric or hyperbolic functions [Equation (16.14)].

The dynamic responses of the cantilever beam (Figure 16.6) have been computed by the lumped and consistent mass method by only changing the magnitude of the member axial force f_{ax} from zero to its critical value $(f_{ax})_{crit}$ [Equation (16.23) and Equation (16.24)]. The same computations have been performed using the continuous mass method [Equation (16.14)].

The ratios for ϕ ,

$$\phi_{mi,mj} = \omega_{1,mi}/\omega_{01,mj} \quad (16.34)$$

of the first natural frequency by method mi (with the effect of member axial force) versus that of method mj (without the effect of member axial force) are plotted in Figure 16.7. The index mi or mj designates LM , CS , and CT , the lumped mass, consistent mass, and continuous mass methods.

The comparison of the variations of the ratios $\phi_{LM,LM}$ with $\phi_{LM,CT}$ [Equation (16.24)] exhibits rough approximation. The approximation involved in the variations of ratios $\phi_{CS,CS}$ and $\phi_{CS,CT}$ is very close to the actual one.

The comparison of the variations of the ratios $\phi_{LM,CT}$ and $\phi_{CS,CT}$ with $\phi_{CT,CT}$ exhibits some degree of approximation.

Frames

All the columns of the three-story steel frame are assumed to be subjected to a static axial force, f_{ax} , of the same magnitude.

The dynamic responses of the three-story frame were evaluated by lumped, consistent, and continuous mass methods. Two different cases were considered. In the first case, only the magnitudes of the weights acting on the beams have been increased by a factor m . In the second case, the magnitudes of the member axial force, f_{ax} , and the weights acting on each beam have been increased by p_x and m , in such a way that both factors have the same magnitude, $p_x = m$.

For a same-method mj , the ratio

$$\alpha_{i,mj} = (\omega_i/\omega_{oi})_{mj} \quad (16.35)$$

of the i th natural frequency ω_i (including the effect of member axial force and/or additional mass, only on the beams) versus the i th natural frequency ω_{oi} (excluding all the additional effect) is plotted in Figure 16.8. The ratio $\alpha_{i,CT}$ — for first, second, and third natural frequencies computed by the continuous mass method — is also shown in Figure 16.8.

The sways at the floor level D_{mj} , including and excluding the effect of the axial force f_{ax} , are computed by the lumped, consistent, and continuous mass matrix methods. The variations of the sway at the floor levels D_{mj} are plotted in Figure 16.9.

When the effects of member axial forces are excluded, the sways at the floor levels obtained by the lumped, consistent, and continuous mass methods are almost the same. The effect of member axial force has shown small variations in the floor sways evaluated by the lumped and consistent mass methods. But the variation in the sways at the floor levels computed by the continuous mass method is large.

Although the first buckling mode for lumped and consistent mass methods occurs by increasing sways from lower to upper floors, for the continuous mass method the first buckling mode occurs between the base and the first floor. The relative displacement of second and third floors with respect to the displacement of the first floor tends to zero.

Offshore Structures

The dynamic behavior of the plane frame of the offshore platform similar to Conoco's Main Pass 296A is selected as a structural system that includes the effects of member axial force and soil-structure interaction. Thus, the results obtained through the computations can be easily compared with those obtained previously [Ovunc, 1984 and 1985]. The static loads on the members vibrating within the plane

FIGURE 16.8 Beam subjected to axial force.

FIGURE 16.9 Effect of member axial force.

of the frame are considered as distributed on these members, whereas the static loads acting on the transversal members are lumped at the joints of the plane frame. Load factors m and l are introduced on the distributed and lumped loads. When the distributed load factor m tends to zero, the continuous mass matrix approach tends to the lumped mass matrix approach. Two different boundary conditions are taken into account at the bottom tips of the piles: fixed and free tips. The ratio of the rigidity of the beams to columns and the embedded length of the piles can be selected as additional parameters.

A dimensionless parameter α_i is defined as

$$\alpha_i = \omega_{pi} / \omega_{oi}$$

the ratio of the natural circular frequencies of the i th mode ω_{pi} and ω_{oi} , corresponding to the structures with and without soil–structure interaction and/or with or without the member axial force, respectively.

The data related to the structural system are assumed to be similar to those of Conoco’s offshore platform. The data for the wave forces and soil characteristics are collected from information related to the Gulf of Mexico.

Defining Terms

Damping — Results from the internal friction within the material or from system vibration within another material.

Damping energy — Work done by the internal friction within the material as a result of the motion.

Kinetic energy — Work done by a mass particle as a result of its motion.

Stiffness coefficient $K_{i,j}$ — Force or moment in the direction of the first index (i) required to maintain the equilibrium of the body due to a unit displacement or rotation in the direction of the second index (j), while all the other specified displacements and rotations are equal to zero.

Strain energy — Work done by a particle due to its stress and strain.

External energy — Work done by an external force due to a displacement in its direction.

In this chapter, we consider some practical applications of dynamics and vibrations, with specific emphasis on shock isolation and vibration isolation. In both of these isolation situations, we are concerned with the transmission of interaction forces, $u(t)$, existing between two configurations [which are referred to here as the **base configuration (BC)** and the **structural configuration (SC)**], as illustrated in [Figure 17.1](#). This example system is a first-order representation of an idealized physical system that is general enough to represent *both* shock and vibration design situations. Most of the underlying physical principles impacting the design of either kind of isolation can be explained and illustrated with this simple one-degree-of-freedom model. The governing equations of motion can be generated from the three-part sequence shown in [Figure 17.1](#). In [Figure 17.1\(a\)](#), the BC and SC are in the unloaded condition, and the two configurations are initially separated by a length L . This corresponds to the state where the model is lying horizontal relative to the vertical direction of the gravity field, or where the model is in the vertical position *before* the gravity field (acceleration of gravity $g = 386 \text{ in./sec}^2$) is taken into account. For vertically oriented models, it is convenient to write the equation of motion relative to an initially gravity-loaded model, as in [Figure 17.1\(b\)](#), where the SC is shown at rest in a compressed state (the linear isolator has a preloaded compressive force of $u_T = -K\delta_s$, where $\delta_s = Mg/K$ is defined *positively* as the **static deflection**). Next, [Figure 17.1\(c\)](#) corresponds to a body in motion, and the governing equations of motion are obtained by constructing a free-body diagram of the SC and equating the sum of all vertical forces acting on the body to its mass, M , times its acceleration, $d^2z/dt^2 \equiv \ddot{z}$ (where dot notation is used to refer to time differentiation from here on), resulting in the following dynamic equilibrium equation:

$$M\ddot{z} + u_T(x, \dot{x}) + Mg - F(t) = 0 \quad (17.1)$$

The relation between the total z displacement and the isolator stretch variable x is given by

FIGURE 17.1 Multipurpose single-degree-of-freedom system.

$$z = y + x + (L - \delta_s) \quad (17.2)$$

and it follows that

$$\ddot{z} = \ddot{x} + \ddot{y} \quad (17.3)$$

In general, the isolator force, $u_T(x, \dot{x})$, could be a nonlinear function of the relative displacement x and relative velocity \dot{x} ; however, for the purposes of this introductory development, only linear isolators will be considered. Thus, the total isolator force acting on the mass M in Figure 17.1(c) is given by

$$u_T(x, \dot{x}) = Kx + C\dot{x} - K\delta_s \equiv u(x, \dot{x}) - K\delta_s \quad (17.4)$$

where $u(x, \dot{x})$ is the dynamic portion of the isolator force not including the static deflection force. Substituting Equation (17.2) through Equation (17.4) into Equation (17.1) gives

$$M\ddot{x} + C\dot{x} + Kx = F(t) - M\ddot{y}(t) \quad (17.5)$$

subject to initial conditions

$$x(t=0) = x_0, \quad \dot{x}(t=0) = \dot{x}_0 \quad (17.6)$$

It is noted that the Mg term and $-K\delta_s$ cancel in the formation of Equation (17.5).

The shock and vibration will take place about the static equilibrium position shown in Figure 17.1(b); that is, when the vibrating body comes to rest (i.e., $x = 0$, $\dot{x} = 0$), the isolator is still compressed an amount equal to the static deflection δ_s . The general solution to Equation (17.5) subject to initial conditions [Equation (17.6)] can be obtained by several different methods; however, the method of Laplace transforms is used here because it readily applies to situations where:

1. The boundary conditions are of the initial-value type.
2. The right-hand side is an arbitrary function of time.
3. An equivalence between an impulse-loaded right-hand side (rapidly applied loading) and a suddenly applied initial-velocity problem with no right-hand side can be easily illustrated.

Thus, taking the Laplace transform of Equation (17.5) with respect to the Laplace transform variable s results in

$$x(s) = \frac{x_0 \cdot (sM + C)}{(s^2M + sC + K)} + \frac{\dot{x}_0 \cdot (M)}{(s^2M + sC + K)} + \frac{F(s) - M\bar{y}(s)}{(s^2M + sC + K)} \quad (17.7)$$

Upon taking the inverse transform, this leads to the general solution for displacement and velocity:

$$x(t) = e^{-\eta t} \left(x_0 \cos(\omega_d t) + \frac{\dot{x}_0 + \eta x_0}{\omega_d} \sin(\omega_d t) \right) + \int_{\lambda=0}^{\lambda=t} \frac{e^{-\eta(t-\lambda)} \sin[\omega_d(t-\lambda)] [F(\lambda) - M\bar{y}(\lambda)] d\lambda}{M\omega_d} \quad (17.8)$$

$$\dot{x}(t) = -\eta x(t) + e^{-\eta t} [-x_0 \omega_d \sin(\omega_d t) + (\dot{x}_0 + \eta x_0) \cos(\omega_d t)] + \int_{\lambda=0}^{\lambda=t} \frac{e^{-\eta(t-\lambda)} \cos[\omega_d(t-\lambda)] [F(\lambda) - M\bar{y}(\lambda)] d\lambda}{M} \quad (17.9)$$

In the applications to follow, it will be more convenient to work with the variables $\omega_n \equiv \sqrt{K/M} = 2\pi f_n$, corresponding to the **isolator natural frequency**, and $\zeta \equiv C/(4\pi M f_n)$, corresponding to the **critical damping ratio**. The variables ω_d and η appearing in Equation (17.8) and Equation (17.9) are called the **damped natural frequency** and **decay constant**, respectively, and can be expressed in terms of variables ω_n and ζ using $\omega_d = \omega_n \sqrt{1 - \zeta^2}$ and $\eta = \omega_n \zeta$. These new variables have the following physical meanings: ω_n corresponds to the free harmonic vibration (no driver present) of the isolator in the absence of damping; ω_d corresponds to the damped free harmonic vibration; ζ determines whether the system is *underdamped* ($\zeta < 1$) or *overdamped* ($\zeta > 1$), where in the former case the free motion oscillates harmonically with damped natural frequency ω_d and in the latter case the free motion does not vibrate harmonically; and finally, η corresponds to the rate at which the underdamped system exponentially decays in time.

The solutions represented by Equation (17.8) and Equation (17.9) will be used to evaluate the dynamic responses in all the example problems to follow. The forms of the solutions are general and apply to either the situation where the drivers $[F(t), \bar{y}(t)]$ are given as an analytical expression or when they are given as a digital representation (e.g., earthquake responses). In the case of digital driver representations, the integrations in Equation (17.8) and Equation (17.9) can easily be performed by numerical integration (e.g., Simpson's rule), and in the case of analytical driver representations, closed-form integrals can be obtained with the aid of integral tables or with the aid of symbolic evaluation packages such as Maple [Redfern, 1994], MATLAB's version of Maple [Sigmon, 1994], and Mathematica [Wolfram, 1991]. A computer program using MATLAB script language [Math Works, 1992] was used to generate the results presented here.

Given the displacement and velocity versus time from Equation (17.8) and Equation (17.9), back-substituting $x(t)$ and $\dot{x}(t)$ into Equation (17.4) gives the dynamic portion of the isolator force $u(x, \dot{x})$, which serves as the major ingredient for isolating the structural configuration from the base configuration. The total acceleration \ddot{z} of the SC can be obtained by substitution of $u_T(x, \dot{x})$ into Equation (17.1). We will refer to the single-degree-of-freedom model in Figure 17.1(c) for the example problems considered here, and the physical significance of the ingredients of the model will be different for each usage. We will consider two types of applications:

Base configuration loaded: Here the base configuration has a prescribed displacement motion time history, $y(t)$ (and therefore the base acceleration $d^2 y / dt^2 \equiv \ddot{y}$) is the basic input load, and the structural configuration has a zero-value *external forcing function* $[F(t) = 0]$. Some examples of this type of problem are:

- A. *Earthquake-resistant structures*, where the ground (base configuration) movement from fault slip motion excites buildings or bridges (structural configuration)
- B. *Vehicle suspension*, where the ground displacement road profile [$y(\xi)$ vs. distance, ξ , in the forward direction of the vehicle traveling at constant velocity V as it moves parallel to the ground] results in the ground acting as the equivalent base configuration, with prescribed displacement road profile shape $y(\xi) = y(Vt)$ and corresponding *apparent base acceleration* $d^2y/dt^2 = V^2 d^2y/d\xi^2$ measured perpendicular to the ground, and the vehicle car body (structural configuration) responds to these irregularities in the road
- C. *Electronic component isolation*, where the ship superstructure (base configuration) cabinet houses electronic components mounted in cabinets (structural configuration) that are subject to waterborne shock waves that impart known base motion accelerations, \ddot{y} (based on previously measured experimental data)

Structural configuration loaded: Here the structural configuration has a directly applied force time history, $F(t)$, and the base configuration has no motion (i.e., $y(t) = 0$). Some examples of this type of problem are:

- A. *Unbalanced rotating mass*, where an eccentric mass m_e with offset r_e is rotating at constant angular speed ω (simple motor model with an unbalanced offset mass m_e) and is mounted inside the motor housing (structural configuration) and the base configuration is taken as fixed ($y(t) = 0$), where the explicit harmonic forcing function is $F(t) = m_e r_e \omega^2 \cos(\omega t)$; and
- B. *Free-falling mass*, where a free-falling mass (structural configuration) is prevented from impacting a rigid surface (base configuration) by having an intermediate shock isolator break the fall of the object dropped from height H (e.g., a stunt motorcycle jumps off a ramp or a package containing fragile equipment drops), where the force on the structural configuration is $F = -mg$ for $t \geq 0$ and $F = 0$ and $t < 0$, with initial condition $dx/dt = -\sqrt{2gH}$ at $t = 0$ and $x = 0$ at $t = 0$.

17.1 Base Configuration Loaded Applications

Problem 1: Vehicle Suspension

In this example, a vehicle moving with horizontal constant velocity V passes over a roadway that has a ground profile of $y(\xi) = Y_0 \sin(k\xi)$, $0 \leq \xi \leq N_c L$, $k = 2\pi/L$, where L is the period of the ground swell. Since the relation between horizontal distance traveled and time is given by $\xi = Vt$, the vertical BC base motion can be rewritten as

$$y(t) = Y_0 \sin(\omega t), \quad \ddot{y}(t) = -\omega^2 Y_0 \sin(\omega t), \quad \omega = 2\pi V / L \quad (17.10)$$

applied over the range $0 \leq t \leq N_c L / V$ and $\ddot{y}(t) = 0$ over the rest of the time duration. If the vehicle is four-wheeled, then a higher-degree-of-freedom model is needed to represent the response due to the rotational degrees of freedom; therefore, it is assumed that the vehicle is two-wheeled and is being towed while the load is balanced over the axle. Assume that all other forces acting are negligible; therefore, $F(t) = 0$. Consider a vehicle weighing $W = 2000$ lb and traveling at a speed of $V = 60$ mph that encounters a two-cycle ($N_c = 2$) road swell of amplitude $Y_0 = -1.01$ in. and period $L = 20$ ft. Substituting the data into Equation (17.10) results in a peak base acceleration of $\ddot{y}_{\max} = A_0 = 2$ gs and a drive frequency of $f = \omega / 2\pi = 4.4$ Hz. Design a spring-damper isolator (i.e., find K and C) that limits the vehicle (structural configuration) steady state vibration **acceleration transmission ratio**, $T_A = \text{peak}|\ddot{z} / \ddot{y}_{\max}|$ to a value of 0.4 and limits of maximum relative displacement of the isolator $x_{\max} = \pm \frac{3}{4} \delta_s$.

Before solving for K and C , it must be noted that isolator manufacturers often use a terminology other than explicitly stating these constants. Typically, in place of K and C , a natural frequency (f_n) versus load (Mg) curve is supplied and the acceleration transmission ratio T_A is given at resonance,

FIGURE 17.2 Transmission for harmonic structure force or base acceleration.

as in Barry, 1993. Later, it will be shown how K and C can be back-calculated from f_n and T_A . For the present, however, attention is focused on finding the desired f_n as the first step. The key ingredient in this approach is to use the transmission ratio versus drive frequency ($\beta \equiv f/f_n$) curve, as shown in Figure 17.2. This curve is obtained by substituting a solution of the form $x(t) = \bar{A} \sin(\omega t) + \bar{B} \cos(\omega t)$ into Equation (17.5), and solving for the \bar{A}, \bar{B} constants, resulting in the following acceleration transmission ratio:

$$T_A = \sqrt{\frac{1 + (2\zeta\beta)^2}{(1 - \beta^2)^2 + (2\zeta\beta)^2}}, \quad \beta \equiv \omega/\omega_n = f/f_n \quad (17.11)$$

It is of interest to note that all the curves in Figure 17.2 pass through the same frequency ratio, $\beta = \sqrt{2}$, and this special value forms the dividing line between isolation and amplification. Therefore, as a design strategy, to get isolation of the base configuration from the structural configuration, the isolator κ is selected such that its natural frequency f_n results in β values $> \sqrt{2}$.

Another response ratio that applies when the relative displacements are of particular interest is the **displacement magnification ratio**, denoted as $T_D = \text{peak } |x/y_{\max}|$, which can be derived in a manner similar to the above relation, resulting in the expression

$$T_D = \frac{\beta^2}{\sqrt{(1 - \beta^2)^2 + (2\zeta\beta)^2}} \quad (17.12)$$

FIGURE 17.3 Magnification for harmonic base acceleration.

This is shown in Figure 17.3 plotted against the drive frequency parameter β .

At this point, the designer must decide whether to solve for the natural frequency f_n that gives the desired transmission ratio T_A , and live with the resulting displacement, *or* solve for the natural frequency f_n that gives the displacement magnification ratio T_D , and live with the resulting maximum acceleration \ddot{z} . It is noted that solving for β is equivalent to solving for f_n , since the drive frequency, f , is known. In this sample problem, it is decided that reducing peak acceleration has priority; therefore, with the aid of Equation (17.11), we solve for the β that gives the desired T_A . Thus,

$$\beta = \sqrt{\frac{(a + 2T_A^2 - aT_A^2) + \sqrt{(a + 2T_A^2 - aT_A^2)^2 - 4T_A^2(T_A^2 - 1)}}{2T_A^2}}, \quad a = (2\zeta)^2 \quad (17.13)$$

where for light damping ($\zeta < 0.05$), β can be approximated with

$$\beta \approx \sqrt{1 + 1/T_A} \quad (17.14)$$

Before solving for β using Equation (17.13) [or Equation (17.14)], you must select a critical damping ratio ζ .

At this point, a ζ value can simply be selected according to whether light damping or heavy damping is desired, and a moderately heavy value of $\zeta = 0.5$ is chosen in this example. Therefore, for the

problem at hand, substituting $\zeta = 0.50$ and $T_A = 0.40$ into Equation (17.13) gives $\beta = 2.8131$. Upon substituting this value of β along with the drive frequency, $f = 4.4$ Hz, into the β definition [i.e., the second equation in Equation (17.11)], we can solve for the natural frequency, $f_n = 1.564$ Hz, required to limit the acceleration transmission to $T_A = 0.40$. As the final step, the actual spring constant K and damping constant C can easily be back-calculated from the f_n and ζ values in the following manner. In the sample problem, the 2000 lb load is divided equally over two isolators, so each one must carry a mass of $M = 2000 / (2 \times 386) = 2.5906$ lb-in./sec². Therefore, $K = (2\pi f_n)^2 M = 250.2$ lb/in., and $C = 4\pi M \zeta f_n = 25.46$ lb-sec/in. for each of the two isolators. The dynamic response for important variables such as $x(t)$, $\dot{x}(t)$, $\dot{y}(t)$, and $\ddot{z}(t) / \dot{y}_{\max}$ (i.e., the SC transient acceleration transmission ratio) is computed by evaluating Equation (17.8), Equation (17.9), and Equation (17.1) over the two cycles of input and for an equally long coastdown time duration after the road profile has become flat again. Upon observing the Figure 17.4 solution, it is observed that the deflection stays within the maximum allowable constraint space of $x_{\text{con}} = \pm 0.75 \delta_s = \pm 3.00$ in.; however, the transient portion of the peak acceleration ratio $\ddot{z}(t) / \dot{y}_{\max} = 0.62$ overshoots the target steady state solution. $T_A = 0.40$. The isolator design employed the steady state solution; therefore, it is not unusual that the transient could exceed the steady state limit. It is further noted that by the end of the second response cycle, the acceleration ratio is already approaching the 0.40 target. When the road profile turns flat, the acceleration ratio rapidly tails off toward zero, due to the large damping value. To compensate for the overshoot in transient acceleration, a larger β (and thus a smaller f_n) can be used on a second pass through the design process [e.g., enter $T_A = 0.40 \times (0.40 / 0.62)$ into Equation (17.13) and repeat the design process, where the peak $\ddot{z}(t) / \dot{y}_{\max}$ is lowered from 0.62 to 0.45].

FIGURE 17.4 Roadway base acceleration transmission to structure.

In building an isolator from scratch, one can simply design it to have the physical properties K and C directly. However, if isolators are to be selected from off-the-shelf stock, a few comments are in order regarding the selection process. Manufacturers often supply a set of load (Mg) versus f_n curves for each isolator in a class of isolators. Upon entering such a set with a 1000 lb load, the isolator having a natural frequency nearest the target value, say $f_n = 1.564$ Hz, is selected. Typically there will not be an isolator corresponding to the exact f_n desired at the operating load. Thus, picking an isolator with f_n on the low side will make the steady state transmission on the low side. In some cases, the manufacturer must be contacted directly to get damping data, and in other cases damping information is given indirectly via a stated transmissibility, T_A , at resonance. The β location of the peak resonance T_A value in Figure 17.2 in terms of the damping ratio ζ is given by

$$\beta^2 = \frac{1}{4\zeta^2}(-1 + \sqrt{1 + 8\zeta^2})$$

Substituting this expression into Equation (17.11) results in a relationship between T_A and ζ as plotted in Figure 17.5. For design purposes, the exact curve in inverse form can be approximated by the simpler expression

$$\zeta_{\text{res}} \approx 0.5\sqrt{1/(T_A^2 - 1)} \tag{17.15}$$

FIGURE 17.5 Transmission at resonance (harmonic force or base acceleration).

In Figure 17.5, both the exact curve and the Equation (17.15) approximation are plotted side by side. For example, if the manufacturer states that an isolator has a transmission ratio $T_A = 1.5$ at resonance, then substituting this value into Equation (17.15) gives a corresponding critical damping ratio of $\zeta = 0.45$. Finally, substituting $\zeta = 0.45$ into $C = 4\pi M \zeta f_n$ provides the numerical value for the isolator damping constant in question.

Problem 2: Shock Isolation of Fragile Equipment

Consider a 50 lb structural configuration, initially at rest [i.e., $x(t=0) = 0$, $\dot{x}(t=0) = 0$], that is subject to a half-sine pulse-type BC acceleration input of the form

$$\begin{aligned}\ddot{y} &= A_0 \sin(\omega t), & 0 \leq t \leq T_p; \\ \ddot{y} &= 0.0, & T_p < t \leq \infty; \quad T_p = \pi/\omega\end{aligned}\tag{17.16}$$

and specifically the peak value of the base acceleration input is $A_0 = 16$ gs and the pulse duration is $T_p = 11$ msec. In this problem, the direct force $F(t)$ is taken as zero.

The design problem is to synthesize a shock isolator that will limit the acceleration transmitted to the SC to 4 gs; therefore, a target transmission ratio of $T_A = 4/16 = 0.25$ is sought. It is also desired that the maximum displacement be limited to $x = \pm 1.0$ in. At this point it is noted upon comparing the base motion of the previous application [Equation (17.10)] to the base motion of the current problem [Equation (17.16)] that there is a similarity between the first and second problems, except for the fact that the current shock problem has a short pulse length where only one-half of a sine wave ($N_c = 0.5$) is applied. The principle governing shock isolation is different from the corresponding vibration isolation of the previous problem in that the shock isolation process is characterized as a storage device for a sharply increasing acceleration waveform, and the design concept is to attempt to instantaneously absorb the energy and then release it at the natural frequency of the device but at a lower-level mass deceleration. One approach is, for guessed K and C values, to simply substitute these values and the input waveform of Equation (17.16) into Equation (17.7), Equation (17.8), and Equation (17.1) to get the response motion, observe the response, and reiterate the process with new K and C values until a desired response is obtained. We cannot use the steady state method of the previous problem because the steady state assumption of the input waveform would not be valid. An alternative design process is to convert the base input motion into a nearly equivalent initial, suddenly applied velocity problem, $\dot{x}(t=0) = V_0$, with no explicit driver on the right-hand side of Equation (17.5).

The extreme case of a rapidly applied loading is a special mathematical function called a *delta function*, $\delta(t)$, whose value is ∞ at $t = 0$ and zero for $t > 0$. The right-hand-side loading can then be represented as

$$-M\ddot{y}(t) \approx -M\tilde{A}\delta(t)\tag{17.17}$$

where

$$\tilde{A} = \int_{\lambda=0}^{\lambda=T_p} \ddot{y}(\lambda) d\lambda\tag{17.18}$$

Upon substituting Equation (17.17) into Laplace-transformed Equation (17.7), with initial displacement $x_0 = 0$ and $F(s) = 0$, and noting that the Laplace transform of a delta function is 1.0, it can be seen that the $\dot{x}_0 M$ term and $-MA$ have exactly the same form (same denominator); therefore, by interchanging the roles of the driver and initial condition, we can let a problem with a zero initial

velocity and pulse-type \tilde{y} driver having area \tilde{A} [by Equation (17.18)] be replaced with an equivalent problem having a zero \tilde{y} driver but an initial velocity of $\dot{x}_0 \equiv V_0 = -\tilde{A}$. The V_0 quantity can therefore be interpreted as a suddenly applied velocity change. The advantage of this approach is that estimates of the maximum response can easily be made and used to back-calculate the isolator properties needed to achieve the desired isolator performance. Thus, for the equivalent initial velocity representation, we immediately get the solution as a special case of Equation (17.8) that simply reduces to

$$x(t) = -\tilde{A}e^{-\eta t} \sin(\omega_d t) / \omega_d \quad (17.19)$$

Upon differentiating Equation (17.19) and solving for the maximum displacement x_{\max} and maximum mass acceleration \ddot{z}_{\max} , the following result is obtained:

$$x_{\max} = -\tilde{A}e^{-\alpha} / \omega_n, \quad \text{where } \alpha = (\zeta / \sqrt{1-\zeta^2}) \sin^{-1}(\sqrt{1-\zeta^2}) \quad (17.20)$$

$$\ddot{z}_{\max} = \tilde{A}\omega_n D_i \quad (17.21)$$

$$\text{with } D_i = \exp(-\zeta \hat{t} / \sqrt{1-\zeta^2}) \left(\frac{(1-2\zeta^2)}{\sqrt{1-\zeta^2}} \sin(\hat{t}) + 2\zeta \cos(\hat{t}) \right) \quad 0 \leq \zeta \leq 0.5$$

$$D_i = 2\zeta, \quad 0.5 < \zeta \leq 1.0$$

$$\text{where } \hat{t} = \tan^{-1} \left(\frac{(1-4\zeta^2)\sqrt{1-\zeta^2}}{\zeta(3-4\zeta^2)} \right)$$

As in the previous example, the acceleration transmission ratio is defined as $T_A = \text{peak}|\ddot{z}/\dot{y}_{\max}|$. Substituting Equation (17.21) into this T_A expression and solving for the natural frequency gives

$$f_n = \frac{|\dot{y}_{\max}| T_A}{2\pi \tilde{A} D_i} \quad (\text{general shock}) \quad (17.22)$$

and, for very light damping (say, $\zeta < 0.1$), the approximation $D_i \approx 1.0$ can be used. The isolator selection follows the same concept as in the previous problem where the natural frequency needed to limit the transmissibility is determined. For the problem at hand, substituting the given half-sine input \tilde{y} into Equation (17.18) corresponds to a velocity change of $\tilde{A} = 2A_0/\omega = 2A_0 T_p/\pi$, where it is also noted that $|\dot{y}_{\max}| = A_0$. Upon using these data, Equation (17.21) reduces to

$$f_n = \frac{T_A}{4T_p D_i} \quad (\text{for half-sine pulse shock}) \quad (17.23)$$

From this point forward, the selection procedure for obtaining the isolator parameters is conceptually the same, except that the computation of the desired natural frequency is different and is governed by Equation (17.22) or Equation (17.23) as appropriate. For the problem at hand, substituting the target transmissibility $T_A = 0.25$, pulse length $T_p = 0.011$ sec, and designer-selected damping ratio $\zeta = 0.2$ (using $\zeta = 0.2$ in the D_i expression of Equation (17.21) gives $D_i = 0.8209$) results in a desired natural frequency of $f_n = 6.92$ Hz. For the 50 lb SC ($M = 50/386$), the $f_n = 6.92$

and $\zeta = 0.2$ data translate into spring and damping constants of $K = (2\pi f_n)^2 M = 244.97$ lb/in. and $C = 4\pi M \zeta f_n = 2.253$ lb-sec/in. Also, using Equation (17.20), the estimated maximum deflection is $x_{\max} = 0.7520$ in.; therefore, this isolator design should meet the space constraint imposed on the problem. This x_{\max} value should also be checked against the isolator manufacturer's maximum allowable spring deflection (sometimes called sway space), which is usually given in the selection catalog. Upon substituting the above K , M , and C design parameters and actual half-sine base motion $\dot{y}(t)$ into Equation (17.8), Equation (17.9), and Equation (17.1), the dynamic response for important variables such as $x(t)$, $\dot{x}(t)$, $\dot{y}(t)$, and $\ddot{z}(t)/\dot{y}_{\max}$ (i.e., the SC transient acceleration transmission ratio) is computed. The results are shown in Figure 17.6, where it is noted that the desired 0.25 transmissibility is achieved and the displacement constraints are not exceeded. It should be noted that the curves labeled in the legend correspond to using the actual half-sine input base motion. These results will not be exactly the same as the equivalent suddenly applied velocity (V_0) solution that was used to size the isolators, because the half-sine pulse is not exactly the idealized delta function. For illustrative purposes, the equivalent suddenly applied velocity solution is superimposed on the same plot and denoted with the unconnected symbolic markers "x" for displacement, "o" for velocity, and "+" for acceleration ratio. As expected, the velocity comparison will be different in the early time [e.g., with the actual $\dot{y}(t)$ input the initial condition is $\dot{x}_0 = 0$, whereas in the equivalent problem the initial velocity is not zero and represents the entire input to the problem]. As a final comment, the selection of the isolators from the manufacturer's catalog follows along the same lines here and therefore will not be repeated; also check that $T_p \ll 1/f_n$ when using Equation (17.22) or Equation (17.23).

FIGURE 17.6 Base configuration half-sine acceleration loading.

17.2 Structural Configuration Loaded Applications

Problem 3: Rotating Machinery Force Transmission

In this class of problems, the base configuration is considered fixed; thus $y(t) = \dot{y}(t) = \ddot{y}(t) = 0$, and therefore the only system loading comes through the structural configuration loading $F(t)$. Perhaps one of the most common such loading problems is the situation where a piece of equipment with some sort of rotating member is spinning in a steady state mode at drive frequency ω and is resting on the structural configuration, where the total mass M of the equipment to be supported by the isolators is $M = M_s + m_e$, where M_s is the mass of the structural configuration including the rotating machinery (except for the offset mass m_e), and m_e represents the off-center eccentric mass at radius r_e . The m_e term is analogous to wet clothes clinging to the spinning drum during the spin-dry cycle of a common washing machine, where excessive vibrations are set up when the clothes are not uniformly distributed around the drum. The radial acceleration, $A_r = r_e \omega^2$, results in a reciprocating force that is represented by

$$F(t) = m_e r_e \omega^2 \cos(\omega t) \quad (17.24)$$

Therefore, by comparing Equation (17.24) to the first steady state loading example in Equation (17.10), it is seen that the $M\omega^2 Y_0 \sin(\omega t)$ driver in the differential equation is just like the current $m_e r_e \omega^2 \cos(\omega t)$ driver except for a cosine in place of a sine driver function. In fact, the steady state solutions for the transmissibility of an isolator force transmission ratio of $T_U = \text{peak} |u(t)/F_{\max}|$ has the exact same form as Equation (17.11); therefore, $T_U = T_A$ for this class of problem, where the driver force amplitude varies as ω^2 . It is cautioned that for other harmonically varying forces, ones that have, say, a frequency-independent amplitude, the form of the T_U would not be the same as Equation (17.11). It is also noted that although the actual value of the amplitude of $F(t)$ depends on the size of $m_e r_e$, this value cancels out in forming the T_U force transmission ratio.

As a specific example, consider a structural configuration, whose total weight (including m_e) is 800 lb, and the equipment is rotating at 540 rpm (i.e., $\omega_0 = 2\pi \cdot 9$ rad/sec), which due to an offset ($r_e = 10.0$ in.), an eccentric rotating mass ($m_e = 0.25$ lb-sec²/in.), transmits unwanted vibrations to the floor. It is required that the force transmission ratio be no more than $T_U = 0.2$ (sometimes equivalently referred to as 80% isolation). It is also required that the maximum displacement $x(t)$ not exceed ± 0.5 in. It is further assumed that the SC is to be supported by four isolators and that they are centered so that the dead weight is distributed equally among them. If this centering assumption is not met, rocking modes will be present and more degrees of freedom will be needed to model the system. The motor cannot go from $\omega = 0$ up to the operating frequency instantly; therefore, it is assumed that ω has a simple linear time ramp:

$$\omega = \omega_0 t / t_c, \quad 0 \leq t \leq t_c; \quad \omega = \omega_0, \quad t_c \leq t \quad (17.25)$$

where for the problem at hand $t_c = 10 \times (2\pi/\omega_0)$, which corresponds to 10 periods of the steady state frequency. The first step in designing the isolator is to select a critical damping ratio ζ . Because the motor has a variable speed and the rotational frequency varies with time during the startup according to Equation (17.25), the isolator is expected to have a designer-selected amplification of no more than $T_U = 10$ at resonance, should the motor ever be run at or near the resonant frequency. Thus, substituting $T_U = T_A = 10$ into Equation (17.15) results in a damping ratio of $\zeta = 0.0502$. The next step is to solve for the natural frequency that will limit the steady state vibration force transmission ratio (operating at speed $f = \omega_0/2\pi = 9$ Hz) to a value of $T_U = 0.2$. This is accomplished by substituting $\zeta = 0.0502$ and $T_U = T_A = 0.2$ into Equation (17.13), which results in $\beta = 2.4792$.

FIGURE 17.7 Transient-into-steady-state force transmission applied to foundation.

There are four isolators; therefore, the mass assigned to each isolator is determined from $M = (800/386)/4 = 0.5181$ lb-sec²/in. The natural frequency is computed from $f_n = f/\beta = 9/2.4792 = 3.63$ Hz. Finally, the spring and damping constants are computed from $K = (2\pi f_n)^2 M = 269.5$ lb/in. and $C = 4\pi M \zeta f_n = 1.186$ lb-sec/in. (Refer to the discussion on selecting isolators from manufacturers' catalogs in the first suspension isolator design example.) Upon substituting the above K , M , C design parameters and driver $F(t)$ defined by Equation (17.24) and Equation (17.25) into Equation (17.8), Equation (17.9), and Equation (17.4), the dynamic response for important variables such as $x(t)$, $\dot{x}(t)$, $F(t)$, and $|u(t)/F_{max}|$ (i.e., the SC force transmission ratio) is computed. It is noted that during the startup phase, the variable angular velocity $\omega(t)$ results in an additional tangential acceleration component that is neglected in the analysis. The transient portion of the results is shown in Figure 17.7, where it is noted that the desired 0.20 transmissibility is exceeded ($T_A = 0.28$) during the transient (and also that the displacement constraints are not exceeded). The damping is light in this example; therefore, it takes many more cycles to reach the steady state. The horizontal dotted lines in Figure 17.7 align with the steady state limit reached for $u(t)/F_{max}$ after running the solution out to $t = 4.0$.

This demonstration example also illustrates the need to balance rotating machinery. Instead of having to live with the vibrations, it would be better to kill the source of the vibration and rebalance the equipment (e.g., make r_e smaller in this example), so that even if the vibration is still present, its magnitude will be small enough that it will have the same effect as if isolators were used to reduce the transmissibility.

Problem 4: Free-Fall Shock

This class of problem is similar to the base-excited impulse problem, where a falling object (structural configuration) strikes the ground (base configuration) and, due to the impact, a suddenly applied velocity is imparted to the falling object. The ground is idealized as rigid, and it is assumed that the object falls from a height H . The velocity of the object *just prior to hitting the ground* is $V = \sqrt{2gH}$. The problem is to design an isolator that limits the maximum force transmissibility T_U to a prescribed amount (often referred to as the fragility factor, nondimensional gs). The solution of this problem follows along the same lines as the initial impulse problem described earlier in this section; therefore, only a rough outline will be presented. The governing differential equations have to be modified slightly to account for the fact that the free-falling body–isolator configuration has no prestretch (static deflection δ_s), and therefore the static deflection force term $K\delta_s$ does not cancel with the dead weight term in the derivation of Equation (17.5). Therefore, in solving this problem, $x(t)$ in Equation (17.5) should be viewed as the deflection measured *from the unstretched equilibrium position*. Once the base of the isolator has just touched the ground at impact, the isolator starts to compress and the $x(t)$ solution describes the ensuing motion of the SC. The loading in Equation (17.5) becomes simply the dead weight (i.e., $F(t) = -Mg$ for $t \geq 0$, with $\dot{y}(t) = 0$) and the initial conditions in Equation (17.6) are $x_0 = 0$, $\dot{x}_0 = -V = -\sqrt{2gH}$ [the sign convention is that the extension (+x) of the isolator is positive]. Thus, with these conditions substituted into Equation (17.8), Equation (17.9), and Equation (17.4), the dynamic response for important variables such as $x(t)$, $\dot{x}(t)$, $F(t)$, and $T_U = |u(t)/F_{\max}|$ (i.e., the SC force transmission ratio) can be evaluated, where F_{\max} in this application is simply the dead weight, $-Mg$. Solving for the exact solution for $u(t)$ as described above, and finding its maximum value in time, one obtains

$$T_U = \left| -1 + \exp(-\zeta \hat{t} / \sqrt{1 - \zeta^2}) \left[\frac{(-\Omega(1 - 2\zeta^2) - \zeta)}{\sqrt{1 - \zeta^2}} \sin(\hat{t}) + (1 - 2\Omega\zeta) \cos(\hat{t}) \right] \right| \quad 0 \leq \zeta \leq \zeta_b \quad (17.26a)$$

or

$$T_U = |-2\zeta\Omega| \quad \zeta_b \leq \zeta \quad (17.26b)$$

with

$$\zeta_b = \frac{1}{4\Omega} + 0.5\sqrt{(1 + 1/(2\Omega))^2}, \quad \Omega = \frac{V\omega_n}{g}, \quad (17.26c)$$

$$\hat{t} = \tan^{-1} \left[\frac{(\Omega(1 - 4\zeta^2) + 2\zeta)\sqrt{1 - \zeta^2}}{(-1 + 3\Omega\zeta + 2\zeta^2 - 4\Omega\zeta^3)} \right]$$

For intermediate damping, Equation (17.26a) corresponds to the nondimensional time value, $\hat{t} = \omega_d t_{\max}$, where the slope $du/dt = 0.0$, and Equation (17.26b) corresponds to the large damping case where the maximum force occurs at the beginning of impact, $t = 0.0$. When the damping ζ is zero (or very small), then using Equation (17.26a) with $\hat{t} \approx \tan^{-1}(\Omega/(-1))$ and solving for Ω in terms of T_U , we can solve for the natural frequency that limits the maximum transmitted force to the desired T_U value, where

$$f_n \approx \frac{g}{2\pi V} \sqrt{T_U(T_U - 2)} \quad \text{for light damping, } \zeta \approx 0.0, \text{ and } T_U > 2.0 \quad (17.27)$$

The $T_U > 2.0$ limitation comes from the fact that *with zero or low damping*, fragility factors lower than 2.0 are not reachable without substantial damping. In the case of heavy damping, the maximum force occurs at the beginning, $t = 0.0$, and using Equation (17.26b), one obtains:

$$f_n \approx \frac{gT_U}{4\pi V\zeta} \quad \text{for heavy damping, } \zeta_b \leq \zeta \quad (17.28)$$

where the breakpoint ζ_b is determined by setting the numerator of the arctan expression for \hat{t} equal to zero. Finally the determination of the f_n value in terms of T_U for the intermediate damping, $0 \leq \zeta \leq \zeta_b$, is the most difficult case because the solution involves obtaining roots to a transcendental equation. It is noted that for large values $\Omega \geq 10.0$, the breakpoint value is $\zeta_b \approx 0.5$. Use the smallest positive root for \tan^{-1} in Equation (17.26c) (e.g., atan2 in MATLAB).

The procedure is numerical and can easily be accomplished by substituting the desired damping ratio ζ and fragility factor T_U into Equation (17.26a) and iterating Ω until the left side equals the right side (this root, $\Omega = \Omega_{rt}$, can be found with a simple numerical root finder routine such as the “fzero” routine in MATLAB). Next, simply convert Ω_{rt} to f_n using the second of Equations (17.26c), to get

$$f_n = g\Omega_{rt}/(2\pi V) \quad \text{for intermediate damping, } 0 \leq \zeta \leq \zeta_b \quad (17.29)$$

To illustrate the general drop application for intermediate damping, consider a 50 lb weight ($M = 50/g$) that is dropped a height $H = 6.00$ in. (i.e., $V = 68.06$ in./sec), where it is required that T_U be no bigger than 8.0, with a prescribed intermediate damping ratio $\zeta = 0.2$. Next insert these data into Equation (17.26a), solve for the root $\Omega_{rt} = 8.870$, and finally compute the isolator natural frequency $f_n = 8.0066$ Hz with Equation (17.29). The breakpoint value ζ_b must be checked to ensure that the inequality bounds of Equation (17.29) are not violated; thus, substituting $\Omega = \Omega_{rt} = 8.870$ into the first of Equations (17.26c) gives $\zeta_b = 0.5290$, which is above the $\zeta = 0.2$ value required by the constraint bounds for intermediate damping. These f_n and ζ data translate into $K = (2\pi f_n)^2 M = 327.82$ lb/in. and $C = 4\pi M \zeta f_n = 2.607$ lb-sec/in. Evaluating the dynamic response as described above with Equation (17.8), Equation (17.9), and Equation (17.4) results in the response illustrated in Figure 17.8 which, as indicated, has peak $|u(t)/F_{\max}| = 8.0$. Note that the isolator force turns into tension after 0.062 sec, which implies that the structural configuration will jump up off the floor (i.e., “pogo stick effect”) at a later time after the energy is absorbed. It is also noted that the $x(t)$ solution does not settle down to zero, but rather to the static deflection value; this is because Figure 17.1(a) rather than Figure 17.1(b) was the coordinate reference configuration for this free-fall problem. For comparison purposes, the solution generated with Equation (17.8), Equation (17.9), and Equation (17.4) is compared with a solution to the same problem in Church, 1963 and is indicated by the unconnected symbolic markers “*” for displacement, “o” for velocity, and “+” for the $|u(t)/F_{\max}|$ ratio (after adjusting for a different sign convention for positive x). As can be seen, the agreement between the two solutions is perfect.

17.3 Additional Information

The sample problems considered here represent simple single-degree-of-freedom (SDF) models of what is often a more complicated multiple-degree-of-freedom (MDF) system. These simple example problems illustrate the main concepts involved in shock and vibration isolation; however, great care must be taken not to apply these idealized SDF-type models in situations where a MDF model is needed to represent the full picture (e.g., the four-wheel vehicle over a roadway needs a MDF model that allows the front and rear wheels to experience different parts of the roadway profile to allow for any rocking modes that may be present). Perhaps one of the most comprehensive references for shock and vibration isolation

FIGURE 17.8 Free-falling structural configuration shock.

issues is Harris, 1988, which not only covers SDF models in detail for all kinds of inputs, but covers MDF models as well. Good design tips are often found directly in the manufacturer’s design guides, for example, Aeroflex, 1994; Barry, 1993; Lord, 1994; and Firestone, 1994. For some more advanced ideas on optimum shock and vibration isolation concepts, see Sevin and Pilkey, 1971. The effects of nonlinearity should also be considered when necessary; for example, the simple Voigt model linear spring-damper isolators considered here eventually turn nonlinear when the deflections become large. In such cases the actual nonlinear isolator force function $u(x, \dot{x})$ could be obtained from the manufacturer and Equation (17.1) resolved as a nonlinear differential equation (which could also easily be solved with a MATLAB script file similar to the one used to generate the sample solutions).

For the analysis of MDF systems consisting of a collection of rigid bodies interconnected by any “Rube Goldberg” collection of linkages, pivot points, and so forth, a handy computer program called Working Model exists [Knowledge Revolution, 1994], enabling the user to geometrically construct the configuration to be analyzed on the computer screen. It is not unlike the object-drawing programs that come with practically all modern-day word processors. The key difference is that once the model is drawn on the screen, following the assignment of initial conditions, spring constants, damping coefficients, and loading via pull-down menus, the user is one “mouse click” away from setting the program to work and getting a graphical display of selected pertinent response variables (displacement, velocity, acceleration) as the solution is in progress. Versions exist for a variety of platforms, including Macintoshes, PCs, and workstations. Depending on the user’s on-screen drawing skills, an entire analysis of a rather complex MDF system can be completed in a very short time (e.g., 5 to 10 min).

17.4 Base Motion Excitation for Multiple D.O.F. Problems

In problems 1 and 2, the base excitation was a prescribed vertical motion $y(t)$. However, the model for the physical representation was a simple single D.O.F. For more complex structures, many degrees of freedom will of course be acting, and it is then useful to employ finite element methods to solve the problem. For example, in the [Figure 17.6](#) inset sketch, the base could represent a building foundation, and the structural configuration above it could be a finite element representation of the building structure. The loading could still be the base excitation $y(t)$ and would correspond to the vertical base excitation of, say, some reference earthquake data or to some prescribed shock base motions for shock and vibration testing of mounted equipment. The equations of motion look like Equation (17.5), except that the M , K , and C are now finite element method mass, stiffness, and damping matrices, respectively, and the relative displacement $x(t)$ is replaced by a vector of unknown $\{Z(t)\}$ total displacements and the $y(t)$ prescribed base motion is replaced by a vector of known driver $\{Y(t)\}$ nodal displacements. Following Przemieniecki [1969], for a treatment of enforced displacement problems, the full displacement vector is partitioned into an unknown and known partitions, $\{\{Z(t)\}, \{Y(t)\}\}^T$. We start the analysis without damping present and will add its effect on the undamped solution later. Thus the equations of motion become

$$\begin{bmatrix} M_{zz} & M_{zy} \\ M_{yz} & M_{yy} \end{bmatrix} \begin{Bmatrix} \dot{Z} \\ \dot{Y} \end{Bmatrix} + \begin{bmatrix} K_{zz} & K_{zy} \\ K_{yz} & K_{yy} \end{bmatrix} \begin{Bmatrix} Z \\ Y \end{Bmatrix} = \begin{Bmatrix} 0 \\ F_y \end{Bmatrix} \quad (17.30)$$

where F_y corresponds to the yet-unknown forces of constraint causing the known displacements $\{Y(t)\}$ of the base structure (e.g., this motion could be an earthquake history or a base motion from a shaker table or shock machine). Expanding the top partition, we have:

$$[M_{zz}]\{\ddot{Z}\} + [K_{zz}]\{Z\} = \{\bar{F}_z\} \quad (17.31)$$

where

$$\{\bar{F}_z\} = -[M_{zy}]\{\ddot{Y}\} - [K_{zy}]\{Y\} \quad (17.32)$$

Direct Solution

The direct solution subject to the unknown structure nodal time history $\{Z(t)\}$ would be to integrate this system of coupled ordinary differential equations with a standard second order in time, integration scheme (see, for example, Bathe [1996] and Cook [1988]), subject to, say, zero displacement and zero velocity initial conditions. Once having the total displacement vector $\{Z(t)\}$, the strains and stresses are then post computed. Also, the forces of constraint, $\{\bar{F}_z\}$, are post computed with the lower half of Equation (17.30). In order to account for damping, we simply add a damping term on the l.h.s. of Equation (17.31) of the form $[C_{zz}]\{\dot{Z}\}$, and correspondingly add a term $- [C_{zy}]\{\dot{Y}\}$ to the r.h.s. of Equation (17.32) and integrate the damped system of differential equations in the same manner.

Modal Solution

The goal of the modal solution is to simplify the solution so that it does not require integrating coupled equations of the entire system equations like that of the above direct approach, but rather obtains a set (one for each mode) of uncoupled second-order differential equations in time, of the form of Equation (17.5) (specifically, rewrite Equation (17.5)) by dividing it by M to obtain:

$$\ddot{x} + 2\omega_n \zeta \dot{x} + \omega_n^2 x = F(t)/M - \ddot{y} \quad (17.33)$$

A second reason is a byproduct of the uncoupled approach and corresponds to the case where the user is given a “shock spectrum” [Cunniff, 1989; Geers, 1998; Remmers, 1983], which is the response to a single degree of freedom, subject to a base motion $\{Y(t)\}$ (e.g., like Problem 1 and Problem 2 earlier).

With limited space, we can only outline the procedure; the reader is referred to Cook [1988], for detailed derivations of what is called the *mode displacement method*. The first step is to temporarily leave off the damping in Equation (17.31) and extract the normal undamped modes of vibration of Equation (17.31), with the r.h.s. set = 0, thus producing $I = 1, 2, \dots, I_{\max}$ normalized Eigenfunctions $\{\Phi_i\}$, stored columnwise in a matrix $[\Phi] = [\{\Phi_1\}, \{\Phi_2\}, \dots, \{\Phi_i\}]$, and Eigenvalues ω_i associated with each mode, $\{\Phi_i\}$, where I_{\max} is the length of the displacement vector $\{Z\}$. The modes can be extracted using any standard finite element computer code with a structural dynamics option such as ABAQUS, or NASTRAN, or for smaller problems using MATLAB, in conjunction with m-file scripts code found in [Hwon, 2000]. Since damping is left out, these are not the actual damped modes of the system (which typically are complex), but rather modes that are used as a change in variable to uncouple the system of coupled equations Equation (17.5). We introduce a change in variable $\{Z\} = [\Phi]\{\chi\}$, where $\{\chi\}$ is defined as the new *generalized variable* unknown. Next substitute this variable change into the damped version of Equation (17.31) and into the damped version of the driver Equation (17.32). The new differential equations will now be with respect to $\{\chi\}$ and its derivatives on time, but so far the equations will still be coupled. The usual step for uncoupling the equations is to premultiply the new transformed equation by $[\Phi]^T$ and then take advantage of the orthogonality of the Eigenfunctions. When there is no damping matrix $[C_{zz}]$ or if damping is present and can be represented as *Rayleigh damping* (also known as *proportional damping*), i.e.,

$$\ddot{x} + 2\omega_n \zeta \dot{x} + \omega_n^2 x = F(t)/M - \ddot{y} \quad (17.34)$$

(where α and β are user-defined constants), then we can simplify the equations on χ , resulting in the set of uncoupled equations for each mode “ i ”.

$$\ddot{\chi}_i + 2\omega_i \zeta_i \dot{\chi}_i + \omega_i^2 \chi_i = f_i(t) \quad i = 1, 2, \dots, i_{\max} \quad (17.35)$$

where χ_i is the i th row variable in the transformation variable $\{\chi\}$, ζ_i is the i th row constant in the proportional damping *diagonal matrix*

$$\text{diag}[\zeta_i] \equiv [\Phi]^T [C_{zz}] [\Phi] = [\alpha [\Phi]^T [K_{zz}] [\Phi] + \beta [\Phi]^T [M_{zz}] [\Phi]]$$

and the driver is given by $f_i(t) = \{\Phi_i\}^T \{\bar{F}_z\}$, where the damping term $[C_{zy}]\{\dot{Y}\}$ is in place in the r.h.s. of Equation (17.32). The final step is to integrate these I_{\max} equations, producing each row entry of the χ_i , of the $\{\chi\}$ generalized column matrix. Once these have been found, the desired actual displacement vector $\{Z\}$ can be found by back-substituting into the transformation equation to obtain:

$$\{Z(t)\} = \sum_{i=1}^{i=I_{\text{cut}}} \chi_i(t) \{\Phi_i\} \quad (17.36)$$

where the inequality $I_{\text{cut}} \leq I_{\max}$ denotes the notion that in many cases the higher modes in frequency are truncated from the final construction of the solution at a mode cutoff I_{cut} , for modes that are ordered from low to high frequency.

Integration of Uncoupled Equations

There are three options here worth noting, regarding the integration of Equations (17.35)

1. Simply integrate Equations (17.35) for each i , using a direct explicit or implicit numerical time integration scheme for ordinary differential equations.
2. Note that, remarkably, the l.h.s. of Equation (17.36) looks just like the simple single-degree-of-freedom damped harmonic motion oscillator of Equation (17.33). Therefore, by comparing like terms in these two differential equations, we can directly use Equation (17.8) and Equation (17.9) to obtain the solution for each i , where simple integration quadratures (e.g., *Simpson's rule*) can be used to obtain the solution in place of solving differential equations. Simply make the following correspondence between Equation (17.8) \leftrightarrow Equation (17.33), where: $x(t) \leftrightarrow \chi_i(t)$; $\omega_n \leftrightarrow \omega_i$; $\zeta \leftrightarrow \zeta_i$; $F(t)/M \leftrightarrow f_i(t)$; $\ddot{y} \leftrightarrow 0$ [i.e., set $\ddot{y} = 0$ in Equation (17.8)].
3. Analyst is given a *shock spectrum*, which represents a single D.O.F. response to the given motion input $\{Y(t)\}$, in lieu of the input itself as in options (1) and (2). There is not enough space to treat this in any detail, but briefly the shock spectrum maxima can then be related to the maximum of each mode contribution maximum [Remmers, 1983]. The total maximum response is typically performed by adding the contributions of each mode in a root mean square sense (i.e., the square root of the sum of the squares of the contributions of each mode for displacements, and stresses). This assumes all peaks occur at the same instant in time and squaring kills any chance of cancellation. Therefore this approach (e.g., [Geers, 1998]), "is far too conservative." In contrast, however, options (1) and (2) do take proper phasing into consideration and therefore are more accurate.

Defining Terms

C : Isolator damping constant (lb-sec/in.).

K : Isolator spring constant (lb/in.).

M : Net structural configuration mass (lb-sec/in.²).

g : Acceleration of gravity (386 in./sec²).

u : Isolator force not including static deflection (lb).

$\beta = ff_n$: Ratio of drive frequency to natural frequency (unitless).

ζ : Critical damping ratio = $C/(4\pi Mf_n)$ (unitless).

δ_s : Static deflection = Mg/K , amount spring deflects under dead weight of mass M (in.).

ω_n : Natural frequency (rad/sec).

$\omega_n = \omega_d \sqrt{1 - \zeta^2}$: damped natural frequency (rad/sec).

η : Damping decay constants (sec⁻¹).

T_U : Force transmission ratio = $\text{peak} |u(t)/F_{\max}|$ (unitless).

T_A : Acceleration transmission ratio = $\text{peak} |\ddot{z}/\ddot{y}_{\max}|$ (unitless).

T_D : Displacement magnification ratio = $\text{peak} |x/y_{\max}|$ (unitless).

BC : Base configuration, refers to the lower isolator attachment point (where base input accelerations \ddot{y} are applied).

SC : Structural configuration, refers to the net vibrating mass (upper connection to the isolator).

A primary concern in performing vibration analysis is just how to represent the response once the model and the various inputs of interest are known. For linear systems with a single degree of freedom, the analytical solution is closed form and can be simply plotted to illustrate the response and its important features. Historically, computation has been difficult and response vibration data have been presented in nomographs consisting of log plots of the maximum amplitudes of displacement, velocity, and acceleration versus frequency on a single two-dimensional four-axis plot. Although this approach is useful and incorporated into military and manufacturer specifications, wide availability of high-speed computing and computer codes to simulate detailed responses has produced a trend to display exact responses in both the time and frequency domains. Advances in computer algorithms and commercialization of codes has also made the computing of natural frequencies and mode shapes much easier. The following section introduces an example of a commercial computer simulation package and its use in representing the response of vibrating systems. Methods of computing natural frequencies and mode shapes are also given. In addition, the basic use of nomographs is presented.

18.1 Models for Numerical Simulation

The most common model of a vibrating system is the multiple degree of freedom (MDOF) model, which can be expressed as a vector differential equation with matrix coefficients of the form

$$M\ddot{\mathbf{x}}(t) + C\dot{\mathbf{x}}(t) + K\mathbf{x}(t) = \mathbf{f}(t) \quad \mathbf{x}(0) = \mathbf{x}_0, \quad \dot{\mathbf{x}}(0) = \dot{\mathbf{x}}_0 \quad (18.1)$$

where $\mathbf{x}(t)$ is an $n \times 1$ vector of displacement coordinates, its derivative $\dot{\mathbf{x}}(t)$ is an $n \times 1$ vector of velocities, and its second derivative $\ddot{\mathbf{x}}(t)$ is an $n \times 1$ vector of accelerations. The coefficients M , C , and K are $n \times n$ matrices of mass, damping, and stiffness elements, respectively (see [Chapter 14](#) for examples). These coefficient matrices are often symmetric and at least positive semidefinite for most common devices and

structures. Equation (18.1) follows from simple modeling using Newton's laws, energy methods, or dynamic finite elements. The constant vectors \mathbf{x}_0 and $\dot{\mathbf{x}}_0$ represent the required initial conditions. The simulation problem consists of calculating $\mathbf{x}(t)$, satisfying Equation (18.1) as time evolves, and producing a time record of each element of $\mathbf{x}(t)$, or of each degree of freedom, as opposed to a single coordinate as used in nomographs.

Currently many very well-written numerical integration codes are available commercially for less cost than is involved in writing the code and, more importantly, with less error. Codes used to solve Equation (18.1) are written based on the definition of a derivative and almost all require the equations of motion to appear in first-order form, that is, with only one instead of two time derivatives. Equation (18.1) can be easily placed into the form of a first-order vector differential equation by some simple matrix manipulations.

If the inverse of the mass matrix M exists, then the second-order vibration model of Equation (18.1) can be written as an equivalent first-order equation using new coordinates defined by the $2n \times 1$ vector:

$$\mathbf{z}(t) = \begin{bmatrix} \mathbf{x}(t) \\ \dot{\mathbf{x}}(t) \end{bmatrix}$$

Let $\mathbf{z}_1 = \mathbf{x}(t)$ and $\mathbf{z}_2 = \dot{\mathbf{x}}(t)$; then Equation (18.1) can be written as

$$\begin{aligned} \dot{\mathbf{z}}_1 &= \mathbf{z}_2 \\ \dot{\mathbf{z}}_2 &= -M^{-1}K\mathbf{z}_1 - M^{-1}C\mathbf{z}_2 + M^{-1}\mathbf{f}(t) \\ \mathbf{z}(0) &= \begin{bmatrix} \mathbf{x}_0 \\ \dot{\mathbf{x}}_0 \end{bmatrix} \end{aligned} \tag{18.2}$$

which combine to form

$$\dot{\mathbf{z}} = A\mathbf{z} + \mathbf{F}(t), \quad \mathbf{z}(0) = \mathbf{z}_0 \tag{18.3}$$

Here \mathbf{z} is called a *state vector* and the *state matrix* A is defined by

$$A = \begin{bmatrix} 0 & I \\ -M^{-1}K & -M^{-1}C \end{bmatrix} \tag{18.4}$$

where I is the $n \times n$ identity matrix and 0 is an $n \times n$ matrix of zeros. The forcing function $\mathbf{F}(t)$ is "mass" scaled to be the $2n \times 1$ vector

$$\mathbf{F}(t) = \begin{bmatrix} \mathbf{0} \\ M^{-1}\mathbf{f}(t) \end{bmatrix} \tag{18.5}$$

Here $\mathbf{0}$ denotes an $n \times 1$ vector of zeros. Note that in solving vibration problems using this state space coordinate system, the first n components of the solution vector $\mathbf{z}(t)$ correspond to the individual displacements of the n degrees of freedom and the second list of n components of $\mathbf{z}(t)$ are the velocities.

18.2 Numerical Integration

The numerical solution or simulation of the system described by Equation (18.1) is easiest to discuss by first examining the scalar homogeneous (unforced) case given by

$$\dot{x}(t) = ax(t) \quad x(0) = x_0$$

where a is a simple constant. The derivative $\dot{x}(t)$ is written from its definition as

$$\frac{x(t_i + \Delta t) - x(t_i)}{\Delta t} = ax(t_i) \quad (18.6)$$

where Δt is a finite interval of time. Rewriting this expression yields

$$x(t_i + \Delta t) = x(t_i) + ax(t_i)\Delta t \quad (18.7)$$

or using a simpler notation

$$x_{i+1} = x_i + ax_i\Delta t \quad (18.8)$$

where x_i denotes $x(t_i)$. This formula gives a value of the response x_{i+1} at the “next” time interval, given the equation’s coefficient a , the time increment Δt , and the previous value of the response x_i . Thus, starting with the initial value x_0 , the solution is computed at each time step incrementally until the entire record over the interval of interest is calculated. This simple numerical solution is called the **Euler formula** or tangent line method and only involves addition and multiplication. Of course, the smaller Δt is, the more accurate the approximation becomes (recall the derivative is defined as the limit $\Delta t \rightarrow 0$). Unfortunately, reducing the step size Δt increases the computational time. Numerical errors (rounding and truncation) also prevent the simulations from being perfect, and users should always check their results accordingly.

The rule used to perform the simulation is often called an *algorithm*. One way to improve the accuracy of numerical simulation is to use more sophisticated algorithms. In the late 1800s, C. Runge and M.W. Kutta developed some clever formulas to improve the simple tangent or Euler methods. Essentially, these methods examine $x(t + \Delta t)$ as a Taylor series expanded in powers of Δt . The **Runge-Kutta** methods insert extra values between x_i and x_{i+1} to provide estimates of the higher-order derivative in the Taylor expansion and thus improve the accuracy of the simulation. There are several Runge-Kutta methods, thus only an example is given here.

One of the most widely used Runge-Kutta methods solves the scalar equation $\dot{x} = f(x, t)$ with initial condition $x(0) = x_0$ where $f(x, t)$ can be linear or nonlinear as well as time varying. This includes the case $\dot{x}(t) = ax(t) + g(t)$ where a is constant and $g(t)$ is an externally applied force. With x_i and Δt defined as before, the formulas for the response are

$$x_{i+1} = x_i + \frac{\Delta t}{6}(h_{i1} + 2h_{i2} + 2h_{i3} + h_{i4}) \quad (18.9)$$

where

$$\begin{aligned} h_{i1} &= f(x_i, t_i) & h_{i2} &= f\left(x_i + \frac{\Delta t}{2}h_{i1}, t_i + \frac{\Delta t}{2}\right) \\ h_{i3} &= f\left(x_i + \frac{\Delta t}{2}h_{i2}, t_i + \frac{\Delta t}{2}\right) & h_{i4} &= f(x_i + \Delta t h_{i3}, t_i + \Delta t) \end{aligned}$$

This is referred to as a four-stage formula and represents a substantial improvement over the Euler method.

Additional improvement can be gained by adjusting the time step Δt at each interval based on how rapidly the solution $x(t)$ is changing. If the solution is not changing very rapidly, a large value of Δt_i , the i th increment of time is used. On the other hand if $x(t)$ is changing rapidly, a small Δt_i is chosen. In fact, the Δt_i can be chosen automatically as part of the algorithm.

18.3 Vibration Response by Computer Simulation

All of these methods (as well as many others not mentioned) can be applied to the simulation of the response of vibrating systems. Essentially the Runge-Kutta and Euler formulas can be applied directly to Equation (18.3) by simply enforcing a vector notation. For instance, the Euler formula applied to Equation (18.3) becomes

$$\mathbf{z}(t_{i+1}) = \mathbf{z}(t_i) + \Delta t \mathbf{A} \mathbf{z}(t_i) + \mathbf{F}(t_i) \tag{18.10}$$

using $\mathbf{z}(0)$ as the initial value. The result will be a list of numerical values for $\mathbf{z}(t_i)$ versus the successive times t_i . Equation (18.10) can be programmed on a programmable calculator or computer system. However, many commercially available codes provide more than adequate numerical integration schemes for solving ordinary differential equations and systems of ordinary differential equations as described by Equation (18.10). Such codes are easy to use and allow studies of the effects of initial conditions and parameter changes while providing detailed solutions to complex problems.

Next, a simple example is introduced to illustrate the formulation of a vibration problem into state space form in preparation for numerical simulation. Consider then the equations of motion of a damped two-degree-of-freedom system

$$\begin{bmatrix} 9 & 0 \\ 0 & 1 \end{bmatrix} \begin{bmatrix} \dot{x}_1(t) \\ \dot{x}_2(t) \end{bmatrix} + \begin{bmatrix} 2.7 & -0.3 \\ -0.3 & 0.3 \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \end{bmatrix} + \begin{bmatrix} 27 & -3 \\ -3 & 3 \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \end{bmatrix} = \begin{bmatrix} 3 \\ 0 \end{bmatrix} \sin 3t \tag{18.11}$$

subject to the initial conditions

$$\mathbf{x}(0) = \begin{bmatrix} 0.1 \\ 0 \end{bmatrix}, \quad \dot{\mathbf{x}}(0) = \begin{bmatrix} 0 \\ 0 \end{bmatrix}$$

Here all units are SI so that $\mathbf{x}(t)$ is in meters, etc. However, any consistent set of units can be used. This is a simple example with only two degrees of freedom so chosen to fit the given space limitations. The procedure is, however, not dependent on such low order. The matrix M^{-1} in this case is simply

$$M^{-1} = \begin{bmatrix} \frac{1}{9} & 0 \\ 0 & 1 \end{bmatrix}$$

so that

$$M^{-1}K = \begin{bmatrix} 3 & -0.333 \\ -3 & 3 \end{bmatrix} \quad \text{and} \quad M^{-1}C = \begin{bmatrix} 0.3 & -0.033 \\ -0.3 & 0.3 \end{bmatrix}$$

and the state matrix becomes

$$A = \begin{bmatrix} 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \\ -3 & 0.333 & 0.3 & 0.033 \\ 3 & -3 & 0.3 & -0.3 \end{bmatrix}$$

where the state vector and forcing vector are

$$\mathbf{z} = \begin{pmatrix} x_1 \\ x_2 \\ \dot{x}_1 \\ \dot{x}_2 \end{pmatrix} \quad \text{and} \quad \mathbf{F}(t) = \begin{bmatrix} 0 \\ 0 \\ \sin 3t \\ 0 \end{bmatrix}$$

respectively. Next, Equation (18.10) can be applied with these values. In the past it was required of the vibration engineer to program Equation (18.10) or some other versions of it. However, commercial software allows the matrix A to be easily assembled and allows easy simulation of the time response and plotting the frequency response.

18.4 Commercial Software for Simulation

A variety of simple-to-use, efficient, and relatively inexpensive interactive software packages are available for simulating the response. Such programs reduce by a factor of ten the amount of computer code that actually has to be written by the user. Some examples of available software containing numerical integration packages are `MALAB`[®], `Mathematica`, and `Mathcad`. Many finite element packages also contain numerical integration routines. Here we illustrate the use of `MALAB` to simulate the result of the simple example above and to print the results. The `MALAB` code is listed in [Table 18.1](#) and the output is plotted in [Figure 18.2](#). The algorithm used in [Table 18.1](#) is a modification of the formulas given in Equation (18.9), known as a Runge-Kutta-Fehlberg integration method. This method uses a fourth- and fifth-order pair of formulas and an automatic step size.

The use of high-level computational software such as `MALAB`, `Mathcad`, and `Mathematica` is commonplace. The slide rule has given way to the calculator, and the calculator to the personal computer. Combined with commercial software, the simulation of large and complex vibration problems can be performed without resorting to writing code in lower-level languages. This time-saving allows the vibration engineer more time to devote to design and analysis. It is, however, important to note that simulation through numerical integration is still an approximation and as such is subject to error — both **formula errors** and **round-off errors**. These should be well understood by the user. More detailed examples of these three codes used to solve vibration problems can be found in Inman [2001].

These same computer codes also contain sophisticated routines for obtaining the solutions to the eigenvalue problems associated with vibration and hence are very useful in obtaining the mode shapes and natural frequencies. These methods are discussed next.

18.5 Computing Natural Frequencies and Mode Shapes

Natural frequencies and mode shapes form the language of modern vibration analysis and are often used among practicing engineers and researchers to describe the vibration characteristics of a structure or machine. Computing natural frequencies and mode shapes use to involve many approximate techniques. The rise of modern computing and advances in numerical linear algebra and subsequent commercialization have made the computing of natural frequencies and mode shapes relatively easy. However,

TABLE 18.1 MATLAB SIMULATION Code

MATLAB code for computing and plotting the displacement versus time response of the two-degree-of-freedom system in the text. The % symbol denotes comments. Part A indicates how to input the given system and part B illustrates how to integrate and plot the response.

Part A

```
function zdot = system (t, z)
%This m-file defines the mechanical properties of the system being studied.
%The input is the current time and the previous state vector (initial conditions).
%The output is obtained by solving the state equation: zdot = A * z + f
%First, the mass, damping and stiffness matrices are defined.
M = [9, 0; 0, 1];
C = [2, 7, -0.3; -0.3, 0.3];
K = [27, -3; -3, 3];
f = [0; 0; sin(3 * t); 0];
%The vector of external forces is defined next.
%The state matrix is assembled.
A = [zeros(2, 2) eye(2, 2); -inv(M) * K -inv(M) * C];
```

Part B

```
%This is the main file used in the simulation.
%First the initial state is defined.
z0 = [0.1; 0; 0; 0];
%Then, the solution is obtained through numerical integration using the ode command
calling the "system" input file proposed in part A.

ti = 0; %Initial time of the simulation
tf = 50; %Final time of the simulation
[time,solution] = ode45('system', ti, tf, z0); %Perform integration

%The displacement of each degree-of-freedom is plotted.

title('Second DOF');
```

commercial codes have centered on implementing numerical linear algebra results, i.e., implementing solutions of the algebraic eigenvalue problem, rather than focusing on vibration problems directly. Thus, computations of natural frequencies and mode shapes are best done by converting the definition of these physical quantities into the algebraic eigenvalue problem. There are several ways to make this transformation and these are presented here along with their strengths and weaknesses.

Undamped systems are systems modeled by Equation (18.1) with no damping present ($C = 0$). Natural frequencies are defined as the frequencies at which a system will vibrate given an arbitrary initial displacement and velocity disturbance. Undamped natural frequencies (rad/sec) are denoted ω_n , and there will be one frequency for each degree of freedom in a linear system such as those successfully modeled by Equation (18.1) with $C = 0$. Natural frequencies are calculated from assuming a solution to Equation (18.1), for the undamped case of $C = 0$, of the form $\mathbf{x}(t) = \mathbf{u}e^{j\omega t}$, where \mathbf{u} is an unknown vector of constants, $j = \sqrt{-1}$, t is the time, and ω is the yet-to-be-determined natural frequency. Substitution of this assumed solution into Equation (18.1) yields:

FIGURE 18.1 The output of the MATLAB Code of Table 18.1, illustrating the simulation of the displacement versus time response of the system given by Equation (18.11).

$$(-\omega^2 M + K)\mathbf{u} = 0, \quad \mathbf{u} \neq 0 \quad (18.12)$$

This last expression can only hold true if the coefficient matrix is singular, which happens if and only if the determinant of $(-\omega^2 M + K)$ vanishes. This yields an n th order polynomial in ω^2 , the roots of which are the n values of the squares of the natural frequencies ω_i^2 indexed $i = 1, 2, 3, \dots, n$. The yet unknown vectors \mathbf{u}_i corresponding to each ω_i are called the mode shapes, and they are found from solving the n scalar equations given by Equation (18.12) for each of the n values of ω_i^2 . Since the coefficient is singular (because its determinant is zero) at each value of ω_i^2 , Equation (18.12) will result in only $n - 1$ independent equations for each element of the mode shape vector \mathbf{u}_i . This allows for the solution of all but one value of the n elements of each mode shape vector. The n th value is computed by forcing the vector to have a unit magnitude (normalized). Rewriting Equation (18.12) reveals its relationship to the generalized eigenvalue problem:

$$K\mathbf{u}_i = \omega_i^2 M\mathbf{u}_i \Leftrightarrow A\mathbf{u}_i = \lambda_i B\mathbf{u}_i, \quad \mathbf{u}_i \neq 0 \quad (18.13)$$

The generalized eigenvalue problem, stated on the right side of the above, is to compute \mathbf{u}_i and λ_i given the matrices $A = K$ and $B = M$. This is exactly equivalent to computing mode shapes and natural frequencies. This is a symmetric generalized eigenvalue problem, since the matrices M and K are both symmetric.

The algorithms for computing the generalized eigenvalue problem are more costly than those of the normal eigenvalue problem, which can be obtained by multiplying Equation (18.13) by the inverse of the mass matrix M (or B) to get

FIGURE 18.2 An example of a vibration nomograph for specifying acceptable limits of sinusoidal vibration. (Source: Inman, D. J. 2001. *Engineering Vibration, 2nd Edition*, Prentice Hall, Upper Saddle River, NJ. With permission.)

$$M^{-1}Ku_i = \omega_i^2 u_i \Leftrightarrow Au_i = \lambda_i u_i \quad u_i \neq 0 \quad (18.14)$$

Here the matrix A in the statement of the eigenvalue problem is now $A = M^{-1}K$, where M^{-1} denotes the matrix inverse. The mode shapes are given directly by the vector \mathbf{u} but since A is not symmetric there is no guarantee that the eigenvectors will be real valued or orthogonal (in fact they are not), nor is it obvious that the values of $\lambda_i = \omega_i^2$ will be nonnegative real numbers, as we expect for the vibration problem.

If the eigenvalue problem of Equation (18.13) is transformed by mass normalizing the stiffness matrix, a symmetric eigenvalue problem results. There are two strong advantages to using the symmetric eigenvalue problem. The first is that symmetric eigenvalue problems are known to produce orthogonal eigenvectors, even in the case of repeated frequencies, and the second is that the numerical procedure for computing the solution to the symmetric eigenvalue problem is not as subject to round-off error as the asymmetric eigenvalue problem is. To this end, assume the matrix M is positive definite and symmetric (it usually is), so that it has a positive definite matrix square root. Let $\mathbf{u} = M^{-1/2}\mathbf{v}$ in Equation (18.13) and multiply the equation by $M^{-1/2}$. This yields:

$$M^{-1/2}KM^{-1/2}\mathbf{v}_i = \omega_i^2 \mathbf{v}_i \Leftrightarrow A\mathbf{v}_i = \lambda_i \mathbf{v}_i \quad \mathbf{v}_i \neq 0 \quad (18.15)$$

where the matrix $A = \tilde{K} = M^{-1/2}KM^{-1/2}$, called the mass normalized stiffness matrix, is now symmetric, and the corresponding eigenvalue problem is symmetric. From the theory of eigenvalue problems (matrix theory or linear algebra) it is well known that the solution of a symmetric eigenvalue problem results in a set of n real valued, orthogonal eigenvectors, one for each value of λ_i (regardless of repeated eigenvalues) and that the eigenvalues are all real valued and nonnegative if the matrix A is positive semidefinite (which it is in this case). This is precisely the theory needed to ensure analytical solutions such as modal expansion methods (since the \mathbf{v}_i form an orthonormal basis) and in computing the time response given initial conditions. In addition, the computational algorithms for symmetric eigenvalue problems are considerably simplified compared with those needed for Equation (18.14). In particular, all the calculations assume real rather than complex arithmetic. Note that while the eigenvalues are the squares of the natural frequencies in all three eigenvalue problems listed above, the mode shapes defined from Equation (18.14) are different from the eigenvectors of Equation (18.15) and are related by $\mathbf{u} = M^{-1/2}\mathbf{v}$. In particular, the mode shapes computed by Equation (18.14) are not orthogonal as often stated in many texts, but rather are only orthogonal when weighted by the mass matrix.

This symmetric method can also proceed by using the Cholesky factors of M rather than the square root of the mass matrix. A symmetric positive definite matrix M has an upper triangular matrix (all elements below the diagonal are zero) factor L such that $L^T L = M$. If M is diagonal, then the factor L is identical to the square root of M as used in Equation (18.15). For dynamically coupled systems (i.e., those with nondiagonal mass matrices), it is more efficient to compute the mass normalized stiffness matrix in Equation (18.15) using the Cholesky factors rather than the matrix square root. The mass normalized stiffness matrix then becomes $\tilde{K} = (L^T)^{-1}KL^{-1}$. This version of the mass normalized stiffness matrix is used as the matrix A in Equation (18.15) to compute the eigenvalues and eigenvectors. (Note that some codes use a lower triangular Cholesky factor rather than upper, causing the transpose to flip sides.)

Proportionally damped systems form the most commonly used damped case. Computing natural frequencies and mode shapes when viscous damping is present, $C \neq 0$, becomes much more complicated and bifurcates into two distinct cases. The first case, often referred to as proportional damping, occurs if and only if the coefficient matrices (assumed to be symmetric) form a product $CM^{-1}K$ that is in turn symmetric. Then the eigenvectors calculated from the (undamped) symmetric eigenvalue problem of Equation (18.15) become the eigenvectors of the damped expression as well and satisfy ($\tilde{C} = M^{-1/2}CM^{-1/2}$):

$$\left(\lambda^2 I + \lambda \tilde{C} + \tilde{K}\right)\mathbf{v} = 0, \quad \mathbf{v} \neq 0 \quad (18.16)$$

where I denotes the $n \times n$ identity matrix. The matrix $\tilde{C} = M^{-1/2}CM^{-1/2}$ is called the mass normalized damping matrix. Here, λ_i are the system eigenvalues which are in general complex (for underdamped systems), and these are related to the natural frequency and damping ratio by:

$$\omega_i = \sqrt{\text{Re}(\lambda_i)^2 + \text{Im}(\lambda_i)^2}, \quad \zeta_i = \frac{-\text{Re}(\lambda_i)}{\sqrt{\text{Re}(\lambda_i)^2 + \text{Im}(\lambda_i)^2}} \quad (18.17)$$

Not many numerical algorithms exist for solving Equation (18.16) for λ_i and \mathbf{v}_i directly from Equation (18.16). However, because the assumption of symmetry of $CM^{-1}K$, the eigenvectors of the mass normalized stiffness matrix are also eigenvectors of the mass normalized damping matrix. Hence the eigenvectors of Equation (18.15) serve as the system eigenvectors for Equation (18.16), and the undamped natural frequencies are also computed from Equation (18.15). Hence, the natural frequencies and eigenvectors for Equation (18.16) are best calculated using Equation (18.15).

To compute the damping ratios, the system of Equation (18.16) is transformed into a diagonal system using the eigenvectors to form the orthogonal matrix P constructed by taking the columns of P to be the orthonormal vectors \mathbf{v}_i :

$$P = [\mathbf{v}_1 \quad \mathbf{v}_2 \quad \cdots \quad \mathbf{v}_n] \quad (18.18)$$

Substitution of $\mathbf{v} = P\mathbf{r}$ into Equation (18.16) and multiplying P^T yields

$$(\lambda^2 I + \text{diag}(2\zeta_i \omega_i) \lambda + \text{diag}(\omega_i)) \mathbf{r} = 0 \quad (18.19)$$

Here the vector \mathbf{r} is called the modal coordinate system and the coefficient matrix of \mathbf{r} is diagonal. The properties of the orthonormal matrix P for the case of proportional damping are

$$P^T P = I \quad P^T \tilde{K} P = \begin{bmatrix} \omega_1^2 & 0 & \cdots & 0 \\ 0 & \omega_2^2 & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & \omega_n^2 \end{bmatrix} \quad P^T \tilde{C} P = \begin{bmatrix} 2\zeta_1 \omega_1 & 0 & \cdots & 0 \\ 0 & 2\zeta_2 \omega_2 & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & 2\zeta_n \omega_n \end{bmatrix} \quad (18.20)$$

This last expression is used to compute the modal damping ratios ζ_i given the matrices M , C , and K . In practice, the modal damping ratios are guessed based on material measurements or measured using a vibration test.

The symmetry of $CM^{-1}K$ is a necessary and sufficient condition for the above analysis and results from the linear algebra theory that two matrices share the same eigenvectors if and only if they commute. However, other, simpler conditions are used in practice. These are

$$C = \alpha M + \beta K$$

$$C = \sum_{i=1}^n \alpha_{i-1} K^{i-1} \quad (18.21)$$

Here the constants α , α_i , and β are arbitrary scalars chosen by the analyst so that C is positive semidefinite and to produce some reasonable amount of damping. If these conditions are satisfied, then the eigenvectors, damping ratios, and natural frequencies can be determined by Equation (18.15) and Equation (18.20). Such systems are said to possess classical normal modes (because the eigenvectors are real valued and form an orthonormal basis). They are also called normal mode systems.

General viscous damping refers to the situation when viscous damping is present but not of the proportional type. If the matrix $CM^{-1}K$ is not symmetric, then the above analysis fails and the system is said not to be proportionally damped and in general (assuming all modes to be underdamped) will have complex mode shapes. The only choice to compute the modal information is then to use the state space matrix of Equation (18.4). The associated eigenvalue problem is not symmetric and is given by

$$A\mathbf{z} = \lambda\mathbf{z} \quad (18.22)$$

Here the eigenvector \mathbf{z} is related to the eigenvector in physical coordinates of Equation (18.12) by

$$\mathbf{z} = \begin{bmatrix} \mathbf{u} \\ \lambda\mathbf{u} \end{bmatrix} \quad (18.23)$$

Here both the eigenvectors \mathbf{z} and the eigenvalues λ are in general complex numbers appearing in complex conjugate pairs. The relationships of these eigenvalues computed from Equation (18.22) to the natural frequencies and damping ratios are given by Equations (18.17). The mode shapes are a little more difficult to compute but are basically the first n values of the vector \mathbf{z} of Equation (18.23).

Next, the simple example of Equation (18.11) is used to illustrate the various eigenvalue problems and their solution in MATLAB. First note that this example has proportional damping since

$$CM^{-1}K = \begin{bmatrix} 2.7 & -0.3 \\ -0.3 & 3 \end{bmatrix} \begin{bmatrix} 1/9 & 0 \\ 0 & 1 \end{bmatrix} \begin{bmatrix} 27 & -3 \\ -3 & 3 \end{bmatrix} = \begin{bmatrix} 9 & -1.8 \\ -1.8 & 1 \end{bmatrix}$$

is obviously symmetric. Thus the eigenvectors and mode shapes of the undamped system serve as the eigenvectors and mode shapes of the damped system. When one proceeds to compute the solution of the eigenvalue problem (for $C = 0$) using a code, the question naturally arises: is there a numerically superior method? Table 18.2 illustrates the results of computing the eigenvalues and eigenvectors for each of the eigenvalue problems listed above applied to this simple example. The “flops” command (no longer available in MATLAB) is used to indicate how many floating-point operations are used in each calculation. Note that the most expensive choice of computing the eigenvalues and eigenvectors is using the state space formulation of Equation (18.22) followed by the generalized eigenvector problem of Equation (18.13). The cheapest computationally uses the Cholesky form of the symmetric eigenvalue problem of Equation (18.15). It should be noted that while using Equation (18.14) is relatively low, it does not result in orthogonal eigenvectors, and additional steps are required to solve the associated vibration problem. A sample code is given in Table 18.3. Detailed examples in MATLAB, Mathematica, and Mathcad for vibration analysis can be found in Inman [2001]. For simple small-order problems, the differences between eigenvalue problems is numerically not too significant. However, for practical, larger-order systems or for systems with order of magnitude differences in mass and stiffness terms, the choice of eigenvalue problem formulation could become critical.

18.6 Nomograph Fundamentals

Nomographs are graphs used to represent the relationship between displacement, velocity, acceleration, and frequency for vibrating systems. These graphs are frequently used to represent vibration limits for given parts, machines, buildings, and components. The basic premise behind a vibration nomograph is

that the response of a system is harmonic of the form $x(t) = A \sin \omega_n(t)$. Here A is the amplitude of vibration and ω_n is the natural frequency of vibration in rad/sec. The velocity is the derivative $\dot{x}(t) = \omega_n A \cos \omega_n t$, and the acceleration is the second derivative $\ddot{x}(t) = -\omega_n^2 A \sin \omega_n t$. Thus, if a vibrating system has displacement amplitude A , its velocity has amplitude $\omega_n A$ and the acceleration amplitude is $\omega_n^2 A$. For a given harmonic motion, these three amplitudes can be plotted versus frequency, commonly using a log scale as illustrated in Figure 18.1. In this log scale plot, the log of the frequency (denoted f in Hz, where $f = \omega_n / 2\pi$) is plotted along the horizontal and the corresponding velocity amplitude is plotted along the vertical, also on a log scale. The lines slanting to the right, of slope +1, correspond to the log of the displacement amplitude versus frequency, whereas those slanting to the left, with slope -1, correspond to the log of the acceleration amplitude versus frequency. Thus a given point on the monograph corresponds to the amplitude of displacement, velocity, and acceleration at a specific frequency. Nomographs can be used to specify regions of acceptable vibration. Often it is not enough to specify just displacement; restrictions may also exist on velocity and acceleration amplitudes. By sketching a closed shape on a nomograph, ranges of acceptable levels of maximum displacement, velocity, and acceleration over a frequency range of interest can be easily specified. The bold lines in Figure 18.2 illustrate an example. The bold lines in the figure are used to illustrate vibration between 2 and 8 Hz with displacement amplitude limited by 30 mm, velocity amplitude limited by 400 mm/sec and acceleration limited to amplitude by 10^4 mm/sec².

Rather than maximum amplitude, root mean square values of displacement, velocity, and acceleration can be plotted as nomographs. As mentioned, such plots are often used in formal documents, vendor specifications, and military specifications. The International Organization for Standardization presents vibration standards for severity, which are often represented in nomograph form.

As useful as nomographs are and as frequently as they appear in codes and standards, modern computational abilities allow detailed representations of vibration data for much more complicated systems. In particular, it has become very common to simulate time responses directly.

Defining Terms

Eigenvalue problem — The algebraic process of computing the eigenvalues and eigenvectors of a given matrix.

Euler method — A simple numerical solution to a first-order ordinary differential equation based on approximating the derivative by a slope.

Formula error — Error in the computed response due to the difference between the exact solution and the approximate formula.

Mode shape — The eigenvector of the mass normalized stiffness matrix multiplied by the inverse square root of the mass matrix, indicating the shape in which a system naturally tends to vibrate.

Natural frequencies — The square roots of the eigenvalues of the mass normalized stiffness matrix and the frequencies at which a freely responding system will oscillate.

Nomograph — A graph of displacement, velocity, and acceleration versus frequency for a single-degree-of-freedom system.

Round-off error — Error in the computed response due to numerical round-off and truncation in computer arithmetic.

Runge-Kutta method — A numerical solution to a first-order ordinary differential equation based on approximating the derivative by several estimates of the first few terms of a Taylor series expansion of the solution.

Simulation — Numerical integration to solve an (ordinary) differential equation using time steps to produce the time history of the response (of a vibrating system).

Terrence W. Baird
Hewlett-Packard Company

Dynamic test and measurement finds application in many engineering and scientific disciplines. Although each has evolved uniquely in its types of equipment and methods employed, a degree of commonality exists in the operating principles and performance criteria of the various apparatuses used. Rather than attempting comprehensive treatment of each application or equipment type available, focus will be directed toward this commonality through a discussion of the components of a generalized test system.

The generalized model from which the discussion will be developed is as follows. A device is subjected to a specified dynamic environment produced by a test machine. The test machine input and device response motions are measured by **transducers**, whose signals are conditioned and subsequently analyzed for purposes of data reduction and test machine control. Descriptions will be limited to some commonly used test equipment and instrumentation and their key performance criteria.

Although the model described will be used as the basis for this introduction to test equipment, it is the author's intent that the technical content and principles of equipment performance be relevant to any application. The reader is encouraged to research the references and resources cited at the end of the chapter to more fully explore today's dynamic test technology on an application-specific basis.

19.1 Vibration and Shock Test Machines

Vibration Test Machines

Vibration test machines, also referred to as *shakers*, are available in several distinct designs. Two common shaker designs are electrohydraulic and electrodynamic; the names are based on the method of force generation.

Electrohydraulic shakers generate force through electrically controlled hydraulics where power is converted from the high-pressure flow of hydraulic fluid to the vibratory motion of the shaker's table. [Figure 19.1](#) [Unholtz, 1988] illustrates a block diagram of a typical electrohydraulic shaker system and

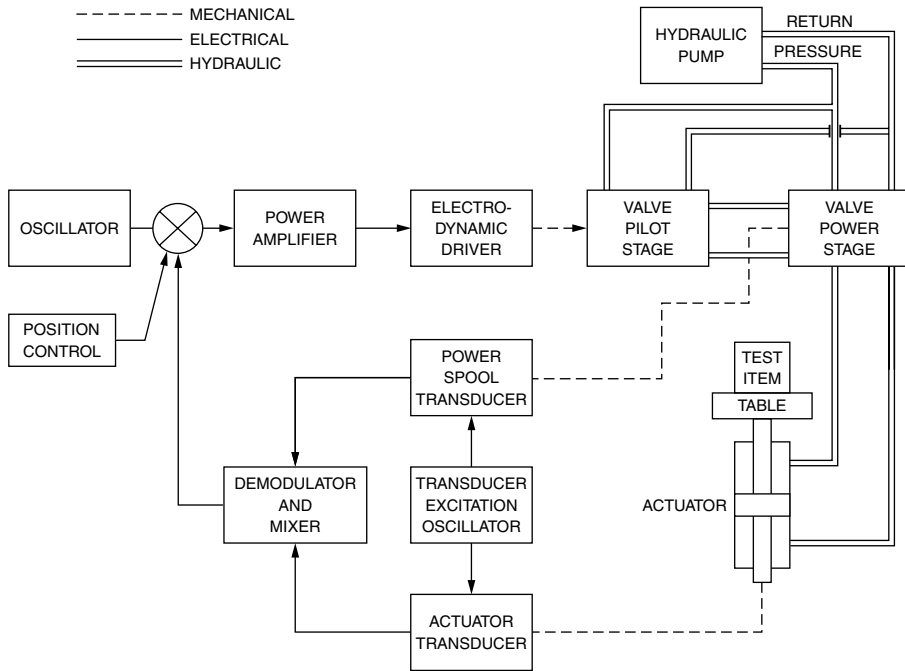

FIGURE 19.1 Block diagram of an electrohydraulic shaker. (Source: Harris, C. and Crede, C. 1988. *Shock and Vibration Handbook*, 3rd ed. McGraw-Hill, New York. Reproduced with permission.)

Figure 19.2 shows an actual system. Availability of large force generation, long displacement stroke, and low-frequency performance are advantages of an electrohydraulic shaker.

Electrodynamic (also called *electromagnetic*) shakers generate force by means of a coil carrying a current flow placed in a magnetic field, which passes through the coil, causing motion of the coil, moving element, and table assembly (called the *armature*). The operating principle is not unlike that of a loudspeaker system. Some electrodynamic shakers use a “double-ended” design, which incorporates both an upper and a lower field coil, resulting in reduced stray magnetic fields above the table and increased operating efficiency. A typical double-ended shaker design is shown in Figure 19.3. Higher frequency performance is a major advantage of an electrodynamic shaker.

FIGURE 19.2 Electrohydraulic shaker system including hydraulic supply, shaker, and digital controller. (Courtesy Lansmont Corp.)

FIGURE 19.3 Schematic of double-ended electrodynamic shaker design. (Courtesy Unholtz-Dickie Corp.)

Shaker Performance Considerations

The following criteria should be evaluated relative to the application regardless of shaker type.

1. *Force rating.* The maximum force available is typically specified as a continuous rating for sine vibration through a usable frequency range. Estimated acceleration performance can be determined from:

$$A = F/W \quad (19.1)$$

where A = maximum acceleration, g ; F = force rating in pounds-force, lbf; and W = total load, lb, including armature, table, and test specimen weight.

2. *Frequency range.* Frequency versus amplitude performance is generally specified in a series of performance curves presented for various test loads. Representative ranges for typical general-purpose shakers are 1 to 500 Hz for electrohydraulic and 10 to 3000 Hz for electrodynamic, depending on test parameters.
3. *Waveform quality/harmonic distortion.* This will vary by design but should be specified.
4. *Magnetic fields.* This may be a concern for some applications, in which case it should be specified for electrodynamic shakers. It is not a concern with electrohydraulic shakers.
5. *Table or head expander frequency response.* The practical frequency range will depend, in part, on the table attached to the shaker. Basic design, mass, damping, and frequency response characteristics should be specified.
6. *Test orientation.* Consideration should be given to design type if independent vertical and horizontal test capability is desired. For instance, it is relatively common for an electrodynamic shaker to be supported by a base with a trunnion shaft, whereby the entire body can be rotated about its center providing for either vertical or horizontal vibration.

Shock Test Machines

Three specification types are used in defining a shock test:

1. Specification of the shock test machine (also called *shock machine*) including mounting and operating procedures. Shock machines unique to a specification will not be discussed.
2. Specification of shock motion described by simple shock pulse waveforms and parameters of peak acceleration, duration, and **velocity change**. An example is shown in [Figure 19.4](#).
3. Specification of the **shock response spectrum (SRS)** that the test produces.

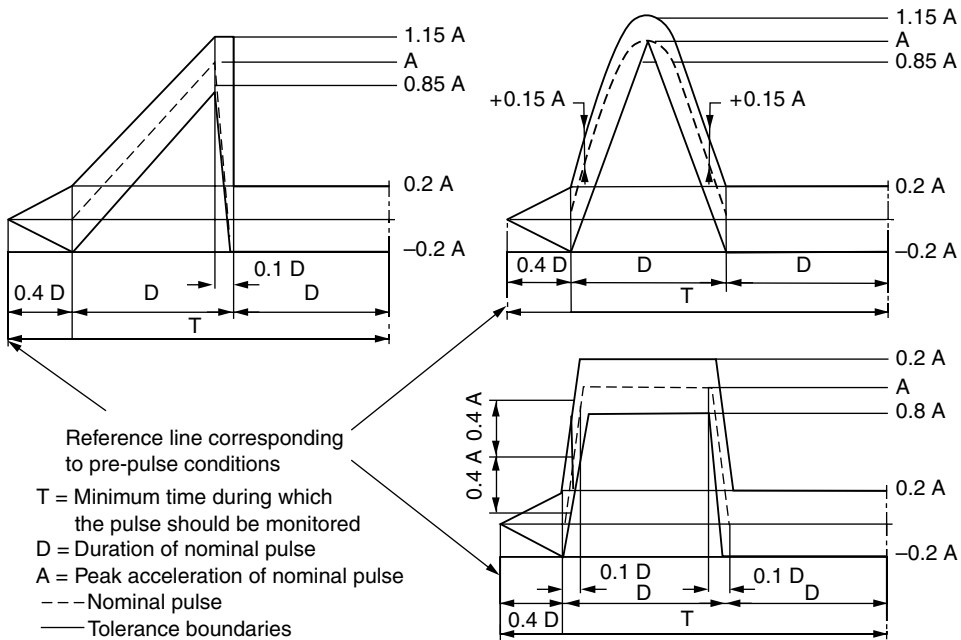

FIGURE 19.4 Preferred shock pulse waveforms of IEC 68-2-27. (Source: Broch, J. T. 1984. *Mechanical Vibration and Shock Measurement*, 2nd ed. Bruel and Kjaer, Naerum, Denmark. Reproduced with permission.)

Two types of machines used for shock generation are the free-fall shock machine and the previously described shakers.

A typical free-fall shock machine (sometimes called a *drop table* or *drop tester*) is shown in Figure 19.5 and is used for generating simple or classical pulse waveforms such as those in Figure 19.4. Operation is straightforward. The shock table, whose orientation and free-fall path are controlled by guide rods, is raised to a desired height and allowed to fall and impact upon a pulse programmer. Brakes are employed to prevent multiple impacts after rebound. Shock pulse velocity change is controlled by drop height. Pulse waveform, resulting peak acceleration, and duration are determined by programmer type. Significant velocity and peak acceleration capabilities are advantages of this type of shock machine.

Shakers with appropriate digital controllers are not only capable of producing classical waveforms, but can also be used for applications such as SRS programming or capturing a real-world shock pulse and using it as a control waveform for subsequent shock tests. Shakers have limitations for shock test in terms of available displacement, velocity, and peak acceleration. However, for low-level shocks of light- to medium-weight specimens, test flexibility, control, and repeatability are excellent if the test parameters are within the performance limits of the shaker.

Shock Test Machine Performance Considerations

Performance criteria that should be evaluated against the intended application include:

1. *Maximum peak acceleration.* Some shakers can achieve 100 to 200 g. A general-purpose free-fall shock machine is usually limited to less than 1000 g, whereas a high-performance shock machine may be capable of 20,000 g for lightweight specimens.
2. *Pulse duration,* maximum and minimum.
3. *Velocity change.* Shakers will normally be limited to less than 100 inches /second (ips). A general-purpose free-fall shock machine will achieve 300 ips, and a high-performance shock machine may be capable of 1000 ips. For very low velocity changes (0 to 50 ips), control and repeatability can be difficult with a free-fall shock machine.

FIGURE 19.5 Shock machine and associated instrumentation. (Courtesy MTS Systems Corp.)

4. *Waveform flexibility and programmer design.*
5. *Table size and weight capacity.*
6. *Table performance, frequency response, damping, and waveform quality.*
7. *Potential need for SRS control and waveform synthesis.*

19.2 Transducers and Signal Conditioners

Transducers

The ANSI/ISA definition of transducer is “a device which provides a usable output in response to a specified measurand” [ANSI/ISA S37.1]. The measurand is the physical quantity to be measured, and the output is an electrical quantity whose amplitude is proportional to that of the measurand. The measurand is the primary descriptor of a transducer type and for dynamic testing would likely be displacement, velocity, or acceleration. The most common measurand is acceleration, so this discussion will be limited to acceleration transducers, more commonly referred to as *accelerometers*. Two common categories of accelerometers are piezoelectric and piezoresistive, which differ fundamentally in their electrical transduction principles.

FIGURE 19.6 Accelerometer designs. (Courtesy Endevco Corp.)

Piezoelectric (PE) accelerometers incorporate sensing elements, typically quartz or ceramic crystals, that have the property of producing a charge when mechanically stressed. Specifically, when subjected to an acceleration, the PE accelerometer produces a charge proportional to the applied acceleration and is said to be *self-generating* in that the electrical output is produced without the need for auxiliary power excitation to the accelerometer. Typically, this charge then needs to be converted to a voltage in an external signal conditioner for subsequent analysis or readout. An exception to this rule is the now commonly available PE accelerometer with built-in integrated-circuit signal conditioning.

Piezoresistive (PR) accelerometers incorporate a semiconductor material such as a solid state silicon resistor, which serves as a strain-sensing or strain gage element. Arranged in pairs and typically connected electrically in a Wheatstone-bridge circuit, these PR elements exhibit a change in electrical resistance proportional to an applied acceleration. The PR accelerometer is referred to as a *passive* type accelerometer in that it does require an external power source to operate. The PR accelerometer's primary advantage is its ability to measure down to DC or steady-state acceleration, making it particularly suitable to long-duration pulses and other low-frequency applications. PE and PR accelerometer designs are shown in Figure 19.6.

Transducer Performance Considerations

The following performance criteria should be evaluated prior to an accelerometer's use. The first three are most critical and for a given design are interrelated, representing the likely trade-offs or compromises in accelerometer selection.

1. *Sensitivity.* Defined as the ratio of change in output to change in acceleration, sensitivity is expressed as coulomb/g or volt/g, depending on accelerometer type. The higher the sensitivity, the greater the system signal-to-noise ratio will be.
2. *Frequency response.* Both low- and high-frequency response may be important to an application.
3. *Mass and size.* Accelerometer weights can range from 1 to 60 g. Typically, minimizing size and mass is desirable.
4. *Mass loading effect.* Mounting an accelerometer with finite mass onto a structure changes the mechanics of the structure at that point. If the mass of the accelerometer is a significant percentage of the effective mass of the structure at the point of attachment, the structure's frequency response will be altered, resulting in a poor measurement. A simple rule of thumb or exercise to determine if mass loading is a problem is to:
 - A. Measure a frequency response function of the structure using the desired accelerometer.
 - B. Mount a second accelerometer of the same mass at the same point of attachment (i.e., mass is now doubled) and repeat the measurement.
 - C. Compare the two measurements for amplitude changes and frequency shifts. If differences are significant, then mass loading is a problem. (Although not discussed in the text, some mea-

surement situations do exist in which mass loading effects, extreme surface temperatures, rotating structures, or other test conditions preclude the practical use of a *contact* transducer, such as an accelerometer. In these instances, a *noncontact* transducer can be employed — such as a *laser Doppler vibrometer* for motion detection — where the *electro-optical* transduction principle is employed.)

5. *Amplitude range and linearity.* Sensitivity is constant within stated tolerances over a certain amplitude range, beyond which sensitivity is nonlinear. This is usually expressed as a percentage deviation from nominal sensitivity as a function of the applied acceleration.
6. *Transverse sensitivity.* For a single-axis accelerometer, there is still a small sensitivity to transverse accelerations, which is usually expressed as a percentage of main axis sensitivity.
7. *Temperature sensitivity.* Percent deviation from the nominal sensitivity is expressed as a function of temperature.
8. *Mounting considerations.* Although not a characteristic of accelerometer design, the way in which an accelerometer is mounted to the structure for measurement has a significant influence on its effective frequency response. [Figure 19.7](#) shows various methods used to mount accelerometers and their effect on frequency response.

Signal Conditioners

It is typical for a signal conditioner to be located in the measurement system between the transducer and the final readout or recording instruments. Signal conditioners range from simple to sophisticated and can employ internal electronics for significant signal modification or calculation of related physical quantities. Rather than describe the operating principles of signal conditioners, the following simply lists some of the key functions and available features:

1. Supply excitation voltage to a passive-circuit transducer (e.g., PR accelerometer)
2. Charge conversion to voltage from a PE accelerometer
3. “Dial-in” accelerometer sensitivity normalization
4. Gain or attenuation control to provide optimum signal-to-noise ratio in the readout instrument
5. Low-pass or high-pass filters
6. Grounding options
7. Internal electronics to perform functions such as single or double integration to obtain velocity or displacement data from acceleration signals

19.3 Digital Instrumentation and Computer Control

It is assumed the reader is familiar with the application and operating principles of time-based instruments such as the oscilloscope. Time-based instruments will be not be discussed in this text.

Today’s laboratories are commonly equipped with fast Fourier transform (FFT) analysis and digital micro-processor control capabilities both for data analysis and reduction as well as test machine signal control. It is beyond the scope of this chapter to provide a comprehensive treatment of signal analysis and computer control techniques or of the many software, firmware, and hardware platforms in which these capabilities are available. The reader can find such treatments in several of the references cited at the end of this chapter. Rather, it is the author’s intent to simply recognize some of the functionality and features available to the user in applying these techniques and instruments.

Dynamic signal or FFT analyzers may be used independently of test machine control for purposes of data collection and analysis. Available functionality includes:

1. Time domain or frequency domain analysis
2. Shock analysis
 - Waveform capture
 - Digital filtering

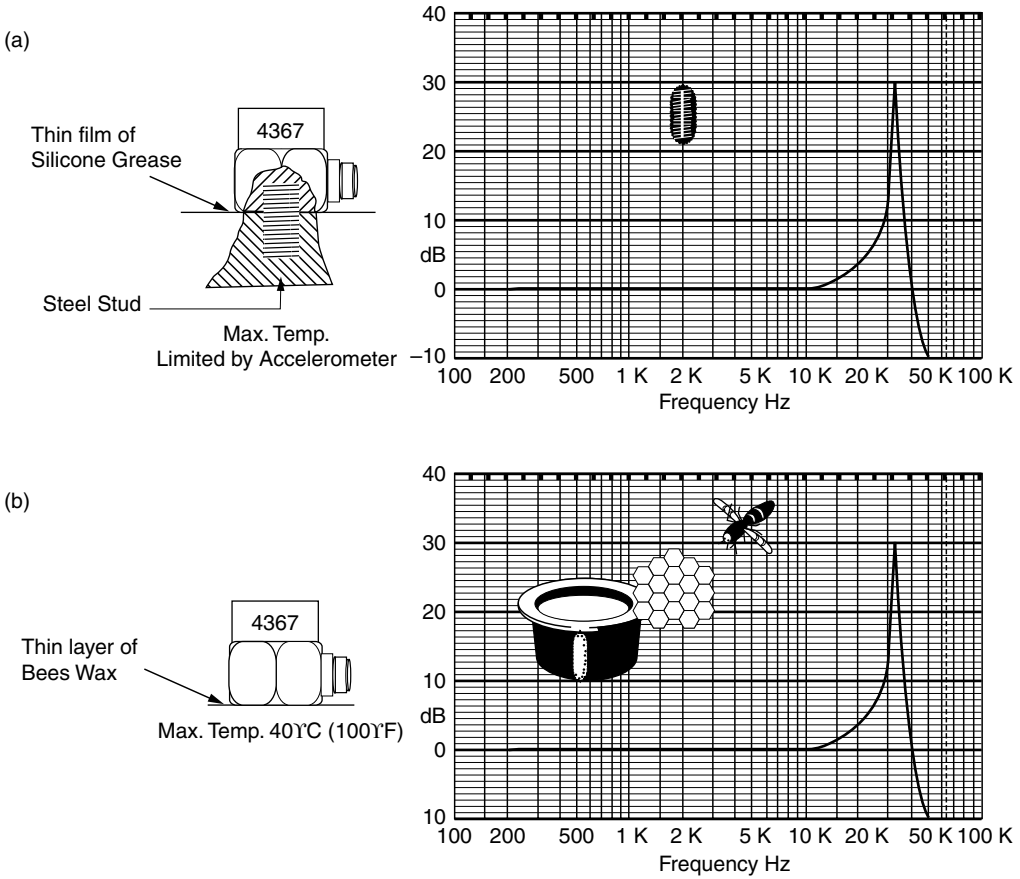

FIGURE 19.7 Typical accelerometer mounting techniques and relative frequency response characteristics. (Source: Broch, J. T. 1984. *Mechanical Vibration and Shock Measurement*, 2nd ed. Bruel and Kjaer, Naerum, Denmark. Reproduced with permission of Bruel and Kjaer.)

Continued.

- Math capabilities, such as integration, differentiation, and multiaxis vector resolution
 - SRS computation
3. Vibration analysis
 - Power/auto spectrum analysis
 - Frequency response and transfer functions
 - Band power, harmonic power, and harmonic distortion measurements
 - Waterfall analysis
 4. Programming capabilities to allow user-defined functionality

Digital control for vibration testing is generally tailored specifically to closed-loop shaker control and would normally contain fewer general analysis capabilities as compared to an independent dedicated FFT analyzer. Functions typically include:

1. Sine or random vibration control
2. Swept-sine on random
3. Narrow band random on random
4. Multiple control and response channels
5. Test control and abort limits
6. Capability of using field vibration data as shaker input signal

(c)

(d)

FIGURE 19.7 Continued.

7. Basic vibration data analysis (e.g., FFT, frequency response)

Digital control for shock-testing refers specifically to the case of controlling a shaker for shock test generation. Functions typically include:

1. Classical waveform control (e.g., half sine)
2. Direction of shock and multiple shock control
3. Transient capture of real-world shock pulses and subsequent use as shaker control
4. SRS and waveform synthesis, a function allowing the operator to specify a required SRS to the controller, which in turn synthesizes a control waveform resulting in the desired SRS
5. Basic waveform analyses such as single/double integration, vector resolution, FFT, and SRS computation

This section has provided a brief introduction to some of the test equipment, capabilities, and performance considerations associated with dynamic test and measurement. The reader is reminded that the examples cited represent only a small sample of what is available and currently in use. More thorough presentation of the concepts introduced and additional discussion on application-specific methods and equipment can be found through the resources provided at the end of the section.

Defining Terms

Frequency response — As a transducer characteristic, frequency response is the change of transducer sensitivity as a function of frequency. Normally, an operating frequency range is specified over

which the sensitivity does not vary more than a stated percentage from the rated sensitivity. More generally, for a mechanical system, frequency response is a ratio of output response to input excitation as a function of frequency.

g — The acceleration produced by the force of gravity. Acceleration amplitudes are commonly described as multiples of *g*, where $1\text{ g} = 980.665\text{ cm/sec}^2 = 386.087\text{ in./sec}^2 = 32.1739\text{ ft/sec}^2$.

Shock response spectrum (SRS) — Also called *shock spectrum*, the SRS is a curve that indicates a theoretical maximum response as a function of pulse duration and responding system natural frequency. The shock spectrum of a waveform is an indication of the shock's damage potential in the frequency domain.

Transducer — A device that provides a usable output in response to a specified measurand [ANSI/ISA S37.1-1975].

Velocity change — The acceleration-time integral or the area under an acceleration-time shock pulse waveform. It is a function of the energy of the shock pulse and can be related to other physical quantities such as equivalent free-fall drop height.

- 20.4 Linkage Design
- 20.5 Cam Design
- 20.6 Classification of Cams and Followers
- 20.7 Displacement Diagrams

Mechanical movement of various machine components can be coordinated using linkages and cams. These devices are assembled from hinges, ball joints, sliders, and contacting surfaces and transform an input movement such as a rotation into an output movement that may be quite complex.

20.1 Linkages

Rigid links joined together by hinges parallel to each other are constrained to move in parallel planes; the system is called a **planar linkage**. A generic value for the **degree of freedom**, or mobility, of the system is given by the formula $F = 3(n - 1) - 2j$, where n is the number of links and j is the number of hinges.

Two links and one hinge form the simplest *open chain* linkage. Open chains appear as the structure of robot manipulators. In particular, a three-degree-of-freedom planar robot is formed by four bodies joined in a series by three hinges, as in [Figure 20.1\(b\)](#).

If the series of links closes to form a loop, the linkage is a simple *closed chain*. The simplest case is a quadrilateral ($n = 4, j = 4$) with one degree of freedom (See [Figure 20.1\(a\)](#) and [Figure 20.3](#)); notice that a triangle has mobility zero. A single loop with five links has two degrees of freedom and one with six links has three degrees of freedom. This latter linkage also appears when two planar robots hold the same object.

A useful class of linkages is obtained by attaching a two-link chain to a four-link quadrilateral in various ways to obtain a one-degree-of-freedom linkage with two loops. The two basic forms of this linkage are known as the Stephenson and Watt six-bar linkages, shown in [Figure 20.2](#).

In each of these linkages, a sliding joint, which constrains a link to a straight line rather than a circle, can replace a hinge to obtain a different movement. For example, a slider-crank linkage is a four-bar closed chain formed by three hinges and a sliding joint.

20.2 Spatial Linkages

The axes of the hinges connecting a set of links need not be parallel. In this case the system is no longer constrained to move in parallel planes and forms a **spatial linkage**. The robot manipulator with six hinged joints (denoted R for **revolute joint**) is an example of a spatial 6R open chain.

FIGURE 20.1 (a) Planar four-bar linkage; and (b) planar robot.

FIGURE 20.2 (a) A Watt six-bar linkage and (b) a Stephenson six-bar linkage.

FIGURE 20.3 Dimensions used to analyze a planar 4R linkage.

Spatial linkages are often constructed using joints that constrain a link to a sphere about a point, such as a ball-in-socket joint, or a gimbal mounting formed by three hinges with concurrent axes — each termed a **spherical joint** (denoted S). The simplest spatial closed chain is the RSSR linkage, which is often used in place of a planar four-bar linkage to allow for misalignment of the cranks (Figure 20.4).

Another useful class of spatial mechanisms is produced by four hinges with concurrent axes that form a spherical quadrilateral known as a **spherical linkage**. These linkages provide a controlled reorientation movement of a body in space (Figure 20.5).

20.3 Displacement Analysis

The closed loop of the planar 4R linkage (Figure 20.3) introduces a constraint between the crank angles θ and ψ given by the equation

$$A \cos \psi + B \sin \psi = C \tag{20.1}$$

FIGURE 20.4 A spatial RSSR linkage.

FIGURE 20.5 A spherical 4R linkage.

where $A = 2gb - 2ab \cos \theta$, $B = -2ab \sin \theta$, and $C = h^2 - g^2 - b^2 - a^2 + 2ga \cos \theta$

This equation can be solved to give an explicit formula for the angle ψ of the output crank in terms of the input crank rotation θ ,

$$\psi(\theta) = \tan^{-1} \left(\frac{B}{A} \right) \pm \cos^{-1} \left(\frac{C}{\sqrt{A^2 + B^2}} \right). \quad (20.2)$$

This solution has two values because for a given input angle θ the output angle ψ is given by the intersection of the circles traced by the coupler and the output cranks. If the discriminant $A^2 + B^2 - C^2$ is greater than zero, then there are two solutions, if it equals zero then there is a single solution, and if it is less than zero, then there is no solution because the chain cannot close for this input angle.

The constraint equations for the spatial RSSR and spherical 4R linkages have the same form as that of the planar 4R linkage, but with coefficients as follows. For, spatial RSSR linkage (Figure 20.4),

$$A = -2ab \cos \gamma \cos \theta - 2br_1 \sin \gamma,$$

$$B = 2bg - 2ab \sin \theta,$$

$$C = h^2 - g^2 - b^2 - a^2 - r_1^2 - r_2^2 + 2r_1r_2 \cos \gamma + 2ar_2 \sin \gamma \cos \theta + 2ga \sin \theta;$$

and for a spherical 4R linkage (Figure 20.5),

$$A = \sin \alpha \sin \beta \cos \gamma \cos \theta - \cos \alpha \sin \beta \sin \gamma,$$

$$B = \sin \alpha \sin \beta \sin \theta,$$

$$C = \cos \eta - \sin \alpha \cos \beta \sin \gamma \cos \theta - \cos \alpha \cos \beta \cos \gamma.$$

The formula for the output angle ψ in terms of θ for both cases is identical to that already given above for the planar 4R linkage.

20.4 Linkage Design

The planar RR chain has the property that the moving pivot traces a circle around the fixed pivot. This means the moving pivot with coordinates $\mathbf{W} = (x, y)$ satisfies the equation of a circle

$$(X - u)^2 + (Y - v)^2 = R^2, \quad (20.3)$$

with center $\mathbf{G} = (u, v)$ and radius R . Notice that if we specify three points \mathbf{W}^i , $i = 1, 2, 3$, then we can substitute these values sequentially into Equation (20.3) in order to obtain three quadratic equations that define the parameters u , v , and R . This is described as saying three points define a circle. This approach can be generalized to design an RR chain that guides a body through a set of five arbitrary task positions.

Let the five task positions be defined by the rotation angles θ_i and translation vectors $\mathbf{d}_i = (a_i, b_i)$, $i = 1, \dots, 5$. And let $\mathbf{w} = (x, y)$ be the coordinates of the moving pivot measured relative to the end-effector. Then, for the given task positions, we can compute the five points

$$\mathbf{W}^i = \begin{pmatrix} X \\ Y \end{pmatrix} = \begin{bmatrix} \cos\theta_i & -\sin\theta_i \\ \sin\theta_i & \cos\theta_i \end{bmatrix} \begin{pmatrix} x \\ y \end{pmatrix} + \begin{pmatrix} a_i \\ b_i \end{pmatrix}, \quad i = 1, \dots, 5. \quad (20.4)$$

Substitute this into Equation (20.3) to obtain five quadratic equations in the five parameters, x , y , u , v , and R . These equations are easily solved to obtain as many as four RR chains that guide the end-effector through the specified task positions.

The planar RR chains defined in this way can be assembled into as many as six 4R linkages. The chains can individually reach the specified task positions; however, their ability to move smoothly between these positions, while connected by a coupler link, must be determined by displacement analysis of the 4R chain.

This approach to the design of serial chains can be applied to spherical RR and spatial SS chains, as well as to several other more complicated systems.

20.5 Cam Design

A *cam pair* (or *cam-follower*) consists of two primary elements called the *cam* and *follower*. The cam's motion, which is usually rotary, is transformed into either follower translation, oscillation, or combination, through direct mechanical contact. Cam pairs are found in numerous manufacturing and commercial applications requiring motion, path, and/or function generation. Cam pair mechanisms are usually simple, inexpensive, compact, and robust for the most demanding design applications. Moreover, a **cam profile** can be designed to generate virtually any desired follower motion, by either graphical or analytical methods.

20.6 Classification of Cams and Followers

The versatility of cam pairs is evidenced by the variety of shapes, forms, and motions for both cam and follower. Cams are usually classified according to their basic shape as illustrated in [Figure 20.6](#): (a) plate cam, (b) wedge cam, (c) cylindrical or barrel cam, and (d) end or face cam.

Followers are also classified according to their basic shape, with optional modifiers describing their motion characteristics. For example, a follower can oscillate [[Figure 20.7](#) (a) and [Figure 20.7](#) (b)] or translate [[Figure 20.7](#) (c) through [Figure 20.7](#) (g)]. As required by many applications, follower motion may be offset from the cam shaft's center as illustrated in [Figure 20.7](#) (g). For all cam pairs, however, the follower must maintain constant contact with the cam surface. Constant contact can be achieved by gravity, springs, or other mechanical constraints such as grooves.

FIGURE 20.6 Basic types of cams.

FIGURE 20.8 Displacement diagram.

20.7 Displacement Diagrams

The cam's primary function is to create a well-defined follower displacement. If the cam's displacement is designated by θ and follower displacement by y , a given cam is designed such that a displacement function

$$y = f(\theta) \quad (20.5)$$

is satisfied. A graph of y versus θ is called the *follower displacement diagram* (Figure 20.8). On a displacement diagram, the abscissa represents one revolution of cam motion (θ) and the ordinate represents the corresponding follower displacement (y). Portions of the displacement diagram, when follower motion is away from the cam's center, are called *rise*. The maximum rise is called *lift*. Periods of follower rest are referred to as *dwells*, and *returns* occur when follower motion is toward the cam's center.

The cam profile is generated from the follower displacement diagram via graphical or analytical methods that use parabolic, simple harmonic, cycloidal, and/or polynomial profiles. For many applications, the follower's velocity, acceleration, and higher time derivatives are necessary for proper cam design.

Cam profile generation is best illustrated using graphical methods where the cam profile can be constructed from the follower displacement diagram using the principle of kinematic inversion. As shown in Figure 20.9, the prime circle is divided into a number of equal angular segments and assigned station numbers. The follower displacement diagram is then divided along the abscissa into corresponding segments. Using dividers, the distances are then transferred from the displacement diagram directly onto the cam layout to locate the corresponding trace point position. A smooth curve through these points is the pitch curve. For the case of a roller follower, the roller is drawn in its proper position at each station, and the cam profile is then constructed as a smooth curve tangent to all roller positions. Analytical methods can be employed to facilitate computer-aided design of cam profiles.

FIGURE 20.9 Cam layout.

FIGURE 20.10 Cam terminology.

Defining Terms

Linkage Terminology

Standard terminology for linkages includes the following:

Degree of freedom — The number of parameters, available as input, that prescribe the configuration of a given linkage, also known as its *mobility*.

Planar linkage — A collection of links constrained to move in parallel planes.

Revolute joint — A hinged connection between two links that constrains their relative movement to the plane perpendicular to the hinge axis.

Serial chain — A series of rigid bodies connected by joints to form a chain.

Spatial linkage — A linkage with at least one link that moves out of a plane.

Spherical joint — A connection between two links that constrains their relative movement to a sphere about a point at the center of the joint.

Spherical linkage — A collection of links constrained to move on concentric spheres.

Cam Terminology

The standard cam terminology is illustrated in [Figure 20.10](#) and defined as follows:

Base circle — The smallest circle, centered on the cam axis, that touches the cam profile (radius R_b).

Cam profile — The cam's working surface.

Pitch circle — The circle through the pitch point, centered on the cam axis (radius R_p).

Pitch curve — The path of the trace point.

Pitch point — The point on the pitch curve where pressure angle is maximum.

Pressure angle — The angle between the normal to the pitch curve and the instantaneous direction of trace point motion.

Prime circle — The smallest circle, centered on the cam axis, that touches the pitch curve (radius R_a).

Trace point — The contact point of a knife-edge follower, the center of a roller follower, or a reference point on a flat-faced follower.

Further Information

An interesting array of linkages that generate specific movements can be found in *Mechanisms and Mechanical Devices Sourcebook* by Nicholas P. Chironis.

The displacement analysis of linkages is presented in the book *Mechanism Design: Analysis and Synthesis* by Arthur Erdman, George Sandor (late), and Sridar Kota. These authors also provide a number of animations that illustrate interesting mechanical movement. The book by John Uicker, Gordon Pennock, and the late Joseph Shigley also provides the mathematical theory for linkage analysis and is particularly useful for the design of cam profiles for various applications.

A comprehensive presentation of planar, spherical and spatial linkage design can be found in the book *Kinematics and Mechanism Design* by Chung Ha Suh and Charles W. Radcliffe. The Fortran code provided in this text is still useful after many years. *Geometric Design of Linkages* is a more recent presentation of planar, spherical, and spatial linkage synthesis focusing on open chains typical to robotic systems.

Proceedings of the ASME Design Engineering Technical Conferences are published annually by the American Society of Mechanical Engineers. These proceedings document the latest developments in mechanism and machine theory.

The quarterly *ASME Journal of Mechanical Design* reports on advances in the design and analysis of linkage and cam systems. For a subscription contact American Society of Mechanical Engineers, 3 Park Ave., New York, NY 10016.

In this chapter we first present the history of macrotribology and micro/nanotribology and their significance. We then describe mechanisms of friction, wear, and lubrication, followed by micro/nanotribology.

21.1 History of Tribology and its Significance to Industry

Tribology is the science and technology of two interacting surfaces in relative motion and of related subjects and practices. The popular equivalent is friction, wear, and lubrication. The word *tribology*, coined in 1966, is derived from the Greek word *tribos* meaning “rubbing,” so the literal translation would be the science of rubbing [Jost, 1966]. It is only the name tribology that is relatively new, because interest in the constituent parts of tribology is older than recorded history [Dowson, 1979]. It is known that drills made during the Paleolithic period for drilling holes or producing fire were fitted with bearings made from antlers or bones, and potters’ wheels or stones for grinding cereals clearly had a requirement for some form of bearings [Davidson, 1957]. A ball thrust bearing dated about 40 A.D. was found in Lake Nemi near Rome.

Records show the use of wheels from 3500 B.C., which illustrates our ancestors’ concern with reducing friction in translational motion. The transportation of large stone building blocks and monuments required the know-how of frictional devices and lubricants, such as water-lubricated sleds. [Figure 21.1](#) illustrates the use of a sledge to transport a heavy statue by Egyptians circa 1880 B.C. [Layard, 1853]. In this transportation, 172 slaves are being used to drag a large statue weighing about 600 kN along a wooden track. One man, standing on the sledge supporting the statue, is seen pouring a liquid into the path of motion; perhaps he was one of the earliest lubrication engineers. (Dowson [1979] has estimated that

FIGURE 21.1 Egyptians using lubricant to aid movement of Colossus, El-Bersheh, ca. 1880 B.C.

each man exerted a pull of about 800 N. On this basis the total effort, which must at least equal the friction force, becomes 172×800 N. Thus, the coefficient of friction is about 0.23.) A tomb in Egypt that was dated several thousand years B.C. provides evidence of use of lubricants. A chariot in this tomb still contained some of the original animal-fat lubricant in its wheel bearings.

During and after the glory of the Roman empire, military engineers rose to prominence by devising both war machinery and methods of fortification, using tribological principles. It was the Renaissance engineer and artist Leonardo da Vinci (1452–1519), celebrated in his days for his genius in military construction as well as for his painting and sculpture, who first postulated a scientific approach to friction. Leonardo introduced for the first time the concept of coefficient of friction as the ratio of the friction force to normal load. In 1699, Amontons found that the friction force is directly proportional to the normal load and is independent of the apparent area of contact. These observations were verified by Coulomb in 1781, who made a clear distinction between static friction and kinetic friction.

Many other developments occurred during the 1500s, particularly in the use of improved bearing materials. In 1684, Robert Hooke suggested the combination of steel shafts and bell-metal bushes as preferable to wood shod with iron for wheel bearings. Further developments were associated with the growth of industrialization in the latter part of the eighteenth century. Early developments in the petroleum industry started in Scotland, Canada, and the U.S. in the 1850s [Parish, 1935; Dowson, 1979].

Though essential laws of viscous flow had earlier been postulated by Newton, scientific understanding of lubricated bearing operations did not occur until the end of the nineteenth century. Indeed, the beginning of our understanding of the principle of hydrodynamic lubrication was made possible by the experimental studies of Tower [1884] and the theoretical interpretations of Reynolds [1886] and related work by Petroff [1883]. Since then, developments in hydrodynamic bearing theory and practice have been extremely rapid in meeting the demand for reliable bearings in new machinery.

Wear is a much younger subject than friction and bearing development, and it was initiated on a largely empirical basis.

Since the beginning of the twentieth century, from enormous industrial growth leading to demand for better tribology, our knowledge in all areas of tribology has expanded tremendously [Holm, 1946; Bowden and Tabor, 1950, 1964; Bhushan, 1990, 1992; Bhushan and Gupta, 1991].

Tribology is crucial to modern machinery, which uses sliding and rolling surfaces. Examples of productive wear are writing with a pencil, machining, and polishing. Examples of productive friction are brakes, clutches, driving wheels on trains and automobiles, bolts, and nuts. Examples of unproductive friction and wear are internal combustion and aircraft engines, gears, cams, bearings, and seals. According to some estimates, losses resulting from ignorance of tribology amount in the U.S. to about 6% of its gross national product or about 200 billion dollars per year, and approximately one-third of the world's

FIGURE 21.2 Comparison between macrotribology and micro/nanotribology.

energy resources in present use appear as friction in one form or another. Thus, the importance of friction reduction and wear control cannot be overemphasized for economic reasons and long-term reliability. According to Jost [1966, 1976], the United Kingdom could save approximately 500 million pounds per annum and the U.S. could save in excess of 16 billion dollars per annum by better tribological practices. The savings are both substantial and significant and could be obtained without the deployment of large capital investment.

The purpose of research in tribology is understandably the minimization and elimination of losses resulting from friction and wear at all levels of technology where the rubbing of surfaces are involved. Research in tribology leads to greater plant efficiency, better performance, fewer breakdowns, and significant savings.

21.2 Origins and Significance of Micro/Nanotribology

The advent of new techniques to measure surface topography, adhesion, friction, wear, lubricant film thickness, and mechanical properties all on micro- to nanometer scale; to image lubricant molecules; and to conduct atomic-scale simulations with the availability of supercomputers has led to development of a new field referred to as *microtribology*, *nanotribology*, *molecular tribology*, or *atomic-scale tribology*. This field deals with experimental and theoretical investigations of processes ranging from atomic and molecular scales to micro scales, occurring during adhesion, friction, wear, and thin-film lubrication at sliding surfaces. The differences between conventional or macrotribology and micro/nanotribology are contrasted in Figure 21.2. In macrotribology, tests are conducted on components with relatively large mass under heavily loaded conditions. In these tests, wear is inevitable, and the bulk properties of mating components dominate the tribological performance. In **micro/nanotribology**, measurements are made on components, at least one of the mating components with relatively small mass under lightly loaded conditions. In this situation negligible wear occurs, and the surface properties dominate the tribological performance.

Micro/nanotribological studies are needed to develop fundamental understanding of interfacial phenomena on a small scale and to study interfacial phenomena in micro- and nanostructures used in magnetic storage systems, microelectromechanical systems (MEMS), and other industrial applications [Bhushan, 1990, 1992]. The components used in micro- and nanostructures are very light (on the order of few micrograms) and operate under very light loads (on the order of few micrograms to few milligrams). As a result, friction and wear (on a nanoscale) of lightly loaded micro/nanocomponents are highly dependent on the surface interactions (few atomic layers). These structures are generally lubricated with molecularly thin films. Micro- and nanotribological techniques are ideal to study the friction and wear processes of micro- and nanostructures. Although micro/nanotribological studies are critical to study micro- and nanostructures, these studies are also valuable in fundamental understanding of interfacial phenomena in macrostructures to provide a bridge between science and engineering. Friction and wear on micro- and nanoscales have been found to be generally small compared to that at macroscales. Therefore, micro/nanotribological studies may identify the regime for ultra-low friction and near zero wear.

To give a historical perspective of the field [Bhushan, 1995], the *scanning tunneling microscope* (STM) developed by Dr. Gerd Binnig and his colleagues in 1981 at the IBM Zurich Research Laboratory, Forschungslabor, is the first instrument capable of directly obtaining three-dimensional (3-D) images of solid surfaces with atomic resolution [Binnig et al., 1982]. G. Binnig and H. Rohrer received a Nobel Prize in physics in 1986 for their discovery. STMs can only be used to study surfaces that are electrically conductive to some degree. Based on their design of STM, Binnig et al. developed, in 1985, an *atomic force microscope* (AFM) to measure ultrasmall forces (less than 1 μN) present between the AFM tip surface and the sample surface [1986]. AFMs can be used for measurement of *all engineering surfaces*, which may be either electrically conducting or insulating. AFM has become a popular surface profiler for topographic measurements on micro- to nanoscale. Mate et al. [1987] were the first to modify an AFM in order to measure both normal and friction forces; this instrument is generally called a *friction force microscope* (FFM) or *lateral force microscope* (LFM). Since then, Bhushan and other researchers have used FFM for atomic-scale and microscale friction and boundary lubrication studies [Bhushan and Ruan, 1994; Bhushan et al., 1994; Ruan and Bhushan, 1994; Bhushan, 1995; Bhushan et al., 1995]. By using a standard or a sharp diamond tip mounted on a stiff cantilever beam, Bhushan and other researchers have used AFM for scratching, wear, and measurements of elastic/plastic mechanical properties (such as indentation hardness and modulus of elasticity) [Bhushan et al., 1994; Bhushan and Koinkar, 1994a,b; Bhushan, 1995; Bhushan et al., 1995].

Surface force apparatuses (SFAs), first developed in 1969 [Tabor and Winterton, 1969], are other instruments used to study both static and dynamic properties of the molecularly thin liquid films sandwiched between two molecularly smooth surfaces [Israelachvili and Adams, 1978; Klein, 1980; Tonck et al., 1988; Georges et al., 1993, 1994]. These instruments have been used to measure the dynamic shear response of liquid films [Bhushan, 1995]. Recently, new friction attachments were developed that allow for two surfaces to be sheared past each other at varying sliding speeds or oscillating frequencies while simultaneously measuring both the friction forces and normal forces between them [Peachey et al., 1991; Bhushan, 1995]. The distance between two surfaces can also be independently controlled to within ± 0.1 nm, and the force sensitivity is about 10 nN. The SFAs are used to study rheology of molecularly thin liquid films; however, the liquid under study has to be confined between molecularly smooth optically transparent surfaces with radii of curvature on the order of 1 mm (leading to poorer lateral resolution as compared to AFMs). SFAs developed by Tonck et al. [1988] and Georges et al. [1993, 1994] use an opaque and smooth ball with large radius (≈ 3 mm) against an opaque and smooth flat surface. Only AFMs/FFMs can be used to study *engineering surfaces* in the *dry and wet conditions* with *atomic resolution*.

21.3 Friction

Definition of Friction

Friction is the resistance to motion that is experienced whenever one solid body slides over another. The resistive force, which is parallel to the direction of motion, is called the friction force, [Figure 21.3\(a\)](#). If the solid bodies are loaded together and a tangential force (F) is applied, then the value of the tangential force that is required to initiate sliding is the static friction force. It may take a few milliseconds before sliding is initiated at the interface (F_{static}). The tangential force required to maintain sliding is the kinetic (or dynamic) friction force (F_{kinetic}). The kinetic friction force is either lower than or equal to the static friction force, [Figure 21.3\(b\)](#).

It has been found experimentally that there are two basic laws of intrinsic (or conventional) friction that are generally obeyed over a wide range of applications. The first law states that the friction is independent of the apparent area of contact between the contacting bodies, and the second law states that the friction force F is proportional to the normal load W between the bodies. These laws are often referred to as *Amontons laws*, after the French engineer Amontons, who presented them in 1699 [Dowson, 1979].

The second law of friction enables us to define a coefficient of friction. The law states that the friction force F is proportional to the normal load W . That is,

FIGURE 21.3 (a) Schematic illustration of a body sliding on a horizontal surface. W is the normal load and F is the friction force. (b) Friction force versus time or displacement. F_{static} is the force required to initiate sliding and F_{kinetic} is the force required to sustain sliding. (c) Kinetic friction force versus time or displacement showing irregular stick-slip.

$$F = \mu W \quad (21.1)$$

where μ is a constant known as the *coefficient of friction*. It should be emphasized that μ is a constant only for a given pair of sliding materials under a given set of operating conditions (temperature, humidity, normal pressure, and sliding velocity). Many materials show sliding speed and normal load dependence on the coefficients of static and kinetic friction in dry and lubricated contact.

It is a matter of common experience that the sliding of one body over another under a steady pulling force proceeds sometimes at constant or nearly constant velocity and on other occasions at velocities that fluctuate widely. If the friction force (or sliding velocity) does not remain constant as a function of distance or time and produces a form of oscillation, it is generally called a *stick-slip phenomenon*, Figure 21.3(c). During the stick phase, the friction force builds up to a certain value and then slip occurs at the interface. Usually, a sawtooth pattern in the friction force–time curve [Figure 21.3(c)] is observed during the stick-slip process. Stick-slip generally arises whenever the coefficient of static friction is markedly

FIGURE 21.4 Schematic representation of an interface, showing the apparent (A_a) and real (A_r) areas of contact. Typical size of an asperity contact is from submicron to a few microns. Inset shows the details of a contact on a submicron scale.

greater than the coefficient of kinetic friction or whenever the rate of change of coefficient of kinetic friction as a function of velocity at the sliding velocity employed is negative. The stick-slip events can occur either repetitively or in a random manner.

The stick-slip process generally results in squealing and chattering of sliding systems. In most sliding systems the fluctuations of sliding velocity resulting from the stick-slip process and associated squeal and chatter are considered undesirable; measures are normally taken to eliminate, or at any rate to reduce, the amplitude of the fluctuations.

Theories of Friction

All engineering surfaces are rough on a microscale. When two nominally flat surfaces are placed in contact under load, the contact takes place at the tips of the asperities, the load is supported by the deformation of contacting asperities, and the discrete contact spots (junctions) are formed (Figure 21.4). The sum of the areas of all the contact spots constitutes the real (true) area of the contact (A_r) and for most materials at normal loads, this will be only a small fraction of the apparent (nominal) area of contact (A_a). The proximity of the asperities results in adhesive contacts caused by either physical or chemical interaction. When these two surfaces move relative to each other, a lateral force is required to overcome adhesion. This force is referred to as *adhesion friction force*. From classical theory of adhesion, this friction force (F_A) is defined as follows [Bowden and Tabor, 1950]. For a dry contact,

$$F_A = A_r \tau_a \quad (21.2a)$$

and for a lubricated contact,

$$F_A = A_r [\alpha \tau_a + (1 - \alpha) \tau_l] \quad (21.2b)$$

and

$$\tau_l = \eta_l V/h \quad (21.2c)$$

where τ_a and τ_l are the shear strengths of the dry contact and of the lubricant film, respectively; α is the fraction of unlubricated area; η_l is the dynamic viscosity of the lubricant; V is the relative sliding velocity; and h is the lubricant film thickness.

The contacts can be either elastic or plastic, depending primarily on the surface topography and the mechanical properties of the mating surfaces. The expressions for real area of contact for elastic (e) and plastic (p) contacts are as follows [Greenwood and Williamson, 1966; Bhushan, 1984, 1990]. For $\psi < 0.6$, elastic contacts,

$$A_{re}/W \sim 3.2/E_c(\sigma_p/R_p)^{1/2} \quad (21.3a)$$

For $\psi > 1$, plastic contacts,

$$A_{rp}/W = 1/H \quad (21.3b)$$

Finally,

$$\psi = (E_c/H)(\sigma_p/R_p)^{1/2} \quad (21.3c)$$

where E_c is the composite modulus of elasticity, H is the hardness of the softer material, and σ_p and $1/R_p$ are the composite standard deviation and composite mean curvature of the summits of the mating surfaces. The real area of contact is reduced by improving the mechanical properties and in some cases by increasing the roughness (in the case of bulk of the deformation being in the elastic contact regime).

The adhesion strength depends upon the mechanical properties and the physical and chemical interaction of the contacting bodies. The adhesion strength is reduced by reducing surface interactions at the interface. For example, presence of contaminants or deliberately applied fluid film (e.g., air, water, or lubricant) would reduce the adhesion strength. Generally, most interfaces in vacuum with intimate solid–solid contact would exhibit very high values for coefficient of friction. A few pp of contaminants (air, water) may be sufficient to reduce μ dramatically. Thick films of liquids or gases would further reduce μ , as it is much easier to shear into a fluid film than to shear a solid–solid contact.

So far we have discussed theory of adhesional friction. If one of the sliding surfaces is harder than the other, the asperities of the harder surface may penetrate and plow into the softer surface. Plowing into the softer surface may also occur as a result of impacted wear debris. In addition, interaction of two rather rough surfaces may result in mechanical interlocking on micro or macro scale. During sliding, interlocking would result in plowing of one of the surfaces. In tangential motion, the plowing resistance is in addition to the adhesional friction. There is yet another mechanism of friction — deformation (or hysteresis) friction — which may be prevalent in materials with elastic hysteresis losses such as in polymers. In boundary lubricated conditions or unlubricated interfaces exposed to humid environments, the presence of some liquid may result in formation of menisci or adhesive bridges and the meniscus/viscous effects may become important; in some cases these may even dominate the overall friction force [Bhushan, 1990].

Measurements of Friction

In a friction measurement apparatus, two test specimens are loaded against each other at a desired normal load; one of the specimens is allowed to slide relative to the other at a desired sliding speed, and the tangential force required to initiate or maintain sliding is measured. Numerous apparatuses can be used to measure friction force [Benzing et al., 1976; Bhushan and Gupta, 1991]. The simplest method is an inclined-plane technique. In this method the flat test specimen of weight W is placed on top of another

FIGURE 21.5 Inclined-plane technique to measure static friction force.

flat specimen whose inclination can be adjusted, as shown in Figure 21.5. The inclination of the lower specimen is increased from zero to an angle at which the block begins to slide. At this point, downward horizontal force being applied at the interface exceeds the static friction force, F_{static} . At the inclination angle θ , at which the block just begins to slide,

$$F_{static} = W \sin \theta$$

and the coefficient of static friction μ_s is

$$\mu_s = \frac{F_{static}}{W \cos \theta} = \tan \theta \quad (21.4)$$

The angle θ is referred to as the *friction angle*. This simple method only measures the coefficient of static friction and does not allow the measurements of the effect of sliding. However, this method demonstrates the effects of friction and provides the simplest method to measure the coefficient of static friction.

Typical values of the coefficient of friction of various material pairs are presented in Table 21.1 [Avallone and Baumeister, 1987]. It should be noted that values of the coefficient of friction depend on the operating conditions — loads, speeds, and the environment — thus, the values reported in Table 21.1 should be used with caution.

21.4 Wear

Wear is the removal of material from one or both of two solid surfaces in a solid-state contact. It occurs when solid surfaces are in a sliding, rolling, or impact motion relative to one another. Wear occurs through surface interactions at asperities, and components may need replacement after a relatively small amount of material has been removed or if the surface is unduly roughened. In well-designed tribological systems, the removal of material is usually a very slow process but it is very steady and continuous. The generation and circulation of wear debris — particularly in machine applications where the clearances are small relative to the wear particle size — may be more of a problem than the actual amount of wear.

Wear includes six principal, quite distinct phenomena that have only one thing in common: the removal of solid material from rubbing surfaces. These are [Archard, 1980; Bhushan et al., 1985a,b; Bhushan, 1990]:

1. Adhesive
2. Abrasive
3. Fatigue
4. Impact by erosion or percussion
5. Corrosive
6. Electrical arc-induced wear

TABLE 21.1 Coefficient of Friction μ for Various Material Combinations

| Materials | μ , Static | | μ , Sliding (Kinetic) | |

Other commonly encountered wear types are fretting and fretting corrosion. These are not distinct mechanisms, but rather combinations of the adhesive, corrosive, and abrasive forms of wear. According to some estimates, two-thirds of all wear encountered in industrial situations occurs because of adhesive- and abrasive-wear mechanisms.

Of the aforementioned wear mechanisms, one or more may be operating in any particular machinery. In many cases wear is initiated by one mechanism and results in other wear mechanisms, thereby complicating failure analysis.

Adhesive Wear

Adhesive wear occurs when two nominally flat solid bodies are in rubbing contact, whether lubricated or not. Adhesion (or bonding) occurs at the asperity contacts on the interface, and fragments are pulled off one surface to adhere to the other surface. Subsequently, these fragments may come off the surface on which they are formed and either be transferred back to the original surface or form loose wear particles. Severe types of adhesive wear are often called *galling*, *scuffing*, *scoring*, or *smearing*, although these terms are sometimes used loosely to describe other types of wear.

Although the adhesive wear theory can explain transferred wear particles, it does not explain how loose wear particles are formed. We now describe the actual process of formation of wear particles. Asperity contacts are sheared by sliding and a small fragment of *either surface* becomes attached to the other surface. As sliding continues, the fragment constitutes a new asperity that becomes attached once more to the original surface. This transfer element is repeatedly passed from one surface to the other

FIGURE 21.6 Schematic showing generation of wear particle as a result of adhesive wear mechanism.

and grows quickly to a large size, absorbing many of the transfer elements so as to form a flake-like particle from materials of both rubbing elements. Rapid growth of this transfer particle finally accounts for its removal as a wear particle, as shown in Figure 21.6. The occurrence of wear of the harder of the two rubbing surfaces is difficult to understand in terms of the adhesion theory. It is believed that the material transferred by adhesion to the harder surface may finally get detached by a fatigue process.

As a result of experiments carried out with various unlubricated materials — the vast majority of them metallic — it is possible to write the laws of adhesive wear, commonly referred to as Archard's law, as follows [Archard, 1953]. For plastic contacts,

$$V = kWx/H \quad (21.5)$$

where V is the volume worn away, W is the normal load, x is the sliding distance, H is the hardness of the surface being worn away, and k is a nondimensional wear coefficient dependent on the materials in contact and their exact degree of cleanliness. The term k is usually interpreted as the probability that a wear particle is formed at a given asperity encounter.

Equation (21.5) suggests that the probability of a wear-particle formation increases with an increase in the real area of contact, A_r ($A_r = W/H$ for plastic contacts), and the sliding distance. For elastic contacts occurring in materials with a low modulus of elasticity and a very low surface roughness, Equation (21.5) can be rewritten for elastic contacts (Bhushan's law of adhesive wear) as [Bhushan, 1990]

$$V = k' Wx / E_c (\sigma_p / R_p)^{1/2} \quad (21.6)$$

where k' is a nondimensional wear coefficient. According to this equation, elastic modulus and surface roughness govern the volume of wear. We note that in an elastic contact — though the normal stresses remain compressive throughout the entire contact — strong adhesion of some contacts can lead to generation of wear particles. Repeated elastic contacts can also fail by surface/subsurface fatigue. In addition, as the total number of contacts increases, the probability of a few plastic contacts increases, and the plastic contacts are especially detrimental from the wear standpoint.

Based on studies by Rabinowicz [1980], typical values of wear coefficients for metal on metal and nonmetal on metal combinations that are unlubricated (clean) and in various lubricated conditions are presented in Table 21.2. Wear coefficients and coefficients of friction for selected material combinations are presented in Table 21.3 [Archard, 1980].

TABLE 21.2 Typical Values of Wear Coefficients for Metal on Metal and Nonmetal on Metal Combinations

| Condition | Metal on Metal | | Nonmetal on Metal |
|-----------------------|----------------------|---------------------------|---------------------|
| | Like | Unlike ^a | |
| Clean (unlubricated) | $1500 \cdot 10^{-6}$ | 15 to $500 \cdot 10^{-6}$ | $1.5 \cdot 10^{-6}$ |
| Poorly lubricated | 300 | 3 to 100 | 1.5 |
| Average lubrication | 30 | 0.3 to 10 | 0.3 |
| Excellent lubrication | 1 | 0.03 to 0.3 | 0.03 |

^a The values depend on the metallurgical compatibility (degree of solid solubility when the two metals are melted together). Increasing degree of incompatibility reduces wear, leading to higher value of the wear coefficients.

TABLE 21.3 Coefficient of Friction and Wear Coefficients for Various Materials in Unlubricated Sliding

| Materials | | Vickers Microhardness (kg/mm ²) | Coefficient of Friction | Wear Coefficient (<i>k</i>) |
|--------------------------|------------------|--|----------------------------|----------------------------------|
| Wearing Surface | Counter Surface | | | |
| Mild steel | Mild steel | 186 | 0.62 | $7.0 \cdot 10^{-3}$ |
| 60/40 leaded brass | Tool steel | 95 | 0.24 | $6.0 \cdot 10^{-4}$ |
| Ferritic stainless steel | Tool steel | 250 | 0.53 | $1.7 \cdot 10^{-5}$ |
| Stellite | Tool steel | 690 | 0.60 | $5.5 \cdot 10^{-5}$ |
| PTFE | Tool steel | 5 | 0.18 | $2.4 \cdot 10^{-5}$ |
| Polyethylene | Tool steel | 17 | 0.53 | $1.3 \cdot 10^{-7}$ |
| Tungsten carbide | Tungsten carbide | 1300 | 0.35 | $1.0 \cdot 10^{-6}$ |

Note: Load = 3.9 N; speed = 1.8 m/sec. The stated value of the hardness is that of the softer (wearing) material in each example.

Source: Archard, J. F. 1980. Wear theory and mechanisms. In *Wear Control Handbook*, ed. M. B. Peterson and W. O. Winer, pp. 35–80. ASME, New York.

Abrasive Wear

Abrasive wear occurs when a rough, hard surface slides on a softer surface and plows a series of grooves in it. The surface can be plowed (plastically deformed) without removal of material. However, after the surface has been plowed several times, material removal can occur by a low-cycle fatigue mechanism. Abrasive wear is also sometimes called *plowing*, *scratching*, *scoring*, *gouging*, or *cutting*, depending on the degree of severity. There are two general situations for this type of wear. In the first case, the hard surface is the harder of two rubbing surfaces (two-body abrasion), for example, in mechanical operations such as grinding, cutting, and machining. In the second case the hard surface is a third body, generally a small particle of grit or abrasive, caught between the two other surfaces and sufficiently harder that it is able to abrade either one or both of the mating surfaces (three-body abrasion), for example, in lapping and polishing. In many cases the wear mechanism at the start is adhesive, which generates wear debris that gets trapped at the interface, resulting in a three-body abrasive wear.

To derive a simple quantitative expression for abrasive wear, we assume a conical asperity on the hard surface (Figure 21.7). Then the volume of wear removed is given as follows [Rabinowicz, 1965]:

$$V = k W x \overline{\tan \theta} / H \quad (21.7)$$

where $\overline{\tan \theta}$ is a weighted average of the $\tan \theta$ values of all the individual cones and k is a factor that includes the geometry of the asperities and the probability that a given asperity cuts (removes) rather than plows. Thus, the roughness effect on the volume of wear is very distinct.

Fatigue Wear

Subsurface and surface fatigue are observed during repeated rolling and sliding, respectively. For the pure rolling condition, the maximum shear stress responsible for nucleation of cracks occurs some distance

FIGURE 21.7 Abrasive wear model in which a cone removes material from a surface. (Source: Rabinowicz, E. 1965. *Friction and Wear of Materials*. John Wiley & Sons, New York. With permission.)

below the surface, and its location moves towards the surface with an application of the friction force at the interface. The repeated loading and unloading cycles to which the materials are exposed may induce the formation of subsurface or surface cracks, which eventually, after a critical number of cycles, will result in the breakup of the surface with the formation of large fragments, leaving large pits in the surface. Prior to this critical point, negligible wear takes place, which is in marked contrast to the wear caused by adhesive or abrasive mechanisms, where wear causes a gradual deterioration from the start of running. Therefore, the amount of material removed by fatigue wear is not a useful parameter. Much more relevant is the useful life in terms of the number of revolutions or time before fatigue failure occurs. Time to fatigue failure is dependent on the amplitude of the reversed shear stresses, the interface lubrication conditions, and the fatigue properties of the rolling materials.

Impact Wear

Two broad types of wear phenomena belong in the category of impact wear: erosive and percussive wear. Erosion can occur by jets and streams of solid particles, liquid droplets, and implosion of bubbles formed in the fluid. Percussion occurs from repetitive solid body impacts. Erosive wear by impingement of solid particles is a form of abrasion that is generally treated rather differently because the contact stress arises from the kinetic energy of a particle flowing in an air or liquid stream as it encounters a surface. The particle velocity and impact angle combined with the size of the abrasive give a measure of the kinetic energy of the erosive stream. The volume of wear is proportional to the kinetic energy of the impinging particles, that is, to the square of the velocity. Wear rate dependence on the impact angle differs between ductile and brittle materials [Bitter, 1963].

When small drops of liquid strike the surface of a solid at high speeds (as low as 300 m/sec), very high pressures are experienced, exceeding the yield strength of most materials. Thus, plastic deformation or fracture can result from a single impact, and repeated impact leads to pitting and erosive wear. Cavitation erosion arises when a solid and fluid are in relative motion and bubbles formed in the fluid become unstable and implode against the surface of the solid. Damage by this process occurs in such components as ships' propellers and centrifugal pumps.

Percussion is a repetitive solid body impact, such as experienced by print hammers in high-speed electromechanical applications and high asperities of the surfaces in a gas bearing (e.g., head-medium interface in magnetic storage systems). In most practical machine applications the impact is associated with sliding; that is, the relative approach of the contacting surfaces has both normal and tangential components known as *compound impact* [Engel, 1976].

Corrosive Wear

Corrosive wear occurs when sliding takes place in a corrosive environment. In the absence of sliding, the products of the corrosion (e.g., oxides) would form a film typically less than a micrometer thick on the surfaces, which would tend to slow or even arrest the corrosion, but the sliding action wears the film away, so that the corrosive attack can continue. Thus, corrosive wear requires both corrosion and rubbing. Machinery operating in an industrial environment or near the coast generally corrode more rapidly than

those operating in a clean environment. Corrosion can occur because of chemical or electrochemical interaction of the interface with the environment. Chemical corrosion occurs in a highly corrosive environment and in high-temperature and high-humidity environments. Electrochemical corrosion is a chemical reaction accompanied by the passage of an electric current; for this to occur a potential difference must exist between two regions.

Electrical Arc-Induced Wear

When a high potential is present over a thin air film in a sliding process, a dielectric breakdown results that leads to arcing. During arcing, a relatively high-power density (on the order of 1 kW/mm^2) occurs over a very short period of time (on the order of $100 \text{ }\mu\text{sec}$). The heat-affected zone is usually very shallow (on the order of $50 \text{ }\mu\text{m}$). Heating is caused by the Joule effect due to the high power density and by ion bombardment from the plasma above the surface. This heating results in considerable melting, corrosion, hardness changes, other phase changes and even the direct ablation of material. Arcing causes large craters, and any sliding or oscillation after an arc either shears or fractures the lips, leading to abrasion, corrosion, surface fatigue, and fretting. Arcing can thus initiate several modes of wear, resulting in catastrophic failures in electrical machinery [Bhushan and Davis, 1983].

Fretting and Fretting Corrosion

Fretting occurs where low-amplitude vibratory motion takes place between two metal surfaces loaded together [Anonymous, 1955]. This is a common occurrence because most machinery is subjected to vibration, both in transit and in operation. Examples of vulnerable components are shrink fits, bolted parts, and splines. Basically, fretting is a form of adhesive or abrasive wear where the normal load causes adhesion between asperities and vibrations cause ruptures, resulting in wear debris. Most commonly, fretting is combined with corrosion, in which case the wear mode is known as *fretting corrosion*.

21.5 Lubrication

Sliding between clean solid surfaces is generally characterized by a high coefficient of friction and severe wear due to the specific properties of the surfaces, such as low harness, high surface energy, reactivity, and mutual solubility. Clean surfaces readily adsorb traces of foreign substances, such as organic compounds, from the environment. The newly formed surfaces generally have a much lower coefficient of friction and wear than the clean surfaces. The presence of a layer of foreign material at an interface cannot be guaranteed during a sliding process; therefore, lubricants are deliberately applied to produce low friction and wear. The term **lubrication** is applied to two different situations: solid lubrication and fluid (liquid or gaseous) film lubrication.

Solid Lubrication

A solid lubricant is any material used in bulk or as a powder or a thin, solid film on a surface to provide protection from damage during relative movement to reduce friction and wear. Solid lubricants are used for applications in which any sliding contact occurs, for example, a bearing operative at high loads and low speeds and a hydrodynamically lubricated bearing requiring start/stop operations. The term *solid lubricants* embraces a wide range of materials that provide low friction and wear [Bhushan and Gupta, 1991]. Hard materials are also used for low wear under extreme operating conditions.

Fluid Film Lubrication

A regime of lubrication in which a thick fluid film is maintained between two sliding surfaces by an external pumping agency is called *hydrostatic lubrication*.

A summary of the lubrication regimes observed in fluid (liquid or gas) lubrication without an external pumping agency (self-acting) can be found in the familiar Stribeck curve in [Figure 21.8](#). This plot for a

FIGURE 21.8 Lubricant film parameter (Λ) and coefficient of friction as a function of $\eta N/p$ (Stribeck curve) showing different lubrication regimes observed in fluid lubrication without an external pumping agency. Schematics of interfaces operating in different lubrication regimes are also shown.

hypothetical fluid-lubricated bearing system presents the coefficient of friction as a function of the product of viscosity (η) and rotational speed (N) divided by the normal pressure (p). The curve has a minimum, which immediately suggests that more than one lubrication mechanism is involved. The regimes of lubrication are sometimes identified by a lubricant film parameter Λ equal to h/σ , which is mean film thickness divided by composite standard deviation of surface roughnesses. Descriptions of different regimes of lubrication follow [Booser, 1984; Bhushan, 1990].

Hydrostatic Lubrication

Hydrostatic bearings support load on a thick film of fluid supplied from an external pressure source — a pump — which feeds pressurized fluid to the film. For this reason, these bearings are often called “externally pressurized.” Hydrostatic bearings are designed for use with both incompressible and com-

pressible fluids. Since hydrostatic bearings do not require relative motion of the bearing surfaces to build up the load-supporting pressures as necessary in hydrodynamic bearings, hydrostatic bearings are used in applications with little or no relative motion between the surfaces. Hydrostatic bearings may also be required in applications where, for one reason or another, touching or rubbing of the bearing surfaces cannot be permitted at startup and shutdown. In addition, hydrostatic bearings provide high stiffness. Hydrostatic bearings, however, have the disadvantage of requiring high-pressure pumps and equipment for fluid cleaning, which adds to space and cost.

Hydrodynamic Lubrication

Hydrodynamic (HD) lubrication is sometimes called *fluid-film* or *thick-film lubrication*. As a bearing with convergent shape in the direction of motion starts to spin (slide in the longitudinal direction) from rest, a thin layer of fluid is pulled through because of viscous entrainment and is then compressed between the bearing surfaces, creating a sufficient (hydrodynamic) pressure to support the load without any external pumping agency. This is the principle of hydrodynamic lubrication, a mechanism that is essential to the efficient functioning of the self-acting journal and thrust bearings widely used in modern industry. A high load capacity can be achieved in the bearings that operate at high speeds and low loads in the presence of fluids of high viscosity.

Fluid film can also be generated only by a reciprocating or oscillating motion in the normal direction (*squeeze*), which may be fixed or variable in magnitude (transient or steady state). This load-carrying phenomenon arises from the fact that a viscous fluid cannot be instantaneously squeezed out from the interface with two surfaces that are approaching each other. It takes time for these surfaces to meet, and during that interval — because of the fluid's resistance to extrusion — a pressure is built up and the load is actually supported by the fluid film. When the load is relieved or becomes reversed, the fluid is sucked in and the fluid film often can recover its thickness in time for the next application. The squeeze phenomenon controls the buildup of a water film under the tires of automobiles and airplanes on wet roadways or landing strips (commonly known as *hydroplaning*) that have virtually no relative sliding motion.

HD lubrication is often referred to as the ideal lubricated contact condition because the lubricating films are normally many times thicker (typically 5 to 500 μm) than the height of the irregularities on the bearing surface, and solid contacts do not occur. The coefficient of friction in the HD regime can be as small as 0.001 (Figure 21.8). The friction increases slightly with the sliding speed because of viscous drag. The behavior of the contact is governed by the bulk physical properties of the lubricant, notable viscosity, and the frictional characteristics arise purely from the shearing of the viscous lubricant.

Elastohydrodynamic Lubrication

Elastohydrodynamic (EHD) lubrication is a subset of HD lubrication in which the elastic deformation of the bounding solids plays a significant role in the HD lubrication process. The film thickness in EHD lubrication is thinner (typically 0.5 to 2.5 μm) than that in HD lubrication (Figure 21.8), and the load is still primarily supported by the EHD film. In isolated areas, asperities may actually touch. Therefore, in liquid lubricated systems, boundary lubricants that provide boundary films on the surfaces for protection against any solid–solid contact are used. Bearings with heavily loaded contacts fail primarily by a fatigue mode that may be significantly affected by the lubricant. EHD lubrication is most readily induced in heavily loaded contacts (such as machine elements of low geometrical conformity), where loads act over relatively small contact areas (on the order of one-thousandth of journal bearing), such as the point contacts of ball bearings and the line contacts of roller bearings and gear teeth. EHD phenomena also occur in some low elastic modulus contacts of high geometrical conformity, such as seals and conventional journal and thrust bearings with soft liners.

Mixed Lubrication

The transition between the hydrodynamic/elastohydrodynamic and boundary lubrication regimes constitutes a gray area known as *mixed lubrication*, in which two lubrication mechanisms may be functioning.

TABLE 21.4 Surface Roughness and Micro- and Macroscale Coefficients of Friction of Various Samples

| Material | RMS Roughness, nm | Microscale Coefficient of Friction versus Si ₃ N ₄ Tip ^a | Macroscale Coefficient of Friction versus Alumina Ball ^b | |
|------------------------------|----------------------|---|--|------|
| | | | 0.1 N | 1 N |
| Si (111) | 0.11 | 0.03 | 0.18 | 0.60 |
| C ⁺ -implanted Si | 0.33 | 0.02 | 0.18 | 0.18 |

^a Si₃N₄ tip (with about 50 nm radius) in the load range of 10–150 nN (1.5–3.8 Gpa), a scanning speed of 4 μm/sec and scan area of 1 × 1 μm.

^b Alumina ball with 3-mm radius at normal loads of 0.1 and 1 N (0.23 and 0.50 Gpa) and average sliding speed of 0.8 mm/sec.

There may be more frequent solid contacts, but at least a portion of the bearing surface remains supported by a partial hydrodynamic film (Figure 21.8). The solid contacts, if between unprotected virgin metal surfaces, could lead to a cycle of adhesion, metal transfer, wear particle formation, and snowballing into seizure. However, in liquid lubricated bearings, the physi- or chemisorbed or chemically reacted films (boundary lubrication) prevent adhesion during most asperity encounters. The mixed regime is also sometimes referred to as *quasihydrodynamic*, *partial fluid*, or *thin-film* (typically 0.5 to 2.5 μm) *lubrication*.

Boundary Lubrication

As the load increases, speed decreases or the fluid viscosity decreases in the Stribeck curve shown in Figure 21.8; the coefficient of friction can increase sharply and approach high levels (about 0.2 or much higher). In this region, it is customary to speak of boundary lubrication. This condition can also occur in a starved contact. Boundary lubrication is that condition in which the solid surfaces are so close together that surface interaction between monomolecular or multimolecular films of lubricants (liquids or gases) and the solids dominates the contact. (This phenomenon does not apply to solid lubricants.) The concept is represented in Figure 21.8, which shows a microscopic cross-section of films on two surfaces and areas of asperity contact. In the absence of boundary lubricants and gases (no oxide films), friction may become very high (>1).

21.6 Micro/Nanotribology

AFM/FFMs are commonly used to study engineering surfaces on micro- to nanoscales. These instruments measure the normal and friction forces between a sharp tip (with a tip radius of 30 to 100 nm) and an engineering surface. Measurements can be made at loads as low as less than 1 nN and at scan rates up to about 120 Hz. A sharp AFM/FFM tip sliding on a surface simulates a single asperity contact. FFMs are used to measure coefficient of friction on micro- to nanoscales, and AFMs are used for studies of surface topography, scratching/wear and boundary lubrication, mechanical property measurements, and nanofabrication/nanomachining [Bhushan and Ruan, 1994; Bhushan et al., 1994; Bhushan and Koinkar, 1994a,b; Ruan and Bhushan, 1994; Bhushan, 1995; Bhushan et al., 1995]. For surface roughness, friction force, nanoscratching and nanowear measurements, a microfabricated square pyramidal Si₃N₄ tip with a tip radius of about 30 nm is generally used at loads ranging from 10 to 150 nN. For microscratching, microwear, nanoindentation hardness measurements, and nanofabrication, a three-sided pyramidal single-crystal natural diamond tip with a tip radius of about 100 nm is used at relatively high loads ranging from 10 to 150 μN. Friction and wear on micro- and nanoscales are found to be generally smaller compared to that at macroscales. For an example of comparison of coefficients of friction at macro- and microscales see Table 21.4.

Defining Terms

Friction — The resistance to motion whenever one solid slides over another.

- Lubrication** — Materials applied to the interface to produce low friction and wear in either of two situations — solid lubrication or fluid (liquid or gaseous) film lubrication.
- Micro/nanotribology** — The discipline concerned with experimental and theoretical investigations of processes (ranging from atomic and molecular scales to microscales) occurring during adhesion, friction, wear, and lubrication at sliding surfaces.
- Tribology** — The science and technology of two interacting surfaces in relative motion and of related subjects and practices.
- Wear** — The removal of material from one or both solid surfaces in a sliding, rolling, or impact motion relative to one another.

[22.1 Threaded Fasteners](#)

[22.2 Clutches and Brakes](#)

[Rim-Type Clutches and Brakes](#) • [Axial-Type Clutches and Brakes](#) • [Disk Clutches and Brakes](#) • [Cone Clutches and Brakes](#) • [Positive-Contact Clutches](#)

Section 22.1 presents a discussion of threaded fasteners, namely, the nut and bolt, the machine screw, the cap screw, and the stud. Equations are presented for the spring stiffness of the portion of a bolt, or a cap screw, within the clamped zone, which generally consists of the unthreaded shank portion and the threaded portion. Equations for the resultant bolt load and the resultant load on the members are also included in the discussion. The section concludes with a relation that provides an estimate of the torque that is required to produce a given preload. Section 22.2 presents a discussion of clutches and brakes and the important features of these machine elements. Various types of frictional-contact clutches and brakes are included in the discussion, namely, the radial, axial, disk, and cone types. Information on positive-contact clutches and brakes is also provided. The section includes energy considerations, equations for the temperature-rise, and the characteristics of a friction material. Section 22.3 presents material on gears, including computing gear ratios for simple, compound, and epicyclic gear trains. Section 22.4 discusses roller element bearings and their selection for use in machines. Section 22.5 presents the fundamental equations for designing shafts and presents equations for constant and fluctuating torques.

22.1 Threaded Fasteners

The bolted joint with hardened steel washers is a common solution when a connection is required that can be easily disassembled (without destructive methods) and is strong enough to resist external tensile loads and shear loads. The clamping load, which is obtained by rotating the nut until the bolt is close to the elastic limit, stretches or elongates the bolt. This bolt tension will remain as the clamping force, or preload, providing the nut does not loosen. The preload induces compression in the members, which are clamped together, and exists in the connection after the nut has been properly tightened, even if there is no external load. Care must be taken to ensure that a bolted joint is properly designed and assembled [Blake, 1986]. When tightening the connection, the bolt head should be held stationary and the nut twisted. This procedure will ensure that the bolt shank will not experience the thread-friction torque. During the tightening process, the first thread on the nut tends to carry the entire load. However, yielding occurs with some strengthening due to the cold work that takes place, and the load is eventually distributed over about three nut threads. For this reason, it is recommended that nuts should not be reused; in fact, it can be dangerous if this practice is followed [Shigley and Mischke, 1989].

There are several styles of hexagonal nut, namely:

1. The general hexagonal nut
2. The washer-faced regular nut
3. The regular nut chamfered on both sides
4. The jam nut with washer face
5. The jam nut chamfered on both sides

Flat nuts only have a chamfered top [Shigley and Mischke, 1986]. The material of the nut must be selected carefully to match that of the bolt. Carbon steel nuts are usually made to conform to ASTM A563 Grade A specifications or to SAE Grade 2. A variety of machine screw head styles also exist; they include:

1. Fillister head
2. Flat head
3. Round head
4. Oval head
5. Truss head
6. Binding head
7. Hexagonal head (trimmed and upset)

There are also many kinds of locknuts, which have been designed to prevent a nut from loosening in service. Spring and lock washers placed beneath an ordinary nut are also common devices to prevent loosening.

Another tension-loaded connection uses cap screws threaded into one of the members. Cap screws can be used in the same applications as nuts and bolts and also in situations where one of the clamped members is threaded. The common head styles of the cap screw include:

1. Hexagonal head
2. Fillister head
3. Flat head
4. Hexagonal socket head

The head of a hexagon-head cap screw is slightly thinner than that of a hexagon-head bolt. An alternative to the cap screw is the stud, which is a rod threaded on both ends. Studs should be screwed into the lower member first, then the top member should be positioned and fastened down with hardened steel washers and nuts. The studs are regarded as permanent and the joint should be disassembled by removing only the nuts and washers. In this way, the threaded part of the lower member is not damaged by reusing the threads.

The grip of a connection is the total thickness of the clamped material [Shigley and Mischke, 1989]. In the bolted joint, the grip is the sum of the thicknesses of both the members and the washers. In a stud connection, the grip is the thickness of the top member plus that of the washer. The spring stiffness, or spring rate, of an elastic member such as a bolt is the ratio of the force applied to the member and the deflection caused by that force. The spring stiffness of the portion of a bolt, or cap screw, within the clamped zone generally consists of two parts, namely (1) that of the threaded portion and (2) that of the unthreaded shank portion. Therefore, the stiffness of a bolt is equivalent to the stiffness of two springs in series:

$$\frac{1}{k_b} = \frac{1}{k_T} + \frac{1}{k_d} \quad \text{or} \quad k_b = \frac{k_T k_d}{k_T + k_d} \quad (22.1)$$

The spring stiffnesses of the threaded and unthreaded portions of the bolt in the clamped zone, respectively, are

$$k_T = \frac{A_t E}{L_T} \quad \text{and} \quad k_d = \frac{A_d E}{L_d} \quad (22.2)$$

where A_t is the tensile-stress area, L_T is the length of the threaded portion *in the grip*, A_d is the major-diameter area of the fastener, L_d is the length of the unthreaded portion (shank), and E is the modulus of elasticity. Substituting Equation (22.2) into Equation (22.1), the estimated effective stiffness of the bolt (or cap screw) in the clamped zone can be expressed as

$$k_b = \frac{A_t A_d E}{A_t L_d + A_d L_T} \quad (22.3)$$

For short fasteners, the unthreaded area is small and so the first of the expressions in Equation (22.2) can be used to evaluate k_b . In the case of long fasteners, the threaded area is relatively small, so the second expression in Equation (22.2) can be used to evaluate the effective stiffness of the bolt. Expressions can also be obtained for the stiffness of the members in the clamped zone [Juvinal, 1983]. Both the stiffness of the fastener and the stiffness of the members in the clamped zone must be known in order to understand what happens when the connection is subjected to an external tensile load. There may be more than two members included in the grip of the fastener. Taken together the members act like compressive springs in series, and hence the total spring stiffness of the members is

$$\frac{1}{k_m} = \frac{1}{k_1} + \frac{1}{k_2} + \frac{1}{k_3} + \dots \quad (22.4)$$

If one of the members is a soft gasket, its stiffness relative to the other members is usually so small that for all practical purposes the other members can be neglected and only the gasket stiffness need be considered. If there is no gasket, the stiffness of the members is difficult to obtain, except by experimentation, because the compression spreads out between the bolt head and the nut and hence the area is not uniform. There are, however, some cases in which this area can be determined. Ultrasonic techniques have been used to determine the pressure distribution at the member interface in a bolt-flange assembly [Ito et al., 1977]. The results show that the stress stays high out to about 1.5 times the bolt radius and then falls off farther away from the bolt. Rotsher's pressure-cone method has been suggested for stiffness calculations with a variable cone angle. This method is quite complicated; a simpler approach is to use a fixed cone angle [Little, 1967]. Both Shigley and Mischke and Juvinal and Marshek show examples of computing the material stiffness using the cone model. A cone angle of 30° has been shown to be best for standard engineering materials.

More recently, Wideman et al. (1991) used FEA (finite element analysis) to model the stiffness of clamped material for steel, aluminum, copper, and cast iron. By representing the problem in a nondimensionalized manner, they were able to develop relationships that characterized the stiffness of the material so that it could be represented by an exponential curve that could be represented by a set of parameters, A and B in the equation, i.e.,

$$\frac{k_m}{Ed} = Ae^{B(d/L)} \quad (22.5)$$

where k_m is the material stiffness, E is modulus of elasticity, d is the diameter of the bolt, L is the length of the clamped material, and A and B are the parameters that have been determined of the material being clamped, e.g., steel. Wideman et al. include a table of values as follows:

| Material | Elastic Modulus [GPa] | A | B |
|----------------|-----------------------|---------|---------|
| Steel | 206.8 | 0.78715 | 0.63816 |
| Aluminum | 71.0 | 0.79670 | 0.63816 |
| Copper | 118.6 | 0.79568 | 0.63553 |
| Gray cast iron | 100.0 | 0.77871 | 0.61616 |

Using this approach, the material stiffness can be computed in a straightforward manner. For example, for a bolted joint with 50 mm of clamped material steel and a 20-mm diameter bolt, the material stiffness would be

$$k_m = EdAe^{B(d/L)} = (206.8e9N/m^2)(0.02m)(0.078715)e^{0.62873(0.020/0.05)} = 4.187e9N/m \quad (22.6)$$

As the authors state, this approach should be used with full appreciation for the assumptions that have been made in order to arrive at this result; otherwise, its use could lead to nonconservative results. Specifically, the following assumptions were made:

1. The distance from the bolt axis to the edge of the members is several times the bolt diameter.
2. Thread friction is not excessive.
3. Shear loads are not excessive.
4. There is no slippage at the member interface.
5. The surface finish of the members is not overly rough.

The first assumption is the most important and one that designers will want to consider closely. If the design results in less than two bolt diameters between the edge and bolt hole, a larger safety factor is recommended, since these equations will compute a larger material stiffness than in fact exists. If the joint contains an unconfined gasket, then each of the materials must be considered separately and then combined using Equation (22.4), above.

Consider what happens when an external tensile load is applied to a bolted connection. Assuming that the preload has been correctly applied (by tightening the nut before the external tensile load is applied), the tensile load causes the connection to stretch through some distance. This elongation can be related to the stiffness of the bolts, or the members, by the equation

$$\delta = \frac{P_b}{k_b} = \frac{P_m}{k_m} \quad \text{or} \quad P_b = \frac{k_b}{k_m} P_m \quad (22.7)$$

where P_b is the portion of the external tensile load P taken by the bolt and P_m is the portion of P taken by the members. Since the external tensile load P is equal to $P_b + P_m$,

$$P_b = \left(\frac{k_b}{k_b + k_m} \right) P \quad \text{and} \quad P_m = \left(\frac{k_m}{k_b + k_m} \right) P \quad (22.8)$$

The resultant bolt load is $F_b = P_b + F_i$ and the resultant load on the members is $F_m = P_m - F_i$, where F_i is the preload. Therefore, the resultant bolt load can be written as

$$F_b = \left(\frac{k_b}{k_b + k_m} \right) P + F_i, \quad F_m < 0 \quad (22.9)$$

and the resultant load on the members can be written as

$$F_m = \left(\frac{k_m}{k_b + k_m} \right) P - F_i, \quad F_m < 0 \quad (22.10)$$

The best joint designs are ones in which the largest portion of the load is taken by the material, rather than the bolt. When the material carries more of the load, the bolt will see smaller stress changes when

the joint is exposed to fluctuating loads. Thus one can see from Equation (22.9) and Equation (22.10) that the goal is to have the material have the larger stiffness since this will lead to the material carrying the larger load. Note, however, that Equation (22.9) and Equation (22.10) are only valid for the case when some clamping load remains in the members, which is indicated by the qualifier in the two equations. Making the grip longer causes the members to take an even greater percentage of the external load. However, if the external load is large enough to completely remove the compression, then the members will separate and the entire load will be carried by the bolts.

Since it is desirable to have a high preload in important bolted connections, methods of ensuring that the preload is actually developed when the parts are assembled must be considered. If the overall length of the bolt, L_b , can be measured (say with a micrometer) when the parts are assembled, then the bolt elongation due to the preload F_i can be computed from the relation

$$\delta = \frac{F_i L_b}{AE} \quad (22.11)$$

where A is the cross-sectional area of the bolt. The nut can then be tightened until the bolt elongates through the distance δ , which ensures that the desired preload has been obtained. In many cases, however, it is not practical or possible to measure the bolt elongation. For example, the elongation of a screw cannot be measured if the threaded end is in a blind hole. In such cases the wrench torque that is required to develop the specified preload must be estimated. Torque wrenching, pneumatic-impact wrenching, or the **turn-of-the-nut method** can be used [Blake and Kurtz, 1965]. The torque wrench has a built-in dial that indicates the proper torque. With pneumatic-impact wrenching, the air pressure is adjusted so that the wrench stalls when the proper torque is obtained or, in some cases, the air shuts off automatically at the desired torque.

The **snug-tight condition** is defined as the tightness attained by a few impacts of an impact wrench or the full effort of a person using an ordinary wrench. When the snug-tight condition is attained, all additional turning develops useful tension in the bolt. The turn-of-the-nut method requires that the fractional number of turns necessary to develop the required preload from the snug-tight condition be computed. For example, a 1-in. UNC bolt and nut that has a perfect fitup in its snug-tight condition would call for a turn of the nut of approximately 30° to bring the bolt tension up to its proof strength. A good estimate of the torque required to produce a given preload F_i can be obtained from the relation [Shigley and Mischke, 1989]

$$T = \frac{F_i d_m}{2} \left(\frac{L + \pi \mu d_m \sec \alpha}{\pi d_m - \mu L \sec \alpha} \right) + \frac{F_i \mu_c d_c}{2} \quad (22.12)$$

where d_m is the mean diameter of the bolt, L is the lead of the thread, α is half the thread angle, μ is the coefficient of thread friction, μ_c is the coefficient of collar friction, and d_c is the mean collar diameter. The coefficients of friction depend upon the surface smoothness, the accuracy, and the degree of lubrication. Although these items may vary considerably, it is interesting to note that on the average both μ and μ_c are approximately 0.15. Using the standard thread angle for SAE/ISO threads (60°) and 0.15 for friction, and approximating the mean diameter by the major diameter, we can obtain the following expression

$$T = 0.21dF_i \quad (22.13)$$

where d is the major diameter of the bolt and F_i is the desired initial load. This expression can be used to compute the torque necessary to develop the desired clamping force in the bolt.

22.2 Clutches and Brakes

A clutch is a coupling that connects two shafts rotating at different speeds and brings the output shaft smoothly and gradually to the same speed as the input shaft. Clutches and brakes are machine elements associated with rotation and have in common the function of storing or transferring rotating energy [Remling, 1983]. When the rotating members are caused to stop by means of a brake, the kinetic energy of rotation must be absorbed by the brake. In the same way, when the members of a machine that are initially at rest are brought up to speed, slipping must occur in the clutch until the driven members have the same speed as the driver. Kinetic energy is absorbed during slippage of either a clutch or a brake, and this energy appears in the form of heat. The important features in the performance of these devices are:

1. The actuating force
2. The transmitted torque
3. The energy loss
4. The temperature rise

The torque that is transmitted is related to the actuating force, the coefficient of friction, and the geometry of the device. Essentially this is a problem in statics and can be studied separately for each geometric configuration. The rise in temperature, however, can be studied without regard to the type of device because the heat-dissipating surfaces are the geometry of interest. An approximate guide to the rise in temperature in a drum brake is the horsepower per square inch [Spotts, 1985].

The torque capacity of a clutch or brake depends upon the coefficient of friction of the material and a safe normal pressure. The character of the load may be such, however, that if this torque value is permitted, the clutch or brake may be destroyed by the generated heat. Therefore, the capacity of a clutch is limited by two factors:

1. The characteristics of the material
2. The ability of the clutch to dissipate the frictional heat

The temperature rise of a clutch or brake assembly can be approximated by the relation

$$\Delta T = \frac{H}{CW} \quad (22.11)$$

where ΔT is in $^{\circ}\text{F}$, H is the heat generated in Btu, C is the specific heat in Btu/(lbm $^{\circ}\text{F}$), and W is the mass of the clutch or brake assembly in lbm. If SI units are used, then

$$\Delta T = \frac{E}{Cm} \quad (22.12)$$

where ΔT is in $^{\circ}\text{C}$, E is the total energy dissipated during the clutching operation or the braking cycle in J, C is the specific heat in J/(kg $^{\circ}\text{C}$), and m is the mass of the clutch or brake assembly in kg. Equation (22.11) or Equation (22.12) can be used to explain what happens when a clutch or a brake is operated. However, so many variables are involved that it is most unlikely that the analytical results would approximate experimental results. For this reason, such analyses are only useful, for repetitive cycling, in pinpointing the design parameters that have the greatest effect on performance.

The friction material of a clutch or brake should have the following characteristics, to a degree that is dependent upon the severity of the service:

1. A high and uniform coefficient of friction
2. Imperviousness to environmental conditions, such as moisture
3. The ability to withstand high temperatures, as well as good heat conductivity

4. Good resiliency
5. High resistance to wear, scoring, and galling

The manufacture of friction materials is a highly specialized process, and the selection of a friction material for a specific application requires some expertise. Selection involves a consideration of all the characteristics of a friction material as well as the standard sizes that are available. The woven-cotton lining is produced as a fabric belt, which is impregnated with resins and polymerized. It is mostly used in heavy machinery and can be purchased in rolls up to 50 feet in length. The thicknesses that are available range from 0.125 to 1 in. and the width may be up to 12 in. A woven-asbestos lining is similar in construction to the cotton lining and may also contain metal particles. It is not quite as flexible as the cotton lining and comes in a smaller range of sizes. The woven-asbestos lining is also used as a brake material in heavy machinery. Due to health concerns, asbestos use has been reduced in recent years.

Molded-asbestos linings contain asbestos fiber and friction modifiers; a thermoset polymer is used, with heat, to form a rigid or a semirigid molding. The principal use is in drum brakes. Molded-asbestos pads are similar to molded linings but have no flexibility; they are used for both clutches and brakes. Sintered-metal pads are made of a mixture of copper and/or iron particles with friction modifiers, molded under high pressure and then heated to a high temperature to fuse the material. These pads are used in both brakes and clutches for heavy-duty applications. Cermet pads are similar to the sintered-metal pads and have a substantial ceramic content. Typical brake linings may consist of a mixture of asbestos fibers to provide strength and ability to withstand high temperatures; various friction particles to obtain a degree of wear resistance and higher coefficient of friction; and bonding materials. Some clutch friction materials may be run wet by allowing them to dip in oil or to be sprayed by oil. This reduces the coefficient of friction, but more heat can be transferred and higher pressure can be permitted.

The two most common methods of coupling are the frictional-contact clutch and the positive-contact clutch. Other methods include the overrunning or freewheeling clutch, the magnetic clutch, and the fluid coupling. In general, the types of frictional-contact clutches and brakes can be classified as rim type or axial type [Marks, 1987]. The analysis of all types of frictional clutches and brakes follows the same general procedure, namely:

1. Determine the pressure distribution on the frictional surfaces.
2. Find a relation between the maximum pressure and the pressure at any point.
3. Apply the conditions of static equilibrium to find the actuating force, the torque transmitted, and the support reactions.

The analysis is useful when the dimensions are known and the characteristics of the friction material are specified. In design, however, synthesis is of more interest than analysis. Here the aim is to select a set of dimensions that will provide the best device within the limitations of the frictional material that is specified by the designer [Proctor, 1961].

Rim-Type Clutches and Brakes

The rim-type brake can be designed for **self-energizing**, that is, using friction to reduce the actuating force. Self-energization is important in reducing the required braking effort; however, it also has a disadvantage. When rim-type brakes are used as vehicle brakes, a small change in the coefficient of friction will cause a large change in the pedal force required for braking. For example, it is not unusual for a 30% reduction in the coefficient of friction (due to a temperature change or moisture) to result in a 50% change in the pedal force required to obtain the same braking torque that was possible prior to the change.

The rim types may have internal expanding shoes or external contracting shoes. An internal shoe clutch consists essentially of three elements:

1. A mating frictional surface
2. A means of transmitting the torque to and from the surfaces
3. An actuating mechanism

Depending upon the operating mechanism, such clutches can be further classified as expanding-ring, centrifugal, magnetic, hydraulic, or pneumatic. The expanding-ring clutch benefits from centrifugal effects, transmits high torque even at low speeds, and requires both positive engagement and ample release force. This type of clutch is often used in textile machinery, excavators, and machine tools in which the clutch may be located within the driving pulley. The centrifugal clutch is mostly used for automatic operations. If no spring is present, the torque transmitted is proportional to the square of the speed [Beach, 1962]. This is particularly useful for electric motor drives in which, during starting, the driven machine comes up to speed without shock. Springs can be used to prevent engagement until a certain motor speed has been reached, but some shock may occur. Magnetic clutches are particularly useful for automatic and remote-control systems and are used in drives subject to complex load cycles. Hydraulic and pneumatic clutches are useful in drives with complex loading cycles, in automatic machinery, and in manipulators. Here the fluid flow can be controlled remotely using solenoid valves. These clutches are available as disk, cone, and multiple-plate clutches.

In braking systems, the internal-shoe or drum brake is used mostly for automotive applications. The actuating force of the device is applied at the end of the shoe away from the pivot. Since the shoe is usually long, the distribution of the normal forces cannot be assumed to be uniform. The mechanical arrangement permits no pressure to be applied at the heel; therefore, frictional material located at the heel contributes very little to the braking action. It is standard practice to omit the friction material for a short distance away from the heel, which also eliminates interference. In some designs the hinge pin is allowed to move to provide additional heel pressure. This gives the effect of a floating shoe. A good design concentrates as much frictional material as possible in the neighborhood of the point of maximum pressure. Typical assumptions made in an analysis of the shoe include the following:

1. The pressure at any point on the shoe is proportional to the distance from the hinge pin (zero at the heel).
2. The effect of centrifugal force is neglected (in the case of brakes, the shoes are not rotating and no centrifugal force exists; in clutch design, the effect of this force must be included in the equations of static equilibrium).
3. The shoe is rigid (in practice, some deflection will occur depending upon the load, pressure, and stiffness of the shoe; therefore, the resulting pressure distribution may be different from the assumed distribution).
4. The entire analysis is based upon a coefficient of friction that does not vary with pressure. Actually, the coefficient may vary with a number of conditions, including temperature, wear, and the environment.

For pivoted external shoe brakes and clutches, the operating mechanisms can be classified as solenoids, levers, linkages or toggle devices, linkages with spring loading, hydraulic devices, and pneumatic devices. It is common practice to concentrate on brake and clutch performance without the extraneous influences introduced by the need to analyze the statics of the control mechanisms. The moments of the frictional and normal forces about the hinge pin are the same as for the internal expanding shoes. It should be noted that when external contracting designs are used as clutches, the effect of the centrifugal force is to decrease the normal force. Therefore, as the speed increases, a larger value of the actuating force is required. A special case arises when the pivot is symmetrically located and also placed so that the moment of the friction forces about the pivot is zero.

Axial-Type Clutches and Brakes

In an axial clutch, the mating frictional members are moved in a direction parallel to the shaft. One of the earliest axial clutches was the cone clutch, which is simple in construction and yet quite powerful. Except for relatively simple installations, however, it has been largely replaced by the disk clutch, which employs one or more disks as the operating members. Advantages of the disk clutch include:

1. No centrifugal effects
2. A large frictional area that can be installed in a small space
3. More effective heat dissipation surfaces
4. A favorable pressure distribution

There are two methods in general use to obtain the axial force necessary to produce a certain torque and pressure (depending upon the construction of the clutch). The two methods are:

1. Uniform wear
2. Uniform pressure

If the disks are rigid then the greatest amount of wear will first occur in the outer areas, since the work of friction is greater in those areas. After a certain amount of wear has taken place, the pressure distribution will change so as to permit the wear to be uniform. The greatest pressure must occur at the inside diameter of the disk in order for the wear to be uniform. The second method of construction employs springs to obtain a uniform pressure over the area.

Disk Clutches and Brakes

No fundamental difference exists between a disk clutch and a disk brake [Gagne, 1953]. The disk brake has no self-energization and, hence, is not as susceptible to changes in the coefficient of friction. The axial force can be written as

$$F_a = 0.5\pi p D_1 (D_2 - D_1) \quad (22.13)$$

where p is the maximum pressure, and D_1 and D_2 are the inner and outer diameters of the disk, respectively. The torque transmitted can be obtained from the relation

$$T = 0.5\mu F_a D_m \quad (22.14)$$

where μ is the coefficient of friction of the clutch material, and the mean diameter

$$D_m = 0.5(D_2 + D_1) \text{ or } D_m = \frac{2(D_2^3 - D_1^3)}{3(D_2^2 - D_1^2)} \quad (22.15)$$

for uniform wear or for uniform pressure distribution, respectively.

A common type of disk brake is the floating caliper brake. In this design the caliper supports a single floating piston actuated by hydraulic pressure. The action is much like that of a screw clamp, with the piston replacing the function of the screw. The floating action also compensates for wear and ensures an almost constant pressure over the area of the friction pads. The seal and boot are designed to obtain clearance by backing off from the piston when the piston is released.

Cone Clutches and Brakes

A cone clutch consists of:

1. A cup (keyed or splined to one of the shafts)
2. A cone that slides axially on the splines or keys on the mating shaft
3. A helical spring to hold the clutch in engagement

The clutch is disengaged by means of a fork that fits into the shifting groove on the friction cone. The axial force, in terms of the clutch dimensions, can be written as

$$F_a = \pi D_m p b \sin \alpha \quad (22.16)$$

where p is the maximum pressure, b is the face width of the cone, D_m is the mean diameter of the cone, and α is one-half the cone angle in degrees. The mean diameter can be approximated as $0.5(D_2 + D_1)$. The torque transmitted through friction can be obtained from the relation

$$T = \frac{\mu F_a D_m}{2 \sin \alpha} \quad (22.17)$$

The cone angle, the face width of the cone, and the mean diameter of the cone are the important geometric design parameters. If the cone angle is too small, say, less than about 8° , the force required to disengage the clutch may be quite large. The wedging effect lessens rapidly when larger cone angles are used. Depending upon the characteristics of the friction materials, a good compromise can usually be found using cone angles between 10° and 15° . For clutches faced with asbestos, leather, or a cork insert, a cone angle of 12.5° is recommended.

Positive-Contact Clutches

A positive-contact clutch does not slip, does not generate heat, cannot be engaged at high speeds, sometimes cannot be engaged when both shafts are at rest, and, when engaged at any speed, is accompanied by shock. The greatest differences among the various types of positive-contact clutches are concerned with the design of the jaws. To provide a longer period of time for shift action during engagement, the jaws may be ratchet shaped, spiral shaped, or gear-tooth shaped. The square-jaw clutch is another common form of a positive-contact clutch. Sometimes a great many teeth or jaws are used, and they may be cut either circumferentially, so that they engage by cylindrical mating, or on the faces of the mating elements. Positive-contact clutches are not used to the same extent as the frictional-contact clutches.

Defining Terms

Snug-tight condition — The tightness attained by a few impacts of an impact wrench or the full effort of a person using an ordinary wrench.

Turn-of-the-nut method — The fractional number of turns necessary to develop the required preload from the snug-tight condition.

Proof strength — The stress at which the bolt *begins* to take on a permanent deformation, i.e., plastic yield.

Self-energizing — A state in which friction is used to reduce the necessary actuating force. The design should make good use of the frictional material because the pressure is an allowable maximum at all points of contact.

Self-locking — When the friction moment assists in applying the brake shoe, the brake will be self-locking if the friction moment exceeds the normal moment. The designer must select the dimensions of the clutch, or the brake, to ensure that self-locking will not occur unless it is specifically desired.

Fail-safe and dead-man — These two terms are often encountered in studying the operation of clutches and brakes. Fail-safe means that the operating mechanism has been designed such that, if any element should fail to perform its function, an accident will not occur in the machine or befall the operator. Dead-man, a term from the railroad industry, refers to the control mechanism that causes the engine to come to a stop if the operator should suffer a blackout or die at the controls.

Glacier Clevite Heavywall Bearings

In modern internal combustion engines, there are two kinds of bearings in the category of crankshaft journal bearings — namely, the main bearings and the connecting rod bearings. Basically, these are wraparound, semicylindrical shell bearings. Two of them make up a set and, depending on the position in the assembly, one is called the upper and the other the lower bearing. They are of equal sizes. The main bearings support the crankshaft of the engine and the forces transmitted to the crankshaft from the cylinders. The connecting rod bearings (or simply, rod bearings) are instrumental in transferring the forces from the cylinders of the internal combustion engine to the crankshaft. These connecting rod bearings are also called big end bearings or crank pin bearings. Supporting the crankshaft and transferring the pressure-volume work from the cylinders to the pure rotational mechanical energy of the crankshaft are accomplished elegantly with minimal energy loss by shearing a suitable lubricating medium between the bearings and the journals. The segment of the crankshaft within the bounds of a set of bearings, whether main bearings or rod bearings, is called the journal. Consequently, these bearings are called journal bearings.

23.1 Role of the Journal Bearings in the Internal Combustion Engine

The crankshafts of internal combustion engines of sizes from small automotive to large slow-speed engines run at widely varying rpm (e.g., 72 to 7700). When the internal combustion engine continues to run after the startup, the crankshaft, including the crank pins, is suspended in the lubricating oil — a fluid

FIGURE 23.1 Schematic representation of the hydrodynamic lubricant film around a rotating journal in its bearing assembly. (Source: Slaymaker, R. R. 1955. *Bearing Lubrication Analysis*, John Wiley & Sons, New York. With permission.)

of very low friction. In such a condition, it is conceivable that precision-machined, semicylindrical steel shells can function as good bearings. However, there are stressful conditions, particularly in the case of automotive, truck, and medium-speed engines, when the crankshaft remains in contact with the bearings and little or no lubricating oil is present. This condition corresponds to the initial and subsequent startups. The oil pump is driven directly by the engine, and it takes several revolutions of the crankshaft before a good oil film is developed, as shown in Figure 23.1, so that the journals are completely lifted and suspended. During the revolutions prior to the formation of a sufficiently thick oil film, the journal contacts the bearing surface. In such situations, the bearings provide sufficient lubrication to avoid scuffing and **seizure**. Another stressful situation, but not as critical as the startup, is the slowing down and shutting off of the engine when the oil film reduces to a **boundary layer**.

In the case of slow-speed engines, the oil pump, which is electrically driven, is turned on to prelubricate the bearings. This provides some lubrication. Nonetheless, bearings with liners and overlays are used to avoid seizure, which can result in costly damage.

Essentially, the function of journal bearings can be stated as follows:

Development of the **hydrodynamic lubrication oil films** in the journal bearings lifts the journals from the surfaces of the bearings and suspends the entire crankshaft on the oil films by the journals. [Theoretical aspects of this will be considered later.] The lifting of the crankshaft or, equivalently, lifting of the journals is in the range of 30 to 1000 micro-inch in the entire range of IC engines. This process allows the crankshaft to rotate with minimal energy loss. The journal bearings make it possible so that the internal combustion engine can be started, utilized, and stopped as many times as needed.

23.2 Construction of Modern Journal Bearings

The majority of modern crankshaft journal bearings have three different layers of metallic materials with distinct characteristics and functions. Conventionally, these are called trimetal bearings. The remaining bearings belong to the class of bimetal bearings and have two different metallic material layers. Bimetallic bearings are becoming very popular in the automotive industry.

All crankshaft journal bearings have a steel backing, normally of low-carbon steel. Steel backing is the thickest layer in the bearing. The next layer bonded to the steel backing is the bearing liner. This is the layer that supports the load and determines the life of the bearing. The third layer bonded to the bearing liner is the overlay. Generally, this is a precision electrodeposited layer of (1) lead, tin, and copper, (2) lead and tin, or (3) lead and indium. A very thin electrodeposited layer of nickel (0.000 05 in.) is used as a bonding layer between the liner and the lead-tin-copper overlay. This nickel layer is considered a part of the overlay, not a separate layer. Construction of a trimetal bronze bearing is illustrated in Figure 23.2.

There are two classes of bearing liners in widespread use nowadays. These are leaded bronzes and aluminum-based (frequently precipitation-strengthened) materials, such as aluminum-tin and aluminum-silicon. Bimetallic bearings have the advantage of being slightly more precise (about 0.0002 to 0.0003 in.) than trimetal bearings. The bimetal bearings have a bored or broached internal diametral (ID) surface. The electrodeposited layer in trimetal bearings is applied onto the bored or broached surface. The nickel bonding layer is applied first onto the liner, followed by the deposition of the lead-tin-copper overlay. The

electrodeposited overlay introduces a certain degree of variation in the wall thickness of the bearings. In a limited application, babbitt overlays are centrifugally cast on bronze liners for slow-speed diesel engine journal bearings.

Another class of bearings is single layer solid metal bearings — namely, solid bronze and solid aluminum bearings. These bearings are not generally used as crankshaft journal bearings. However, solid aluminum is used in some medium-speed and slow-speed diesel engines.

The most popular copper-tin-based leaded bearing liner in current use has 2 to 4% tin, 23 to 27% lead, and 69 to 75% copper (all by weight). This material is applied directly on mild steel by casting or sintering. The aluminum materials are roll-bonded to steel. The material as such is produced by powder rolling as a strip or by casting and rolling.

FIGURE 23.2 Schematic representation of the construction of a trimetal bearing.

23.3 The Function of the Different Material Layers in Crankshaft Journal Bearings

The bulk of modern crankshaft journal bearings is mild steel (1008 to 1026 low-carbon steels). This is the strongest of the two or three layers in the bearing. It supports the bearing liner, with or without the overlay. The bearing liner derives a certain degree of strength from the steel backing. The function of the steel backing is to carry the bearing liner, which on its own is weaker, much thinner, and less ductile. With the support of the steel backing, the bearings can be seated with a high degree of conformance and good interference fit in the housing bore (steel against steel).

The bearing liners in automotive and truck bearings have a thickness in the range of 0.006 to 0.030 in. In the case of medium-speed and slow-speed engines, the thickness of the liner ranges from 0.010 to 0.080 in. The liner material contains sufficient amounts of antifriction elements, such as lead and tin. Lead is the most valuable antifriction element in the current materials and is present as a separate phase in the matrix of copper-tin alloy in the leaded bronze materials. Similarly, tin is present as an insoluble second phase in the matrix of aluminum-based materials. Lead is also insoluble in the aluminum matrix. The liner materials play the most critical role in the bearings. Once the liner material is damaged significantly, the bearing is considered unfit for further use. In a trimetal bearing, when the overlay is lost due to wear or fatigue, the bronze liner will continue to support the load and provide adequate lubrication in times of stress. The friction coefficient of liner materials is designed to be low. Besides, the soft phases of lead (in bronze) and tin (in aluminum) function as sites for embedment of dirt particles.

The overlay, which by definition is the top layer of the bearing surface, is the softest layer in the bearing. Its functions are to provide lubrication to the journal in initial start-up situations, adjust to any misalignment or out-of-roundness of the journal, and capture dirt particles by embedment. The overlay provides sufficient lubrication during the subsequent start-up and shut-down conditions also. The journal makes a comfortable running environment in the bearing assembly during the initial runs by “bedding in.” As a result of this, the wear rate of the overlay is higher in the beginning. As long as the overlay is present, the phenomenon of seizure will not occur. Once the wear progresses through the overlay, the bearing liner will provide adequate lubrication during start-up and shut-down conditions. However, if the oil supply is severely compromised or cut off for more than several seconds to a minute or so, seizure can take place once the overlay is gone, depending on the nature of the bearing liner and the load.

23.4 The Bearing Materials

All modern crankshaft journal bearing materials are mainly composed of five elements — namely, copper, aluminum, lead, tin, and silicon. These elements account for the leaded bronze and aluminum-tin,

FIGURE 23.3 SEM photomicrograph of a typical cross-section of the cast leaded bronze diesel locomotive engine bearing material manufactured by Glacier Clevite Heavy-wall Bearings. The nominal composition is 3% tin, 25% lead, and 72% copper. The light gray, irregular spots represent lead in a matrix of copper-tin. This material is bonded to mild steel at the bottom. (Magnification 50 \times)

FIGURE 23.4 SEM photomicrograph of a typical cross-section of aluminum-tin material roll bonded to mild steel, manufactured by Glacier Vandervell Ltd. The nominal composition is 20% tin, 1% copper, and 79% aluminum. The light gray, irregular spots represent tin in the aluminum-copper matrix. Below the aluminum-tin layer is a layer of pure aluminum which functions as a bonding layer to the mild steel underneath. (Magnification 210 \times)

aluminum-lead, and aluminum-silicon materials. Indium is used as a constituent of the overlays. Antimony is used in babbitts. Silver is a bearing material with good tribological properties, but it is too expensive to use as a bearing liner in journal bearings. However, it is used in special applications in some locomotive engines. An important characteristic of a good bearing material is its ability to conduct heat. Silver, copper, and aluminum are, indeed, good conductors of heat. Silver has no affinity for iron, cobalt, and nickel [Bhushan and Gupta, 1991]. Therefore, it is expected to run very well against steel shafts. Both copper and aluminum possess a certain degree of affinity for iron. Therefore, steel journals can bond to these metals in the absence of antifriction elements, such as lead and tin, or lubricating oil. Aluminum spontaneously forms an oxide layer, which is very inert, in the presence of air or water vapor. This suppresses the seizure or the bonding tendency of aluminum. Besides, the silicon particles present in the aluminum-silicon materials keep the journals polished to reduce friction.

The microstructure of the most widely used cast leaded bronze bearing liner is shown in [Figure 23.3](#). This has a composition of 2 to 4% tin, 23 to 27% lead, and 69 to 75% copper. Another material in widespread use, especially in automotive applications, is aluminum with 20% tin. A typical microstructure of this material is shown in [Figure 23.4](#). It can be used as the liner for both bimetal and trimetal bearings. The copper-tin-lead material shown in [Figure 23.3](#) is mainly used in trimetal bearings.

23.5 Basics of Hydrodynamic Journal Bearing Theory

Load-Carrying Ability

As mentioned previously, when running in good condition, the journal which was initially lying on the surface of the bearing is lifted and surrounded by the lubricant. It becomes suspended in the surrounding film of lubricating oil. If the engine keeps running, the journal will remain in its state of suspension indefinitely. The inertial load of the crankshaft and the forces transmitted from the cylinders to the crankshaft are supported by the lubricant films surrounding the main bearing journals. The oil film surrounding the rod bearing journal supports the gas forces developed in the cylinder and the inertial load of the piston and connecting rod assembly. Around each journal, a segment of the oil film develops a positive pressure to support the load, as shown in [Figure 23.5](#). In the following brief theoretical consideration, the process that develops this load-carrying positive pressure will be illustrated.

FIGURE 23.5 Schematic representation of the profile of the load supporting pressure in the oil film. (Source: Slaymaker, R. R. 1955. *Bearing Lubrication Analysis*, John Wiley & Sons, New York. By permission.)

As a background to the theoretical considerations, the following assumptions are made. The flow of the lubricating oil around the journal at all speeds is assumed to be laminar. The length of the bearing L is assumed to be infinite, or the flow of the lubricant from the edges of the bearing is negligible. The lubricant is assumed to be incompressible.

Consider a very small volume element of the lubricant moving in the direction of rotation of the journal — in this case, the x direction. The forces that act on this elemental volume and stabilize it are shown in [Figure 23.6](#). Here, P is the pressure in the oil film at a distance x . It is independent of the thickness of the oil film or the y dimension. S is the shear stress in the oil film at a distance y above the bearing surface, which is at $y = 0$. The length L of the bearing is in the z direction. The equilibrium condition of this volume element gives us the following relationship [Slaymaker, 1955; Fuller, 1984]:

$$\left[P + \left(\frac{dP}{dx} \right) dx \right] dy dz + S dx dz - \left[S + \left(\frac{dS}{dy} \right) dy \right] dx dz - P dy dz = 0 \quad (23.1)$$

Therefore,

$$\left(\frac{dS}{dy} \right) = \left(\frac{dP}{dx} \right) \quad (23.2)$$

Equation (23.2) represents a very important, fundamental relationship. It clearly shows how the load-carrying pressure P is developed. It is the rate of change of the shear stress in the direction of the oil film thickness that generates the hydrostatic pressure P . As we shall see from Equation (23.3), the shear stress

FIGURE 23.6 Schematic representation of the forces acting on a tiny volume element in the hydrodynamic lubricant film around a rotating journal.

is directly proportional to the shearing rate of the oil film (dv/dy) — as (dv/dy) increases, (dS/dy) must increase. Since the thickness of the oil film decreases in the direction of rotation of the journal, a progressive increase in the shearing rate of the oil film automatically occurs because the same flow rate of oil must be maintained through diminishing cross-sections (i.e., decreasing y dimension). This progressive increase in the shearing rate is capable of generating very high positive hydrostatic pressures to support very high loads. A profile of the pressure generated in the load-supporting segment of the oil film is shown in Figure 23.5. By introducing the definition of the coefficient of viscosity, we can relate the shear stress to a more measurable parameter, such as the velocity, v , of the lubricant, as

$$S = \mu(dv/dy) \tag{23.3}$$

Substituting for (dS/dy) from Equation (23.3) in Equation (23.2), we obtain a second-order partial differential equation in v . This is integrated to give the velocity profile as a function of y . This is then integrated to give Q , the total quantity of the lubricant flow per unit time. Applying certain boundary conditions, one can deduce the well-known Reynolds equation for the oil film pressure:

$$\left(\frac{dP}{dx}\right) = \frac{6\mu V}{h^3}(h - h_1) \tag{23.4}$$

where h is the oil film thickness, h_1 is the oil film thickness at the line of maximum oil film pressure, and V is the peripheral velocity of the journal. The variable x in the above equation can be substituted in terms of the angle of rotation θ and then integrated to obtain the Harrison equation for the oil film pressure. With reference to the diagram in Figure 23.7, the thickness of the oil film can be expressed as

$$h = c(1 + \epsilon \cos \theta) \tag{23.5}$$

where c is the radial clearance and ϵ is the eccentricity ratio. The penultimate form of the Harrison equation can be expressed as

$$\int_0^{2\pi} dP = \int_0^{2\pi} \frac{6\mu V r \epsilon}{c^2} \left[\frac{\cos \theta - \cos \theta_1}{(1 + \epsilon \cos \theta)^3} \right] d\theta = P - P_0 \tag{23.6}$$

where P_0 is the pressure of the lubricant at $\theta = 0$ in Figure 23.7, and θ_1 is the angle at which the oil film pressure is a maximum. Brief derivations of the Reynolds equation and the Harrison equation are given in Section 23.8.

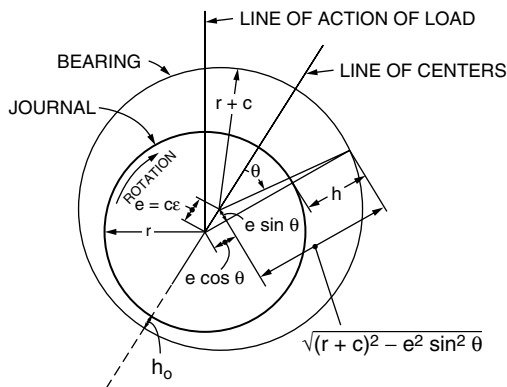

FIGURE 23.7 Illustration of the geometric relationship of a journal rotating in its bearing assembly. (Source: Slaymaker, R. R. 1955. *Bearing Lubrication Analysis*, John Wiley & Sons, New York. By permission.)

TABLE 23.1 Side Leakage Correction Factors for Journal Bearings

| L/D Ratio | Eccentricity Ratio | | | | | | |
|--------------|--------------------|-------|-------|-------|-------|-------|-------|
| | 0.80 | 0.90 | 0.92 | 0.94 | 0.96 | 0.98 | 0.99 |
| 0 | 1.0 | 1.0 | 1.0 | 1.0 | 1.0 | 1.0 | 1.0 |
| 2 | — | 0.867 | 0.88 | 0.905 | 0.937 | 0.97 | 0.99 |
| 1 | 0.605 | 0.72 | 0.745 | 0.79 | 0.843 | 0.91 | 0.958 |
| 0.5 | 0.33 | 0.50 | 0.56 | 0.635 | 0.732 | 0.84 | 0.908 |
| 0.3 | 0.17 | 0.30 | 0.355 | 0.435 | 0.551 | 0.705 | 0.81 |
| 0.1 | — | 0.105 | 0.115 | 0.155 | 0.220 | 0.36 | 0.53 |

For practical purposes, it is more convenient to carry out the integration of Equation (23.6) numerically rather than using Equation (23.14) in Section 23.8. This is done with good accuracy using special computer programs. The equations presented above assume that the end leakage of the lubricating oil is equal to zero. In all practical cases, there will be end leakage and hence, the oil film will not develop the maximum possible pressure profile. Therefore, its load-carrying capability will be diminished. The flow of the lubricant in the z direction needs to be taken into account. However, the Reynolds equation for this case has no general solution [Fuller, 1984]. Hence, a correction factor between zero and one is applied, depending on the length and diameter of the bearing (L/D ratio) and the eccentricity ratio of the bearing. Indeed, there are tabulated values available for the side leakage factors for bearings with various L/D ratios and eccentricity ratios [Fuller, 1984]. Some of these values are given in Table 23.1.

Booker [1965] has done considerable work in simplifying the journal center orbit calculations without loss of accuracy by introducing new concepts, such as dimensionless journal center velocity/force ratio (i.e., mobility) and maximum film pressure/specific load ratio (i.e., maximum film pressure ratio). This whole approach is called the *mobility method*. This has been developed into computer programs that are widely used in the industry to calculate film pressures and thicknesses. Further, this program calculates energy loss due to the viscous shearing of the lubricating oil. These calculations are vital for optimizing the bearing design and selecting the appropriate bearing liner with the required fatigue life. This is determined on the basis of the **peak oil film pressure** (POFP). In Booker's mobility method, the bearing assembly, including the housing, is assumed to be rigid. In reality, the bearings and housings are flexible to a certain degree, depending on the stiffness of these components. Corrections are now being made to these deviations by the elastohydrodynamic theory, which involves finite element modeling of the bearings and the housing. Also, the increase in viscosity as a function of pressure is taken into account in this calculation. The elastohydrodynamic calculations are presently done only in very special cases and have not become part of routine bearing analysis.

23.6 The Bearing Assembly

Housing

The housing into which a set of bearings is inserted and held in place is a precision-machined cylindrical bore with close tolerance. The surface finishes of the housing and the backs of the bearings must be compatible. Adequate contact between the backs of the bearings and the surface of the housing bore is a critical requirement to ensure good heat transfer through this interface. The finish of the housing bore is expected to be in the range of 60 to 90 $\mu\text{in.}$ (R_a) (39.4 $\mu\text{in.}$ = 1 micron). The finish on the back of the bearings is generally set at 80 $\mu\text{in.}$ maximum. Nowadays, the finishes on the housing bore and the backs of the bearings are becoming finer. The finish at the parting line face of bearings of less than 12 in. gage size is expected to be less than 63 $\mu\text{in.}$ For larger bearings, this is set at a maximum of 80 $\mu\text{in.}$ The bearing backs may be rolled, turned, or ground. All automotive and truck bearings have rolled steel finish at the back. The housing can be bored, honed, or ground, but care must be taken to avoid circumferential and axial banding.

FIGURE 23.8 Schematic illustration of the components of crush of a bearing in the thinwall bearing inspection block, before application of load (i.e., in the free state). The magnitude of the crush components is exaggerated.

The Bearing Crush

The term **crush** is not used in a literal sense in this context. A quantitative measure of the crush of a bearing is equal to the excess length of the exterior circumference of the bearing over half the interior circumference of the bearing housing. Effectively, this is equal to the sum of the two parting line heights. When the bearing assembly is properly torqued, the parting line height of each bearing in the set is reduced to zero. In that state, the back of the bearing makes good contact with the housing and applies a radial pressure in the range of 800 to 1200 psi (5.5 to 8.24 Mpa). Thereby, a good interference fit is generated. If the bearings are taken out of the assembly, they are expected to spring back to their original state. Therefore, nothing is actually crushed.

The total crush or the parting line height of a bearing has three components — namely, the housing bore tolerance crush, the checking load crush, and the engineering crush. The housing bore tolerance crush is calculated as $0.5\pi(D_2 - D_1)$, where D_1 and D_2 are the lower and upper limits of the bore diameter, respectively. Suppose a bearing is inserted in its own inspection block (the diameter of which corresponds to the upper limit of the diameter of the bearing housing). The housing bore tolerance crush does not make a contribution to the actual crush, as shown in [Figure 23.8](#) (high limit bore). If load is applied on its parting lines in increasing order and the values of these loads are plotted as a function of the cumulative decrease in parting line height, one may expect it to obey Hooke's law. Initially, however, it does not obey Hooke's law, but it does so thereafter. The initial nonlinear segment corresponds to the checking load crush. The checking load corresponds to the load required to conform the bearing properly in its housing. The final crush or the parting line height of the bearing is determined in consultation with the engine manufacturer.

Other Factors Affecting Bearing Assembly

These factors are:

1. Freespread
2. Bore distortion
3. Cap offset or twist
4. Misalignment of the crankshaft
5. Out-of-roundness of the journal
6. Deviation of the bearing clearance

The outside diameter of the bearing at the parting lines must be slightly greater than the diameter of the housing bore. This is called the freespread. It helps to snap the bearings into the housing. The required degree of freespread is determined by the wall thickness and the diameter. In the case of wall thickness,

the freespread is inversely proportional to it. For a wide range of bearings, the freespread is in the range of 0.025 to 0.075 in. Bearings with negative freespread are not used because, when bolted, the side of the parting lines could rub against the journal and lead to possible seizure while running. It is possible to change the freespread from negative to positive by reforming the bearing. Bore distortion, cap offset or twist, and misalignment of the crankshaft can lead to the journal making rubbing contacts with the bearing surface. The conformability of the bearings can take care of these problems to a certain degree by local wearing of the overlay in a trimetal bearing or by melting the soft phase in a bimetal bearing, which results in the two-phase structure crushing and conforming. In severe cases, the liner materials in both cases are damaged.

By developing high oil film pressures on the peaks of the lobes, out-of-roundness in the journal can accelerate fatigue of the bearing.

If the clearance is not adequate, the bearing will suffer from oil starvation and the temperature will rise. In extreme cases, this will lead to bearing seizure and engine damage. On the other hand, if the clearance is excessive, there will be increased noise and increased peak oil film pressure, which will bring about premature fatigue of the loaded bearing.

23.7 The Design Aspects of Journal Bearings

Even though the journal bearings are of simple semicylindrical shape and apparently of unimpressive features, there are important matters to be taken into account in their design. The bearing lengths, diameters, and wall thicknesses are generally provided by the engine builder or decided in consultation with the bearing manufacturer. A journal orbit study must be done to optimize the clearance space between the journal and the bearing surface. This study also provides the **minimum oil film thickness** (MOFT) and the POFP (Figure 23.9). Values of these parameters for the optimized clearance are impor-

FIGURE 23.9 Journal center orbit diagram of two-stroke cycle medium-speed (900 rpm) diesel engine main bearings (no. 1 position). The inner circle represents the clearance circle of the bearings. It also represents the bearing surface. The entire cross-section of the journal is reduced to a point coinciding with the center of the journal. The upper main bearing has an oil hole at the center with a circumferential groove at the center of the bearing represented by the dark line. Maximum unit load: 1484 psi. MOFT: 151 μ in. @ 70/166. POFP: 11 212 psi @ 55/171. Oil: SAE 30W. Cylinder pressure data given by the manufacturer of the engine. Clockwise rotation. The journal orbit analysis was performed at Glacier Clevis Heavywall Bearings. — * — 0–180 crank angle, — + — 180–360 crank angle, @ crank angle/bearing angle. Arrow indicates the location of MOFT.

tant factors. The MOFT is used in the calculation of the oil flow, temperature rise, and heat balance. According to Conway-Jones and Tarver [1993], about 52% of the heat generated in connecting rod bearings in automobile engines is carried away by the oil flow. Approximately 38% of the remaining heat flows into the adjacent main bearings via the crankshaft. The remaining 10% is lost by convection and radiation. In the case of main bearings, about 95% of the total heat is carried away by the oil flow, which is estimated to be more than five times the flow through the connecting rod bearings, which were fed by a single oil hole drilled in the crank pin. The POFP is the guiding factor in the selection of a bearing liner with adequate fatigue strength or fatigue life.

The bearing must be properly located in the housing bore. This is achieved by having a notch at one end of the bearing at the parting line. There must be provisions to bring in the lubricant and remove it. Therefore, appropriate grooves and holes are required. The best groove to distribute the lubricant is a circumferential groove with rounded edges, centrally placed in both bearings. If this is a square groove, the flow will be diminished by 10%. If these grooves are in the axial direction, the oil flow is decreased by 60% with respect to the circumferential ones. Having a circumferential groove in the loaded half of the bearings does increase the POFP. In the case of large slow-speed diesel engines, the POFPs are generally very low compared to the pressures in automotive, truck, and medium-speed diesel engines. Therefore, central circumferential grooves are best suited for slow-speed engines.

In the automotive, truck, and medium-speed engines, the loaded halves of the bearings do not have circumferential grooves. However, the other halves have circumferential grooves. Some of the loaded bearings have partial grooves. Otherwise, some type of oil spreader machined in the location below the parting line is desirable in the case of larger bearings. If the oil is not spread smoothly, problems of cavitation and erosion may show up. The end of the partial groove or the oil spreader must be blended.

The edges of all the bearings must be rounded or chamfered to minimize the loss of the lubricant. Edges are also chamfered to eliminate burrs. A sharp edge acts as an oil scraper and thereby enhances oil flow in the axial direction along the edges, which is harmful. Finally, bearings have a small relief just below the parting lines along the length on the inside surface. This is meant to protect the bearings in case of slight misalignment or offset at the parting lines.

23.8 Derivations of the Reynolds and Harrison Equations for Oil Film Pressure

The background for deriving these equations is given in Section 23.5 of the text. The equilibrium condition of a tiny volume element of the lubricating oil (Figure 23.6) is represented by the following equation [Slaymaker, 1955; Fuller, 1984]:

$$\left[P + \left(\frac{dP}{dx} \right) dx \right] dy dz + S dx dz - \left[S + \left(\frac{dS}{dy} \right) dy \right] dx dz - P dy dz = 0 \quad (23.7)$$

Therefore,

$$\left(\frac{dS}{dy} \right) = \left(\frac{dP}{dx} \right) \quad (23.8)$$

Now, by introducing the definition of the coefficient of viscosity μ , we can relate the shear stress to a more measurable parameter, such as the velocity v of the lubricant, as

$$S = \mu \left(\frac{dv}{dy} \right) \quad (23.9)$$

Substituting for (dS/dy) from Equation (23.9) in Equation (23.8), a second-order partial differential equation in v is obtained. This is integrated to give an expression for the velocity profile as

$$v = \frac{V}{h}y - \frac{1}{2\mu} \left(\frac{dP}{dx} \right) (hy - y^2) \quad (23.10)$$

In Equation (23.10), V is the peripheral velocity of the journal and h is the oil film thickness. The boundary conditions used to derive Equation (23.10) are (1) $v = V$ when $y = h$, and (2) $v = 0$ when $y = 0$ (at the surface of the bearing). Now applying the relationship of continuity, the oil flowing past any cross-section in the z direction of the oil film around the journal must be equal. The quantity Q of oil flow per second is given by

$$Q = L \int_0^h v \, dy \quad (23.11)$$

where L is the length of the bearing that is in the z direction. Now substituting for v from Equation (23.10) in Equation (23.11) and integrating,

$$Q = L \left[\frac{Vh}{2} - \frac{h^3}{12\mu} \left(\frac{dP}{dx} \right) \right] \quad (23.12)$$

The pressure P varies as a function of x in the oil film, which is in the direction of rotation of the journal. At some point, it is expected to reach a maximum. At that point, (dP/dx) becomes zero. Let h_1 represent the oil film thickness at that point. Therefore,

$$Q = \frac{LV}{2} h_1 \quad (23.13)$$

Now we can use Equation (23.13) to eliminate Q from Equation (23.12). Hence,

$$\left(\frac{dP}{dx} \right) = \frac{6\mu V}{h^3} (h - h_1) \quad (23.14)$$

Equation (23.14) is the Reynolds equation for the oil film pressure as a function of distance in the direction of rotation of the journal. The variable x in Equation (23.14) can be substituted in terms of the angle of rotation θ and then integrated to obtain the Harrison equation for the oil film pressure. With reference to the diagram in [Figure 23.7](#), the oil film thickness h can be expressed as

$$h = e \cos \theta + \sqrt{(r+c)^2 - e^2 \sin^2 \theta} - r \quad (23.15)$$

Here, e is the eccentricity, c is the radial clearance, and $e = c\varepsilon$, where ε is the eccentricity ratio. The quantity $e^2 \sin^2 \theta$ is much smaller compared to $(r+c)^2$. Therefore,

$$h = c(1 + \varepsilon \cos \theta) \quad (23.16)$$

Now, (dP/dx) is converted into polar coordinates by substituting $rd\theta$ for dx . Therefore, Equation (23.14) can be expressed as

$$\left(\frac{dP}{d\theta}\right) = \frac{6\mu V r \epsilon}{c^2} \left[\frac{\cos\theta - \cos\theta_1}{(1 + \epsilon \cos\theta)^3} \right] \quad (23.17)$$

where θ_1 is the angle at which the oil film pressure is a maximum. Integration of Equation (23.17) from $\theta = 0$ to $\theta = 2\pi$ can be expressed as

$$\int_0^{2\pi} dP = \int_0^{2\pi} \frac{6\mu V r \epsilon}{c^2} \left[\frac{\cos\theta - \cos\theta_1}{(1 + \epsilon \cos\theta)^3} \right] d\theta = P - P_0 \quad (23.18)$$

where P_0 is the pressure of the lubricant at the line of centers ($\theta = 0$) in Figure 23.7. If $(P - P_0)$ is assumed to be equal to zero at $\theta = 0$ and $\theta = 2\pi$, the value of $\cos\theta_1$, upon integration of Equation (23.18), is given by

$$\cos\theta_1 = -\frac{3\epsilon}{2 + \epsilon^2} \quad (23.19)$$

and the Harrison equation for the oil film pressure for a full journal bearing by

$$P - P_0 = \frac{6\mu V r \epsilon}{c^2} \frac{\sin\theta(2 + \epsilon \cos\theta)}{(2 + \epsilon^2)(1 + \epsilon \cos\theta)^2} \quad (23.20)$$

Acknowledgment

The author wishes to express his thanks to David Norris, President of Glacier Clevis Heavywall Bearings, for his support and interest in this article, and to J. M. Conway-Jones (Glacier Metal Company, Ltd., London), George Kingsbury (Consultant, Glacier Vandervell, Inc.), Charles Latreille (Glacier Vandervell, Inc.), and Maureen Hollander (Glacier Vandervell, Inc.) for reviewing this manuscript and offering helpful suggestions.

Defining Terms

Boundary layer lubrication — This is a marginally lubricating condition. In this case, the surfaces of two components (e.g., one sliding past the other) are physically separated by an oil film that has a thickness equal to or less than the sum of the heights of the asperities on the surfaces. Therefore, contact at the asperities can occur while running in this mode of lubrication. This is also described as “mixed lubrication.” In some cases, the contacting asperities will be polished out. In other cases, they can generate enough frictional heat to destroy the two components. Certain additives can be added to the lubricating oil to reduce asperity friction drastically.

Crush — This is the property of the bearing that is responsible for producing a good interference fit in the housing bore and preventing it from spinning. A quantitative measure of the crush is equal to the excess length of the exterior circumference of the bearing over half the interior circumference of the housing. This is equal to twice the parting line height, if measured in an equalized half height measurement block.

Hydrodynamic lubrication — In this mode of lubrication, the two surfaces sliding past each other (e.g., a journal rotating in its bearing assembly) are physically separated by a liquid lubricant of suitable viscosity. The asperities do not come into contact in this case and the friction is very low.

Minimum oil film thickness (MOFT) — The hydrodynamic oil film around a rotating journal develops a continuously varying thickness. The thickness of the oil film goes through a minimum. Along this line, the journal most closely approaches the bearing. The maximum wear in the bearing is expected to occur around this line. Therefore, MOFT is an important parameter in designing bearings.

Peak oil film pressure (POFP) — The profile of pressure in the load-carrying segment of the oil film increases in the direction of rotation of the journal and goes through a maximum (Figure 23.5). This maximum pressure is a critical parameter because it determines the fatigue life of the bearing. This is also called maximum oil film pressure (MOFP).

Positive freespread — This is the excess in the outside diameter of the bearing at the parting line over the inside diameter of the housing bore. As a result of this, the bearing is clipped in position in its housing upon insertion. Bearings with negative freespread will be loose and lead to faulty assembly conditions.

Seizure — This is a critical phenomenon brought about by the breakdown of lubrication. At the core of this phenomenon is the occurrence of metal-to-metal bonding, or welding, which can develop to disastrous levels, ultimately breaking the crankshaft. With the initiation of seizure, increased generation of heat will occur, which will accelerate this phenomenon. Galling and adhesive wear are terms that refer to the same basic phenomenon. The term *scuffing* is used to describe the initial stages of seizure.

Alan O. Lebeck
Mechanical Seal Technology, Inc.

The passage of fluid (leakage) between the mating parts of a machine and between other mechanical elements is prevented or minimized by a fluid seal. Commonly, a gap exists between parts formed by inherent roughness or misfit of the parts — where leakage must be prevented by a seal. One may also have of necessity gaps between parts that have relative motion, but a fluid seal is still needed. The fluid to be sealed can be any liquid or gas. Given that most machines operate with fluids and must contain fluids or exclude fluids, most mechanical devices or machines require a multiplicity of seals.

Fluid seals can be categorized as *static* or *dynamic* as follows.

Static:

- Gap to be sealed generally very small
- Accommodates imperfect surfaces, both roughness and out-of-flatness
- Subject to very small relative motions due to pressure and thermal cyclic loading
- Allows for assembly/disassembly

Dynamic:

- Gap to be sealed is much larger and exists of necessity to permit relative motion.
- Relatively large relative motions exist between surfaces to be sealed.
- Motion may be continuous (rotation) in one direction or large reciprocating or amount of motion may be limited.
- Seal must not constrain motion (usually).

Although some crossover exists between static and dynamic seal types, by categorizing based on the static and dynamic classification, the distinction between the various seal types is best understood.

24.1 Fundamentals of Sealing

Sealing can be accomplished by causing the gap between two surfaces to become small but defined by the geometric relationship between the parts themselves. In this case one has a fixed-clearance seal. One may also force two materials into contact with each other, and the materials may be either sliding relative to each other or static. In this case one has a surface-guided seal where the **sealing clearance** now becomes defined by the materials themselves and the dynamics of sliding in the case of a sliding seal.

There are two broad classes of surface-guided material pairs. The first and most common involves use of an **elastomeric**, plastic, or other soft material against a hard material. In this case, the soft material deforms to conform to the details of the shape of the harder surface and will usually seal off completely in the static case and nearly completely in the dynamic case. A rubber gasket on metal is an example. The second class, far less common, is where one mates a hard but wearable material to a hard material. Here the sealing gap derives from a self-lapping process plus the alignment of the faces of the material. Since both materials are relatively hard, if one material develops a roughness or grooves, the seal will leak. A mechanical face seal is an example.

24.2 Static Seals

Static seals can be categorized as follows:

Gaskets

- Single or composite compliant material
- Metal encased
- Wrapped and spiral wound
- Solid metal

Self-energized elastomeric rings

- Circular cross-section (O-ring)
- Rectangular cross-section

Chemical compound or liquid sealants as gaskets

- Rubbers
- Plastics

Gaskets

Within the category of static seals, gaskets comprise the greatest fraction. The sealing principle common to gaskets is that a material is clamped between the two surfaces being sealed. The clamping force is large enough to deform the gasket material and hold it in tight contact even when the pressure attempts to open the gap between the surfaces.

A simple single-material gasket clamped between two surfaces by bolts to prevent leakage is shown in [Figure 24.1](#). Using a compliant material, the gasket can seal even though the sealing surfaces are not flat. As shown in [Figure 24.2](#), the gasket need not cover the entire face being sealed. A gasket can be trapped in a groove and loaded by a projection on the opposite surface as shown in [Figure 24.3](#). Composite material gaskets or metal gaskets may be contained in grooves as in [Figure 24.4](#). Gaskets are made in a wide variety of ways. A spiral-wound metal/fiber composite, metal or plastic clad, solid metal with sealing projections, and a solid fiber or rubber material are shown in [Figure 24.5](#).

Gaskets can be made of relatively low-stiffness materials such as rubber or cork for applications at low pressures and where the surfaces are not very flat. For higher pressures and loads, one must utilize various composite materials and metal-encased materials as in [Figure 24.5](#).

FIGURE 24.1 Gasket.

FIGURE 24.2 Gasket.

FIGURE 24.3 Loaded gasket.

FIGURE 24.4 Hard ring gasket.

FIGURE 24.5 Varieties of gaskets.

For the highest pressures and loads a gasket may be retained in a groove and made either of very strong composite materials or even metal, as shown in Figure 24.4.

Self-Energized Seals

Elastomeric or **self-energized** rings can seal pressures to 20 MPa or even higher. As shown in Figure 24.6 and Figure 24.7, the two metal parts are clamped tightly together, and they are not supported by the elastomer. As the pressure increases, the rubber is pushed into the corner through which leakage would otherwise flow. An elastomer acts much like a fluid so that the effect of pressure on one side is to cause equal pressure on all sides. Thus, the elastomer pushes tightly against the metal walls and forms a seal. The limitation of this type of seal is that the rubber will flow or extrude out of the clearance when the pressure is high enough. This is often not a problem for static seals, since the gap can be made essentially zero as shown in Figure 24.6, which represents a typical way to utilize an elastomeric seal for static sealing.

Although the O-ring (circular cross-section) is by far the most common elastomeric seal, one can also utilize rectangular cross-sections (and even other cross-sections) as shown in Figure 24.7.

Chemical Compound or Liquid Sealants as Gaskets

Formed-in-place gaskets such as in Figure 24.8 are made by depositing a liquid-state compound on one of the surfaces before assembly. After curing, the gasket retains a thickness and flexibility, allowing it to seal very much like a separate gasket. Such gaskets are most commonly created using room-temperature vulcanizing rubbers (RTV), but other materials including epoxy can be used.

FIGURE 24.6 Elastomeric O-ring.

FIGURE 24.7 Elastomeric rectangular ring.

FIGURE 24.8 Formed-in-place elastomeric gasket.

While formed-in-place gaskets retain relatively high flexibility, other types of plastic materials (including epoxy and anaerobic hardening fluids) can also be used to seal two surfaces. These fluids are coated on their surfaces before assembly. Once the joint is tightened and the material hardens, it acts like a form-fitted plastic gasket, but it has the advantage that it is also bonded to the sealing surfaces. Within the limits of the ability of the materials to deform, these types of gaskets make very tight joints. But one must be aware that relative expansion of dissimilar materials so bonded can weaken the bond. Thus, such sealants are best utilized when applied to tight-fitting assemblies. These same materials are used to lock and seal threaded assemblies, including pipe fittings.

There have been many developments of chemical compounds for sealing during the past 25 years, and one is well advised to research these possibilities for sealing/assembly solutions.

24.3 Dynamic Seals

Dynamic seals can be categorized as follows:

- Rotating or oscillating shaft
 - Fixed clearance seals
 - Labyrinth
 - Clearance or bushing
 - Visco seal
 - Floating-ring seal
 - Ferrofluid seal
 - Surface-guided seals
 - Cylindrical surface
 - Circumferential seal
 - Packing
 - Lip seal
 - Elastomeric ring
 - Annular** surface (radial face)
 - Mechanical face seal
 - Lip seal
 - Elastomeric ring
- Reciprocating
 - Fixed clearance seals
 - Bushing seal
 - Floating-ring seal
 - Clearance or bushing
 - Surface-guided seals
 - Elastomeric rings
 - Solid cross section
 - U-cups, V-rings, chevron rings
 - Split piston rings
 - Limited-travel seals
 - Bellows
 - Diaphragm

One finds considerable differences between dynamic seals for rotating shaft and dynamic seals for reciprocating motion, although there is some crossover. One of the largest differences in seal types is between fixed-clearance seals and surface-guided seals. Fixed-clearance seals maintain a sealing gap by virtue of the rigidity of the parts and purposeful creation of a fixed sealing clearance. Surface-guided seals attempt to close the sealing gap by having one of the sealing surfaces actually (or nearly) touch and rub on the other, so that the position of one surface becomes guided by the other. Fixed-clearance seals

FIGURE 24.9 Labyrinth seal. (Source: Lebeck, A. O. 1991. *Principles and Design of Mechanical Face Seals*, John Wiley & Sons, New York. With permission.)

FIGURE 24.10 Bushing seal. (Source: Lebeck, A. O. 1991. *Principles and Design of Mechanical Face Seals*, John Wiley & Sons, New York. With permission.)

leak more than surface-guided seals as a rule, but each has its place. Finally, dynamic seals usually seal to either cylindrical surfaces or annular (radial) surfaces. Sealing to cylindrical surfaces permits easy axial freedom, whereas sealing to radial surfaces permits easy radial freedom. Many seals combine these two motions to give the needed freedom of movement in all directions.

Rotating or Oscillating Fixed-Clearance Seals

The labyrinth seal is shown in Figure 24.9. This seal has a calculable leakage depending on its exact shape, number of stages, and clearance and is commonly used in some compressors and turbomachinery as interstage seals and sometimes as seals to atmosphere. Its components can be made of readily wearable material so that a minimum initial clearance can be utilized.

The clearance or bushing seal in Figure 24.10 may leak more for the same clearance, but this represents the simplest type of clearance seal. Clearance bushings are often used as backup seals to limit flow in the event of failure of yet other seals in the system. As a first approximation, flow can be estimated using flow equations for fluid flow between parallel plates. Clearance-bushing leakage increases significantly if the bushing is eccentric.

In high-speed pumps and compressors, bushing seals interact with the shaft and bearing system dynamically. Bushing seals can utilize complex shapes and patterns of the shaft and seal surfaces to minimize leakage and to modify the dynamic stiffness and damping characteristics of the seal.

The visco seal or windback seal in Figure 24.11 is used to seal highly viscous substances, where it can be fairly effective. It acts like a screw conveyor, extruder, or spiral pump to make the fluid flow backward against sealed pressure. It can also be used at no differential pressure to retain oil within a shaft seal system by continuously pumping leaked oil back into the system.

The floating-ring seal in Figure 24.12 is used in gas compressors (it can be a series of floating rings). It can be used to seal oil where the oil serves as a barrier to gas leakage or it can seal product directly.

FIGURE 24.11 Visco seal. (Source: Lebeck, A. O. 1991. *Principles and Design of Mechanical Face Seals*, John Wiley & Sons, New York. With permission.)

FIGURE 24.12 Floating-ring seal. (Source: Lebeck, A. O. 1991. *Principles and Design of Mechanical Face Seals*, John Wiley & Sons, New York. With permission.)

FIGURE 24.13 Ferrofluid seal. (Source: Lebeck, A. O. **FIGURE 24.14** Circumferential seal. 1991. *Principles and Design of Mechanical Face Seals*, John Wiley & Sons, New York. With permission.)

This seal can be made with a very small clearance around the shaft because the seal can float radially to handle larger shaft motions. The floating-ring seal is a combination of a journal bearing where it fits around the shaft and a face seal where it is pressed against the radial face. Most of the leakage is between the shaft and the bore of the bushing, but some leakage also occurs at the face. This seal can be used in stages to reduce leakage. It can be balanced to reduce the load on the radial face. Leakage can be less than with a fixed-bushing seal.

The **ferrofluid** seal in Figure 24.13 has found application in computer disk drives where a true “positive seal” is necessary to exclude contaminants from the flying heads of the disk. The ferrofluid seal operates by retaining a ferrofluid (a suspension of iron particles in a special liquid) within the magnetic flux field, as shown. The fluid creates a continuous bridge between the rotating and nonrotating parts at all times and thus creates a positive seal. Each stage of a ferrofluid seal is capable of withstanding on the order of 20,000 Pa (3 psi), so although these seals can be staged they are usually limited to low-differential pressure applications.

Rotating Surface-Guided Seals — Cylindrical Surface

Figure 24.14 shows a segmented circumferential seal. The seal consists of angular segments with overlapping ends, and the segments are pulled radially inward by garter spring force and the sealed pressure. The seal segments are pushed against the shaft and thus are surface guided. They are also pushed against a radial face by pressure. This seal is similar to the floating-ring seal except that the seal face is pushed tight against the shaft because the segments allow for circumferential contraction. Circumferential segmented seals are commonly used in aircraft engines to seal oil and gas.

Many types of soft packing are used in the manner shown in Figure 24.15. The packing is composed of various types of fibers and is woven in different ways for various purposes. It is often formed into a rectangular cross-section so it can be wrapped around a shaft and pushed into a packing gland as shown. As the packing nut is tightened the packing deforms and begins to press on the shaft (or sleeve). Contact or near contact with the shaft forms the seal. If the packing is overtightened, the packing material will generate excessive heat from friction and burn. If it is too loose, leakage will be excessive. At the point where the packing is properly loaded, there is some small leakage, which acts to lubricate between the shaft and the packing material. Although other types of sealing devices have replaced soft packing in many applications, there are still many applications (e.g., pump shafts, valve stems, and hot applications) that utilize soft packing, and there has been a continuous development of new packing materials. Soft packing for continuously rotating shafts is restricted to moderate pressure and speeds. For valve stems and other reciprocating applications, soft packing can be used at high pressure and temperature.

The lip seal (oil seal) operating on a shaft surface represents one of the most common sealing arrangements. The lip seal is made of rubber (or, much less commonly, a plastic) or similar material that can be

FIGURE 24.15 Soft packing.

FIGURE 24.16 Lip seal.

readily deflected inward toward the shaft surface by a garter spring. The lip is very lightly loaded, and, in operation in oils with rotation, a small liquid film thickness develops between the rubber lip and the shaft. The shape of the cross-section determines which way the seal will operate. As shown in Figure 24.16, the seal will retain oil to the left. Lip seals can tolerate only moderate pressure (100,000 Pa maximum). The normal failure mechanism is deterioration (stiffening) of the rubber, so lip seals have a limited speed and temperature of service. Various elastomers are best suited for the variety of applications.

The elastomeric ring as described for static seals can also be used to seal continuous or oscillating rotary motion, given low-pressure and low-speed applications. As shown in Figure 24.17, the control of the pressure on the rubber depends on the squeeze of the rubber itself, so that compression set of the rubber will cause a loss of the seal. But if the squeeze is too high, the seal will develop too much friction heat. The use of a backup ring under high-pressure or high-gap conditions and the slipper seal to reduce friction are also shown in Figure 24.17.

FIGURE 24.17 Elastomeric ring seals for rotating and reciprocating motion.

Rotating Surface-Guided Seals — Annular Surface

The mechanical face seal, as shown in Figure 24.18, has become widely used to seal rotating and oscillating shafts in pumps and equipment. The mechanical face seal consists of a self-aligning primary ring, a rigidly mounted mating ring, a secondary seal such as an O-ring or bellows that gives the primary ring freedom to self-align without permitting leakage, springs to provide loading of the seal faces, and a drive mechanism to flexibly provide the driving torque. It is common for the pressure to be sealed on the outside, but in some cases the pressure is on the inside. The flexibly mounted primary ring may be either the rotating or the nonrotating member.

Face seal faces are initially lapped very flat (1 micrometer or better) so that when they come into contact only a very small leakage gap results. In fact, using suitable materials,

FIGURE 24.18 Mechanical face seal. (Source: Lebeck, A. O. 1991. *Principles and Design of Mechanical Face Seals*, John Wiley & Sons, New York. With permission.)

FIGURE 24.19 Elastomeric ring seal.

FIGURE 24.20 Cup seal.

such faces lap themselves into conformity so that such a seal can leak as little as a drop of liquid per hour. Face seals also can be used for sealing gas.

One may also utilize a lip seal or an elastomeric ring to seal rotationally on an annular face.

Reciprocating Fixed-Clearance Seals

The clearance or bushing seal (Figure 24.10) and the floating-ring seal (Figure 24.12) can also be used for reciprocating motion, such as sealing piston rods. In fact, the bushing can be made to give a near-zero clearance by deformation in such applications.

Reciprocating Surface-Guided Seals

An elastomeric ring can be used to seal the reciprocating motion of a piston, as shown in Figure 24.19. But more commonly used for such applications are cup seals (Figure 24.20), U-cups, V- or chevron rings, or any of a number of specialized shapes (Figure 24.21). Various types of these seals are used to seal piston rods, hydraulic cylinders, air cylinders, pumping rods, and pistons.

FIGURE 24.21 Elastomeric ring reciprocating seals.

FIGURE 24.22 Split ring seal (piston ring).

FIGURE 24.23 Diaphragm.

FIGURE 24.24 Welded metal bellows.

FIGURE 24.25 Rubber bellows.

Split rings such as shown in Figure 24.22 can be made of rigid materials. They are split for installation and so that they are loaded tightly against the wall by fluid pressure. Metal piston rings can be used in very hot environments. Plastic piston rings are suited to lower-temperature compressors.

Reciprocating Limited-Travel Seals

Most commonly used in pressure regulator and other limited-travel devices is the diaphragm shown in Figure 24.23. Properly designed, this seal can be absolute and have significant travel. It can also allow for angular misalignment. In Figure 24.24 is shown a metal bellows and in Figure 24.25 is a rubber bellows. Both of these permit limited axial and angular motion. They have the advantage of being absolute seals because they do not rely on a sealing interface or suffer from wear and have no significant friction. Metal bellows may be made from edge-welded disks as shown or formed from a thin metal tube.

24.4 Gasket Practice

For a gasket to seal, certain conditions must be met. There must be enough bolt or clamping force initially to seat the gasket. Then there also must be enough force to keep the gasket tightly clamped as the joint is loaded by pressure.

One may take the ASME Pressure Vessel Code [1980] formulas and simplify the gasket design procedure to illustrate the basic ideas. The clamping force, to be applied by bolts or other suitable means, must be greater than the larger of the following:

$$W_1 = \frac{\pi}{4} D^2 P + \pi 2b D m P \quad (24.1)$$

$$W_2 = \pi D b y \quad (24.2)$$

TABLE 24.1 Gasket Factors

| Type | m | y (Mpa) |
|-----------------------------------|-----|-----------|
| Soft elastometer | 0.5 | 0 |
| Elastometer with fabric insertion | 2.5 | 20 |
| Metal jacketed and filled | 3.5 | 55 |
| Solid flat soft copper | 4.8 | 90 |

where D = effective diameter of gasket (m), b = effective seating width of gasket (m), $2b$ = effective width of gasket for pressure (m), P = maximum pressure (Pa), m = gasket factor, and y = seating load (Pa). Equation (24.1) is a statement that the clamping load must be greater than the load created by pressure plus a factor m times the same pressure applied to the area of the gasket in order to keep the gasket tight. Equation (24.2) is a statement that the initial clamping load must be greater than some load associated with a seating stress on the gasket material. To get some idea of the importance of the terms, a few m and y factors are given in Table 24.1. One should recognize that the procedure presented here is greatly simplified, and the user should consult one of the comprehensive references cited for details.

24.5 O-Ring Practice

To seal properly, an O-ring must have the proper amount of squeeze or **preload**, have enough room to thermally expand, not have to bridge too large a gap, have a rubber hardness suitable to the job, and be made of a suitable rubber. Table 24.2 shows an abbreviated version of recommendations for static O-rings and Table 24.3 for reciprocating O-rings. In many cases, one will want to span gaps larger or smaller than those recommended in the tables, so Figure 24.26 shows permissible gap as a function of pressure and hardness based on tests.

24.6 Mechanical Face Seal Practice

Figure 24.27 shows how, in general, the area on which the pressure is acting to load the primary ring may be smaller (or larger) than the area of the face. Thus, the balance ratio for a mechanical seal is defined as

$$B = \frac{r_o^2 - r_b^2}{r_o^2 - r_i^2} \quad (24.3)$$

where balance ratios less than 1.0 are considered to be “balanced” seals where in fact the face load pressure is made less than the sealed pressure. If the balance ratio is greater than 1.0, the seal is “unbalanced.”

The balance radius (r_b) of a seal is used by seal designers to change the balance ratio and thus to change the load on the seal face. With reference to Figure 24.27, and noting that the face area is

$$A_f = \pi(r_o^2 - r_i^2) \quad (24.4)$$

the average **contact pressure** (load pressure not supported by fluid pressure) on the face is given by

$$p_c = (B - K)p + \frac{F_s}{A_f} \quad (24.5)$$

where the K factor represents the average value of the distribution of the fluid pressure across the face. For well-worn seals in liquid, $K = 1/2$ and, for a compressible fluid, K approaches $2/3$.

*REDUCE THE CLEARANCE SHOWN BY 50% WHEN USING SILICONE OR FLUOROSILICONE ELASTOMERS.

BASIS FOR CURVES

1. 100,000 pressure cycles at the rate of 60 per minute from zero to the indicated pressure.
2. Maximum temperature (i. e. test temperature) 160°F.
3. No back-up rings.
4. Total diametral clearance must include cylinder expansion due to pressure.
5. Apply a reasonable safety factor in practical applications to allow for excessively sharp edges and other imperfections and for higher temperatures.

FIGURE 24.26 Limits for extrusion. (Source: Parker Hannifin Corporation. 1990. *Parker O-Ring Handbook*, Parker Hannifin Corporation. Cleveland, OH. With permission.)

FIGURE 24.27 Mechanical seal elementary theory.

The sliding speed of the seal is based on the average face radius, or

$$V = \frac{r_o + r_i}{2} \omega \tag{24.6}$$

The severity of service for the seal is taken as the pressure times the sliding speed, or

$$(PV)_{total} = pV \tag{24.7}$$

TABLE 24.4 Limiting Values for Liquids

| Materials | $(PV)_{\text{net}}$ (psi · ft/min) | $(PV)_{\text{net}}$ (Pa·m/sec) |
|----------------------------------|------------------------------------|--------------------------------|
| Carbon graphite/alumina | 100,000 | $3.5 \cdot 10^6$ |
| Carbon graphite/tungsten carbide | 500,000 | $17.5 \cdot 10^6$ |
| Carbon graphite/silicon carbide | >500,000 | > $17.5 \cdot 10^6$ |

The severity of operating conditions for the seal materials is the contact pressure times the sliding speed, or

$$(PV)_{\text{net}} = p_c V \quad (24.8)$$

The maximum allowable net PV is materials- and environment-dependent. For liquids, the limiting values of Table 24.4 are generally used.

Friction or seal power can be estimated from

$$P = p_c A_f f_c V \quad (24.9)$$

where P is the power and f_c is the friction coefficient, with values ranging from 0.07 for carbon graphite on silicon carbide to 0.1 for carbon graphite on tungsten carbide.

Defining Terms

Annulus — The radial face of a rectangular cross-section ring.

Contact pressure — At a seal interface, part of the force needed for equilibrium is supplied by fluid pressure and part by contact pressure.

Elastomer(ic) — A material having the property of recovery of shape after deformation; rubberlike materials.

Ferrofluid — A liquid containing a suspension of magnetic particles.

Preload — The clamping load before pressure is applied.

Sealing clearance — The effective gap between two surfaces.

Self-energized — The preload is supplied by the elastic behavior of the material itself.

Loads

Peter Gergely
Cornell University

- 25.1 Dead Loads
- 25.2 Live Loads
 - Occupancy Loads • Bridge Live Loads
- 25.3 Impact Loads
- 25.4 Snow Loads

Structures are designed to carry various loads and load combinations without collapse and with an adequate margin of safety. In addition, several **serviceability** conditions (deflections, cracking) must also be satisfied for most structures. The expected maximum values of most loads can be estimated only approximately, and building codes give only estimates of the minimum design loads, based on judgment. The design loads and load combinations rarely occur for most structures.

The two main types of loads are **dead loads** and **live loads**. Dead loads include the weight of structural and most nonstructural components: beams, columns, walls, floor slabs, bridge decks, roofing, partitions, and ceiling and flooring materials. Live loads include occupancy loads (people, building contents, traffic, movable partitions) and snow. Wind forces, earthquake forces, water pressure, and blast are similar to live loads, but they are usually considered separately. The weights of movable materials in warehouses are usually considered as live loads. In addition to these loads, temperature effects can also be considered as loads.

Most designers and building codes rely on the *Minimum Design Loads for Buildings and Other Structures* [ASCE 7-93, 1993] or the *Standard Specifications for Highway Bridges* [AASHTO, 1989] for the design of buildings and bridges, respectively. Loads for special structures, such as liquid containers, towers, cranes, and power plants, are normally specified by trade or professional organizations.

Loads are combined to produce the maximum member forces. However, codes allow reduction of combined loads if the probability of simultaneous occurrence of maximum effects is low. For example, a 0.75 factor may be applied for the combined dead load, live load, and wind or earthquake. These factors are different in the working stress design approach and in the strength (or the load and resistance factor) design approach.

25.1 Dead Loads

Dead loads are made up almost entirely of the weights of all structural elements and permanent fixtures. Therefore, it is generally easy to calculate dead loads. However, in preliminary design the sizes of structural members (beams, columns, walls, and floor slabs) are not yet known and must be estimated. The unit weights of several common materials are listed in [Table 25.1](#).

The maximum forces in structures sometimes occur during construction — for example, during the cantilever construction of bridges. It is important to consider the loads during various stages of construction.

TABLE 25.1 Unit Weight of Common Construction Materials

| | |
|----------------------------------|------------------------------|
| Aluminum | 165 lb/ft ³ |
| Brick | 120 lb/ft ³ |
| Lightweight concrete | 90 to 110 lb/ft ³ |
| Normal-weight concrete | 150 lb/ft ³ |
| Steel | 490 lb/ft ³ |
| Timber | 35 to 40 lb/ft ³ |
| Roofing | 5 to 10 lb/ft ² |
| Tile | 10 to 15 lb/ft ² |
| 6-in. hollow concrete block wall | 43 lb/ft ² |

25.2 Live Loads

There are many types of live loads: occupancy, weights in warehouses, traffic loads on bridges, construction or maintenance forces, automobiles in parking garages, and snow. These are much more variable than dead loads and require larger safety margins. (Wind and earthquake loads are considered separately as environmental loads.) These live loads are gravity loads and must be positioned (acting on all or part of the area) to cause maximum forces in the member being designed.

Occupancy Loads

The major type of live load in buildings is caused by occupants. The minimum specified occupancy loads depend on the use and the likelihood of congregation of many people. Typical values of distributed loads are shown in [Table 25.2](#). In office buildings, a 20 lb/ft² uniform load is used to account for the weight of movable partitions.

In addition to the distributed loads, structures are also designed for concentrated loads to account for concentrations of people or furniture. Typical values are 2000 lb on office floors and on slabs in garages for passenger cars. These are assumed to be acting on a 2.5 ft² area.

Since it is unlikely that a very large area or most floors of a building will have the full occupancy loads, most codes allow a live load reduction factor for such cases. However, reduction is not allowed for garages and areas of public assembly. In the design of a structural member, if the influence area is more than 400 ft², the reduction factor is

$$0.25 + \frac{15}{\sqrt{A}} \quad (25.1)$$

with a minimum value of 0.5 for one floor and 0.4 for columns receiving loads from multiple floors. For columns the influence area is four times the tributary area (thus equal to the area of all four adjoining panels), and for beams it is twice the tributary area.

TABLE 25.2 Typical Occupancy Loads (lb/ft²)

| | |
|-----------------------------|-----|
| Theaters with fixed seats | 60 |
| Theaters with movable seats | 100 |
| Corridors and lobbies | 100 |
| Garages | 50 |
| Restaurants | 100 |
| Library reading rooms | 60 |
| Offices | 50 |
| Stadium bleachers | 100 |
| Stairways | 100 |

Bridge Live Loads

The design forces in a bridge depend on the magnitude and distribution of the vehicle load. It is not reasonable to assume that only heavy trucks will travel at close spacing, especially on a long bridge. For short bridges the actual position of the heaviest truck is important, whereas for long bridges a uniform load could be used in design. Design codes [AASHTO, 1989] specify standard loads for short and long bridges. Several standard trucks are specified — for example, the H20-44, which has a total weight of 20 tons (the 44 signifies the year of adoption). Of this weight, 8000 lb acts under the front axle and 32,000 lb under the rear wheels. Other standard truck loads are H10-44, H15-44, HS15-44, and HS20-44, where the HS designation is for semitrailers, with the weight allocation of 10, 40, and 40% for the cab, front trailer, and rear trailer wheels, respectively.

These concentrated loads must be placed on the bridge to produce maximum forces (shears and moments) in the member being designed. In addition to the individual truck loads, codes specify a uniform lane load combined with a single concentrated load. For an H10-44 loading, the distributed load is 320 lb/ft and the concentrated load is 9000 lb; the respective numbers for HS20-44 are twice as large.

25.3 Impact Loads

Moving loads on bridges and crane girders can cause vibrations and increased stresses. Simple empirical impact formulas have been developed to account for this effect, although a large number of variables, such as surface roughness, speed, and span, influence the impact effect.

In the AASHTO [1989] code the impact formula is

$$I = \frac{50}{L + 125} \quad (25.2)$$

where L is in feet. The maximum value of the impact factor I is 0.3. For shorter bridges the impact effect can be high, especially when a heavy vehicle travels on the bridge at high speed.

The loads created by elevators are often increased by 100% to account for impact. Likewise, impact factors have been recommended for various other types of machinery, ranging from 20 to 50%. Craneways have three factors — 25, 20, and 10% for forces in the vertical, lateral, and longitudinal directions, respectively.

25.4 Snow Loads

The expected maximum snow accumulation in various regions is given in codes, usually for a 50-year mean recurrence interval. Values reach 50 psf in many areas but can be twice as much or more in regions with heavy snowfalls. In some regions — for example, in parts of the Rocky Mountains — local climate and topography dictate the design snow load level. The weight of snow depends on its density and typically ranges from 0.5 to 0.7 psf for 1 in. of snow after some compaction. Fresh dry snow has a specific gravity of only 0.2.

For flat roofs (outside Alaska) the snow load is

$$p_f = 0.7C_e C_t I p_g \quad (25.3)$$

C_e is the exposure factor (0.8 for windy, open areas, 0.9 for windy areas with some shelter, 1.0 if wind does not remove snow, 1.1 with little wind, and 1.2 in a forested area). However, for large roofs (greater than 400 ft in one direction), C_e should not be less than unity [Lew et al. 1987]. C_t is the thermal factor (1.0 for heated structures, 1.1 just above freezing, 1.2 for unheated structures). I is the importance factor (ranges from 0.8 to 1.2 for various occupancies). p_g is the ground snow load from maps.

The flat-roof values are corrected for sloping roofs:

$$p_s = C_s p_f \quad (25.4)$$

where C_s is the slope factor, which is given in a diagram in ASCE 7-93 [1993]. For warm roofs ($C_t = 1.0$), the slope factor is 1.0 for slopes less than about 30° and reduces linearly to zero as the slope increases to 70° . Thus roofs with slopes greater than 70° are assumed to have no snow load. Unbalanced snow load caused by a certain wind direction also must be considered.

Defining Terms

Dead load — Gravity loads produced by the weight of structural elements, permanent parts of structures such as partitions, and weight of permanent equipment.

Impact factor — Accounts for the increase in stresses caused by moving load effects.

Live load — Loads caused by occupancy and movable objects, including temporary loads.

Serviceability — Limit on behavior in service, such as on deflections, vibrations, and cracking.

 - Power Law Profile • Logarithmic Profile
- 26.4 Turbulence
- 26.5 Pressure Coefficients and Load Factors

Wind is one of the two primary sources of lateral forces on land-based buildings and structures; the other is earthquake ground motion. Winds completely engulf the structure and generate complex distributions of pressures and, hence, loads on all exterior surfaces. Most surfaces experience negative pressures or suctions, which tend to pull the building apart. Most roofs also experience negative pressures, which act to lift the roof off of the walls and to pull roofing membranes and sheathing from the supporting structure. If the exterior surface contains openings, either because they were designed that way or because a **cladding** element fails, the interior of the structure can become exposed to some fraction of the external pressure that would have occurred at the opening. Internal pressures can also develop as a result of normal air leakage through the building skin or cladding. Internal pressures tend to be fairly uniform throughout the interior of the building and can significantly increase the loads on the walls and roof.

Wind effects on structures include the direct application of wind-induced forces, movement of the structure, and the flow of the wind around the structure, which may affect pedestrians or the function of the building. Normally, wind effects are grouped according to limit states and safety and serviceability considerations. The selection of structural systems based on their ability to resist wind-induced stresses with appropriate margins of safety is an example of a design for safety or an ultimate limit state. Limiting deflections caused by the wind loads to prevent cracking of walls or partitions and limiting the motion of the structure to prevent occupant discomfort are examples of serviceability limit state design. Following the large economic losses suffered in recent hurricanes, there have been increasing calls for protection of the building envelope against water penetration by protecting glazed openings from failure due to direct wind loads or impact loads from wind-borne debris and by reducing the penetration of wind-driven rain.

The wind effects that should be considered in the design of a particular structure vary depending on the following factors:

1. The wind climate (the expected magnitude and frequency of wind events and consideration of the types of events — that is, hurricanes, thunderstorms, tornadoes, and extra-tropical storms).
 2. The local wind exposure (siting of the building or structure, including the type of terrain and terrain features surrounding the structure and the influence of neighboring structures).
 3. Pressure coefficients and load factors (coefficients that depend on the exterior shape of the building or structure and factors which relate wind loads to reference wind speeds).
-

4. Dynamic effects such as resonance response and aerodynamic instabilities, which can lead to failures or to significant increases in the dynamic response and loading (these dynamic effects are not covered by normal pressure coefficients and load factors; they depend on the shape of the building or structure and properties such as mass, stiffness, damping, and modes of vibration). Typically, tall, slender structures and long, suspended structures should be evaluated for these possible effects. These include long-span bridges, stacks, towers, buildings with height-to-width ratios greater than five, and exposed long, flexible members of structures.

Within the space available, it is possible to present only a brief description of the types of wind effects that should be considered in the design of buildings and structures. Consequently, rather than reproduce a set of codelike requirements, the focus of this chapter is on describing some basic relationships that will help the engineer compare different code approaches to estimating wind loads. There are many different codes available throughout the world that use significantly different types of reference wind speeds. Often, it is not clear whether the codes will produce similar estimates of design loads if applied to the same structure (indeed, they often do produce significantly different loads). It is not the intent of this chapter to promote a particular code. The goal is to provide the tools that will allow the engineer to compare code estimates of design loads by using a consistent set of reference wind speeds, regardless of whether the code calls for a mean hourly speed, a ten-minute speed, a one-minute sustained wind speed, a fastest mile wind speed, or a gust wind speed.

In addition, the field of wind engineering remains highly empirical, which means that accurate estimates of wind loads and wind effects often require the conduct of a physical model study. The “For Further Information” section provides a list of references that can provide additional guidance on when a model study is warranted or desirable.

26.1 Wind Climate

The wind climate encompasses the range of wind events that may occur in a geographical region and the expected frequency and intensity of the event. Types of events include **extra-tropical cyclones**, thunderstorms, downbursts, microbursts, tornadoes, and hurricanes. Each type of storm has potentially different wind characteristics of importance to buildings and structures, as well as separate occurrence rate and intensity relationships. For most engineering purposes, downbursts, microbursts, and tornadoes are not considered in the establishment of design winds and loads. Thunderstorm winds are frequently buried in the historical data records and, thus, are partially built into the design winds estimated from historical data. Recent work has been conducted to extract thunderstorm winds from the historical data at selected stations. This analysis suggests that it will be important in the future to treat thunderstorms as a separate population of wind events in much the same way that current analysis considers hurricane and tornado events as separate populations for statistical analysis.

The current approach to estimating design winds in hurricane-prone regions is to conduct Monte Carlo simulations of the events using statistical information on historical tendencies of hurricanes in the area. The probabilities of experiencing hurricane winds in coastal areas are then developed from the statistics produced from the simulation of thousands of years of storms. These occurrence probabilities are then combined with probabilities for nonhurricane events to estimate design winds for various return periods ranging from 10 to 100 years. This type of analysis has been used to produce design wind speed maps for the continental U.S.; the latest edition of ASCE-7 *Minimum Design Loads for Buildings and Structures* contains the most recent map, which is generally adopted by model building codes in the U.S. This type of systematic analysis of hurricane and nonhurricane winds has not been conducted for the Hawaiian Islands or most of the rest of the world. Consequently, in hurricane-prone regions, the designer should endeavor to determine the source of the estimates for design wind speeds and the basis for the estimates. In some instances, it will be necessary to contract with a group experienced in hurricane simulations in order to produce reasonable estimates of design wind speeds.

In areas where hurricanes are not expected — which normally includes areas 100 miles inland from a hurricane coastline — a series of annual extreme wind speeds can be used to estimate the design wind speed for a specific return period using the following equation [Simiu, 1985], where it is assumed that the extreme wind climate follows a Type I extreme value distribution:

$$U_N = U_{\text{avg}} + 0.78\sigma_N(\ln N - 0.577) \quad (26.1)$$

where U_N is the design wind speed for a return period of N years, U_{avg} is the average of the annual extreme wind speeds, and σ_N is the standard deviation of the annual extreme wind speeds. It should be noted that the number of years of record greatly affects the reliability of the design wind speed estimate [Simiu, 1985].

Note also that an averaging time has not been specified in this discussion. The emphasis is placed on the wind speeds being extreme annual values that must all correspond to the same averaging time, regardless of whether it is a mean hourly, 10-min mean, or shorter-duration averaging time. These maximum speeds must also correspond to a consistent set of terrain conditions and a consistent elevation. The U.S. codes currently use a fastest mile wind speed at a height of 10 m in open terrain as the reference design wind speed and reference conditions. This type of measurement has a variable averaging time since it corresponds to the time required for one mile of wind to pass a location. Thus, any calculation of a fastest mile wind speed requires iteration. The averaging time for the fastest mile wind speed is calculated by:

$$t = 3600/U_{\text{FM}} \quad (26.2)$$

where t is given in seconds and U_{FM} is the fastest mile wind speed expressed in miles per hour.

Other countries use similar terrain conditions and usually specify a 10 m elevation but use a wide variety of averaging times ranging from mean hourly (Canada) to peak gust (Australia), which is normally assumed to correspond to a 2- to 3-sec averaging time. The following section provides relationships for converting maximum wind speeds from one averaging time, terrain exposure, and elevation to maximum wind speeds for a different averaging time, terrain, and elevation. These equations provide a means for converting a design wind speed in an unfamiliar code to one that can be used in a code with which the designer is more familiar, if the reference conditions for the two codes are different.

26.2 Local Wind Exposure

As wind moves over the surface of the earth, the roughness of trees, buildings, and other features reduces the wind speed and creates the **atmospheric boundary layer**. The greatest reduction occurs close to the ground, with reduced effects at greater heights. There is, in fact, a height — known as the *gradient height* — at which the wind is not affected by the surface characteristics. For engineering purposes, the gradient height is generally assumed to be between 300 and 600 m, depending on the terrain. Surface roughness also affects the air flow by creating turbulent eddies (or gusts), which can have a significant effect on buildings. The gusty nature of wind is random and is analyzed using statistical approaches.

26.3 Mean Wind Speed Profile

No single analytical expression perfectly describes the mean wind speed variation with height in the atmospheric boundary layer. The two used most often are the power law profile and the logarithmic profile. The logarithmic profile is the most widely accepted, although both can give adequate descriptions of the wind speed. Each is described below, and sufficient information is given to (a) allow transfer from one profile to the other, (b) effectively convert maximum speeds in one terrain to those in another, and (c) convert from one averaging time to another.

TABLE 26.1 Parameters Used in Mean Velocity Profile Relations

| Terrain | α | z_g (m) | z_0 (m) | p | β |
|---------------|----------|-----------|-----------|------|---------|
| Coastal | 0.1 | 230 | 0.005 | 0.83 | 6.5 |
| Open | 0.14 | 275 | 0.07 | 1 | 6 |
| Suburbs | 0.22 | 375 | 0.3 | 1.15 | 5.25 |
| Dense suburbs | 0.26 | 400 | 1 | 1.33 | 4.85 |
| City center | 0.33 | 500 | 2.5 | 1.46 | 4 |

Power Law Profile

Taking z as the elevation, U as the wind speed (with the bar indicating a mean hourly value), and g as conditions at the gradient height, this profile is written as

$$\frac{\overline{U(z)}}{U_g} = \left(\frac{z}{z_g} \right)^a \quad (26.3)$$

Table 26.1 provides estimates for the gradient height and power law exponent for different terrains.

Logarithmic Profile

This expression for the variation of mean wind speed with height utilizes an aerodynamic roughness length, z_0 , and a shear velocity, u_* , which is a measure of the surface drag:

$$\overline{U(z)} = \frac{u_*}{k} \ln \left(\frac{z}{z_0} \right) \quad (26.4)$$

Here, k is von Karman's constant and is usually taken as 0.4. For rough surfaces, such as dense suburban and urban conditions, a displacement height, d , should be included in Equation (26.4) by replacing z with $z - d$. For z values substantially greater than d , the correction is negligible. Writing the log law at two heights for two different terrain roughnesses (one of which is open country) and taking the ratio gives

$$\frac{\overline{U(z_1)}}{\overline{U(z_2)_{\text{open}}}} = p \frac{\ln(z_1/z_0)}{\ln(z_2/z_0)_{\text{open}}} \quad (26.5)$$

where p is the ratio of the shear velocities for the two different terrain conditions. Table 26.1 gives a summary of the parameters needed to use the profiles.

26.4 Turbulence

The wind speed can be divided into two parts — a mean or time-averaged part, \overline{U} , and a fluctuating or time varying part, u' . The long-term properties of the fluctuating part can be described by the variance or standard deviation, σ_u . The maximum wind speed for any averaging time, t , can be obtained by adjusting the hourly (3600 sec) average as

$$U_t(z) = \overline{U}_{3600}(z) + C(t)\sigma_u(z) \quad (26.6)$$

where the coefficient $C(t)$ is given in Table 26.2. The values of $C(t)$ for extra-tropical winds were obtained by Simiu [1981], while the values of $C(t)$ for hurricane winds reflect recent research that suggests that hurricane winds contain larger fluctuations than extra-tropical strong winds [Kramer, 1992].

TABLE 26.2 Gust Factors for Use in Calculating Maximum Wind Speeds from Mean Speeds

| Conditions | Time (sec) | Time | | | | | | |
|----------------------|---------------|------|------|------|------|------|------|------|
| | | 1 | 3 | 10 | 30 | 60 | 600 | 3600 |
| Hurricane winds | $C(t)$ | 4 | 3.62 | 3.06 | 2.23 | 1.75 | 0.43 | 0 |
| Extra-tropical winds | $C(t)$ | 3 | 2.86 | 2.32 | 1.73 | 1.28 | 0.36 | 0 |

TABLE 26.3 Example Conversions of Maximum Speeds for Different Conditions

| Example | A | B | C | D | E | | F | G |
|-----------------------------|-------|--------|------|-----------------|-----------------|--------------|--------|------|
| | | | | | Iteration #1 | Iteration #2 | | |
| Terrain 2 | Open | Open | Open | Open | Open | | Open | Open |
| z (m) | 10 | 10 | 10 | 10 | 10 | | 10 | 10 |
| u (mph) ^a | | | | | 90 | | | 90 |
| t (sec) | 60 | 3600 | 60 | 3600 | 40 ^b | | 3 | 40 |
| $C(t)$ | 1.28 | 0 | 1.28 | 0 | 1.58 | | 2.86 | 1.58 |
| Terrain 1 | Coast | Suburb | Open | Open | Suburb | | Suburb | Open |
| z (m) | 10 | 10 | 100 | 10 | 10 | | 10 | 10 |
| u (mph) ^a | | | | 90 | 90 ^c | 79 | 90 | |
| t (sec) | 3 | 3600 | 60 | 40 ^b | 40 ^b | 46 | 40 | 3 |
| z_0 (m) | 0.005 | 0.3 | 0.07 | 0.07 | 0.3 | | 0.3 | 0.07 |
| $C(t)$ | 2.86 | 0 | 1.58 | 1.58 | 1.58 | 1.49 | 1.58 | 2.86 |
| • | 6.5 | 5.25 | 6 | 6 | 5.25 | | 5.25 | 6 |
| p | 0.82 | 1.15 | 1 | 1 | 1.15 | | 1.15 | 1 |
| $U_{t_1}(z_1)/U_{t_2}(z_2)$ | 1.39 | 0.81 | 1.42 | 1.31 | 0.88 | 0.86 | 0.56 | 1.19 |

^a Wind speed in fastest mile.

^b Averging time calculated from $3600/U_{FM}$.

^c Initial guess of fastest mile speed for the first iteration selected as open country value. In the second iteration, the 79 mph value was calculated from 90 mph multiplied by the velocity ratio of 0.88.

To convert maximum wind speeds between open terrain conditions for any averaging time and elevation and another set of conditions (i.e., variations in terrain, averaging time, or elevation), the following combination of the above expressions can be used:

$$\frac{U_{t_1}(z_1)}{U_{t_2}(z_2)_{\text{open}}} = P \left[\frac{\ln(z_1/z_0) + 0.4\sqrt{\beta}C(t_1)}{\ln(z_2/z_0)_{\text{open}} + 0.98C(t_2)_{\text{open}}} \right] \quad (26.7)$$

The examples in Table 26.3 serve to illustrate the use of this expression. The first line indicates the example case, the second through fifth rows describe the open terrain wind characteristics, the sixth through thirteenth rows describe the second terrain wind characteristics, and the last row gives the ratio of maximum speeds for the stated conditions and averaging times.

26.5 Pressure Coefficients and Load Factors

Pressure coefficients and load factors, such as terrain exposure factors and gust factors, are available in building codes. These factors must be consistent with the type of reference wind used in the code. Local cladding pressures in modern codes are significantly higher than those found in earlier codes because of the improved understanding of fluctuating loads on structures. Except in areas of positive mean pressures (the windward wall), there is no direct correlation between the local pressure and the occurrence of gusts in the approaching wind.

Defining Terms

Atmospheric boundary layer — The lower part of the atmosphere where the wind flow is affected by the earth's surface.

Cladding — Parts of the exterior building surface that keep out the weather but are generally not considered part of the structural system, although they do transfer loads to the structural system.

Extra-tropical cyclones — Large-scale low-pressure systems that control most of the severe weather conditions and extreme winds in temperate regions.

This chapter provides an overview of earthquakes and their effects, by first discussing the causes of earthquakes, then explaining how earthquakes are measured and how seismicity can be characterized, then discussing the effects of soils on earthquake ground motions, and concluding with an explanation of the effects of earthquakes on structures and how design codes address the earthquake issue.

27.1 Earthquakes: Causes and Faulting

Earthquakes are naturally occurring broad-banded vibratory ground motions, due to a number of causes including tectonic ground motions, volcanism, landslides, rockbursts, and manmade explosions. Of these various causes, tectonic-related earthquakes are the largest and most important. Earthquakes initiate a number of phenomena or agents, termed **seismic hazards**, that can cause significant damage to the built environment — these include fault rupture, vibratory ground motion (i.e., shaking), inundation (e.g., tsunami, seiche, dam failure), various kinds of permanent ground failure (e.g., liquefaction), fire, or hazardous materials release. It is the goal of the earthquake specialist to reduce seismic risk. For most earthquakes, shaking is the dominant and most widespread agent of damage. Typically, earthquake ground motions are powerful enough to cause damage only in the near field (i.e., within a few tens of kilometers from the causative fault); in a few instances, however, long period motions have caused significant damage at great distances to selected lightly damped structures. A prime example of this was the 1985 Mexico City earthquake, where numerous collapses of mid- and high-rise buildings were due to a magnitude 8.1 earthquake occurring at a distance of approximately 400 kilometers from Mexico City. Earthquakes killed an average of 17,000 persons per year during the twentieth century, so the study of earthquakes and the physics of the earth, as well as the design of structures to resist earthquake effects, are of vital importance for the scientific and engineering professions.

FIGURE 27.1 Global tectonic plate boundaries (Courtesy United States Geological Survey).

Causes of Earthquakes and Faulting

In a global sense, tectonic earthquakes result from motion between a number of large plates comprising the earth's crust or lithosphere (about 15 in total). See Figure 27.1.

This sudden slip releases large amounts of energy, which constitute the earthquake. While the accumulation of strain energy within the plate can cause motion (and consequent release of energy) at faults at any location, earthquakes occur with greatest frequency at the boundaries of the tectonic plates. The boundary of the Pacific plate is the source of nearly half of the world's great earthquakes. Tectonic plates move very slowly and irregularly, with occasional earthquakes. Generally, the longer a fault, the larger the earthquake it can generate. Faults are typically classified according to their sense of motion. See Figure 27.2.

FIGURE 27.2 Earthquake fault types.

Generally, earthquakes will be concentrated in the vicinity of faults, faults that are moving more rapidly than others will tend to have higher rates of seismicity, and larger faults are more likely than others to produce a large event. Recent major earthquakes of this type have included the 1994 M_w 6.7 Northridge (California), 1995 M_w 6.9 Kobe (Japan), 1999 M_w 7.6 Kocaeli (Turkey), 1999 M_w 7.7 Ji-Ji (Taiwan), 2001 M_w 7.7 Bhuj (India), and 2003 M_w 6.6 Bam (Iran) events.

Probabilistic methods can be usefully employed to quantify the likelihood of an earthquake's occurrence, and typically form the basis for determining the **design basis earthquake**. However, the earthquake-generating process is not understood well enough to reliably predict the times, sizes, and locations of earthquakes with precision. In general, therefore, communities must be prepared for an earthquake to occur at any time.

27.2 Measurement of Earthquakes and Seismic Hazard Analysis

Measurement of Earthquakes

Engineering design requires measurement of earthquake phenomena in units such as force or displacement. An individual earthquake is a unique release of strain energy; quantification of this energy has formed the basis for measuring the earthquake event. C.F. Richter [1935] was the first to define earthquake **magnitude**, and subsequently a number of other magnitudes have been defined, the most important of which are surface wave magnitude M_s , body wave magnitude m_b , and **moment magnitude** M_w . **Seismic moment** is employed to define moment magnitude M_w [Hanks and Kanamori, 1979; also denoted as boldface **M**]:

$$\log M_0 = 1.5 M_w + 16.0 \quad (27.1)$$

where seismic moment M_0 (dyne-cm) is defined as [Lomnitz, 1974]:

$$\log M_0 = \mu Au \quad (27.2)$$

where μ is the material shear modulus, A is the area of fault plane rupture, and u is the mean relative displacement between the two sides of the fault (the averaged fault slip).

In general, seismic **intensity** is a metric of the effect, or the strength, of an earthquake hazard at a specific location. In the U.S., the Modified Mercalli Intensity scale (Table 27.1) is commonly employed, while other scales (MSK, EMS, JMA, etc.) are employed in other countries. It is difficult to find a reliable relationship between magnitude, which is a description of the earthquake's total energy level, and intensity, which is a subjective description of the level of shaking of the earthquake at specific sites, because shaking severity can vary with building type, design and construction practices, soil type and distance from the event.

Time histories are the actual record of the ground's motion at a site caused by an earthquake. They are recorded on strong or weak motion seismometers, typically in terms of acceleration, and can differ dramatically in duration, frequency content, and amplitude. The maximum amplitude of recorded acceleration is termed the **peak ground acceleration**, PGA (also termed the ZPA, or **zero period acceleration**); peak ground velocity (PGV) and peak ground displacement (PGD) are the maximum respective amplitudes of velocity and displacement. Recent earthquakes (1994 Northridge, M_w 6.7 and 1995 Hanshin [Kobe] M_w 6.9) have recorded PGAs of about 0.8 g and PGVs of about 100 kine¹, although it should be noted that almost 2 g was recorded in the 1992 Cape Mendocino earthquake.

If a single-degree-of-freedom mass is subjected to a time varying motion, the mass or elastic structural response can be readily calculated as a function of time, generating a structural response time history. Figure 27.3 illustrates this process, resulting in S_d , the displacement **response spectrum**, while Figure 27.4 shows:

¹1 kine = 1 cm/sec.

TABLE 27.1 Modified Mercalli Intensity Scale of 1931^a

| | |
|------|--|
| I | Not felt except by a very few under especially favorable circumstances |
| II | Felt only by a few persons at rest, especially on upper floors of buildings; delicately suspended objects may swing |
| III | Felt quite noticeably indoors, especially on upper floors of buildings, but many people do not recognize it as an earthquake; standing motor cars may rock slightly; vibration like passing truck; duration estimated |
| IV | During the day felt indoors by many, outdoors by few; at night some awakened; dishes, windows, and doors disturbed; walls make creaking sound; sensation like heavy truck striking building; standing motorcars rock noticeably |
| V | Felt by nearly everyone; many awakened; some dishes, windows, etc., broken; a few instances of cracked plaster; unstable objects overturned; disturbance of trees, poles, and other tall objects sometimes noticed; pendulum clocks may stop |
| VI | Felt by all; many frightened and run outdoors; some heavy furniture moved; a few instances of fallen plaster or damaged chimneys; damage slight |
| VII | Everybody runs outdoors; damage negligible in buildings of good design and construction, slight to moderate in well-built ordinary structures, considerable in poorly built or badly designed structures; some chimneys broken; noticed by persons driving motor cars |
| VIII | Damage slight in specially designed structures, considerable in ordinary substantial buildings, with partial collapse, great in poorly built structures; panel walls thrown out of frame structures; fall of chimneys, factory stacks, columns, monuments, walls; heavy furniture overturned; sand and mud ejected in small amounts; changes in well water; persons driving motor cars disturbed |
| IX | Damage considerable in specially designed structures, well-designed frame structures thrown out of plumb, great in substantial buildings, with partial collapse; buildings shifted off foundations; ground cracked conspicuously; underground pipes broken |
| X | Some well-built wooden structures destroyed, most masonry and frame structures destroyed with foundations; ground badly cracked; rails bent; landslides considerable from river banks and steep slopes; shifted sand and mud; water splashed over banks |
| XI | Few, if any (masonry) structures remain standing; bridges destroyed; broad fissures in ground; underground pipelines completely out of service; earth slumps and land slips in soft ground; rails bent greatly |
| XII | Damage total; waves seen on ground surfaces; lines of sight and level distorted; objects thrown upward into the air |

^a After Wood and Neumann, 1931.

1. S_d , the displacement response spectrum
2. S_v , the velocity response spectrum (also denoted PSV, the pseudo spectral velocity, pseudo to emphasize that this spectrum is not exactly the same as the relative velocity response spectrum [Hudson, 1979])
3. S_a , the acceleration response spectrum

Response spectra form the basis for much modern earthquake engineering structural analysis and design. They are readily calculated if the ground motion is known. Response spectra are most normally presented for 5% of critical damping. A standardized response spectrum is provided in the International Building Code [IBC, 2000] and other design codes. The spectrum is based on a smoothed average of normalized 5% damped spectrum obtained from actual ground motion records grouped by subsurface soil conditions at the location of the recording instrument, and is applicable for earthquakes characteristic of those that occur in California.

Strong Motion Attenuation and Duration

The rate at which earthquake ground motion decreases with distance, termed **attenuation**, is a function of the regional geology and inherent characteristics of the earthquake and its source. Three major factors affect the severity of ground shaking at a site:

1. Source — the size and type of the earthquake
2. Path — the distance from the source of the earthquake to the site and the geologic characteristics of the media earthquake waves pass through
3. Site-specific effects — type of soil at the site

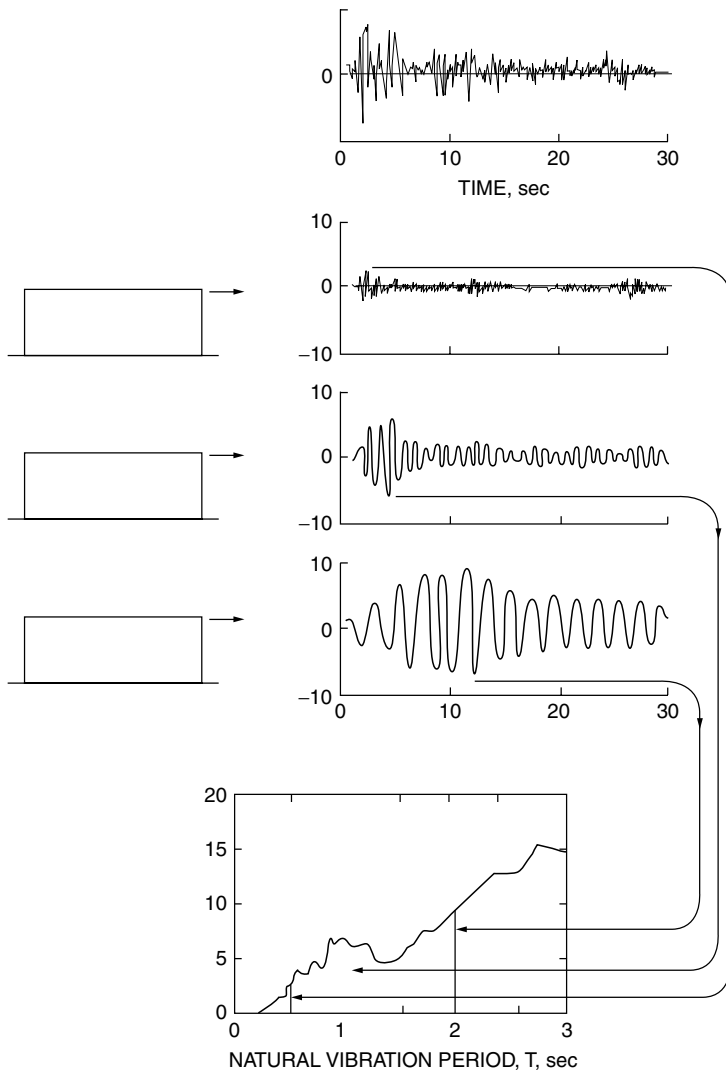

FIGURE 27.3 Computation of deformation (or displacement) response spectrum. (Source: Chopra, A. K. 1981. *Dynamics of Structures, A Primer*, Earthquake Engineering Research Institute, Oakland, CA.)

Figure 27.5 indicates, for alluvium, median values of the attenuation of peak horizontal acceleration with magnitude and style of faulting.

Seismic Hazard and Design Earthquake

The foregoing sections provide an overview of earthquake measures and occurrence; if an earthquake location and magnitude are specified, attenuation relations may be employed to estimate the PGA or response spectra at a site, which can then be employed for the design of a structure. Because the location and magnitude of earthquakes are typically not known beforehand, three approaches are employed in characterizing an earthquake for design purposes — they can be characterized as

1. Code approach
2. Upper-bound approach
3. Probabilistic Seismic Hazard Analysis approach

FIGURE 27.4 Response spectra. (Source: Chopra, A. K. 1981. *Dynamics of Structures, A Primer*, Earthquake Engineering Research Institute, Oakland, CA.)

Code approach —The code approach is to simply employ the lateral force coefficients as specified in the applicable design code. In the United States, a series of national seismic hazard maps for the United States and territories has been developed by the United States Geologic Survey (USGS) specifically for this purpose (available at <http://geohazards.cr.usfs.gov/eq/index.html>). Two sets of maps are available, providing contours of MCE, 5% damped, elastic spectral response acceleration at a period of (a) 0.2 sec, termed S_S , and (b) 1.0 sec, termed S_1 . In both cases, the spectral response acceleration values are representative of sites with subsurface conditions bordering between firm soil or soft rock. By locating a site on the maps and interpolating between the values presented for contours adjacent to the site, it is possible to rapidly estimate the MCE level shaking parameters for the site, given that it has a soft rock or firm soil profile. Figure 27.6 shows, for a portion of the western United States, contours of the 0.2-sec spectral acceleration with a 90% probability of not being exceeded in 50 years. As indicated in the figure, in zones of high seismicity these contours are quite closely spaced, making use of the maps difficult. Therefore, the USGS has furnished software, available both over the Internet (at the URL indicated above) and on a CD-ROM, that permits determination of the MCE spectral response acceleration parameters based on longitude and latitude.

Upper-bound approach — Using historic data and/or fault length–magnitude relations, a maximum magnitude event can be assigned to a fault and, using attenuation relations, a PGA or other engineering

FIGURE 27.5 Campbell and Bozorgnia worldwide attenuation relationship showing (for alluvium) the scaling of peak horizontal acceleration with magnitude and style of faulting. (Source: Campbell, K. W. and Bozorgnia, Y. (1994) Near-Source Attenuation of Peak Horizontal Acceleration from Worldwide Accelerograms Recorded from 1957 to 1993, Proc. Fifth U.S. National Conference on Earthquake Engineering, Earthquake Engineering Research Institute, Oakland, CA.)

measure can be estimated for the site, based on the distance. The effects at a specific site are quantified on the basis of strong ground motion modeling (i.e., attenuation).

Probabilistic Seismic Hazard Analysis approach — The Probabilistic Seismic Hazard Analysis (PSHA) approach entered general practice with Cornell’s [1968] seminal paper, and basically employs the theorem of total probability to formulate:

$$P(Y) = \sum_F \sum_M \sum_R p(Y | M, R) p(M) \tag{27.3}$$

where Y is a measure of intensity, such as PGA, response spectral parameters PSV, etc; $p(Y/M,R)$ is the probability of Y given earthquake magnitude M and distance R (i.e., attenuation); $p(M)$ is the probability of a given earthquake magnitude M ; and F indicates seismic sources, whether discrete such as faults, or distributed.

Typically, various seismic sources (faults modeled as line sources and dipping planes, and various distributed or area sources, including a background source to account for miscellaneous seismicity) are identified, and their seismicity characterized on the basis of historic seismicity and/or geologic data. The effects at a specific site are quantified on the basis of strong ground motion modeling, also termed attenuation. The $p(Y/M,R)$ term represents the full probabilistic distribution of the attenuation relation; summation must occur over the full distribution, due to the significant uncertainty in attenuation. The $p(M)$ term is referred to as the **magnitude–frequency** relation, which was first characterized by Gutenberg and Richter [1954] as

0.2 sec Spectral Accel. (%g) with 10% Probability of Exceedance in 50 Years
site: NEHRP B-C boundary

FIGURE 27.6 MCE seismic hazard map (0.2-sec spectral response acceleration) for the western United States. (Courtesy United States Geological Survey.)

$$\log N(m) = a_N - b_N m \quad (27.4)$$

where $N(m)$ = the number of earthquake events equal to or greater than magnitude m occurring on a seismic source per unit time, and a_N and b_N are regional constants (10^{a_N} = the total number of earthquakes with magnitude >0 , and b_N is the rate of seismicity; b_N is typically 1 ± 0.3). These elements collectively are the seismotectonic model; their integration results in the seismic hazard.

A number of codes have been developed for the integration of Equation (27.3), many of which are based on the public domain FRISK (Fault Risk) code first developed by McGuire [1978].

Most probabilistic seismic hazard analysis models assume the Gutenberg–Richter exponential distribution of earthquake magnitude and that earthquakes follow a Poisson process, occurring on a seismic source zone randomly in time and space. This implies that the time between earthquake occurrences is exponentially distributed, and that the time of occurrence of the next earthquake is independent of the elapsed time since the prior earthquake.¹ The CDF for the exponential distribution is:

$$F(t) = 1 - \exp(-\lambda t) \quad (27.5)$$

Note that this forms the basis for many modern building codes, in that the probabilistic seismic hazard analysis results are selected such that the seismic hazard parameter (e.g., PGA) has a “10% probability of exceedance in 50 years” [UBC, 1994] — that is, if $t = 50$ years and $F(t) = 0.1$ (i.e., only 10% probability that the event has occurred in t years), then $\lambda = .0021$ per year, or 1 per 475 years.

¹For this aspect, the Poisson model is often termed a *memoryless* model.

Equation (27.3) is quite general and is used to develop estimates of MMI, PGA, response spectra or other measures of seismic hazard. Since probabilistic response spectra are a composite of the contributions of varying earthquake magnitudes at varying distances, the ground motions of which attenuate differently at different periods, this method has the drawback that the resulting spectra have varying (and unknown) probabilities of exceedance at different periods.

27.3 Effect of Soils on Ground Motion

The effect of different types of soils on earthquake ground motion and damage has long been noted. Quantification of the effects of soils on ground motion has generally been by either analytical or empirical methods. The current International Building Code [2000] defines seven site coefficients and provides site coefficients for the acceleration and velocity portions of response spectra as a function of expected ground motion.

Liquefaction and Liquefaction-Related Permanent Ground Displacement

Seismic liquefaction of soils has been noted in numerous earthquakes but the phenomenon was only well understood following the 1964 Alaska and, particularly, 1964 Niigata (Japan) earthquakes, where dramatic effects were observed. The process typically consists of loose granular soil with a high water table being strongly shaken during an earthquake — that is, cyclically sheared. The soil particles initially have large voids between them; due to shaking, the particles are displaced relative to each other and tend to more tightly pack, decreasing the void volume. The water, which had occupied the voids (and being incompressible), comes under increased pressure and migrates upward towards or to the surface, where the pressure is relieved. The water usually carries soil with it, and the resulting ejecta are variously termed **sand boils** or **mud volcanoes**.

Liquefaction is a major source of damage in earthquakes, since:

1. The soil's loss of shear strength results in partial or total loss of bearing capacity, resulting in foundation failure unless the structure is founded below the liquefying layer.
2. Liquefaction may result in large lateral spreads and permanent ground displacements, often measured in meters and occasionally resulting in catastrophic slides, such as occurred at Turnagain Heights in the 1964 Alaska earthquake [Seed and Wilson, 1967].
3. For both of these reasons, various lifelines, particularly buried water, wastewater, and gas pipes, typically sustain numerous breaks that can result in system failure and lead to major secondary damage, such as fire following earthquake.

Evaluating liquefaction potential requires consideration of a number of factors, including grain-size distribution. Generally, poorly graded sands (i.e., most particles about the same size) are much more susceptible to liquefaction than well-graded ones (i.e., particles of many differing sizes), since good grading results in better natural packing and better grain–grain contact. Silts and clays are generally much less susceptible to liquefaction, although the potential should not be ignored, and large-grained sands and gravels have such high permeability that pore water pressures usually dissipate before liquefaction can occur. Relative density is basically a measure of the packing; higher relative density means better packing, with more grain–grain contact, while lower relative density, or looseness, indicates a higher potential for liquefaction. Water table depth is critical, as only submerged deposits are susceptible to liquefaction. A loose sandy soil above the water table is not liquefiable by itself, although upward-flowing water from a lower liquefying layer can initiate liquefaction even above the pre-event water table. Note also that water table depths can fluctuate significantly, seasonally or over longer periods and for natural reasons or due to human intervention. Earthquake acceleration and duration are also critical, as these are the active causative agents for liquefaction.

Mitigation of liquefaction is accomplished by a number of methods, including:

- *Excavation and replacement* — that is, if the structure is sufficiently large or important, and the liquefiable layer sufficiently shallow, it may be cost-effective to place the foundation of the structure below the liquefiable layer. Note, however, that liquefaction may still occur around the structure, with possible disruption of adjacent streets, entrances and utilities.
- *Compaction* can be accomplished by a number of methods, including:
 - *Vibro-stabilization*:
 - *Vibro-compaction*, in which a vibrating pile or head accompanied by water jetting is dynamically injected into the ground and then withdrawn; vibration of the head as it is withdrawn compacts an annulus of soil, and this is repeated on a closely spaced grid. Sand may be backfilled to compensate for volume reduction. This technique achieves good results in clean granular soils with less than about 20% fines.
 - *Vibro-replacement* (stone columns) — used in soils with higher fines content (>20%) or even in clay-ey soils which cannot be satisfactorily vibrated. The stone columns act as vertical drains (see below).
 - *Dynamic compaction* via the use of heavy dropped weights or small explosive charges. Weights up to 40 tons are dropped from heights up to 120 ft on a grid pattern, attaining significant compaction to depths of a maximum of 40 ft. Best used in large open areas due to vibrations, noise and flying debris.
 - *Compaction piles*
 - *Grouting*, where grout is injected at high pressure, filling voids in the soil. This technique offers the advantage of being able to be used in small, difficult to access areas (e.g., in basements of buildings, under bridges). Grouting can be used in several ways:
 - *Compaction* — A very stiff soil–cement–water mixture is injected and compacts an annulus around the borehole; this is repeated on a closely spaced grid.
 - *Chemical* — Low-viscosity chemical gels are injected, forming a strong sandstone-like material. Long-term stability of the grout should be taken into account.
 - *Jet-grouting* — Very high pressure water jets are used to cut a cylindrical hole to the desired depth, and the material is replaced or mixed with admixtures to form a stabilized column.
 - *Soil-mixing* — Large rotary augers are used to churn up and mix the soil with admixtures and form stabilized columns or walls.
- *Permeability* can be enhanced by a number of methods, including:
 - *Placement of stone columns* — Rather than by vibro-replacement, a hole is augered or clamshell-excavated, and filled with gravel or cobbles, on a closely spaced grid. If liquefaction occurs, any increase in pore water pressure is dissipated via the high permeability of the stone columns.
 - *Soil wicks* — Similar to stone columns, but wicks consisting of geotextiles are inserted into the ground on a very closely spaced grid; their high permeability similarly dissipates any increase in pore water pressure.
 - *Grouting* — Many materials are available to cement or otherwise create adhesion between soil grains, thus decreasing their cyclic mobility and any packing due to shaking.

27.4 Structures: Earthquake Effects and Seismic Design

Many different types of earthquake damage occur in structures. This section discusses general earthquake performance of buildings and selected other structures, with the emphasis on buildings, especially those typically built in the western U.S.

Buildings

In buildings, earthquake damage can be divided into two categories: structural damage and nonstructural damage, both of which can be hazardous to building occupants. Structural damage means degradation of the building's structural support systems (i.e., vertical and lateral force resisting systems), such as the

FIGURE 27.7 Resistance of earthquake forces: (a) variety of LFRS, (b) effect of ground acceleration on building.

building frames and walls, while nonstructural items include architectural features, mechanical and other equipment, and contents.

How Earthquake Forces are Resisted

Buildings experience horizontal distortion when subjected to earthquake motion (Figure 27.7). **Lateral Force Resisting Systems (LFRSs)** are usually capable of resisting only forces that result from ground motions parallel to them. However, the combined action of LFRS along the width and length of a building can typically resist earthquake motion from any direction.

In wood frame stud-wall buildings, the resistance to lateral loads is typically provided by (a) for older buildings, especially houses, wood diagonal “let-in” bracing, and (b) for newer (primarily post-World War II) buildings, plywood siding “shear walls.” The earthquake resisting systems in modern buildings take many forms. Moment-resisting or braced steel frames are capable of resisting lateral loads. In concrete structures, shear walls¹ are sometimes used to provide lateral resistance, in addition to moment-resisting frames. Certain problems in earthquake resistiveness are independent of building type, and include:

Configuration, or the general vertical and/or horizontal shape of buildings, is an important factor in earthquake performance and damage. Buildings that have simple, regular, symmetric configurations generally display the best performance in earthquakes. Asymmetry can exist in the placement of bracing systems, shear walls or moment-resisting frames that are used to provide earthquake resistance in a building.

Pounding is the collision of adjacent buildings during an earthquake due to insufficient lateral clearance.

Pounding has been the cause of a number of mid-rise building collapses, most notably in the 1985 Mexico City earthquake.

¹Termed shear walls because the depth-to-width ratio is so large that deformation is primarily due to shear rather than bending.

Types of Buildings and Typical Earthquake Performance

Wood frame structures tend to be mostly low rise (one to three stories, occasionally four stories). Stud wall buildings have performed very well in past U.S. earthquakes for ground motions of about 0.5 g or less, due to inherent qualities of the structural system and because they are lightweight and low rise. Homes built over garages have sustained significant amounts of damage in past earthquakes, with many collapses. Some wood frame structures, especially older buildings in the eastern United States, have masonry veneers that may represent another hazard. Post and beam buildings tend to perform well in earthquakes, if adequately braced. The 1994 M_w 6.7 Northridge earthquake was the largest earthquake to occur directly within an urbanized area since the 1971 San Fernando earthquake; ground motions were as high as 0.9 g, and substantial numbers of modern wood-frame dwellings sustained significant damage, including major cracking of veneers and gypsum board walls and splitting of wood wall studs.

Steel frame buildings generally may be classified as either moment resisting frames (MRF) or braced frames, based on their lateral force resisting systems. Steel frame buildings have tended to perform satisfactorily in earthquakes with ground motions of less than about 0.5 g, because of their strength, flexibility, and lightness. Collapse in earthquakes has been very rare, although steel frame buildings did collapse, for example, in the 1985 Mexico City earthquake.

Concrete: Several construction subtypes fall under this category:

1. Moment resisting frames (nonductile or ductile)
2. Shear wall structures
3. Precast, including tilt-up structures

In areas of high seismicity, it is essential that concrete frame buildings have closely spaced lateral ties in the columns and beams, in order to provide ductility. This was not recognized until the 1970s, so older concrete frames are typically nonductile and a high collapse hazard. Concrete shear wall buildings consist of a concrete box or frame structural system with walls constituting the main LFRS. This building type generally tends to perform better than concrete frame buildings. Damages specific to this building type are:

1. Shear cracking and distress can occur around openings in concrete shear walls during large seismic events.
2. Shear failure can occur at wall construction joints, usually at a load level below the expected capacity.
3. Bending failures can result from insufficient chord steel lap lengths.

Tilt-up buildings are typically one story “box” systems, in which the LFRS is the precast concrete wall panels, which are anchored to the roof diaphragm. During an earthquake, weak wall anchors pull out of the walls, causing the floors or roofs to collapse. Damage to tilt-up buildings was observed again in the 1994 M_w 6.7 Northridge earthquake, where the primary problems were poor wall anchorage into the concrete and excessive forces due to flexible roof diaphragms amplifying ground motion to a greater extent than anticipated in the code.

Reinforced masonry buildings are mostly low-rise perimeter-bearing wall structures, often with wood diaphragms, although precast concrete is sometimes used. Reinforced masonry buildings can perform well in moderate earthquakes if they are adequately reinforced and grouted and if sufficient diaphragm anchorage exists. The collapse of bearing walls can lead to major building collapses. The bearing walls will be heavily damaged and collapse under large loads; wall slenderness — some of these buildings have tall story heights and thin walls.

Passive and Active Control

In about the last two decades, a number of innovative techniques have been developed and introduced to enable buildings and structures to better withstand earthquake ground motions. The general aim of these techniques has been the *avoidance* of earthquake-induced forces, rather than their resistance. These

innovative techniques can be divided into two broad categories: *passive control* (base isolation, energy dissipation) and *active control*, and are increasingly being applied to the design of new structures or to the retrofit of existing structures against wind, earthquakes, and other external loads. The distinction between passive and active control is that passive systems require no active intervention or energy source, while active systems typically monitor the structure and incoming ground motion and seek to actively control masses or forces in the structure (via moving weights, variable tension tendons, etc.) so as to develop a structural response (ideally) equal and opposite to the structural response due to the incoming ground motion. Recently developed semiactive control systems appear to combine the best features of both approaches, offering the reliability of passive devices, yet maintaining the versatility and adaptability of fully active systems. Magnetorheological (MR) dampers, for example, are new semiactive control devices that use MR fluids to create controllable dampers. Initial results indicate that these devices are quite promising for civil engineering applications.

Nonbuilding

Structures

Bridges: Abutment damage rarely leads to bridge collapse. Liquefaction of saturated soils in river channels and floodplains and subsequent loss of support have caused many bridge failures in past earthquakes, notably in the 1990 M_w 7.7 Philippines and 1991 M_w 7.1 Costa Rica earthquakes. Regarding aseismic design, bridge behavior during an earthquake can be very complex. Damage in foundation systems is hard to detect, so bridge foundations should be designed to resist earthquake forces elastically.

Industrial Structures: On-ground storage tanks are subject to a variety of earthquake damage mechanisms, generally due to sliding or rocking; this can be prevented by proper detailing. Waterfront structures include quay walls, sheet-pile bulkheads, and pile-supported piers, all of which often sustain damage due to liquefaction. Many industrial structures perform well in earthquakes, but small details result in loss of service and occasionally major damage. For example, electrical power stations and transmission towers usually perform well in earthquakes, but the porcelain insulators and other elements of high voltage transformers and other substation elements are often damaged, resulting in power blackouts over wide areas.

Seismic Design Codes

Seismic design codes are a subset and are generally a section or portion of many building and other design codes. Design loading levels for earthquake and other hazards are typically set by building codes at levels that have a moderate to low probability of occurrence during the life of the structure. While buildings may be designed for earthquake shaking likely to be experienced once every 500 years, wind loads requirements are based on the anticipation, on the average, of once every 100 years, or for snow loads, on average, once every 20 years. The significant difference in recurrence intervals adopted by codes for these various hazards is a function of the hazard itself, and the adequacy of a given return period to capture a maximum, or near maximum, credible event. Building code provisions for earthquake-resistant design are unique in that, unlike the provisions for other load conditions, they do not intend that structures be capable of resisting design loading within the elastic or near elastic range of response — that is, some level of damage is permitted. Building codes intend only that buildings resist large earthquake loading without life-threatening damage and, in particular, without structural collapse or creation of large, heavy falling debris hazards.

The *2000 NEHRP Recommended Provisions for Seismic Regulation for Buildings and Other Structures (NEHRP Provisions)* represents the current state of the art in prescriptive, as opposed to performance-based, provisions for seismic-resistant design. Its provisions form the basis for earthquake design specifications contained in the 2002 edition of ASCE7, *Minimum Design Loads for Buildings and Other Structures*, either through reference or direct incorporation, the seismic regulations in the 2003 edition of the International Building Code (IBC) and also the 2002 edition of the NFPA 5000 Building Code [NFPA, 2003]. As such, the *NEHRP Provisions* will form the basis for most earthquake-resistant design

in the United States, as well as other nations that base their codes on U.S. practices, throughout much of the first decade of the twenty-first century.

Defining Terms

Attenuation — The rate at which earthquake ground motion decreases with distance.

Design [basis] earthquake — The earthquake (as defined by various parameters, such as PGA, response spectra, etc.) for which the structure will be, or was, designed.

Ductile detailing — Special requirements such as, for reinforced concrete and masonry, close spacing of lateral reinforcement to attain confinement of a concrete core, appropriate relative dimensioning of beams and columns, 135-degree hooks on lateral reinforcement, hooks on main beam reinforcement within the column, etc.).

Ductile frames — Frames required to furnish satisfactory load-carrying performance under large deflections (i.e., ductility). In reinforced concrete and masonry this is achieved by **ductile detailing**.

Fault — A zone of the earth's crust within which the two sides have moved; faults may be hundreds of miles long, from 1 to over 100 miles deep, and not readily apparent on the ground surface.

Intensity — A metric of the effect, or the strength, of an earthquake hazard at a specific location, commonly measured on qualitative scales such as mmi, msk, and jma.

Lateral force resisting system (LFRS) — A structural system for resisting horizontal forces, due for example to earthquake or wind (as opposed to the vertical force resisting system, which provides support against gravity).

Liquefaction — A process resulting in a soil's loss of shear strength, due to a transient excess of pore water pressure.

Magnitude — A unique measure of an individual earthquake's release of strain energy, measured on a variety of scales, of which the **moment magnitude** M_w (derived from seismic moment) is preferred.

Mud volcanoes — see **sand boils**.

Peak ground acceleration (PGA) — The maximum amplitude of recorded acceleration (also termed the Z_{PA} , or **zero period acceleration**).

Pounding — The collision of adjacent buildings during an earthquake due to insufficient lateral clearance.

Response spectrum — A plot of maximum amplitudes (acceleration, velocity, or displacement) of a single-degree-of-freedom oscillator (SDOF), as the natural period of the SDOF is varied across a spectrum of engineering interest (typically, for natural periods from 0.03 to 3 or more sec or frequencies of 0.3 to 30+ hz).

Sand boils — Also known as **mud volcanoes**, these are the small cone-shaped sand piles resulting from sand ejected to the surface during the liquefaction process. They have the appearance of miniature volcanoes, typically less than 1 m high, and at most several meters in diameter.

Seismic hazards — The phenomena and/or expectation of an earthquake-related agent of damage, such as fault rupture, vibratory ground motion (i.e., shaking), inundation (e.g., tsunamis, seiche, dam failure), various kinds of permanent ground failure (e.g., liquefaction), fire, or hazardous materials release.

Seismic moment — The moment resulting from the forces generated on an earthquake fault during slip.

Thrust fault — Low-angle reverse faulting. (**Blind thrust faults** are faults at depth occurring under anticlinal folds; they have only subtle surface expression.)

Transform or strike slip fault — A fault where relative fault motion occurs in the horizontal plane, parallel to the strike of the fault.

28.1 Introduction

Structural analysis deals with the evaluation of the response of a structure subjected to prescribed external loads and imposed deformations. Structural analysis often entails the computation of reactions, internal forces, deflections/deformations, stresses, and strains in a structure. This chapter presents fundamental methods of analysis for structures such as cables, arches, trusses, beams, and frames. A brief discussion of methods used for the analysis of plates and shells will also be presented.

A structure can be successfully analyzed only if it is **geometrically stable**. For a structure to be geometrically stable, the number of unknown reactions and internal forces must equal or exceed the number of *independent* equilibrium equations that can be written for the structure. In addition, the structure must be properly constrained to prevent it from undergoing rigid body motion under any perceivable loading conditions. The geometry of the structure must also be such that local or global collapse will not occur under the applied loads. As an example, the two-dimensional beam labeled Beam I in [Table 28.1](#) is geometrically unstable because it is not properly constrained and can undergo rigid body motion in the horizontal direction under the applied load. Beam II and Beam III are both geometrically stable. Beam II is referred to as **statically determinate** because the number of unknown reactions is equal to the number of independent equilibrium equations

$$\sum F_x = 0, \quad \sum F_y = 0, \quad \sum M_z = 0 \quad (28.1)$$

that can be written for the free body diagram of the beam shown. As a result, all unknown reactions as well as any unknown internal forces and moment (see [Figure 28.1](#)) can be determined by consideration of equilibrium alone. Beam III is referred to as **statically indeterminate** because the use of equilibrium equations alone is not sufficient to solve for all the unknowns. To solve the problem, both compatibility and equilibrium equations have to be used. For instance, a compatibility equation that can be written for Beam III is

TABLE 28.1 Beam Examples

| | Beam I | Beam II | Beam III |
|---------------------------|------------|-----------------------------------|-------------------------------------|
| Original | | | |
| Free body diagram | | | |
| Unknown reactions | A_y, B_y | A_x, A_y, B_y | M_A, A_x, A_y, B_y |
| Stability and determinacy | Unstable | Stable and statically determinate | Stable and statically indeterminate |

FIGURE 28.1 Computation of internal forces.

$$(\delta_{vB})_F + (\delta_{vB})_{B_y} = 0 \tag{28.2}$$

where $(\delta_{vB})_F$ and $(\delta_{vB})_{B_y}$ are the vertical deflection at B caused by the applied force F and the support reaction B_y , respectively, if support B is removed from the beam. The above approach of enforcing the displacement compatibility condition in a statically indeterminate structure is called the method of consistent displacements.

In the event that the applied forces are not coplanar, or the structure does not lie in a plane, the structure has to be analyzed as a three-dimensional system. In this case, Equation (28.1) becomes

$$\sum F_x = 0, \quad \sum F_y = 0, \quad \sum F_z = 0, \quad \sum M_x = 0, \quad \sum M_y = 0, \quad \sum M_z = 0 \tag{28.3}$$

A structure is said to be linearly elastic if its force-deflection behavior is linear under both loading and unloading conditions and no permanent deformation results when the applied loads are removed. For linearly elastic structures, the principle of **superposition** can be used to facilitate the analysis. Superposition means structural responses such as displacements, internal forces, stresses and strains, etc., due to an array of forces acting simultaneously is equal to the sum of the responses due to each force acting by itself. By using superposition, the response of a complex system can be obtained by superposing the responses calculated for a subset of simpler systems derived from the original system. Equation (28.2) is an example of the use of the principle of superposition in structural analysis.

28.2 Cables

For ease of analysis, cables are often assumed to be flexible enough so the only unknown internal force acting at any given point in a cable is a (tangential) tensile force. The funicular shape of a cable is the natural shape taken by the cable under a specific set of applied loads. For the cable shown in [Figure 28.2a](#), in which a system of concentrated forces acts, the 10 unknowns (four reactions, three internal

FIGURE 28.2 Cables.

forces, three angles) can be solved using eight joint equilibrium equations ($\sum F_x = 0$, $\sum F_y = 0$, written for points A, B, C, D) and two geometry equations in the form

$$\sum L_i \cos \theta_i = L, \quad \sum L_i \sin \theta_i = h \quad (i = 1, 2, 3) \quad (28.4)$$

where L_i ($i = 1, 2, 3$), L and h are the (known) segment lengths, span length, and difference in support elevations of the cable, respectively. The segment inclination angle, θ_i , is considered positive if it measures counterclockwise.

For the uniformly loaded cable shown in Figure 28.2b, the funicular shape is a parabola. The maximum tension occurs at the highest point of the cable and is equal to

$$T_{\max} = \sqrt{H^2 + (wL_m)^2} \quad (28.5)$$

where H is the horizontal component of the cable force, which is a constant along the entire length of the cable, given by

$$H = \frac{wL_A^2}{2h_A} = \frac{wL_B^2}{2h_B} \quad (28.6)$$

and L_m is taken as the larger of the two horizontal distances L_A and L_B given by

$$L_A = \frac{\sqrt{h_A h_B} - h_A}{h_B - h_A} L, \quad L_B = \frac{h_B - \sqrt{h_A h_B}}{h_B - h_A} L \quad (28.7)$$

in which L is the span length and h_A and h_B are the elevation of support A and support B of the cable, respectively.

For the cable shown in [Figure 28.2c](#), which is loaded by its own weight, the funicular shape is a catenary. The maximum tension occurs at the highest point of the cable and is given by

$$T_{\max} = H \cosh\left(\frac{wL_m}{H}\right) \quad (28.8)$$

where H is the horizontal component of the cable force, and L_m is taken as the larger of the two horizontal distances L_A and L_B . H , L_A , and L_B are obtained by solving the following equations simultaneously

$$\frac{H}{w} [\cosh\left(\frac{wL_A}{H}\right) - 1] = h_A, \quad \frac{H}{w} [\cosh\left(\frac{wL_B}{H}\right) - 1] = h_B, \quad L_A + L_B = L \quad (28.9)$$

28.3 Arches

Arches can be funicular or nonfunicular. Funicular arches resist applied forces by axial compression only, whereas nonfunicular arches resist applied forces by combined axial compression, shear, and bending or even twisting actions. Funicular arches can be analyzed as inverted cables. As a result, all equations presented in the above section can be used if one replaces T (the tensile force in the cable) by C (the compressive force in the arch). Nonfunicular arches have to be analyzed by other means. For instance, if the arch is statically determinate (e.g., a three-hinged arch), it can be analyzed by first separating the arch into two segments by cutting at the hinge common to both segments and exposing the internal axial and shear forces there. The problem can then be solved by applying Equation (28.1) successively to the two arch segments. The six equilibrium equations (two sets of three equilibrium equations written for the two arch segments) are sufficient to solve for the six unknowns (four unknown reaction components for the two supports and two unknown internal forces at the common hinge). If the arch is statically indeterminate (e.g., a two-hinged or a hingeless arch), the use of the method of consistent displacements [Timoshenko and Young, 1965] or other computer-based methods such as matrix [Kassimali, 1999] or finite element [Cook et al., 2001] must be used. The primary difference between the matrix and the **finite element method** is that element equilibrium is rigorously enforced in the former, but only approximately satisfied in the latter. However, for simple line-type elements such as trusses, beams, and frames, both methods will yield the same stiffness matrix. One computer-based method to analyze statically indeterminate arches is to model the curved profile of an arch by a series of straight frame elements. If the elements are kept small enough (i.e., the number of elements used to model the arch is large enough), reasonably good results can be obtained.

28.4 Trusses

Trusses are structures composed of straight and relatively slender members joined together in the form of triangles or other stable shapes. For purpose of analysis, truss members are assumed to be

connected by frictionless pinned joints and the members are so arranged that loads and reactions exist only at the joints. These assumptions ensure that truss members carry only axial tension or compression forces.

A common method to analyze statically determinate trusses is the method of joints. In this method, the first two equations of Equation (28.1) for a two-dimensional truss, or the first three equations of Equation (28.3) for a three-dimensional truss, are written for each joint of the truss. These equilibrium equations can be used to solve for all unknown reactions and member forces of the truss. If the truss is statically indeterminate, the use of the matrix [Nelson and McCormac, 2003] or finite element method is preferred. In either method, an element stiffness relationship in the form

$$\mathbf{k}\mathbf{u} + \mathbf{r}_F = \mathbf{r} \quad (28.10)$$

where \mathbf{k} is the stiffness matrix, \mathbf{u} is the element end displacement (referred to as degree-of-freedom) vector, \mathbf{r} is the element end force vector, and \mathbf{r}_F is the element equivalent end force vector, is constructed for each truss member. They are then assembled (by enforcing nodal equilibrium and compatibility conditions) into a structure stiffness relationship

$$\mathbf{K}\mathbf{U} + \mathbf{R}_F = \mathbf{R} \quad (28.11)$$

where \mathbf{K} is the structure stiffness matrix, \mathbf{U} is the structural nodal displacement vector, \mathbf{R} is the structural nodal force vector, and \mathbf{R}_F is the structural equivalent nodal force vector.

Equation (28.11) can be rearranged and partitioned in accordance with whether the degrees of freedom (dof) are constrained (c) or unconstrained (u) into two sets of matrix equations

$$\begin{bmatrix} \mathbf{K}_{uu} & \mathbf{K}_{uc} \\ \mathbf{K}_{cu} & \mathbf{K}_{cc} \end{bmatrix} \begin{Bmatrix} \mathbf{U}_u \\ \mathbf{U}_c \end{Bmatrix} + \begin{Bmatrix} \mathbf{R}_{Fu} \\ \mathbf{R}_{Fc} \end{Bmatrix} = \begin{Bmatrix} \mathbf{R}_u \\ \mathbf{R}_c \end{Bmatrix} \quad (28.12)$$

Because the applied nodal forces \mathbf{R}_u and the imposed displacements at the supports \mathbf{U}_c are known, the unknown nodal displacements \mathbf{U}_u can be solved using the first set of equations, and the unknown support reactions \mathbf{R}_c can be solved using the second set of equations from Equation (28.12). Once \mathbf{U}_u is solved, the element end displacements \mathbf{u} can be extracted from \mathbf{U}_u , and the element end force \mathbf{r} calculated from Equation (28.10).

Figure 28.3a shows a four degree-of-freedom two-dimensional truss element. The corresponding 4×4 element stiffness matrix \mathbf{k} is

$$\mathbf{k} = \mathbf{C}^T \mathbf{k}' \mathbf{C} \quad (28.13)$$

where \mathbf{C}^T is the transpose of the coordinate transformation matrix \mathbf{C} given by

$$\mathbf{C} = \begin{bmatrix} \cos\theta & \sin\theta & 0 & 0 \\ -\sin\theta & \cos\theta & 0 & 0 \\ 0 & 0 & \cos\theta & \sin\theta \\ 0 & 0 & -\sin\theta & \cos\theta \end{bmatrix} \quad (28.14)$$

and \mathbf{k}' is the element stiffness matrix in local coordinate given by

FIGURE 28.3 Truss and beam/frame elements.

$$k' = \frac{EA}{L} \begin{bmatrix} 1 & 0 & -1 & 0 \\ 0 & 0 & 0 & 0 \\ -1 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix} \quad (28.15)$$

in which E is the modulus of elasticity, A is the element cross-sectional area, and L is the element length.

The equivalent end force vector \mathbf{r}_F in Equation (28.10) can be used to account for the presence of any element misfit and/or temperature loading. It is equal to

$$\mathbf{r}_F = \mathbf{C}^T \mathbf{r}'_F \quad (28.16)$$

where \mathbf{C}^T is the transpose of the coordinate transformation matrix expressed in Equation (28.14), and \mathbf{r}'_F for the two-dimensional truss element shown in Figure 28.3a is given by

$$\mathbf{r}'_F = \left\{ \frac{EA\delta}{L} \quad 0 \quad -\frac{EA\delta}{L} \quad 0 \right\}^T \quad (28.17)$$

where δ is the amount of element misfit, taken as positive if the element is fabricated too long, and negative if the element is fabricated too short. In the case of temperature loading, $\delta = \alpha\Delta TL$, where α is the coefficient of thermal expansion and ΔT is the temperature change, taken as positive for a rise in temperature, and negative for a drop in temperature.

28.5 Beams and Frames

Beams and frames are structural elements that resist applied loads by axial, shear, bending, and twisting actions. For a two-dimensional beam or frame element experiencing small displacements subjected to a distributed load q acting through the shear center of the cross-section with flexural rigidity EI (i.e., the product of the elastic modulus E and moment of inertia I), the following differential equations relating the applied load q , internal shear V , internal bending moment M , slope θ , and deflection v can be written as

$$q = \frac{dV}{dx}, \quad V = \frac{dM}{dx}, \quad M = EI \frac{d\theta}{dx} \approx EI \frac{d\left(\frac{dv}{dx}\right)}{dx} = EI \frac{d^2v}{dx^2} \quad (28.18)$$

The above equations can be used to construct shear and bending moment diagrams and to derive the equations of the elastic curve (i.e., **deflection functions**) for any beam/frame element subjected to a given set of loadings. A **shear diagram** is a plot of the internal shear force along the length of the element, and a **moment diagram** is a plot of the internal bending moment along the length of the element. By integrating the first two equations of Equation (28.18), one obtains the change in shear ΔV and change in moment ΔM from point i to j as

$$\Delta V = V_j - V_i = \int_{x_i}^{x_j} q dx, \quad \Delta M = M_j - M_i = \int_{x_i}^{x_j} V dx \quad (28.19)$$

and to account for effect of an applied concentrated load or moment, the term $\pm P_o$ is appended to the first, and the term $\pm M_o$ is appended to the second equation of Equation (28.19), respectively. The plus sign is used if the concentrated load (or moment) tends to increase the shear (or moment) at the point of application of the load (or moment). Because the integrals on the right side of the two equations expressed in Equation (28.19) represent the area under the load diagram and the area under the shear diagram between point i and point j , respectively, the equations can be used to construct shear and bending moment diagrams by starting with known values of V and M at one end of the beam and successively adding the area under the load diagram (for drawing the shear diagram) and the area under the shear diagram (for drawing the moment diagram) as one traverses from one point to another along the length of the beam. An example of a shear and moment diagram drawn for a beam is shown in [Figure 28.4](#).

Through successive integration, the last equation of Equation (28.18) can be used to determine the slope dv/dx and deflection functions v of a segment of beam or frame element. For example,

$$\frac{dv}{dx} = \left(\int \frac{M}{EI} dx \right) + C_1, \quad v = \left(\int \frac{dv}{dx} dx \right) + C_2 \quad (28.20)$$

where C_1 and C_2 are constants of integrations that can be determined by enforcing boundary and/or continuity conditions of the beam or frame segment. **Boundary conditions** are enforced at points of supports for the structure (see [Table 28.2](#)), and continuity conditions (i.e., continuity of slopes and deflections) are enforced at points common to two adjacent beam/frame segments.

[Table 28.3](#) gives examples of deflection equations for some basic load cases of a simply supported and a cantilever beam.

An alternative method to analyze beams and frames is the matrix or finite element method. In this method the structure is discretized into a series of elements connected together at points referred to as nodes. To perform the analysis, an element stiffness matrix \mathbf{k} is formed for each element of the structural model. These element stiffness matrices are then assembled into a structure stiffness matrix \mathbf{K} . The unknown nodal displacements \mathbf{U}_n and reactions \mathbf{R}_c are solved as described above in the section on trusses.

For the six-degree-of-freedom two-dimensional frame element shown in [Figure 28.3b](#), the element stiffness matrix \mathbf{k} can be expressed as

FIGURE 28.4 Shear and moment diagrams.

$$\mathbf{k} = \mathbf{C}^T \mathbf{k}' \mathbf{C} \quad (28.21)$$

where \mathbf{C}^T is the transpose of the coordinate transformation matrix \mathbf{C} given by

$$\mathbf{C} = \begin{bmatrix} \cos\theta & \sin\theta & 0 & 0 & 0 & 0 \\ -\sin\theta & \cos\theta & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & \cos\theta & \sin\theta & 0 \\ 0 & 0 & 0 & -\sin\theta & \cos\theta & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 \end{bmatrix} \quad (28.22)$$

and \mathbf{k}' is the element stiffness matrix in local coordinate expressed as

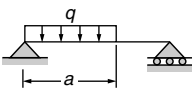

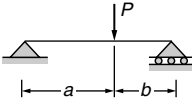

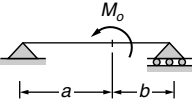

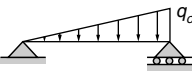

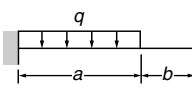

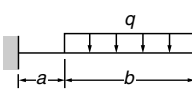

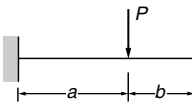

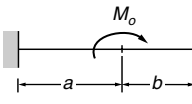

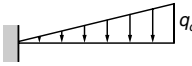

$$\mathbf{k}' = \frac{EI}{L} \begin{bmatrix} \frac{A}{I} & 0 & 0 & -\frac{A}{I} & 0 & 0 \\ 0 & \frac{12}{L^2} & \frac{6}{L} & 0 & -\frac{12}{L^2} & \frac{6}{L} \\ 0 & \frac{6}{L} & 4 & 0 & -\frac{6}{L} & 2 \\ -\frac{A}{I} & 0 & 0 & \frac{A}{I} & 0 & 0 \\ 0 & -\frac{12}{L^2} & -\frac{6}{L} & 0 & \frac{12}{L^2} & -\frac{6}{L} \\ 0 & \frac{6}{L} & 2 & 0 & -\frac{6}{L} & 4 \end{bmatrix} \quad (28.23)$$

It should be noted that unlike trusses in which loads are always applied to truss joints, beam and frame elements are often subjected to in-span or transverse loads. To account for these transverse loads, the equivalent element end force vector \mathbf{r}_f in Equation (28.10) is now redefined as the element fixed-end force vector. For the frame element shown in Figure 28.3b, \mathbf{r}_f can be calculated from the equation

TABLE 28.2 Supports and Boundary Conditions

| Support | Boundary Conditions |
|-----------------|---------------------|
| Roller, rocker | $v = 0$ |
| Hinged, pinned | $v = 0$ |
| Fixed, built-in | $v = 0, dv/dx = 0$ |

TABLE 28.3 Examples of Deflection Equations

| Case | Deflection Equations |
|---|---|
|  | $v = -\frac{qx}{24LEI} (a^4 - 4a^3L + 4a^2L^2 + 2a^2x^2 - 4aLx^2 + Lx^3), \text{ for } 0 \leq x \leq a$ $v = -\frac{qa^2}{24LEI} (-a^2L + 4L^2x + a^2x - 6Lx^2 + 2x^3), \text{ for } a \leq x \leq L$ |
|  | $v = -\frac{Pbx}{6LEI} (L^2 - b^2 - x^2), \text{ for } 0 \leq x \leq a$ |
|  | $v = -\frac{M_0x}{6LEI} (6aL - 3a^2 - 2L^2 - x^2), \text{ for } 0 \leq x \leq a$ |
|  | $v = -\frac{q_0x^3}{360LEI} (7L^4 - 10L^2x^2 + 3x^4)$ |
|  | $v = -\frac{qx^2}{24EI} (6a^2 - 4ax + x^2), 0 \leq x \leq a$ $v = -\frac{qa^3}{24EI} (4x - a), a \leq x \leq L$ |
|  | $v = -\frac{qbx^2}{12EI} (3L + 3a - 2x), 0 \leq x \leq a$ $v = -\frac{q}{24EI} (x^4 - 4Lx^3 + 6L^2x^2 - 4a^3x + a^4), a \leq x \leq L$ |
|  | $v = -\frac{Px^2}{6EI} (3a - x), 0 \leq x \leq a$ $v = -\frac{Pa^2}{6EI} (3x - a), a \leq x \leq L$ |
|  | $v = -\frac{M_0x^2}{2EI}, 0 \leq x \leq a$ $v = -\frac{M_0a^2}{2EI} (2x - a), a \leq x \leq L$ |
|  | $v = -\frac{q_0x^3}{120LEI} (20L^3 - 10L^2x + x^3)$ |

$$\mathbf{r}_F = \mathbf{C}^T \mathbf{r}'_F \quad (28.24)$$

where \mathbf{C}^T is the transpose of the coordinate transformation matrix given in Equation (28.22), and \mathbf{r}'_F is the element fixed-end force vector in local coordinates whose elements are given by

$$r_{F1} = -\int_L \frac{p(L-x)}{L} dx, \quad r_{F4} = -\int_L \frac{px}{L} dx, \quad r_{F3} = -\int_L \frac{qx(L-x)^2}{L^2} dx, \quad r_{F6} = \int_L \frac{qx^2(L-x)}{L^2} dx \quad (28.25)$$

In the above equations, r_{F1} and r_{F4} are the fixed-end axial forces, r_{F3} and r_{F6} are the fixed-end moments of the element. The fixed-end shears r_{F2} and r_{F5} can be obtained by consideration of element equilibrium once r_{F3} and r_{F6} are calculated.

28.6 Plates and Shells

Although analytical solutions for plate and shell structures under simple loading conditions are available [Timoshenko and Woinowsky-Krieger, 1959; Gould, 1999], plates and shells subjected to more complicated load cases are often analyzed using the finite element method [Cook et al., 2001]. In a displacement-based finite element formulation, a displacement field is assumed for each element. By evaluating this assumed displacement field at each degree-of-freedom of the element, a relationship in the form $\mathbf{u}^e = \mathbf{N}\mathbf{u}$, where \mathbf{u}^e is the intraelement displacement, \mathbf{N} is the shape matrix, and \mathbf{u} is the element nodal displacement vector, can be established. An element stiffness matrix \mathbf{k} , whose size is equal to the number of degrees of freedom of the element can be derived using the equation

$$\mathbf{k} = \int_V \mathbf{B}^T \mathbf{D} \mathbf{B} dV \quad (28.26)$$

where V is the volume of the finite element, \mathbf{B} is the strain-displacement matrix (obtained by taking the appropriate derivatives of the shape function matrix \mathbf{N}) relating the vector of nodal displacements \mathbf{u} with the vector of strains $\boldsymbol{\epsilon}$ (i.e., $\boldsymbol{\epsilon} = \mathbf{B}\mathbf{u}$), \mathbf{D} is the material stiffness matrix relating the vector of strains $\boldsymbol{\epsilon}$ with the vector of stresses $\boldsymbol{\sigma}$ (i.e., $\boldsymbol{\sigma} = \mathbf{D}\boldsymbol{\epsilon}$). To account for the effect of body force and/or surface traction, an equivalent nodal force vector can also be computed using the equation

$$\mathbf{r}_F = -\int_V \mathbf{N}^T \mathbf{f}_b dV - \int_S \mathbf{N}^T \mathbf{f}_s dS \quad (28.27)$$

where \mathbf{N}^T is the transpose of the element shape matrix \mathbf{N} , \mathbf{f}_b is the body force, \mathbf{f}_s is the surface traction, and V and S are the volume and surface of the element over which the body force and surface traction act, respectively. Once the element stiffness relationship is assembled into a structure stiffness relationship, the unknown displacements and reactions can be solved in accordance with the procedure outlined in the section Trusses. The matrix equations $\boldsymbol{\epsilon} = \mathbf{B}\mathbf{u}$ and $\boldsymbol{\sigma} = \mathbf{D}\boldsymbol{\epsilon}$ can then be used to solve for strains and stresses. Some examples of plate and shell finite elements are shown in [Figure 28.5](#).

28.7 Influence Lines and Influence Surfaces

An influence line is a plot of the variation of a response function (such as a reaction, an internal shear, an internal moment, etc.) at a given point of a two-dimensional structure when a unit load is applied at different locations on the structure. An influence surface is a collection of influence lines plotted for a three-dimensional structure. Influence lines can be constructed using either the *quantitative method*, in which the desired response function at a given point of the structure is computed repeatedly when a unit

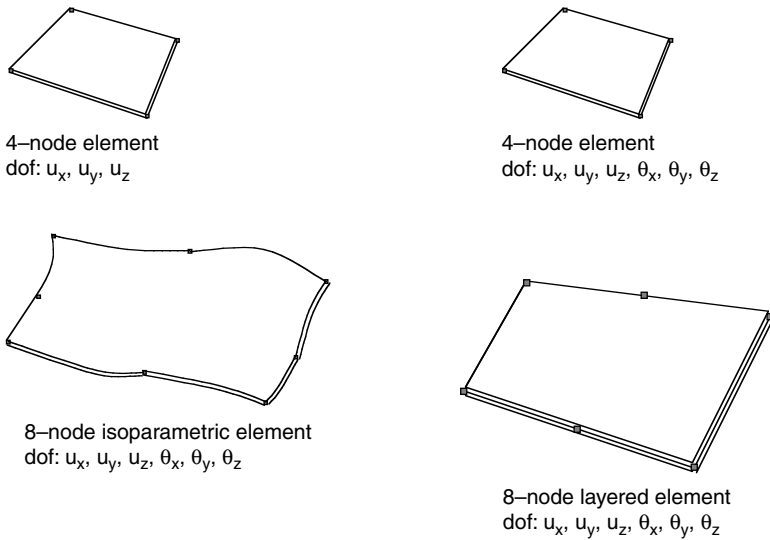

FIGURE 28.5 Plate and shell finite elements.

load is applied at different locations on the structure, or the *qualitative method* in which the Müller-Breslau principle is used [Hibbeler, 2002]. In using the Müller-Breslau principle to construct an influence line, the constraint that gives rise to the response function is removed, but its effect on the structure is retained. The influence line is obtained as the deflected shape of the structure subject to this effect. To obtain the correct values (called **influence coefficients**) for the influence line, the deflected shape of the structure is scaled to a value of unity at the location of the constraint. For instance, to draw the influence line for a support reaction, the support is first removed, but its effect on the structure is retained through the use of a concentrated load applied at the support location. The deflected shape of the structure, scaled to a value of unity at the support, is now the support reaction influence line for the structure. Figure 28.6 shows some examples of influence lines drawn for a statically determinate and a statically indeterminate beam. Note that influence lines for statically determinate beams are straight line segments but influence lines for statically indeterminate beams are curves.

The influence line for a given response function can be used to determine the locations on the structure over which a live load should be placed to educe the maximum effect of that response function on the structure. For instance, suppose the live load is a concentrated load, to obtain the maximum reaction at support B for the statically determinate beam shown in Figure 28.6a, the load should be placed at the internal hinge to the right of B where the influence coefficient has the highest value. However, to obtain the maximum support reaction at B (i.e., R_B) for the statically indeterminate beam shown in Figure 28.6b, the live concentrated load should be placed right over support B. If the maximum positive moment at point D (i.e., M_D) is desired, the live concentrated load should be placed right at point D for both beams. Now, suppose the live load is a distributed load, it should be placed over the entire beam from point A to point C for both beams to obtain the maximum reaction at support B, and over span AB only for both beams to obtain the maximum positive moment at D, and over span BC only for both beams to obtain the maximum negative moment at D. Once the live load is properly placed, its effect on the structure in terms of the magnitude of the response function can be calculated using the equations

$$Py, \quad \text{for a single concentrated load } P$$

$$\sum_{i=1}^n P_i y_i, \quad \text{for a concentrated load series } P_i (i = 1, 2, \dots, n) \quad (28.28)$$

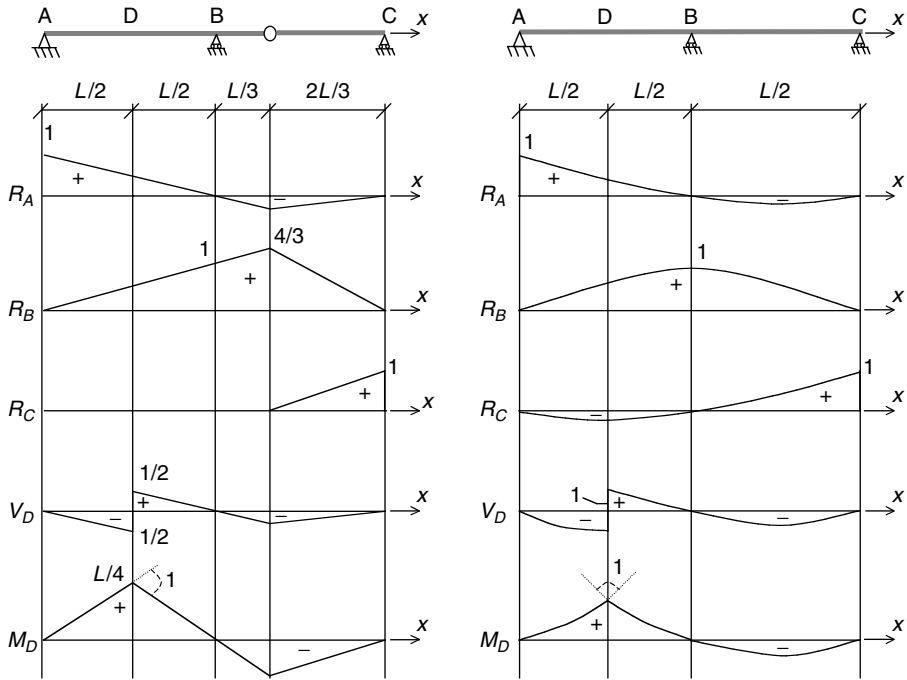

FIGURE 28.6 Influence lines.

$$\int_a^b qy dx, \quad \text{for a distributed load } q \text{ applied from point } a \text{ to } b$$

In the above equations, y is the influence coefficient of the influence line constructed for the specific response function. The above equations can also be used to compute magnitudes of response functions for three-dimensional structures when influence surfaces are available. In this case y will be the influence coefficient of the corresponding influence surface.

28.8 Structural Stability

Structural stability is the ability of a structural system to maintain its geometric integrity under compressive force or stress. When a structure is subjected to high compressive force/stress, it has a tendency to lose its stiffness and deflect in a direction perpendicular to the direction of the applied stress. When this occurs, the ability of the structure to carry the applied load will be compromised. For instance, a slender column buckles (i.e., becomes unstable under a compressive force) when the applied load reaches a critical value. If buckling occurs in the elastic range, this critical load can be computed as an eigenvalue problem [Chen and Lui, 1987] using the differential equation

$$EI \frac{d^4 v}{dx^4} + P \frac{d^2 v}{dx^2} = 0 \quad (28.29)$$

in conjunction with a set of boundary conditions that represent the nature of the supports at the two ends of the column. In the above equation, v is the lateral displacement and EI (the product of the modulus of elasticity of the material and moment of inertia of the cross-section) is the flexural rigidity of the column. The critical load is obtained as the eigenvalue of the characteristic equation, and the buckling mode shape is obtained as the eigenvector of the equation. Examples of critical loads P_{cr} for

TABLE 28.4 P_{cr} for Columns with Different Boundary Conditions

| | | | | | | |
|----------|-----------------------------|-----------------------------|------------------------|------------------------|-----------------------------|-----------------------------|
| Case | | | | | | |
| P_{cr} | $\frac{\pi^2 EI}{(0.5L)^2}$ | $\frac{\pi^2 EI}{(0.7L)^2}$ | $\frac{\pi^2 EI}{L^2}$ | $\frac{\pi^2 EI}{L^2}$ | $\frac{\pi^2 EI}{(2.0L)^2}$ | $\frac{\pi^2 EI}{(2.0L)^2}$ |
| K | 0.5 | 0.7 | 1.0 | 1.0 | 2.0 | 2.0 |

columns with different boundary conditions are given in Table 28.4. Note that P_{cr} for all these columns can be expressed in the following compact form

$$P_{cr} = \frac{\pi^2 EI}{(KL)^2} \quad (28.30)$$

where K is referred to as the effective length factor. The effective length KL of a column can be interpreted as the length between adjacent inflection points (or points of zero moment) in the column.

An alternative method to calculate P_{cr} is the finite element method [McGuire et al., 2000]. In this method P_{cr} is calculated by solving the characteristic polynomial obtained by setting the determinant of the system stiffness matrix equal to zero as follows

$$\det[\mathbf{K} + \mathbf{K}_G] = 0 \quad (28.31)$$

In the above equation, \mathbf{K} is the first-order system stiffness matrix (that does not account for any geometrical nonlinear effect) and \mathbf{K}_G is the geometrical system stiffness matrix (which is a function of P and accounts for the geometrical nonlinear effect).

For instance, if Equation (28.31) is used to compute P_{cr} for a column, the column is first discretized into small elements. The first-order system stiffness matrix \mathbf{K} is then obtained by assembling the element stiffness matrix \mathbf{k} calculated from Equation (28.21) for each element, and the geometrical system stiffness matrix \mathbf{K}_G is obtained by assembling the element geometrical stiffness matrix \mathbf{k}_G calculated from the equation

$$\mathbf{k} = \mathbf{C}^T \mathbf{k}'_G \mathbf{C} \quad (28.32)$$

in which \mathbf{C} is given by Equation (28.22) and \mathbf{k}'_G is given by

$$\mathbf{k}'_G = \frac{P}{L} \begin{bmatrix} 1 & 0 & 0 & -1 & 0 & 0 \\ 0 & \frac{6}{5} & \frac{L}{10} & 0 & -\frac{6}{5} & \frac{L}{10} \\ 0 & \frac{L}{10} & \frac{2L^2}{30} & 0 & -\frac{L}{10} & -\frac{L^2}{30} \\ -1 & 0 & 0 & 1 & 0 & 0 \\ 0 & -\frac{6}{5} & -\frac{L}{10} & 0 & \frac{6}{5} & -\frac{L}{10} \\ 0 & \frac{L}{10} & -\frac{L^2}{30} & 0 & -\frac{L}{10} & \frac{2L^2}{15} \end{bmatrix} \quad (28.33)$$

where P is the axial force in the element. In a column buckling analysis, the effect of initial column shortening in the direction of the applied load is usually ignored. As a result, the first and fourth rows and columns in the matrices expressed in Equation (28.23) and Equation (28.33) are usually deleted from the matrices when Equation (28.31) is used to compute P_{cr} .

If **material nonlinearity** is to be accounted for, the analysis can proceed by replacing the elastic modulus E by the tangent modulus E_t . The tangent modulus is defined as the slope of the nonlinear stress–strain curve of the material. For aluminum columns, the Ramsberg–Osgood [1943] equation for stress–strain behavior can be used to express E_t as follows

$$E_t = \frac{E}{\left[1 + \frac{0.002nE}{\sigma_{0.2}} \left(\frac{\sigma}{\sigma_{0.2}}\right)^{n-1}\right]} \quad (28.34)$$

where $\sigma_{0.2}$ is the 0.2% offset yield stress, and n is the hardening parameter.

For steel columns, E_t can be approximated by [Galambos, 1998]

$$E_t = \begin{cases} 4E \left[\frac{\sigma}{\sigma_y} \left(1 - \frac{\sigma}{\sigma_y}\right) \right] & , \text{ if } \sigma \leq 0.5\sigma_y \\ E & , \text{ if } \sigma > 0.5\sigma_y \end{cases} \quad (28.35)$$

where σ is the axial stress, and σ_y is the material yield stress.

28.9 Advanced Analysis

The term advanced analysis is used to describe any analysis method that explicitly takes into consideration all important parameters that affect the behavior of a structure. For instance, in the analysis of framed structures, a plastic zone analysis is considered an advanced analysis. In a plastic zone analysis, the effects of **geometrical nonlinearity** as well as spread of plasticity from one region to another within the structure are explicitly modeled in the analysis. While the geometrical nonlinear effect can be accounted for by the use of a geometrical stiffness matrix \mathbf{K}_G , one method to account for the material nonlinear effect is the use of fiber elements. In this method, a frame member is modeled by bundling together groups of finite length fiber elements to form the member cross-section. The behavior of each fiber is described by predefined pre- and post-yield constitutive relationships. Needless to say, such an analysis often requires proprietary software and is extremely computationally intensive. It is therefore seldom performed. A somewhat simpler analysis method that can be used for nonlinear frame analysis is the plastic hinge (or its derivative, the modified plastic hinge) method. In a plastic hinge method of analysis, occurrences of plasticity are assumed to concentrate in regions of “zero length” plastic hinges. Regions outside of plastic hinges are assumed to be elastic. Using this assumption, the analysis can proceed with the use of an iterative process applied to the following increment equation

$$\Delta \mathbf{R} = [\mathbf{K} + \mathbf{K}_G + \mathbf{K}_p] \Delta \mathbf{U} \quad (28.36)$$

where $\Delta \mathbf{R}$ is the incremental nodal force vector, $\Delta \mathbf{U}$ is the incremental displacement vector, \mathbf{K} is the first-order system stiffness matrix, \mathbf{K}_G is the system geometrical stiffness matrix, and \mathbf{K}_p is the system plasticity stiffness matrix obtained by assembling \mathbf{k}_p given by [McGuire et al., 2000]

$$\mathbf{k}_p = -\mathbf{k} \mathbf{G} [\mathbf{G}^T \mathbf{k} \mathbf{G}]^{-1} \mathbf{G}^T \mathbf{k} \quad (28.37)$$

where \mathbf{k} is the first-order (or elastic) element stiffness matrix given in Equation (28.21) for a two-dimensional frame element, \mathbf{G} is the gradient matrix that satisfies the orthogonality condition

$$\mathbf{G}^T \Delta \mathbf{R} = 0 \quad (28.38)$$

The gradient matrix \mathbf{G} is obtained by taking partial derivatives of a **yield surface** Φ with respect to each force degree-of-freedom of the element. For the two-dimensional frame element shown in Figure 28.3b, \mathbf{G} can be expressed as

$$\mathbf{G} = \begin{bmatrix} \frac{\partial \Phi}{\partial P_i} & 0 \\ \frac{\partial \Phi}{\partial V_i} & 0 \\ \frac{\partial \Phi}{\partial M_i} & 0 \\ 0 & \frac{\partial \Phi}{\partial P_j} \\ 0 & \frac{\partial \Phi}{\partial V_j} \\ 0 & \frac{\partial \Phi}{\partial M_j} \end{bmatrix} \quad (28.39)$$

where P_i , V_i , and M_i are the axial force, shear force, and bending moment acting on the left end of the element, and P_j , V_j , and M_j are the axial force, shear force, and bending moment acting on the right end of the element.

There are various expressions proposed to describe the yield surface for I-shaped steel sections. One such expression is [McGuire et al., 2000]

$$\Phi = \begin{cases} p^2 + m^2 + 3.5p^2m^2, & \text{for major axis bending} \\ p^2 + m^4 + 3p^6m^2, & \text{for minor axis bending} \end{cases} \quad (28.40)$$

where $p = P/P_p$, $m = M/M_p$, in which P and M are the axial force and bending moment acting on the cross-section, respectively, P_p is the cross-section **yield load**, and M_p is the cross-section **plastic moment** capacity.

Because the problem is nonlinear, it has to be solved incrementally using an iterative technique. In each cycle of analysis \mathbf{K}_G and \mathbf{K}_p in Equation (28.36) are updated to reflect the effects of change in geometry (geometrical nonlinearity) and material inelasticity (material nonlinearity) on the behavior of the structure. Various iterative techniques have been proposed over the years (e.g., the Load Control Newton-Raphson Method, the Displacement Control Method, the Arc Length Method, the Work Control Method, etc.) by a number of researchers. These techniques are also well documented in the literature [see for example, Chen and Lui, 1991, McGuire et al., 2000]. Because advanced analysis can capture structural behavior more accurately, it is becoming more important in the structural engineering profession. A number of international structural design specifications already have provisions for the use of such an analysis for design.

Defining Terms

Boundary conditions — The kinematic and/or force conditions that exist at or along the boundary of a structure.

Deflection functions — Equations that describe the deflected shape of a structure under applied loads.

Finite element method — An analysis method in which a structure is modeled by an array of small elements, each with a predetermined response characteristic.

Geometrically stable — A condition in which a structure will not undergo rigid body motion nor experience local or global collapse under any configurations of applied loads.

Geometrical nonlinearity — Nonlinear response as a result of change in geometry of the structure under the applied loads.

Influence coefficient — Magnitude of a response function at a certain point on the structure due to the application of a unit load on the structure.

Material nonlinearity — Nonlinear response as a result of material yielding or nonlinear stress–strain behavior.

Moment diagram — A diagram showing the variation of internal bending moment in a structural member.

Plastic moment — The moment capacity of a cross-section that corresponds to the condition of full yielding of all fibers in the cross-section.

Shear diagram — A diagram showing the variation of internal shear force in a structural member.

Statically determinate — A condition in which the use of equilibrium equations alone is sufficient to solve for all unknown external reactions and internal forces.

Statically indeterminate — A condition in which the use of equilibrium equations alone is *not* sufficient to solve for all unknown external reactions and internal forces.

Superposition — Structural responses such as displacements, forces, stresses and strains, etc., due to an array of forces acting simultaneously can be obtained by summing the responses due to each force acting alone.

Yield load — An axial load that will cause full yielding of all fibers in a cross-section.

Yield surface — An interaction diagram that shows how two or more forces interact to cause yielding or failure in a cross-section.

Structural steel is used for the framework of buildings and bridges, either alone or in combination with other materials such as reinforced concrete. Steel buildings are usually constructed with standard shapes produced by hot-rolling (Figure 29.1), although custom shapes can be fabricated from plate material. Various grades of steel, as classified by the American Society for Testing and Materials [2003], are suitable for building and bridge construction. One commonly used steel is ASTM A36, with a minimum tensile yield stress F_y of 36 ksi and an ultimate tensile stress F_u between 58 and 80 ksi. (The actual yield stress of most A36 steel currently being produced is close to 50 ksi.) Other currently used steels are ASTM A572 Grade 50 and ASTM A992, both with a yield stress of 50 ksi and an ultimate stress of 65 ksi.

Several design approaches are available to the structural engineer.

In *allowable stress design* (ASD), structural members are proportioned so that the maximum computed stress is less than a permissible, or allowable, stress. This approach is also called *working stress design* or *elastic design*.

In *load and resistance factor design* (LRFD), members are proportioned so that the applied load is less than the resistance (strength) of the member. This approach can be represented by the following relationship:

$$\sum \gamma_i Q_i \leq \phi R_n \quad (29.1)$$

where γ_i is a **load factor**, Q_i is a load effect (force or moment), ϕ is a **resistance factor**, and R_n is the nominal resistance, or **nominal strength**. The summation indicates that the total factored load effect is the sum of the products of individual load effects (such as dead, live, and snow) and corresponding load factors — which are a function of not only the type of load effect, but also the combination of loads under consideration. The nominal strength is a theoretical strength, and the resistance factor reduces it to a practical value. This reduced value, ϕR_n , is called the **design strength**. Equation (29.1) states that the sum of the factored load effects must not exceed the design strength.

A third approach, *plastic design*, also uses load factors but is primarily a structural analysis method of obtaining failure loads by a consideration of collapse mechanisms.

Although all three approaches are acceptable, ASD and LRFD are the most widely used.

FIGURE 29.1 Examples of standard hot-rolled shapes (cross-sectional views).

The design of structural steel buildings in the U.S. is usually based on the provisions of the specifications of the American Institute of Steel Construction. For allowable stress design, the requirements are given in the 1989 Specification [American Institute of Steel Construction, 1989a] and the ninth edition ASD Manual of Steel Construction [American Institute of Steel Construction, 1989b]. For load and resistance factor design, the requirements are given in the 1999 Specification [American Institute of Steel Construction, 1999] and the third edition LRFD Manual of Steel Construction [American Institute of Steel Construction, 2001]. In 2005, AISC will publish a unified specification and manual, covering both ASD and LRFD. All of the requirements covered herein will be based on the current AISC LRFD Specification and Manual.

The loading conditions to be investigated in conjunction with Equation (29.1), along with the associated load factors, are given in ASCE 7-02, *Minimum Design Loads for Buildings and Other Structures* [American Society of Civil Engineers, 2002]. These combinations are not given in the AISC Specification, but they are shown in the LRFD Manual. The value of the resistance factor depends upon the type of member or connecting element being investigated and will be covered in the following sections.

29.1 Members

Tension Members

Tension members are used in trusses, bracing systems, and building and bridge suspension systems. The load and resistance factor relationship of Equation (29.1) can be expressed in the following way for a tension member:

$$P_u \leq \phi_t P_n \quad (29.2)$$

where P_u is the sum of the factored axial tension loads, ϕ_t is the resistance factor for tension, and P_n is the nominal tensile strength.

There are two possible failure modes, or **limit states**, for tension members: excessive deformation caused by yielding of the gross cross-section and fracture of the net cross-section. The net cross-sectional area is the gross area minus any area removed by bolt holes. For yielding of the gross section, the design strength is given by

$$\phi_t P_n = \phi_t F_y A_g = 0.90 F_y A_g \quad (29.3)$$

and the design strength based on fracture of the net section is

$$\phi_t P_n = \phi_t F_u A_e = 0.75 F_u A_e \quad (29.4)$$

where A_g is the gross cross-sectional area and A_e is the *effective* net area. Note that the resistance factor is different for each of the two limit states. Because of a phenomenon called **shear lag**, an effective net area must be used in those cases where some of the cross-sectional elements are unconnected. The effective net area is given by

$$A_e = A_n U \quad (29.5)$$

where A_n is the actual computed net area and U is a reduction factor. Shear lag can also occur in welded connections. In these cases, it is accounted for by using an effective area A_e defined as

$$A_e = A_g U \quad (29.6)$$

Block shear is another potential limit state for tension members. This failure mode must be investigated when the member is connected in such a way that a block of the material could tear out as in [Figure 29.2](#). Two loading conditions are involved: shear and tension. In the case illustrated, the shear is along line ab and the tension is along line bc . The strength, or resistance, is the sum of two contributions — either shear yielding plus tension fracture or shear fracture plus tension yielding. The governing case will be the one that has the larger fracture component. Block shear can also occur in welded connections.

The following tension member example will illustrate the concepts of load combination and design strength.

Example

Select a single-angle tension member of A36 steel to resist a service dead load of 30 kips and a service live load of 90 kips. The member will be connected to a gusset plate at each end with longitudinal welds.

Solution

In this brief introductory example, some details will be omitted, and some AISC requirements will be used without a detailed explanation.

When dead and live loads are the only loads present, the controlling combination from ASCE 7-02 is usually

$$P_u = 1.2D + 1.6L$$

where P_u is the factored load, D is the dead load, and L is the live load. For this example,

$$P_u = 1.2(30) + 1.6(90) = 180 \text{ kips}$$

From Equation (29.2),

$$\phi_t P_n \geq P_u$$

FIGURE 29.2 Block shear in a tension member.

For the limit state of yielding, from Equation (29.3), this becomes

$$0.90F_y A_g \geq P_u$$

$$A_g \geq \frac{P_u}{0.90F_y} = \frac{180}{0.90(36)} = 5.56 \text{ in.}^2$$

From the Manual of Steel Construction [American Institute of Steel Construction, 2001], an $L5 \times 3^{1/2} \times 3/4$ has a cross-sectional area of 5.82 in.^2 and will be investigated for effective area. For this type of welded connection, the shear lag factor U can be taken as 0.85, so

$$A_e = A_g U = 5.82(0.85) = 4.95 \text{ in.}^2$$

From Equation (29.2) and Equation (29.4), the required effective area is

$$A_e \geq \frac{P_u}{0.75F_u} = \frac{180}{0.75(58)} = 4.14 \text{ in.}^2$$

Since the furnished effective area of 4.95 in.^2 is greater than 4.14 in.^2 , this shape is satisfactory. Use an $L5 \times 3^{1/2} \times 3/4$.

Compression Members

Some truss members are compression members, as are vertical supports in buildings and bridges, where they are usually referred to as columns. This discussion will be limited to *axially loaded* compression members. For a slender axially loaded compression member with pinned ends, the nominal strength is given by the Euler formula as

$$P_n = \frac{\pi^2 EI}{L^2} \quad (29.7)$$

where E is the modulus of elasticity, I is the moment of inertia about the minor principal axis of the member cross-sectional area, and L is the length. This equation can also be expressed in the following form:

$$P_n = \frac{\pi^2 E}{(L/r)^2} \quad (29.8)$$

where r is the radius of gyration and L/r is the **slenderness ratio**. For end conditions other than pinned, L can be replaced by an effective length KL , where K is the effective length factor.

AISC uses a modified form of the Euler formula for slender compression members and an empirical equation for nonslender members. The axial compressive design strength is $\phi_c P_n$, where $\phi_c = 0.85$.

The type of buckling just discussed — that is, buckling about one of the principal axes — is called **flexural buckling**. Other modes of failure include the following:

- **Torsional buckling.** Twisting without bending. This can occur in doubly-symmetrical cross-sections with slender elements (none of the standard hot-rolled shapes is subject to this failure mode).
- **Flexural-torsional buckling.** A combination of bending and twisting. Unsymmetrical cross-sections are susceptible to this type of failure.
- **Local buckling.** Localized buckling of a cross-sectional element such as a web or projecting flange.

FIGURE 29.3 Plate girder details.

Beams

The flexural design strength of a beam is $\phi_b M_n$, where $\phi_b = 0.90$ and M_n is the nominal flexural strength, which is the bending moment at failure. The following discussion will be limited to hot-rolled shapes bent about the major principal axis. The nominal flexural strength is based on one of the following limit states:

- *A fully yielded cross-section.* If a beam is prevented from becoming unstable in any way, the resisting moment will be equal to the internal couple corresponding to a uniform compressive stress of F_y on one side of the neutral axis and a uniform tensile stress of F_y on the other side. This is the **plastic moment**, M_p .
- **Lateral-torsional buckling.** If a beam bent about its major principal axis is not adequately supported laterally (that is, in the direction perpendicular to the plane of bending), it can buckle outward, simultaneously bending about its minor principal axis and twisting about its longitudinal axis.
- *Flange local buckling.* This can occur in the *compression* flange if it is too slender.
- *Web local buckling.* This can occur in the compressed part of the web if it is too slender.

Cross-sections can be categorized as compact, noncompact, or slender, depending on the width-to-thickness ratios of their cross-sectional elements. If a shape is compact, as most of the standard hot-rolled shapes are, neither flange local buckling nor web local buckling can occur. Furthermore, if a compact beam has adequate lateral support, lateral-torsional buckling cannot occur, and the nominal strength is equal to the plastic moment; that is,

$$M_n = M_p \quad (29.9)$$

Adequate lateral support will exist when the distance between points of lateral support, called the *unbraced length*, is less than a prescribed value. If the unbraced length is too large, failure will be by either elastic lateral-torsional buckling or inelastic lateral-torsional buckling, depending on whether yielding has begun when the buckling takes place.

In addition to flexure, beams must be checked for shear strength (which usually does not control) and deflections. Deflections should be computed with service, and not factored, loads.

Flexural members with slender webs are classified by AISC as plate girders; otherwise, they are classified as beams. Plate girders (Figure 29.3) are built up from plate elements that are welded together, and their flexural strength is based on one of the following limit states:

- Tension flange yielding
- Compression flange yielding

- Compression flange buckling, which can take the form of either lateral-torsional buckling or flange local buckling

Because plate girders have slender webs, shear strength is often critical. Part of the shear resistance can come from **tension-field action**, which relies on the post-buckling strength of the web. This component of the shear strength is a function of the spacing of transverse stiffeners, illustrated in [Figure 29.3](#). Bearing stiffeners are usually placed at locations of concentrated loading to protect the web from buckling or compression yielding.

Beam-Columns

Many structural components, particularly those in continuous frames, are subjected to significant amounts of both bending and axial load — either tension or compression. If the axial load is compressive, the member is referred to as a *beam-column*. Because compression adds stability problems, bending plus compression is usually more serious than bending plus tension.

Combined loading can be accounted for by the use of interaction equations of the form

$$\frac{P_u}{\phi_c P_n} + \frac{M_u}{\phi_b M_n} \leq 1.0 \quad (29.10)$$

where each term on the left side is a ratio of a factored load effect to the corresponding design strength. The AISC specification uses two interaction equations: one for small axial loads and one for large axial loads. Furthermore, each equation has two bending terms: one for major axis bending and one for minor axis bending.

In addition to bending moment caused by transverse loads and end moments, beam-columns are subjected to secondary moments resulting from the eccentricity of the axial load with respect to the deflected member axis. This can be accounted for in an approximate, but very accurate, way through the use of **moment amplification** factors as follows:

$$M_u = B_1 M_{nt} + B_2 M_{lt} \quad (29.11)$$

where B_1 and B_2 are amplification factors, M_{nt} is the factored load moment corresponding to no joint translation, and M_{lt} is the factored load moment corresponding to lateral joint translation. If the member is part of a braced frame, then no joint translation is possible and $M_{lt} = 0$. If the member is part of an unbraced frame, M_{nt} is computed as if the member were braced against joint translation, and M_{lt} is computed as the result of only the joint translation.

If bending moments are obtained from a frame analysis computer program that performs a second-order analysis, the moments so obtained will not need to be amplified as in Equation (29.11) but can be used directly in Equation (29.10).

29.2 Connections

Modern steel structures are connected with bolts, welds, or both. Although hot-driven rivets can be found in many existing structures, they are no longer used in new construction.

Bolts

Two types of bolts are used: common and high-strength. Common bolts conform to ASTM A307 and are used in light applications. High-strength bolts are usually ASTM A325 or A490. Bolts can be loaded in tension, shear, or both. In addition, bearing stresses act between the bolts and the connected elements of shear connections. Although bearing is a problem for the connected part and not the bolt itself, the bearing load is a function of the bolt diameter and is therefore associated with the bolt strength. Thus,

FIGURE 29.4 Fillet weld properties.

we may speak of the design strength of a bolted connection being based on shear, bearing, or tension. The shear or tension design strength of a single bolt is ϕR_n , where $\phi = 0.75$ and

$$R_n = F_u A_b \quad (29.12)$$

where F_u is the nominal ultimate shearing or tensile stress and A_b is the cross-sectional area of the bolt. Bearing strength depends upon such things as bolt spacing and edge distance and is a function of the *projected* area of contact between the bolt and the connected part.

High-strength bolts can be snug tight, where the bolts are installed by a single worker with an ordinary wrench, or fully tensioned, where they are installed to a prescribed minimum tension of about 70% of the ultimate strength. Fully tensioned bolts are used in slip-critical connections, in which slippage is not permitted. Slip-critical connections are required for members subjected to impact or fatigue loading. The AISC Specification gives the slip resistance of bolts as a function of bolt pretension and the condition of the contact surfaces.

Welds

Weld material is available in several grades, but E70 or E80 series electrodes are usually used. E70 electrodes have a tensile strength of 70 ksi and are designed to be used with steel that has a yield stress between 36 and 60 ksi. E80 electrodes have a tensile strength of 80 ksi and are used with steels that have a yield stress of 65 ksi. Welding can be performed on the job site (field welds) or in the fabricating shop (shop welds). Because of automation, shop welding is generally more economical and of higher quality. The most common types of welds are the *groove weld*, in which the weld metal is deposited into a gap, or groove, and the *fillet weld* (Figure 29.4), which is deposited into a corner. The fillet weld is the type most often used for field welding.

The strength of a fillet weld is based on the premise that failure will occur by shear on a plane through the throat of the weld. The throat is the perpendicular distance from the root to the hypotenuse on the theoretical cross-section of the weld, which is treated as an isosceles right triangle (Figure 29.4). The design strength of the weld is ϕR_n , where $\phi = 0.75$ and

$$R_n = \text{area} \times \text{ultimate shearing stress} = 0.707wLF_w \quad (29.13)$$

In Equation (29.13), w is the weld size, L is the length, and F_w is the ultimate shearing stress, equal to 60% of the ultimate tensile stress of the electrode.

In many connections it is advantageous to use both welds and bolts, with all welding done in the shop and all bolting done in the field. This will usually be the most economical arrangement, since bolting requires less skilled labor.

29.3 Composite Construction

Structural steel shapes acting in combination with reinforced concrete are called composite members. The most common application is a set of parallel steel beams connected to and supporting a reinforced concrete floor slab. The connection is made by attachments that are welded to the top flange of the beam and embedded in the slab. These attachments, called **shear connectors**, are usually in the form of headed studs. A portion of the slab is considered to act with each steel beam as a supplementary compression flange.

The flexural strength of a composite beam is computed in one of two ways:

1. If the web is compact, the strength is based on the plastic condition. This is when the steel has fully yielded and the concrete has reached its maximum compressive stress of $0.85f'_c$, where f'_c is the 28-day compressive strength.
2. If the web of the steel shape is noncompact, the strength is based on the limit state corresponding to the onset of yielding of the steel.

Deflections of composite beams are computed by the usual elastic methods but are based on the transformed section, in which a consideration of strain compatibility is used to transform the concrete into an appropriate amount of steel. The resulting cross-section can then be treated as a homogeneous steel shape.

The composite column is a combination of materials in which a structural steel shape is encased in concrete and supplemented by vertical reinforcing bars. Structural tubes or pipes filled with concrete are also used. The axial compressive strength of a composite column is computed in essentially the same way as for an ordinary steel shape but with modified values of the yield stress, modulus of elasticity, and radius of gyration.

29.4 Computer Applications

Many commercial computer programs are available to the structural steel designer. These include standard structural analysis programs for statically indeterminate structures as well as those containing an AISC “code-checking” feature. These are available for both ASD and LRFD versions of the AISC specification. If the software is capable of performing a second-order frame analysis, the bending moments can be used directly in Equation (29.10) without the need of using the moment amplification factors B_1 and B_2 .

A database of standard steel shapes, as well as other software, is available from the American Institute of Steel Construction.

Defining Terms

Block shear — A limit state in which a block of material is torn from a member or connecting element such as a gusset plate. When this occurs, one or more surfaces of the block fail in shear, either by fracture or yielding, and another surface fails in tension, either by fracture or yielding.

Design strength — The nominal strength, or resistance, multiplied by a resistance factor. This is a reduced strength that accounts for uncertainties in such things as theory, material properties, and workmanship.

- Flexural buckling** — A mode of failure of an axially loaded compression member where buckling occurs by bending about one of the principal axes of the cross section.
- Flexural-torsional buckling** — A mode of failure of an axially loaded compression member in which it simultaneously buckles about one of the principal axes of its cross-section and twists about its longitudinal axis.
- Lateral-torsional buckling** — A limit state in which a beam buckles by deflecting laterally and twisting. This is prevented by providing lateral bracing at sufficiently close spacing.
- Limit state** — A failure condition upon which the strength of a member is based. Yielding of a tension member is an example of a limit state, and the axial tensile force causing the yielding is the corresponding strength.
- Load factor** — A multiplier of a load effect (force or moment) to bring it to a failure level. A load factor is usually greater than unity, although it can be equal to unity.
- Local buckling** — A localized buckling, or wrinkling, of a cross-sectional element. This form of instability is in contrast to overall buckling, as when a compression member buckles by bending.
- Moment amplification** — An approximate technique used to account for the secondary bending moment in beam-columns. The total moment is obtained by multiplying the primary moment by a moment amplification factor.
- Nominal strength** — The theoretical strength of a member before reduction by a resistance factor.
- Plastic moment** — The bending moment necessary to cause yielding throughout the depth of a given cross-section. There will be a uniform compressive stress equal to the yield stress on one side of the neutral axis and tension yielding on the other side. The plastic moment can be attained if the beam does not buckle prior to reaching this state.
- Resistance factor** — A reduction factor applied to the nominal, or theoretical, resistance (strength). Although it can be equal to unity, it is usually less than unity.
- Shear connectors** — Devices that are welded to the top flanges of beams and embedded in the concrete slab supported by the beams. The most common type of shear connector is the headed stud.
- Shear lag** — A reduction in the strength of a tension member caused by not connecting some of the cross-sectional elements. It is accounted for by reducing the actual area of the member to an effective area.
- Slenderness ratio** — The ratio of the effective length of a member to the radius of gyration about one of the principal axes of the cross-section.
- Tension field** — A condition existing in the buckled web of a plate girder in which the web cannot resist compression but is capable of resisting the diagonal tension within a panel defined by transverse web stiffeners.
- Torsional buckling** — A limit state for axially loaded compression members in which the member twists about its longitudinal axis.

Further Information

The American Institute of Steel Construction is a source of useful and up-to-date information on structural steel design. A monthly magazine, *Modern Steel Construction*, available in both printed and online versions, provides information on structural steel construction projects, technical issues, and AISC activities. The *AISC Engineering Journal* is a quarterly refereed journal containing technical papers with a practical orientation. Approximately every two years, AISC conducts a national lecture series on structural steel design topics of current interest, and the annual AISC North American Steel Construction Conference provides a forum for designers, fabricators, and producers.

The commentary that accompanies the AISC specification is a valuable source of background material. This document, which along with the specification is contained in the *Manual of Steel Construction*, explains and elaborates on the specification provisions. The *Manual* also contains many illustrative examples and discussions.

Several textbooks on structural steel design are available. Comprehensive works covering both allowable stress design and LRFD include *Design of Steel Structures*, by E. H. Gaylord, C. N. Gaylord, and J. E. Stallmeyer; and *Steel Structures, Design and Behavior*, by C. G. Salmon and J. E. Johnson. *Structural Steel Design: ASD Method*, by J. C. McCormac, is a current book on allowable stress design. *Structural Steel Design: LRFD Method*, by J. C. McCormac, and *LRFD Steel Design*, by W. T. Segui, treat load and resistance factor design exclusively.

30.1 Structural Concrete

Structural concrete is a product composed of a properly designed mixture comprising portland cement, coarse aggregate (stone), fine aggregate (sand), water, air, and chemical admixtures. The cement acts as the binding matrix to the aggregate and achieves its strength as a result of a process of hydration. This chemical process results in recrystallization in the form of interlocking crystals producing the cement gel, which has high compressive strength when it hardens. The aggregate could be either natural, producing normal concrete, weighing 150 lb/ft³ (2400 kg/m³), or artificial aggregate, such as pumice, producing lightweight concrete weighing ~110 lb/ft³ (1750 kg/m³).

Structural concrete should have a cylinder compressive strength of 3000 psi (20 MPa) at least, but often exceeding 4000 to 5000 psi (34.5 MPa). As the strength exceeds 6000 psi (42 MPa), such concrete is presently considered high-strength concrete. Concrete mixtures designed to produce 6000 to 12,000 psi are easily obtainable today with the use of silica fume or high-range water-reducing agents (plasticizers) to lower the water/cement ratio and hence achieve higher strength and a high performance due to the lower water content in the mix. A low water/cement or water/cementitious ratio of 30 to 25% can be achieved with these admixtures, with good workability and high slump fluidity for placing the concrete in the framework.

Concretes of compressive strengths reaching 20,000 psi (140 MPa) have been used in some buildings in the U.S. Such high strengths merit qualifying such concrete as ultra-high-strength concrete.

Admixtures in Concrete

Admixtures in concrete can be summarized as follows:

1. *Accelerating admixtures.* They hasten the chemical hydration process.
2. *Air-entraining admixtures.* They form minute bubbles 1 mm in diameter and smaller evenly distributed in the mix to protect the concrete from freeze and thaw cycles.
3. *Water-reducing and set-controlling admixtures.* They increase the strength of the concrete through reducing the water content but maintaining the slump (fluidity) of the concrete.
4. *Polymers.* They replace a major portion of the needed water content and can produce concretes of strength in excess of 15,000 psi.
5. *Superplasticizers.* These are high-range water-reducing chemical admixtures. A dosage not exceeding 1 to 2% by weight of cement is recommended.
6. *Silica fume admixtures.* They are pozzolanic materials as a byproduct of high-quality quartz with coal in the electric arc furnace that produces silicon and ferrosilicon alloys. They are used to attain very high-strength concrete in 3 to 7 days with relatively less increase in strength than normal concrete after 28 days. A dosage of 5 to 30% by weight of the cement can be used, depending on the strength needed. A compressive strength of 15,000 psi (105 MPa) or more can be readily achieved with good quality control.

Properties of Hardened Concrete

The mechanical properties of hardened concrete can be classified as (1) short-term or instantaneous properties, and (2) long-term properties.

The short-term properties can be enumerated as (1) strength in compression, tension, and shear, and (2) stiffness measured by the modulus of elasticity. The long-term properties can be classified in terms of creep and shrinkage:

1. *Compressive strength, f'_c .* It is based on crushing 6-in. diameter by 12-in. height standard concrete cylinders at a specified loading rate in a compression testing machine.
2. *Tensile strength, f'_t .* Tensile strength of concrete is relatively low. A good approximation of tensile strength is f'_t ranging between 10 and 15% of f'_c .
3. *Shear strength, v_c .* This value is more difficult to determine experimentally. It can vary from about $2\sqrt{f'_c}$ for normal-weight reinforced concrete beams to about 80% f'_c in direct shear combined with compression.
4. *Modulus of elasticity E_c for stiffness or ductility determination.* The **ACI 318-05 Code** [ACI Committee 318, 2005] specifies using a secant modulus, given in psi or MPa:

$$E_c = 33W_c^{1.5} \sqrt{f'_c} \text{ psi} \quad (30.1)$$

$$E_c = 0.043W_c^{1.5} \sqrt{f'_c} \text{ MPa} \quad (30.2)$$

5. *Shrinkage.* There are two types of shrinkage: plastic shrinkage and drying shrinkage. *Plastic shrinkage* occurs during the first few hours after placing fresh concrete in the forms, resulting in a random map of cracks. *Drying shrinkage* occurs *after* the concrete has already attained its final set and a good portion of the chemical hydration process in the cement gel has been accomplished. Drying shrinkage results in well-defined linear cracks of larger width than plastic shrinkage cracks.
6. *Creep.* This is the lateral flow of the material under external load. The member sustains an increase in lateral strains with time due to the sustained load, hence increased stresses occur in the member and sometimes an almost 100% increase in deflection with time.

Details of all these effects and the ACI 318 Code provisions to control them in the design of reinforced and prestressed concrete structures are given in Nawy [2005a,b].

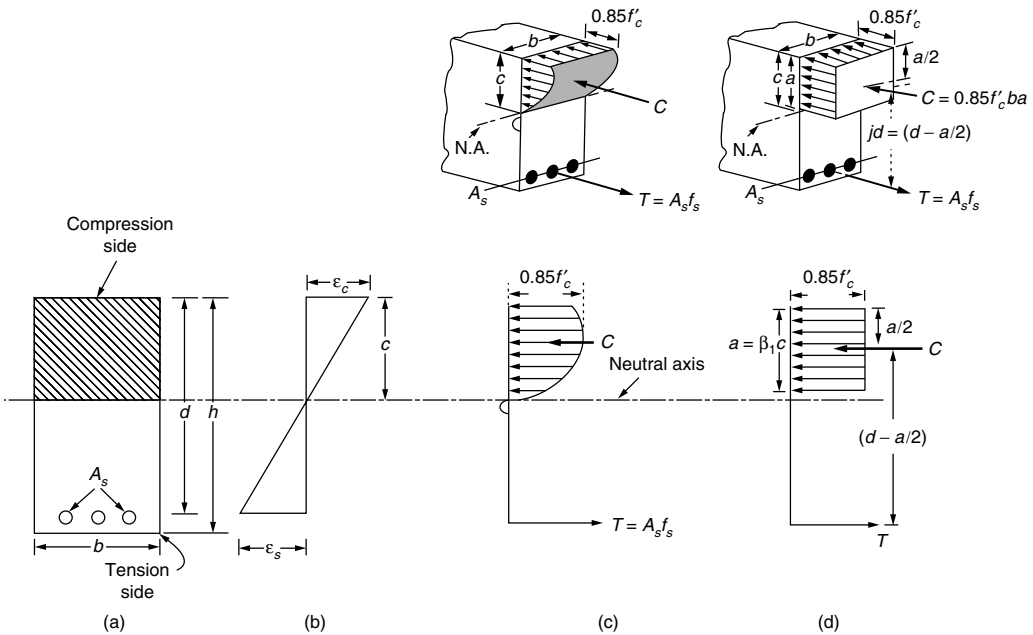

FIGURE 30.1 Stress and strain distribution across reinforced concrete beam depth: (a) beam cross-section, (b) strain distribution, (c) actual stress block, (d) assumed equivalent block. (Source: Nawy, E. G., 2003. *Reinforced Concrete — A Fundamental Approach*, 5th ed. Prentice Hall, Upper Saddle River, NJ.)

30.2 Flexural Design of Reinforced Concrete Members

General Principles

Concrete structural systems are generally composed of floor slabs, **beams**, **columns**, walls, and foundations. Present codes of practice (ACI, PCI, CEB, UBC, IBC) all require ultimate strength procedures in proportioning the structural elements, what is termed *strength design* by the code of the American Concrete Institute (ACI 318-05).

The strength of a particular structural unit is termed *nominal strength*. For example, in the case of a beam, the resisting moment capacity of the section calculated using the equations of equilibrium and the properties of the concrete and the steel reinforcement is called *nominal moment strength* M_n . This nominal strength is reduced using a strength reduction factor, ϕ , to account for inaccuracies in construction such as in the geometrical dimensions or position of reinforcing bars or variation in concrete properties.

The design principles are based on equilibrium of forces and moments in any section. Since concrete is weak in tension, the design assumes that the concrete in the tensile part of a beam cross section does *not* carry any load or stress, hence it is disregarded. By doing so, the tensile equilibrium force is wholly taken by the tension bars A_s , in Figure 30.1(a). The actual distribution of compressive stress is parabolic, as seen in Figure 30.1(c). However, the ACI Code adopted the use of an equivalent rectangular block, as in Figure 30.1(d), in order to simplify the computations.

Singly Reinforced Beam Design

Such a beam would have reinforcement only on the tension side. If one considers the equilibrium forces in Figure 30.1(d):

$$C = \text{Volume of the equivalent rectangular block} = 0.85 f'_c b a$$

$$T = \text{Tensile force in the reinforcement} = A_s f_y, \text{ where } f_y = \text{yield strength of the reinforcement}$$

Then $C = T$ or $0.85 f'_c b a = A_s f_y$. Therefore, the depth of the equivalent rectangular block is

$$a = \frac{A_s f_y}{0.85 f'_c b} \quad (30.3)$$

Since the center of gravity of the compressive force C is at a distance $a/2$ from the top compression fibers, the arm of the moment couple is $[d - (a/2)]$. Hence, the nominal moment strength of the section is

$$M_n = A_s f_y \left(d - \frac{a}{2} \right) \quad (30.4)$$

Note that if the total thickness of the section is h , Equation (30.4) considers d the effective depth to the centroid of the reinforcement, thereby disregarding the concrete cover and assuming it to be only for fire and corrosion protection. The percentage of reinforcement is $\rho = A_s / bd$, and the reinforcement index is $\omega = (A_s / bd) \times (f_y / f'_c)$. Hence, Equation (30.4) can also be written as

$$M_n = [\omega f'_c (1 - 0.59\omega)] b d^2 \quad (30.5)$$

If one uses

$$R = \omega f'_c (1 - 0.59\omega) \quad (30.6)$$

then $M_n = R b d^2$. Figure 30.2, for singly reinforced beams, can give a rapid choice of the width and depth of a beam section, as one can usually use $b = \frac{1}{2} d$. For doubly reinforced beams and for T-beams, the R value obtained from Equation 30.6 should be increased by about 50% for the first trial.

FIGURE 30.2 Strength R curves for singly reinforced concrete beams. (Source: Nawy, E. G., 2005. *Reinforced Concrete — A Fundamental Approach*, 5th ed. Prentice Hall, Upper Saddle River, NJ.)

Interpolation on c/d_t : Spiral $\phi = 0.70 + 0.2[1/(c/d_t) - 5/3]$

Other $\phi = 0.65 + 0.25[1/(c/d_t) - 5/3]$

FIGURE 30.3 Strain limits zones and variation of strength reduction factor ϕ with the net tensile strain ϵ_t (ACI 318-05 Code).

In order to ensure ductility of the structural member and corresponding warning of failure, the ACI Code stipulates a **limit strain** in the reinforcement closest to the tensile face of the section that has to exceed $\epsilon_t = 0.005$. It is advisable to use a strain value in the range of 0.007, which is essentially equivalent to using 50% of the balanced reinforcement ratio used in previous ACI 318 versions of the code in flexural members, such as beams and one-way and two-way slabs. One way of ensuring this higher strain value is to assume the ratio c/d_t to be about 75% of the 0.375 ratio given in Figure 30.3.

This strain state is termed as the **tension-controlled** state, shown in Figure 31.3. In sections subjected to combined flexure and compression, such as column-beams, the limit strain ranges are the **transition** state and the **compression-controlled** state, where lower strain limits are stipulated in the Code. The three strain limits zones and the strength reduction factor ϕ for these zones are shown in Figure 30.3.

The code also requires a minimum reinforcement area so that the beam can behave as a reinforced concrete section. The minimum $A_s = (3\sqrt{f_c} / f_y) b_w d$ or $200 / f_y$ whichever is larger, where b_w = width of the beam web. For the tension reinforcement in flanged sections, twice the minimum A_s in the preceding expressions is required to be used.

Design Example

A simply supported singly reinforced concrete beam is subjected to a total factored moment including its self weight, $M_u = 4.1 \times 10^6$ in.-lb. Given values are $f'_c = 4000$ psi (34.5 MPa), $f_y = 60,000$ psi (414 MPa).

Solution

Required nominal moment strength M_n equals M_u/ϕ , where $\phi = 0.90$ for flexure: $M_n = 4.1 \times 10^6 / 0.90 = 4.56 \times 10^6$ in.-lb. The strain ϵ_t has to exceed 0.005 in order to ensure ductile behavior. Hence use a c/d_t ratio = $0.75 \times 0.375 = 0.281$.

Equation (30.5) yields

$$R = \omega f'_c (1 - 0.59\omega) = 0.215 \times 4000 (1 - 0.59 \times 0.215) \approx 750.$$

Alternatively, entering the chart in Figure 30.2 gives $R \approx 750$. Assuming $b = \frac{1}{2}d$, Equation (30.6) yields

$$d = \sqrt[3]{\frac{M_n}{0.5R}} = \sqrt[3]{\frac{4.5 \times 10^6}{0.5 \times 750}} = 22.8 \text{ in.}$$

Based on practical considerations, use $b = 12$ in. (305 mm), $d = 23$ in. (585 mm), and total depth $h = 26$ in. (660 mm).

$$c = 0.281 \times 23 = 6.46 \text{ in. } a = \beta_1 c = 0.85 \times 6.46 = 5.49 \text{ in.}$$

$$C = 0.85 f'_c b a = 0.85 \times 4000 \times 12 \times 5.49 = 223,992 \text{ lb} = A_s f_y \text{ for equilibrium}$$

of forces giving $A_s = 3.79 \text{ in.}^2$

Hence, try three #10 bars (32.2 mm diameter), $A_s = 3.81 \text{ in.}^2$ (2460 mm²).

To check nominal moment strength, use Equation (30.3) to find the depth of the compression block:

$$a = \frac{A_s f_y}{0.85 f'_c b} = \frac{3.81 \times 60,000}{0.85 \times 4000 \times 12} = 5.60 \text{ in.}$$

From Equation 30.4, available $M_n = 3.81 \times 60,000 [23.0 - (5.49/2)] = 4.64 \times 10^6 \text{ in.-lb}$ ($5.2 \times 10^5 \text{ kN-M}$) > Required $M_n = 4.56 \times 10^6 \text{ in.-lb}$; adopt design.

A check for minimum reinforcement and shear capacity also has to be performed, as must deflection and crack control, as detailed in [Nawy, 2003a].

$$\text{Overdesign} = \frac{4.64 - 4.56}{4.56} = 1.8\%$$

Overdesign should not be in excess of 4 to 6%.

Doubly Reinforced Sections

These are beam sections where compression reinforcement A'_s is used about 2 in. from the compression fibers. The reinforcement A'_s contributes to reducing the required depth of section where there are clearance limitations. An extra nominal moment $M' = A'_s f_y (d - d')$ is added to the section, d' being the depth from the extreme compression fibers to the centroid of the compression reinforcement A'_s . Consequently, Equation (30.4) becomes

$$M_n = (A_s - A'_s) f_y \left(d - \frac{a}{2} \right) + A'_s f_y (d - d') \quad (30.7)$$

A similar expression to Equation (30.7) can be derived for flanged sections, as in Nawy [2003a].

Columns

Columns are compression members that can fail either by material failure if they are nonslender or by buckling if they are slender. Columns designed using the material failure criteria should have a slenderness ratio kl/r not to exceed 22 for nonbraced columns. The value k is the stiffness factor at column ends, l is the effective length, and r is the radius of gyration = $0.3h$ for rectangular sections.

A column is essentially a doubly reinforced flexural section that is also subjected to an axial compression force P_n in addition to the forces C and T as given in Equation (30.8) and Equation (30.9), and shown in [Figure 30.1](#). Therefore, from equilibrium of forces,

$$P_n = 0.85f'_c b a + A'_s f'_s + A_s f_s \quad (30.8)$$

$$M_n = P_{ne} = 0.85f'_c b a \left(\bar{y} - \frac{a}{2} \right) + A'_s f'_s (\bar{y} - d') + A_s f_s (d - \bar{y}) \quad (30.9)$$

$$e = \frac{M_n}{P_n} = \text{eccentricity}$$

where \bar{y} = distance to center of gravity of section = $h/2$ for rectangular section. Notice the similarities between Equation (30.9) and Equation (30.7).

Although initial failure in beams is always by yielding of the reinforcement through limiting ρ , this is not possible in columns, as the mode of failure depends on the magnitude of eccentricity, e , determined by the strain level ϵ_t value in the range of $0.002 \leq \epsilon_t \leq 0.005$. A strain state $\epsilon \leq 0.002$ would denote a concrete section in the compression-controlled region, such as columns subjected to axial compression, as the most common cases.

This subject is very extensive, particularly if buckling is also to be considered. The reader is advised to consult textbooks such as [Nawy, 2003a] and/or specialized handbooks.

Walls and Footings

The same principles for the flexural design of beams and slabs apply to walls and footings. An isolated footing is an inverted cantilever supported by a column and subjected to uniform soil pressure. It is treated as a singly reinforced beam [Equation (30.4)] subjected to a factored moment $M_u = w_u l^2 / 2$, where w_u is the intensity of load per unit length and l is the arm of the cantilever. In the same manner, one can design retaining walls and similar structural systems.

30.3 Shear and Torsion Design of Reinforced Concrete Members

Shear

External transverse load is resisted by internal **shear** in order to maintain section equilibrium. As concrete is weak in tension, the principal tensile stress in a beam cannot exceed the tensile strength of the concrete. The principal tensile stress is composed of two components — shear stress, v , and tensile stress, f_t — causing diagonal tension cracks at a distance d from the face of the support in beams and at a distance $d/2$ from the face of the support in two-way slabs.

Consequently, it is important that the beam web be reinforced with diagonal tension steel, called *stirrups*, in order to prevent diagonal shear cracks from opening. The resistance of the plain concrete in the web sustains part of the shear stress, and the balance has to be borne by the diagonal tension reinforcement. The shear resistance of the plain concrete in the web is termed *nominal shear strength*, V_c . A conservative general expression for V_c from the ACI 318 code is

$$V_c (\text{lb}) = 2.0 \lambda \sqrt{f'_c} b_w d \quad (30.10)$$

$$V_c (\text{newton}) = \lambda \left(\sqrt{f'_c} / 6 \right) b_w d \quad (30.11)$$

where f'_c is in MPa in Equation (30.11) and λ equals

- 1 for stone aggregate concrete
- 0.85 for sand-lightweight concrete
- 0.75 for all lightweight concrete

If $V_n = V_u/\phi$ = the required nominal shear, the stirrups should be designed to take the difference between V_u and V_c — namely, $V_s = [(V_u/\phi) - V_c]$ — where V_u is the factored external shear and $\phi = 0.75$ in shear and torsion. The spacing of the transverse web stirrups is hence

$$s = \frac{A_v f_y d}{(V_u / \phi - V_c)} \quad (30.12)$$

where A_v = cross-sectional area of the web steel (two stirrup legs). Maximum spacing of stirrups is $d/2$ or 12 in., whichever is smaller. A concrete section designed for flexure as described earlier has to be enlarged if $V_s = (V_n - V_c) > 8 \sqrt{f'_c}(b_w d)$.

Torsion

If a beam is also subjected to **torsion** combined with shear, diagonal cracks described in the previous section have to be prevented from opening. This is accomplished by use of *both* vertical closed stirrups and additional longitudinal bars evenly divided among the four faces of the beam.

The longitudinal reinforcement is required since torsion causes a three-dimensional warped surface. The ACI 318-05 code disallows utilization of the nominal torsional strength T_c of the plain concrete in the web and requires that all the torsional moment T_n be borne by the transverse closed stirrups and the longitudinal bars. It assumes that the volume of the transverse stirrups is equal to the volume of the longitudinal bars. The same equations for torsion in reinforced concrete elements are used with adjusting modifiers when applied to prestressed concrete.

Design of the particular component needs to be based on the limit state at failure. Therefore, the nonlinear behavior of a structural system after torsional cracking must be identified in one of the following two conditions

1. No redistribution of torsional stresses to other members after cracking (**equilibrium torsion**)
2. Redistribution of torsional stresses and moments after cracking to effect deformation compatibility between intersecting members (**compatibility torsion**)

For the first case, an edge beam supporting a cantilever canopy is such an example where the edge beam has to be designed to resist the *total* external factored twisting moment due to the cantilever slab; otherwise, the structure will collapse. In the second case, such as in statically indeterminate systems, stiffness assumptions, compatibility of strains at the joints, and redistribution of stresses may affect the stress resultants, leading to a **reduction** in the resulting torsional shearing stresses. The ACI Code permits a maximum factored torsional moment at the critical section d from the face of the supports for reinforced concrete members to be used in the design as follows:

$$T_u = \phi 4 \sqrt{f_c} \left(\frac{A_{cp}^2}{p_{cp}} \right) \quad (30.13a)$$

where A_{cp} = area enclosed by outside perimeter of concrete cross-section and p_{cp} = outside perimeter of concrete cross-section A_{cp} in.

The available torsional moment strength is computed from the following expression:

$$T_n = \frac{2A_o A_l f_{yv}}{s} (\cot \theta) \quad (30.13b)$$

where A_o = gross area enclosed by the shear flow, A_l = area of the added torsional longitudinal steel bars, s = spacing of transverse ties, and $\theta = 45^\circ$ for reinforced concrete and 37.5° for prestressed concrete.

FIGURE 30.4 Stress distribution at service load in prestressed concrete beams with constant tendons. (Source: Nawy, E. G., 2003. *Prestressed Concrete — A Fundamental Approach*, 4th ed. Prentice Hall, Upper Saddle River, NJ.)

30.4 Prestressed Concrete

Reinforced concrete is weak in tension but strong in compression. To maximize utilization of its material properties, an internal compressive force is induced in the structural element through the use of highly stressed prestressing tendons to precompress the member prior to application of the external gravity live load and superimposed dead load. Typical effect of the prestressing action is shown in Figure 30.4, using a straight tendon, as is usually the case in precast elements. For *in situ*-cast elements, the tendon can be either harped or usually draped in a parabolic form. As can be seen from Figure 30.4, the prestressing force P alone induced a compressive stress at the bottom fibers f_b and a tensile stress at the top fibers f_t such that

$$f_b = -\frac{P_i}{A} - \frac{P_i e c}{I} \tag{30.14a}$$

$$f_t = -\frac{P_i}{A} + \frac{P_i e c}{I} \tag{30.14b}$$

where P_i is the initial prestressing force prior to losses.

With addition of stress due to self-weight of the concrete beam and external live and superimposed dead load — moment M_T — the stresses become:

$$f_b = -\frac{P_e}{A} - \frac{P_e c}{I} + \frac{M_T c}{I} \tag{30.15a}$$

$$f_t = -\frac{P_e}{A} + \frac{P_e c}{I} - \frac{M_T c}{I} \tag{30.15b}$$

where P_e is the effective prestressing force after losses in prestress.

The stress diagram at the extreme right in Figure 30.4 indicates zero tension at the bottom fibers and maximum compression at the top fibers. In this manner, prestressing the beam has resulted in full utilization of the properties of the concrete, eliminating tension cracking at the bottom fibers.

Whereas reinforced concrete members are designed only for ultimate load, prestressed concrete members are first designed for service load moments as in Equation (30.15) and then analyzed for ultimate load capacity, namely, the nominal moment strength M_n . This is necessary for determining the reserve strength available in the member between the service load level and collapse, as prestressed beams can be underreinforced (tension steel yielding) or overreinforced (compression side concrete crushing). Figure 30.5 gives the sets of equilibrium forces acting on the concrete section. Notice their similarity to

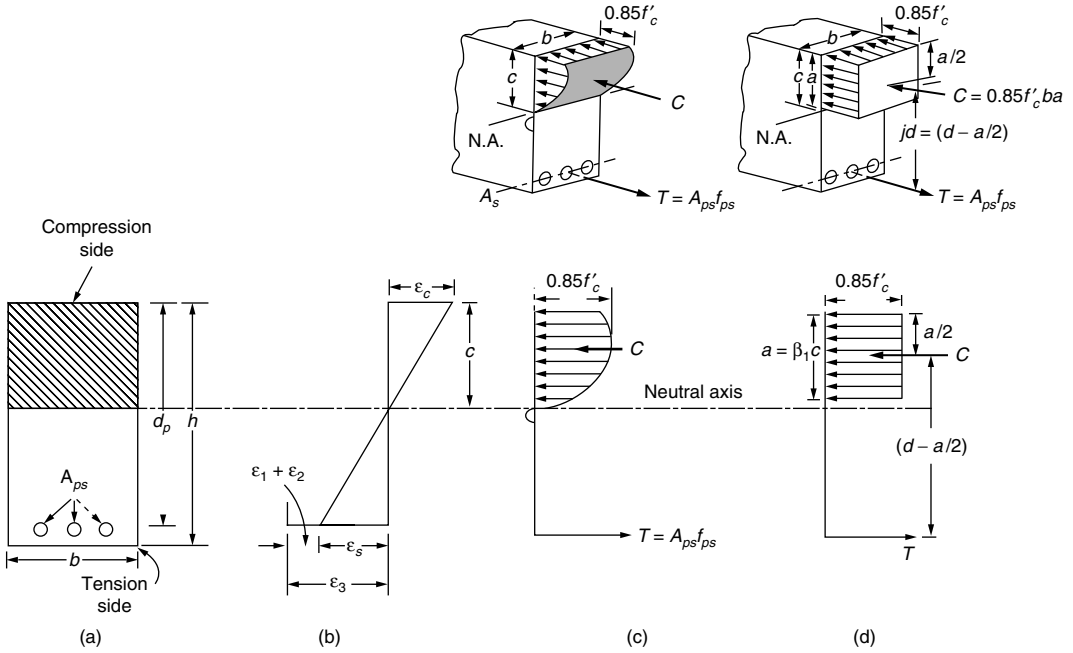

FIGURE 30.5 Stress and strain distribution across prestressed concrete beam depth: (a) beam cross-section, (b) strain distribution, (c) actual stress block, (d) assumed equivalent block. (Source: Nawy, E. G., 2003. *Prestressed Concrete — A Fundamental Approach*, 2nd ed. Prentice Hall, Upper Saddle River, NJ.)

those of reinforced concrete sections in Figure 30.1. If both prestressing tendons and mild steel are used in the prestressed beam, the nominal moment strength is

$$M_n = A_{ps} f_{ps} \left(d_p - \frac{a}{2} \right) + A_s f_y \left(d - \frac{a}{2} \right) + A'_s f_y (d - d') \quad (30.16)$$

It should be noted that the prestressing force P used at the service load design level should be the effective force P_e obtained from reducing the initial prestressing force, P_p in Equation (30.14) to the effective service load, P_e , caused by losses due to concrete shrinkage, concrete creep, relaxation of the prestressing steel, frictional losses in posttensioned beams, and anchorage loss. A loss in the initial prestress of 20 to 25% is not unreasonable, so P_e is quite often 0.75 to 0.80 P_p .

The ACI code prescribes the following allowable stresses at service load. For concrete stresses

| | | |
|---------------------------------|------------------------|----------------------------------|
| $f'_{ci} \approx 0.75 f'_c$ psi | | |
| $f'_{ci} \approx 0.60 f'_c$ psi | | |
| $f_{ti} = 3\sqrt{f'_{ci}}$ psi | on span | $(\sqrt{f'_c}/4 \text{ MPa})$ |
| $= 6\sqrt{f'_{ci}}$ psi | at support | $(\sqrt{f'_{ci}}/2 \text{ MPa})$ |
| $f_c = 0.45 f'_c$ to | $0.60 f'_c$ | |
| $f_t = 6\sqrt{f'_c}$ psi | | $(\sqrt{f'_c}/2 \text{ MPa})$ |
| $= 12\sqrt{f'_c}$ psi | if deflection verified | $(\sqrt{f'_c} \text{ MPa})$ |

and for reinforcing tendon stresses

| | |
|---|---------------------------------------|
| Tendon jacking: | $f_{ps} = 0.94f_{py} \leq 0.80f_{pu}$ |
| Immediately after stress transfer: | $f_{ps} = 0.82f_{py} \leq 0.74f_{pu}$ |
| Posttensioned members at anchorage immediately after anchorage: | $f_{ps} = 0.70f_{pu}$ |

where

| | | |
|----------|---|--|
| f_{ps} | = | Ultimate design stress allowed in tendon |
| f_{py} | = | Yield strength of tendon |
| f_{pu} | = | Ultimate strength of tendon |
| f_{ti} | = | Initial tensile stress in concrete |
| f_c | = | Service load concrete compressive strength |
| f_{ci} | = | Initial compressive stress in concrete |
| f_t | = | Service load concrete tensile strength |

30.5 Serviceability Checks

Serviceability of structural components is a major factor in designing structures to sustain acceptable long-term behavior. It is controlled by limiting deflection and cracking.

For deflection computation and control, an effective moment of inertia is used. Details of design for deflection in reinforced concrete beams and slabs and for deflection and camber in prestressed concrete with design examples are given in ACI Committee 435 [1995]. Table 30.1 (from ACI) gives the allowable deflections in terms of span for reinforced concrete beams.

For crack control in beams and two-way slab floor systems, it is more effective to use smaller-diameter bars at smaller spacing for the same area of reinforcement. ACI Committee 224 [2001] gives a detailed treatment of the subject of crack control in concrete structures. Table 30.2 gives the tolerable crack widths in concrete elements.

TABLE 30.1 Minimum Thickness, h , of Nonprestressed Beams or One-Way Slabs (ACI 319-02 Code)

| Member ^a | Simply Supported | One End Continuous | Both Ends Continuous | Cantilever |
|-------------------------------|------------------|--------------------|----------------------|------------|
| Solid one-way slabs | $l/20$ | $l/24$ | $l/28$ | $l/10$ |
| Beams or ribbed one-way slabs | $l/16$ | $l/18.5$ | $l/21$ | $l/8$ |

Note: Span length l is in inches. For f_y values greater than 60,000 psi, the tabulated values should be multiplied by $(0.4 + f_y/100,000)$.

^a Members not supporting or attached to partitions or other construction are likely to be damaged by large deflections.

TABLE 30.2 Tolerable Crack Widths (ACI 224-01 Report)

| Exposure Condition | Tolerable Crack Width | |
|--|-----------------------|------|
| | in. | mm |
| Dry air or protective membrane | 0.016 | 0.40 |
| Humidity, moist air, soil | 0.012 | 0.30 |
| Deicing chemicals | 0.007 | 0.18 |
| Seawater and seawater spray; wetting and drying | 0.006 | 0.15 |
| Water-retaining structures (excluding nonpressure pipes) | 0.004 | 0.10 |

30.6 Computer Applications for Concrete Structures

In the design of concrete structures, several canned computer programs are available both for reinforced concrete and prestressed concrete systems. They can be either analysis or design programs. These programs are available for personal computers using MS-DOS or MS Windows operating systems. Typical general purpose programs are STRUDEL, ANSYS, SAP Professional, and ETABS. The SAP Professional program can handle in excess of 5000 nodes and requires a larger memory than the others. Except for lack of space, a long list of available programs could be compiled here. The structural engineer can without difficulty get access to all present and forthcoming programs in the market.

The specialized concrete programs are numerous. The following programs are widely used. PCA programs include

1. *ADOSS*. For two-way reinforced concrete slabs and plates
2. *PCA Columns*. For nonslender and slender regular and irregular columns
3. *PCA Frame*. For analysis of reinforced concrete frames, including second-order analysis for slender columns taking into account the $P - \Delta$ effect
4. *PCA MATS*. For the design of flexible mat foundations

Other programs include

1. *ADAPT*. A comprehensive program for the design of reinforced and prestressed concrete two-way action slabs and plates with the capability of drafting many AUTOCAD version 12.0
2. Miscellaneous design or analysis programs for proportioning sections:
 - NRCPAPI*. For reinforced concrete sections [Nawy, 2003a]
 - NRCPAPII*. For prestressed concrete sections [Nawy, 2003b]
 - RCPCDH*. For reinforced concrete beams, columns, and isolated footings
 - RISA2D* and *RISA3D*. General purpose programs for both steel and concrete and frame analysis

Among drafting programs, AUTOCAD is a comprehensive general purpose program very widely used for drafting working drawings including reinforcing details.

In summary, it should be emphasized that the computer programs discussed in this section are only representative. Other good software is available and being developed with time. Users should always strive to utilize the program that best meets their particular needs, preferences, and engineering backgrounds.

Defining Terms

Admixtures — Chemical additives to the concrete mix that change the mechanical and performance characteristics of the hardened concrete.

ACI — American Concrete Institute.

Beams — Supporting elements to floors in structural systems.

Codes — Standards governing the design and performance of constructed systems to ensure the safety and well-being of the users.

Columns — Vertical compression supports.

Ductility — Ability of the member to absorb energy and deform in response to external load.

Flexure — Bending of a structural element due to applied load.

Footings — Foundation elements within the soil supporting the superstructure.

PCI — Prestressed Concrete Institute.

Prestressed concrete — Concrete elements such as beams, columns, or piles subjected to internal (or external) compression prior to the application of external loads.

Serviceability — Cracking and deflection performance of a structural member or system.

Shear — Force due to external load acting perpendicular to the beam span to shear the section.

Torsion — Twisting moment on a section.

IBC — International Building Code.

UBC — Uniform Building Code.

University, Pomona*

- 31.1 Durability of Wood
- 31.2 Wood Product
- 31.3 Member Design
- 31.4 Connections
- 31.5 Lateral Force Design

The four primary building materials used in the construction of civil engineering structures are reinforced concrete, reinforced masonry, structural steel, and *timber*. This chapter will give a brief introduction to *engineered wood structures*.

Wood is often used as the framing material in low-rise buildings (one to four stories), but timber has been used in taller structures. Bridges are also constructed from wood and are generally limited to relatively short-span bridges on rural and forest service roads, but glued-laminated timber framing has been used in the construction of some highway bridges. Wood is also used in foundation systems such as timber piles; utility poles and towers are other examples of wood structures. In addition to these more permanent structures, wood is commonly used for such temporary structures as concrete formwork and falsework and for shoring of trenches during construction. Although many residential structures are engineered to some extent, wood is also used as a structural material in many nonengineered homes that fall into a category known as conventional construction.

As a biological product, wood is a unique structural material. It is a renewable resource that can be obtained by growing and harvesting new trees. Proper forest management is necessary to provide a sustainable supply of wood products and to ensure that this is accomplished in an environmentally responsible way.

Wood can be used to create permanent structures. However, the proper use of wood as a structural material requires that the designer be familiar with more than stress calculations. Pound for pound, wood is stronger than many materials, but wood also has characteristics that, if used improperly, can lead to premature failure. Understanding the unique characteristics of wood is the key to its proper use.

31.1 Durability of Wood

In addition to being overstressed by some types of loading, a wood structure can be destroyed by several environmental causes, including decay, insect attack, and fire.

The moisture content of wood is defined as the weight of water in the wood expressed as a percentage of the oven dry weight of the wood. In a living tree the moisture content can be as high as 200%. In a structure, the moisture content of a wood member will be much less, and for a typical enclosed building the moisture content will range between 7 and 14%, depending on climate. However, if a structure houses a swimming pool or if there are high humidity conditions as in certain manufacturing plants, higher moisture contents will occur.

The best recommendation for preventing *decay* is to keep wood continuously dry. Special detailing may be required to accomplish this. However, the low moisture content of framing lumber in most enclosed buildings generally does not lead to decay. High moisture content or exposure to the weather (alternate wetting and drying) will cause decay in untreated wood products.

Wood that will be exposed to the weather or subject to other high-moisture conditions can be pressure impregnated with an approved chemical treatment to protect against decay. Pressure-treated lumber is obtained from a processing plant that specializes in treating wood products by forcing the appropriate chemicals under pressure into the wood cells. Paint-on chemicals are generally not effective.

Wood can also be destroyed by *insect attack*. Termites are the most common pest, but marine borers are found in ocean water. Termite protection may be obtained by providing a physical barrier, by maintaining a minimum clearance between the wood and soil, or by using pressure-treated wood. The same pressure-treated lumber is effective for both decay and termite protection. Marine borers require a different chemical treatment.

Fire is a threat to any structure, whether it is wood, steel, concrete, or masonry. However, wood is a combustible material, and building codes place restrictions on the height, area, and occupancy classification of a building that uses wood framing. Wood becomes harder to ignite as the cross-sectional dimensions of the framing members increase. Consequently, building codes recognize both *light-frame wood construction* (using relatively small size framing members) and *heavy-timber (HT) construction*. In a fire, a large wood member performs much better because a protective coating of char develops that helps to insulate the member.

31.2 Wood Products

The following wood products are used in structural design:

1. *Solid sawn lumber* (sawn lumber). Lumber of rectangular cross-section cut from trees. A variety of species of commercial lumber are available, and a variety of stress grades are available for each species group. Tabulated design stresses depend on the size category of a member in addition to grade. Size categories include dimension lumber, beams and stringers, posts and timbers, among others. The nominal size of a member (such as 4 × 12) is used for call-out purposes, but actual cross-sectional dimensions are less. Most grading of lumber is done by visual inspection, but some material is machine stress rated. The maximum size of sawn lumber is limited by tree size.
2. *Structural glued-laminated timber* (glu-lam). Lumber formed by gluing together small pieces (usually 2 in. nominal thickness) of wood to form virtually any size structural member. Laminating stock is usually from a western species group or southern pine. Tabulated stresses for glu-lam are generally larger than for sawn lumber because higher-quality wood can be optimized. For example, bending combinations of laminations have higher-quality laminating stock placed in the areas of higher bending stress (i.e., at the top and bottom of a beam) and lower-quality laminating stock near the neutral axis (i.e., at the center). See [Figure 31.1](#).
3. *Structural composite lumber* (SCL). Lumber that is a reconstituted wood product. Because of its manufacturing process, SCL has even higher stress values than glu-lam.
 - A. *Laminated veneer lumber* (LVL). Lumber formed by gluing together thin sheets of wood known as *veneers*.
 - B. *Parallel strand lumber* (PSL). Lumber formed by gluing together thin, narrow pieces of wood known as *strands*.
4. *Round timber poles and piles*.
5. *Structural-use panels*. Usually 4 × 8 ft panels of wood with directional properties used for sheathing and other structural applications.
 - A. *Plywood*
 - B. *Oriented strand board* (OSB)

FIGURE 31.1 Layout of laminating stock in a glu-lam beam. Stronger wood is located at points of higher stress.

These products may be used individually as building components or they may be combined in a manufacturing plant to form composite structural products such as prefabricated wood trusses, wood I joists, or factory-built roof or wall panels.

The basic reference for structural design in wood is the *National Design Specification* [AF&PA, 1991]. The basic reference for plywood is the *Plywood Design Specification* [APA, 1986]. Detailed examples and additional references are given in Breyer [1993] and the *NDS Commentary* [AF&PA, 1993]. Basic building code criteria are available from such sources as the *UBC* [ICBO, 1991], which is one of the three model building codes used in the U.S.

31.3 Member Design

Wood structures are designed to resist vertical (gravity) loads and lateral (wind and earthquake) forces. Generally, a series of beams and columns is used to carry gravity loads. Thus a path is formed for the progressive transfer of gravity loads from the top of the structure down into the foundation. Design includes consideration of dead load, roof live load or snow load, floor live load, and other possible loads.

The 1991 edition of the *National Design Specification* [AF&PA, 1991] introduced sweeping changes to the design equations for engineered wood structures. Revised stresses for lumber were also introduced as a result of a 12-year study known as the *in-grade testing program*. Brief introductions to the design of a wood beam and a wood column are given in the remainder of this section.

Wood beams are designed using familiar formulas from engineering mechanics for bending, shear, deflection, and bearing. Although the basic concepts are simple, wood design can appear to be complicated because of the nature of the material. The variability of mechanical properties for different wood products is one factor. Another is the presence of natural growth characteristics such as knots, density, slope of grain, and others. The natural growth characteristics in wood have led to the development of a relatively involved lumber-grading system. However, the basic design procedure is straightforward. Basic formulas from strength of materials are used to evaluate the *actual stress* in a member. The actual stress is then checked to be less than or equal to an *allowable stress* for the species, grade, and size category. The design size is accepted or revised based on this comparison.

The allowable stress is where the unique nature of the material is taken into account. Determination of allowable stress begins by first finding the tabulated stress for a given species, stress grade, and size category. The tabulated stress applies directly to a set of base conditions (e.g., normal duration of load, dry service conditions, standard size, normal temperature, and so on). The tabulated stress is then subjected to a series of adjustment factors, which converts the base conditions for the table to the conditions for a particular design. See [Figure 31.2](#).

For example, the bending stress in a wood beam is checked as follows:

FIGURE 31.2 Bending stress in a wood beam. A trial member size is structurally safe if the actual stress f_b is less than or equal to the allowable stress F'_b .

$$f_b = \frac{Mc}{I} = \frac{M}{S} \leq F'_b$$

where

- f_b = actual bending stress, psi
- M = moment in beam, in.-lb
- c = distance from neutral axis to extreme fiber, in.
- I = moment of inertia, in.⁴
- S = section modulus, in.³
- F'_b = allowable bending stress, psi
- = $F_b \times$ (series of adjustment factors)
- = $F_b \times (C_D \times C_M \times C_L \times cf. \times C_t \times x \dots)$
- F_b = tabulated bending stress, psi
- C_D = adjustment factor for duration of load (**load duration factor**)
- C_M = adjustment factor for high moisture conditions (**wet service factor**)
- C_L = adjustment factor for lateral torsional buckling (beam stability)
- C_F = adjustment factor for size effect (**size factor**)
- C_t = adjustment factor for high temperature applications (**temperature factor**)
- $x \dots$ = any other adjustment factor that may apply

For the common case of a continuously braced beam in an enclosed building (dry service at normal temperatures), a number of the adjustment factors default to unity. Thus, the complicated nature of the problem is often simplified for frequently encountered design conditions.

Wood columns are checked in a similar manner (See [Figure 31.3](#)) using the following formula for axial compressive stress:

$$f_c = \frac{P}{A} \leq F'_c$$

where

- f_c = actual column stress, psi
- P = axial column load, lb
- A = cross-sectional area of column, in.²

- F'_c = allowable column stress, psi
- = $F_c \times$ (series of adjustment factors)
- = $F_c \times (C_D \times C_M \times C_P \times \text{cf.} \times C_t \times x \dots)$
- C_D = adjustment factor for duration of load
- C_M = adjustment factor for high-moisture conditions (wet service)
- C_P = adjustment factor for column buckling (stability)
- C_F = adjustment factor for size effect
- C_t = adjustment factor for high-temperature use
- $x \dots$ = any other adjustment factor that may apply

The column stability factor C_P is a coefficient that measures the tendency of the column to buckle between points of lateral support. C_P is based on the slenderness ratio

$$l_e/r = \text{column slenderness ratio}$$

where l_e = effective column length, in. and r = radius of gyration associated with the axis of column buckling, in.

For a column with a rectangular cross-section the radius of gyration is directly proportional to the cross-sectional dimension of the member, and the slenderness ratio becomes

$$l_e/d = \text{slenderness ratio for a rectangular column}$$

where d = cross-sectional dimension of column associated with the axis of column buckling, in inches.

In the most recent NDS [AF&PA, 1991] the column stability factor is defined by the Ylinen column equation, which is graphed in Figure 31.3, showing the allowable compressive stress versus column slenderness ratio. However, space does not permit a detailed review of the Ylinen equation.

Wood members that are subject to combined stress (e.g., a beam-column has both a bending moment and an axial compressive force) are handled with an interaction formula. The most recent NDS has a new interaction formula based on work done at the U.S. Forest Products Laboratory by Zahn.

FIGURE 31.3 Compressive stress in a wood column. A trial column size is judged to be safe if the actual stress f_c is less than or equal to the allowable stress F'_c . Column buckling is taken into account by the Ylinen equation in the column stability factor C_P .

31.4 Connections

Connections in engineered wood structures may be made with a variety of fasteners and other materials. These include nails, staples, bolts, lag bolts (lag screws), wood screws, split ring connectors, shear plate connectors, nail plates, and prefabricated metal connection hardware. Fasteners may connect one wood member to another (wood-to-wood connection) or they may connect a wood member to a piece of steel connection hardware (wood-to-metal connection). The most common type of loading on a fastener is perpendicular to the axis of the fastener. This may be described as a *shear-type connection*. Connections are usually either single shear or double shear. In the past, the allowable design load on a shear connection was determined from a table. These tables for nails, bolts, and other fasteners were based on a limited series of tests conducted many years ago and were empirically determined.

The 1991 *NDS* [AF&PA, 1991] introduced a new method for obtaining the nominal design value for these types of connections. The new method is based on engineering mechanics and is referred to as the *yield limit theory for dowel-type fasteners*. In this approach an equation is evaluated for each possible mode of failure for a given type of connection. The nominal design value for the connection is defined as the smallest load capacity from the yield equations. *NDS* tables cover commonly encountered connection problems so that it is not necessary to apply the rather complicated yield limit equations for every connection design.

31.5 Lateral Force Design

Lateral forces include wind and seismic forces. Although both wind and seismic forces involve vertical components, the emphasis is on the effect of horizontal forces. The common lateral force resisting systems (*LFRSs*) are moment-resisting frames, braced frames (horizontal and vertical trusses), and horizontal diaphragms and shearwalls. Most wood frame buildings use a combination of *horizontal diaphragms* and *shearwalls*. Economy is obtained in this approach because the usual sheathing materials on roofs, floors, and walls can be designed to carry lateral forces. In order to make this happen, additional nailing for the sheathing may be required, and additional connection hardware may be necessary to tie the various elements together.

In a shearwall-type building, walls perpendicular to the lateral force are assumed to span vertically between story levels. Thus, in a one-story building, the wall spans between the foundation and the roof. See Figure 31.4. The reaction at the roof becomes a force on the horizontal diaphragm. The diaphragm acts as a large horizontal beam that is loaded in its plane. The beam spans between shearwalls. The diaphragm is composed of the roof sheathing, nailing, boundary members, and anchorage connections. The reactions on the horizontal diaphragm in turn are the forces on the shearwalls. A shearwall is designed

FIGURE 31.4 Lateral forces are distributed from the perpendicular walls to the horizontal diaphragm. The diaphragm in turn transfers the lateral force to the shearwalls.

as a beam that cantilevers vertically from the foundation. A shearwall includes the sheathing, nailing, boundary members, and connections to the horizontal diaphragm and to the foundation.

Defining Terms

Load duration factor, C_D — A multiplying factor used to adjust the allowable stress in a wood member or connection based on the total accumulated length of time that a load is applied to a structure. C_D ranges from 0.9 for long-term (dead) loads to 2.0 for very short-term (impact) loads.

Size factor, C_F — A multiplying factor used to adjust the allowable stress in a wood member based on the dimensions of the cross-section. Depending on the size, type of stress, and grade of lumber, the size factor may be less than, equal to, or greater than unity.

Temperature factor, C_t — A multiplying factor used to adjust the allowable stress in a wood member or connection based on the temperature conditions. C_t is 1.0 for normal temperatures and less than 1.0 for high temperatures.

Wet service factor, C_M — A multiplying factor used to adjust the allowable stress in a wood member or connection based on the moisture content of the wood. C_M is 1.0 for dry service applications and less than 1.0 for high-moisture conditions. The value of C_M depends on the type of stress and material type and may depend on other factors.

Masonry structures have been constructed since the earliest days of mankind, not only for homes but also for works of beauty and grandeur. Stone was the first masonry unit and was used for primitive but breathtaking structures, such as the 4000-year-old Stonehenge ring on England's Salisbury Plains. Stone was also used around 2500 B.C. to build the Egyptian pyramids in Giza. The 1500-mile (2400-km) Great Wall of China was constructed of brick and stone between 202 B.C. and 220 A.D.

Masonry has been used worldwide to construct impressive structures, such as St. Basil's Cathedral in Moscow and the Taj Mahal in Agra, India, as well as homes, churches, bridges, and roads. In the U.S., masonry was used from Boston to Los Angeles and has been the primary material for building construction from the 18th to the 20th centuries.

Currently, the tallest reinforced masonry structure is the 28-story Excalibur Hotel in Las Vegas, Nevada. This large high-rise complex consists of four buildings, each containing 1008 sleeping rooms. The load-bearing walls for the complex required masonry with a specified compressive strength of 4000 psi (28 MPa).

TABLE 32.1 Notation

| | | | |
|------------|---|---------|--|
| a_b = | Depth of stress block for balanced strength design conditions. | F_a = | Allowable compressive stress due to axial load only, psi. |
| A = | Area of compression area for walls or columns. | F_b = | Allowable compressive stress due to flexure only, psi. |
| A_n = | Net cross-sectional area of masonry, in. ² . | F_s = | Allowable tensile or compressive stress in reinforcement, psi. |
| A_s = | Area of tension steel. | F_v = | Allowable shear stress in masonry, psi. |
| A_{se} = | Equivalent area of tension steel considering effect of vertical load. | h = | Effective height of column, wall, or pilaster, in. |
| A_v = | Cross-sectional area of shear reinforcement, in. ² . | I = | Moment of inertia of masonry, in. ⁴ . |
| b = | Width of section, in. ² . | j = | Ratio of distance between centroid of flexural compressive forces and centroid of tensile forces to depth, d . |
| b_w = | Width of wall beam. | k = | Ratio of depth of stress block to depth of section. |
| c_b = | Depth to neutral axis for balanced strength design conditions. | l = | Clear span between supports. |
| C = | Total compression force. | L = | Live load or related internal moments and forces. |
| d = | Distance from extreme compression fiber to centroid of tension reinforcement, in. | M = | Maximum moment occurring simultaneously with design shear force V at the section under consideration, in.-lb. |
| D = | Dead load or related internal moments and forces. | n = | Ratio of the modulus of elasticity of steel to the modulus of elasticity of masonry. |
| e = | Eccentricity of axial load, in. | p = | Ratio of tensile steel area to total area of section, bd. |
| E_m = | Modulus of elasticity of masonry in compression, psi. | P = | Design axial load, lb. |
| E_s = | Modulus of elasticity of steel, psi. | P_u = | Factored load on section, strength design. |
| f = | Calculated stress on section. | r = | Radius of gyration, in. |
| f_a = | Calculated compressive stress in masonry due to axial load only, psi. | s = | Spacing of reinforcement, in. |
| f_b = | Calculated compressive stress in masonry due to flexure only, psi. | S = | Section modulus. |
| f'_m = | Specified compressive strength of masonry, psi. | t = | Nominal thickness of wall. |
| f_s = | Calculated tensile or compressive stress in reinforcement, psi. | T = | Total tension force on section. |
| f_t = | Calculated tension stress on masonry, psi. | v = | Shear stress, psi. |
| f_v = | Calculated shear stress in masonry, psi. | V = | Design shear force. |
| f_y = | Specified yield stress of steel for reinforcement and anchors, psi. | w = | Load or weight per unit length or area. |
| | | W = | Wind load or related internal moments and forces or total uniform load. |

32.1 Basis of Design

This chapter is based on the specification of materials, construction methods, and testing as given in the ASTM standards. The design parameters are in accordance and reprinted with permission from Building Code *Requirements and Commentary for Masonry Structures* (ACI 530-02, ASCE 5-02, TMS 402-02), also referred to as the Masonry Standards Joint Committee (MSJC -02).

In addition, the International Building Code, published by the International Code Council, Falls Church, VA, provides requirements and recommendations for the design and construction of masonry systems both unreinforced (plain) and reinforced. (See Table 32.1.)

32.2 Masonry Materials

The principal materials used in plain masonry are the masonry units, mortar plus grout, and reinforcing steel for reinforced masonry. These materials are assembled into homogeneous structural systems.

FIGURE 32.1 Solid clay brick.

FIGURE 32.2 Hollow clay brick.

32.3 Masonry Units

The masonry units considered are clay brick, concrete brick, hollow clay bricks, and hollow concrete blocks. Masonry units are available in a variety of sizes, shapes, colors, and textures.

Clay Masonry

Clay masonry is manufactured to comply with the ASTM C 62-00, *Specification for Building Brick (Solid Masonry Units Made From Clay or Shale)*; C 216-00, *Specification for Facing Brick (Solid Masonry Units Made From Clay or Shale)*; and C 652-00a, *Specification for Hollow Brick (Hollow Masonry Units Made From Clay or Shale)*. It is made by firing clay in a kiln for 40 to 150 h, depending upon the type of kiln, size and volume of the units, and other variables. For building brick and face brick the temperature is controlled between 1600°F (870°C) and 2200°F (1200°C), whereas the temperature ranges between 2400°F (1315°C) and 2700°F (1500°C) for firebrick.

Solid Clay Units

A solid clay masonry unit, as specified in ASTM C 62-00 and C 216-00, is a unit whose net cross-sectional area, on every plane parallel to the bearing surface, is 75% or more of its gross cross-sectional area measured in the same plane. A solid brick may have a maximum coring of 25%. See [Figure 32.1](#).

Hollow Clay Units

A hollow clay masonry unit, as specified in ASTM C 652-00a, is a unit whose net cross-sectional area in every plane parallel to the bearing surface is less than 75% of its gross cross-sectional area measured in the same plane. See [Figure 32.2](#).

32.4 Concrete Masonry

Concrete masonry units for load-bearing systems can be either concrete brick as specified by ASTM C 55-99, *Specification for Concrete Building Brick*, or hollow load-bearing concrete masonry units as specified by ASTM C 90-00, *Specification for Hollow Load-Bearing Concrete Masonry Units*.

Concrete brick and hollow units are primarily made from portland cement, water, and suitable aggregates with or without the inclusion of other materials and may be made from lightweight or normal weight aggregates or both.

Hollow Load Bearing Concrete Masonry Units

ASTM C 90-00, *Specification for Load Bearing Concrete Masonry Units*, requires all load-bearing concrete masonry units to meet the physical requirements of dimensions, strength, and absorption.

32.5 Mortar

General

Mortar is a plastic mixture of materials used to bind masonry units into a structural mass. It is used for the following purposes:

1. It serves as a bedding or seating material for the masonry units.
2. It allows the units to be leveled and properly placed.
3. It bonds the units together.
4. It provides compressive strength.
5. It provides shear strength, particularly parallel to the wall.
6. It allows some movement and elasticity between units.
7. It seals irregularities of the masonry units.
8. It can provide color to the wall by using color additives.
9. It can provide an architectural appearance by using various types of joints.

Types of Mortar

The requirements for mortar are provided in ASTM C 270-00, *Mortar for Unit Masonry*. There are four types of mortar, which are designated M, S, N, and O. The types are identified by every other letter of the word MaSoNwOrk.

Mortar Proportions

Proportion specifications limit the amount of the constituent parts by volume. Water content, however, may be adjusted by the mason to provide proper workability under various field conditions. The most common cement-lime mortar proportions by volume are:

Type M mortar. 1 Portland cement; π lime; 3] sand

Type S mortar. 1 Portland cement;] lime; 4] sand

Type N mortar. 1 Portland cement; 1 lime; 6 sand

Type O mortar. 1 Portland cement; 2 lime; 9 sand

32.6 Grout

General

Grout is a mixture of Portland cement, sand pea gravel, and water mixed to fluid consistency so that it will have a slump of 8 to 10 in. (200 to 250 mm). The minimum strength of grout is 2000 psi (13.8 MPa). Requirements for grout are given in ASTM C 476-99, *Grout for Masonry*.

Grout is placed in the cores of hollow masonry units or between wythes of solid units to bind the reinforcing steel and the masonry into a structural system. Additionally, grout provides:

1. More cross-sectional area, allowing a grouted wall to support greater vertical and lateral shear forces than a nongrouted wall
2. Added sound transmission resistance, thus reducing the sound passing through the wall
3. Increased fire resistance and an improved fire rating of the wall
4. Improved energy storage capabilities of a wall
5. Greater weight, thus improving the overturning resistance of retaining walls

Types of Grout

Fine grout is used for small grout spaces or where there is an excess of reinforcing steel. **Coarse grout is the standard grout used in the majority of grouted masonry.**

Proportions of Grout

Fine grout is proportioned 1 part portland cement and 3 parts sand with enough water for an 8- to 11-in. slump. Coarse grout is proportioned: 1 part portland cement, 3 parts sand, and 2 parts pea gravel with enough water for an 8- to 11-in. slump.

32.7 Behavior and Limits States of Structural Masonry

The design methods of structural masonry are based on a range of behavior conditions that define the limits for each of the design methods (Figure 32.3).

32.8 Unreinforced or Plain Masonry

Design of Unreinforced Masonry (MSJC 2.2)

Behavior State 1:

1. Stresses are less than the Modulus of Rupture... Masonry is uncracked.
2. Limit reached when masonry is stressed to the modulus of rupture. It cracks.

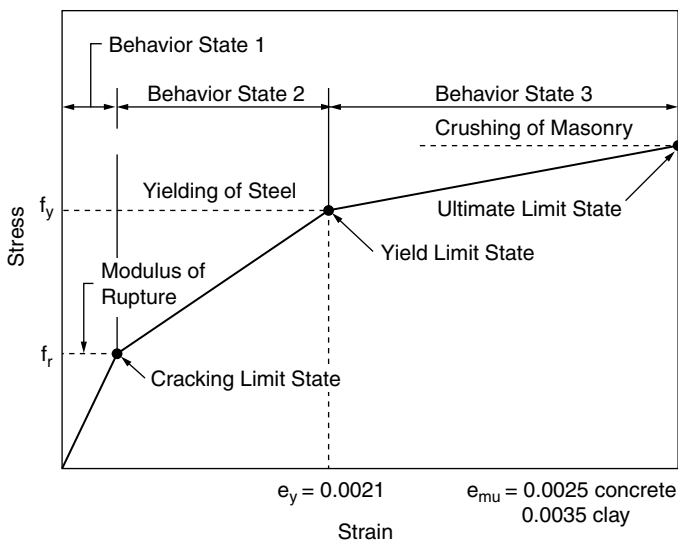

FIGURE 32.3 Behavior and limit states of structural masonry

TABLE 32.2 Allowable Flexural Tension for Clay and Concrete Masonry, psi^a (kPa)

| Masonry Type | Mortar Types | | | | | | | |
|--|----------------------|-----|----|-----|---|-----|----|-----|
| | Portland Cement/Lime | | | | Masonry Cement and Air-Entrained Portland Cement Lime | | | |
| | M or S | kPa | N | kPa | M or S | kPa | N | kPa |
| Normal to Bed Joints | | | | | | | | |
| Solid units | 40 | 276 | 30 | 207 | 24 | 166 | 15 | 103 |
| Hollow units ^a | | | | | | | | |
| UngROUTED | 25 | 172 | 19 | 131 | 15 | 103 | 9 | 62 |
| Fully grouted | 68 | 470 | 58 | 400 | 41 | 283 | 26 | 180 |
| Parallel to Bed Joints in Running Bond | | | | | | | | |
| Solid units | 80 | 550 | 60 | 415 | 48 | 330 | 30 | 207 |
| Hollow units | | | | | | | | |
| UngROUTED and partially grouted | 50 | 345 | 38 | 262 | 30 | 207 | 19 | 131 |
| Fully grouted | 80 | 550 | 60 | 415 | 48 | 330 | 30 | 207 |

^a For partially grouted masonry, allowable stresses shall be determined on the basis of linear interpolation between hollow units, which are fully grouted or ungrouted, and hollow units based on amount of grouting.

3. Masonry resists both tensile and compressive forces.
4. Tensile stress in masonry (mortar) is limited (Table 32.2).
5. Compressive stress in masonry is limited (MSJC 2.2.3.1).
6. Shear stress in masonry is limited (MSJC 2.2.5).

Unreinforced masonry considers the tensile resistance of masonry for the design of structures. The effects of stresses in reinforcement, if present, are neglected and all forces and moments are resisted by the weight of the masonry and the tension and compression capabilities of the system.

The stress due to flexural moment is $f_t = M/S$, where M is the moment on the wall and S is the section modulus. The condition is generally limited to the allowable flexural tension stress shown in Table 32.2.

Example 32.1 — Thickness of Unreinforced Masonry Wall

An unreinforced building wall is 10 ft (3 m) high and spans between footing and roof ledger. It could be subjected to a wind force of 15 psf (103 kPa). Should an 8" (200 mm) CMU wall or a 12" (300 mm) CMU wall be used?

Solution:

Moment on wall

Assumed pinned top and bottom

$$M = \frac{wh^2}{8} = \frac{15 \cdot 10^2}{8} = 187.5 \text{ ft} \cdot \text{lb} / \text{ft} \text{ (} 834 \text{ N} \cdot \text{m} / \text{m)}$$

Allowable tension stress type M or S mortar = 25 psi (172 kPa)

Stress may be increased 1/3 due to temporary wind force

$$S = \frac{M}{1.33f_t} = \frac{187.5 \times 12}{1.33 \times 25} = 67.5 \text{ in.}^3 \text{ (} 1.1 \cdot 10^6 \text{ mm}^3 \text{)}$$

FIGURE 32.4 Vertical plane cross-section of 8" CMU wall, face shells only.

FIGURE 32.5 Vertical plane cross-section of 12" CMU wall, face shells only.

For section modulus at 8" (200 mm) CMU (see Figure 32.4):

$$\begin{aligned}
 I &= 2 \left[\frac{bd^3}{12} + bdx^2 \right] = 2 \left[\frac{12 \times 1.25^3}{12} + 12 \times 1.25 \times 3.1875^2 \right] \\
 &= 2[1.95 + 152.40] = 308.7 \text{ in.}^4 (128.5 \cdot 10^6 \text{ mm}^4) \\
 S &= \frac{308.7 \times 2}{7.625} = 81 \text{ in.}^3 (1.3 \cdot 10^6 \text{ mm}^3)
 \end{aligned}$$

At 12" (300 mm) CMU (see Figure 32.5):

$$\begin{aligned}
 I &= 2 \left[\frac{bd^3}{12} + bdx^2 \right] \\
 &= 2 \left[\frac{12 \times 1.5^3}{12} + 12 \times 1.5 \times 5.0625^2 \right] \\
 &= 2[3.375 + 461.3] = 929.4 \text{ in.}^4 (386.8 \cdot 10^6 \text{ mm}^4) \\
 S &= \frac{I}{t/2} = \frac{2 \times 929.4}{11.625} = 159.9 \text{ in.}^3 (2.6 \cdot 10^6 \text{ mm}^3)
 \end{aligned}$$

Thus, 8" CMU = 81.0 in.³ (1.3 · 10⁶ mm³); 12" CMU = 159.9 in.³ (2.6 · 10⁶ mm³).

Use 8" (200 mm) CMU.

Example 32.2 — Vertical and Lateral Load on Unreinforced Masonry Wall

If a wall is subjected to a 20 psf (958 kPa) wind, and is 15 ft (4.6 m) high, and carries 2000 plf (96 kPa), what thickness concrete masonry unit should be used?

Solution:

$$M = \frac{wh^2}{8} = \frac{20 \times 15^2}{8} = 563 \text{ ft} \cdot \text{lb} / \text{ft} (2500 \text{ N} \cdot \text{m} / \text{m})$$

Try 8'' (200 mm) CMU.

$$\begin{aligned}
 S &= 81 \text{ in.}^3 (1.3 \cdot 10^6 \text{ mm}^3) \\
 \frac{P}{A} \pm \frac{M}{S} &= \frac{2000}{2 \times 12 \times 1.25} \pm \frac{563 \times 12}{81} \\
 &= 66.7 \pm 83 \\
 &= 150 \text{ psi compression (1.0 MPa)} \\
 &= 16.3 \text{ psi tension (115 kPa)}
 \end{aligned}$$

Tension is less than $25 \times \frac{4}{3} = 33.3$ psi (230 kPa) allowable tension, so 8'' (200 mm) CMU is satisfactory.

32.9 Strength of Masonry

The ultimate compressive strength of the masonry assembly is given the symbol f'_{mu} to distinguish it from the specified compressive strength f'_m . See Table 32.3 and Table 32.4 for the allowable specified strength of masonry compared to the strength of the masonry unit.

Modulus of Elasticity

For steel reinforcement, $E_s = 29,000,000$ psi (199 955 MPa).

For concrete masonry, $E_m = 900 f'_m$ (see Table 32.3).

For clay masonry, $E_m = 750 f'_m$ (see Table 32.4).

TABLE 32.3 Concrete Masonry — Compressive Strength, Modulus of Elasticity, Modular Ratio

| Net Area Compressive Strength of Concrete Masonry Units, psi (MPa) | | Net Area Compressive Strength of Masonry, psi ^a (MPa) | Modulus of Elasticity 900 f'_m psi ^a (MPa) | Modular Ratio $n = E_s/E_m$ |
|--|---------------|--|---|-----------------------------|
| Type M or S Mortar | Type N Mortar | | | |
| 1250 (8.62) | 1300 (8.96) | 1000 (6.90) | 900,000 (6207) | 32.2 |
| 1900 (13.10) | 2150 (14.82) | 1500 (10.34) | 1,350,000 (9310) | 21.5 |
| 2800 (19.31) | 3050 (21.03) | 2000 (13.79) | 1,800,000 (12414) | 16.1 |
| 3750 (25.86) | 4050 (27.92) | 2500 (17.24) | 2,250,000 (15518) | 12.9 |
| 4800 (33.10) | 5250 (36.50) | 3000 (20.69) | 2,700,000 (18621) | 10.7 |

^a For units of less than 4 in. (102 mm) height, 85% of the values listed.

TABLE 32.4 Clay Masonry — Compressive Strength, Modulus of Elasticity, Modular Ratio

| 6600 (45.51) | 8250 (56.88) | 2500 (17.24) | 1,875,000 (12,931) | 15.5 |
| 8250 (56.88) | 10,300 (71.02) | 3000 (20.69) | 2,250,000 (15,518) | 12.9 |
| 9900 (68.26) | — | 3500 (24.13) | 2,625,000 (18,104) | 11.0 |
| 13,200 (91.01) | — | 4000 (27.58) | 30,000,000 (20,690) | 9.7 |

Specified Compressive Strength

For specified compressive strength of:

Concrete masonry, see [Table 32.3](#)

Clay masonry, see [Table 32.4](#)

Reinforcing Steel

Reinforcing steel in masonry has been used extensively in the West since the 1930s, revitalizing the masonry industry in earthquake-prone areas. Reinforcing steel extends the characteristics of ductility, toughness, and energy absorption that are so necessary in structures subjected to the dynamic forces of earthquakes.

Reinforcing steel may be either Grade 40, with a minimum yield strength of 40,000 psi (276 MPa), or Grade 60, minimum yield strength of 60,000 psi (414 MPa).

Allowable stresses for reinforcing steel are as follows. Tension stress in reinforcement shall not exceed the following:

| | |
|------------------------------------|----------------------|
| Grade 40 or Grade 50 reinforcement | 20,000 psi (138 MPa) |
| Grade 60 reinforcement | 24,000 psi (165 MPa) |
| Wire joint reinforcement | 30,000 psi (207 MPa) |

Compression stress has these restrictions:

1. The compressive resistance of steel reinforcement is neglected unless lateral reinforcement is provided to tie the steel in position.
2. Compressive stress in reinforcement may not exceed the lesser of $0.4 f_y$ or 24,000 psi (165 MPa).

32.10 Design of Reinforced Masonry Members

Behavior State 2 — Working Stress Design (MSJC 2.3, IBC 2107):

1. Modulus of rupture is exceeded. The masonry is cracked.
2. Cracked cross-section with steel strain is less than the yield strain.
3. Reinforcing steel resists tensile forces.
4. Masonry resists compressive forces.
5. Stresses are well within the elastic range.
6. Compressive stresses are limited in masonry (MSJC 2.3.3).
7. Tensile stresses in reinforcing steel is limited (MSJC 2.3.2).

Reinforced masonry members are designed by elastic analysis using service loads and permissible stresses, which considers that the reinforcing steel resists tension forces and the masonry and grout resist compression forces.

The design and analysis of reinforced masonry structural systems have been by the straight line, elastic working stress method. In working stress design (WSD), the limits of allowable stress for the materials are established based on the properties of each material ([Figure 32.6](#)):

Yield Limit State for Behavior State 2

Steel ratio limited to ensure ductile behavior.

Steel yields well before masonry crushes.

Limit reached at steel first yield.

The procedure presented is based on the working stress or straight line assumptions where all stresses are in the elastic range and:

FIGURE 32.6 Range of behavior state 2.

1. Plane sections before bending remain plane during and after bending.
2. Stress is proportional to strain, which is proportional to distance from the neutral axis.
3. Modulus of elasticity is constant throughout the member.
4. Masonry carries no tensile stresses.
5. Span of the member is large compared to the depth.
6. Masonry elements combine to form a homogeneous and isotropic member.
7. External and internal moments and forces are in equilibrium.
8. Steel is stressed about the center of gravity of the bars equally.
9. The member is straight and of uniform cross-section.

Flexural Design

The basis of the flexural equations for working stress design, WSD, is the concept of the modular ratio. The modular ratio, n , is the ratio of the modulus of elasticity of steel, E_s , to the modulus of elasticity of masonry, E_m .

$$n = \frac{E_s}{E_m}$$

By use of the modular ratio, n , the steel area can be transformed into an equivalent masonry area. The strain is in proportion to the distance from the neutral axis and therefore the strain of the steel can be converted to stress in the steel. In order to establish the ratio of stresses and strains between the materials, it is necessary to locate the neutral axis.

The location of the neutral axis is defined by the dimensions, kd , which are dependent on the modular ratio, n , and the reinforcing steel ratio, $p = A_s/bd$. For a given modular ratio, n , the neutral axis can be raised by decreasing the amount of steel (reducing p) or lowered by increasing the amount of steel (increasing p). See [Figure 32.7](#) and [Figure 32.8](#).

Solving for k ,

$$k = \sqrt{(np)^2 + 2np} - np$$

FIGURE 32.7 Location of neutral axis for a beam.

FIGURE 32.8 Location of neutral axis for a wall, in plane of wall.

Moment Capacity of a Section

The moment capacity of a reinforced structural masonry wall or beam can be limited by the allowable masonry stress (over-reinforced), allowable steel stress (under-reinforced), or both, in which case it would be a balanced design condition.

When a member is designed for the specified loads, and the masonry and reinforcing steel are stressed to their maximum allowable stresses, the design is said to be a “balanced” design. This balanced design is different from the balanced design for the strength design method. For working stresses, balanced design occurs when the masonry is stressed to its maximum allowable compressive stress and the steel is stressed to its maximum allowable tensile stress.

However, in many cases, the “balanced” design does not satisfy the conditions for the materials available or for the predetermined member size or the economy of the project. It may be advantageous to under-stress (under-reinforce) the masonry or under-stress (over-reinforce) the steel so that the size of the member can be maintained.

The moment capability of a section based on the steel stress is defined as $M_s = \text{force} \times \text{moment arm}$, where force in the steel, $T = A_s f_s = p b d f_s$; moment arm = jd ; $M_s = T \times jd = A_s f_s jd$; and $M_s = p b d f_s jd = f_s p j b d^2$.

The moment capability of a section based on the masonry stress is defined as $M_m = \text{force} \times \text{moment arm}$, where force in the masonry, $C = \frac{1}{2} f_b (kd) b = \frac{1}{2} f_b k b d$; moment arm = jd ; $M_m = C \times jd = (\frac{1}{2} f_b k b d) \times (jd)$; $M_m = \frac{1}{2} f_b k j b d^2$.

Example 32.3 — Determination of Moment Capacity of a Wall

A partially grouted 8” (200 mm) concrete masonry wall with type S mortar is reinforced with #5 bars at 32” (813 mm) o.c. The steel is 5.3” (135 mm) from the compression face and is Grade 60. If $t_m = 2500$ psi (17.2 MPa), what is the moment capacity of the wall?

Solution

For $f'_m = 2500$ psi (17.2 MPa), allowable masonry stress,

$$F_b = 0.33 f'_m = 833 \text{ psi (5.6 MPa) max. allowable compression}$$

$$E_m = 900 f'_m = 2,250,000 \text{ psi (15,500 MPa) (see Table 32.3)}$$

Also, for $f_y = 60,000 \text{ psi (414 MPa)}$,

$$F_s = 24,000 \text{ psi (165 MPa) max. allowable tension}$$

$$E_s = 29,000,000 \text{ psi (199 955 MPa)}$$

For steel ratio,

$$\begin{aligned} p &= \frac{A_s}{bd} \\ &= \frac{0.31}{32 \times 5.3} = 0.0018 \end{aligned}$$

For modular ratio,

$$\begin{aligned} n &= \frac{E_s}{E_m} \\ &= \frac{29\ 000\ 000}{2\ 250\ 000} = 12.9 \end{aligned}$$

Furthermore,

$$\begin{aligned} np &= 12.9 \times 0.0018 = 0.023 \\ k &= \sqrt{(np)^2 + 2n} - np \\ &= \sqrt{(0.0023)^2 + 2 \times 0.0023} - 0.0023 \\ &= 0.193 \\ kd &= 0.193 \times 5.3 = 1.03 \text{ in. (26 mm)} \end{aligned}$$

The neutral axis falls on the shell of CMU. Shell thickness = 1.25 inches.

$$\begin{aligned} j &= 1 - \frac{k}{3} = 1 - \frac{0.193}{3} = 0.936 \\ M_m &= \frac{1}{2} f_b k j b d^2 = \frac{1}{2} (833) (0.193) (0.936) (12) (5.3)^2 \\ &= 25.362 \text{ in.} \cdot \text{lb /ft (9208 N} \cdot \text{m/m)} \\ &= 2.11 \text{ ft k /ft (9128 N} \cdot \text{m/m)} \\ M_s &= f_s p j b d^2 = 24\ 000 (0.0021) (0.936) (12) (5.3)^2 \\ &= 15\ 902 \text{ in.} \cdot \text{lb /ft (5800 N} \cdot \text{m/m)} \\ &= 1.33 \text{ ft k /ft (5800 N} \cdot \text{m/m)} \leftarrow \text{Controls} \end{aligned}$$

Beam Shear

Structural elements such as beams, piers, and walls are subjected to shear forces as well as flexural stresses. The unit shear stress is computed based on the formula

$$f_v = V/bd$$

When masonry members, i.e., beams, are designed to resist shear forces without the use of shear-reinforcing steel, the calculated shear stress is limited to $1.0 (f'_m)^{1/2}$, 50 psi max. If the unit shear stress exceeds the allowable masonry shear stress, reinforcing steel must resist all the shear stress.

For flexural members, beams, with reinforcing steel resisting all the shear forces, the maximum allowable shear stress is $3.0 (f'_m)^{1/2}$ psi with 150 psi as a maximum. The steel resists the shear by tension, and it must be anchored in the compression zone of the beam or the wall.

The unit shear, f_v , is used to determine the shear steel spacing based on the formula:

$$\text{Spacing, } s = \frac{A_v F_s}{f_v b}$$

$$\text{Unit shear stress, } f_v = \frac{A_v F_s}{b_s}$$

For continuous or fixed beams, the shear value used to determine the shear steel spacing may be taken at a distance $d/2$ from the face of the support. The shear value at the face of the support should be used to calculate the shear steel spacing in simple beams.

The maximum spacing of shear steel should not exceed $d/2$. The first shear-reinforcing bar should be located at half the calculated spacing but no more than $d/4$ from the face of support.

Vertical Load on a Wall

A load-bearing wall carries the load of the roof plus the load of floor above and is limited to the h/r of the wall. The h/r is the effective height of the wall divided by the radius of gyration, $r = (I/A)^{1/2}$

For walls with h/r not greater than 99 the load limitation is:

$$P_a = (0.25 f'_m A_n + 0.65 A_{st} F_s) \left[1 - \left(\frac{h}{140r} \right)^2 \right]$$

For walls with h/r greater than 99 the load limitation is:

$$P_a = (0.25 f'_m A_n + 0.65 A_{st} F_s) \left(\frac{70r}{h} \right)^2$$

Although there is a term for reinforcing steel in the equation, it is ignored because the steel is not tied to prevent buckling or displacement. Thus the maximum stress in the wall is $0.25 f'_m$ times the reduction factor.

Interaction of Combined Load and Moment, P/M

The direct and simple design or analysis of interaction conditions is to use the unity equation:

$$\frac{f_a}{F_a} + \frac{f_b}{F_b} \leq 1.00 \text{ or } 1.33$$

Wall Shear

For shear walls where M/Vd is less than one the masonry shear stress shall not exceed:

$$F_v = (\frac{1}{3})[4 - (M/Vd)]\sqrt{f'_m}$$

but shall not exceed $80 - 45(M/Vd)$ psi

For shear walls where M/Vd is equal to or greater than one the masonry shear stress shall not exceed:

where $M/Vd \geq 1$,

$$F_v = \sqrt{f'_m}$$

but shall not exceed 35 psi (241 kPa).

When shear reinforcing is used to carry all the shear force.

For shear walls where M/Vd is less than one the shear stress shall not exceed:

where $M/Vd < 1$,

$$F_v = (\frac{1}{2})[4 - (M/Vd)]\sqrt{f'_m}$$

but shall not exceed $120 - 45(M/Vd)$ psi

For shear walls where M/Vd is equal to or greater than one the shear stress shall not exceed:

where $M/Vd \geq 1$,

$$F_v = 1.5\sqrt{f'_m}$$

but shall not exceed 75 psi (517 kPa).

Columns

Columns are vertical members that basically support vertical loads. They may be plain masonry or reinforced masonry. Reduction in the load-carrying capacity is based on the h/r ratio, where h is the unbraced height and r is the minimum radius of gyration for the unbraced height.

The reduction factor for members having an h/r ratio not exceeding 99 is $[1 - (h/140r)^2]$. For members with an h/r greater than 99 the factor is $(70r/h)^2$. The maximum allowable axial stress for walls or plain columns is $F_a \frac{1}{4} f'_m$ times the reduction factor.

The maximum allowable axial load on a reinforced masonry column is:

$$P_a = (0.25f'_m A_e + 0.65A_s F_{sc}) (\text{reduction factor})$$

and is limited to $P_a \leq 1/4 P_e$, where

$$P_e = \frac{\pi^2 E_m I}{h^2} \left(1 - 0.577 \frac{e}{r}\right)^3$$

The maximum allowable unit axial stress is $F_a = P_a / A_e$.

FIGURE 32.9 Typical masonry stress–strain curves.

FIGURE 32.10 Stress due to flexural moment for balanced condition.

The reduction factor based on the h/r ratio is the same for reinforced columns and for walls. The same consideration is made for the determination of the effective height, h .

The effective thickness, t , is the specified thickness in the direction considered. For nonrectangular columns the effective thickness is the thickness of a square column.

32.11 Design of Structural Members

Strength Design — Behavior State 3

General

The structural design of reinforced masonry is changing from the elastic working stress method to strength design procedures.

The concept of strength design states that, when a reinforced masonry section is subjected to high flexural moments, the masonry stress from the neutral axis to the extreme compression fibers conforms to the stress–strain curve of the materials as if it were being tested in compression. See Figure 32.9 and Figure 32.10.

It also states that when the tension reinforcing reaches its yield stress, it will continue to elongate without an increase in moment or forces. This condition occurs at the yield plateau of the steel as shown on the stress–strain curve in Figure 32.11.

At the ultimate limit state, the steel is above yield strain and the masonry just reaches the maximum usable strain (0.0025 concrete; 0.0035 clay).

The compressive stress block of the masonry, as shown in Figure 32.12, is simplified from the curved or parabolic shape to a rectangular configuration. This rectangular stress block, which is called *Whitney's stress block*, is approximated as having a length of $a = 0.80 f'_m$ and a height of $0.80 c$.

Masonry systems have compression stress–strain curves similar to those of concrete, in that the curves are curved or parabola-shaped and that they reach the limit of usable strain.

FIGURE 32.11 Idealized stress–strain diagram for reinforcing steel.

FIGURE 32.12 Assumed stress block at yield condition.

Strength Design Procedure

Two conditions are included in strength design: load parameters and design parameters.

Load Parameters

Service or actual loads are generally used for working stress design procedures. For strength design procedures, the actual or specified loads are increased by appropriate load factors. These load factors consider live and dead load, wind, earthquake, temperature, settlement, and earth pressure. (See IBC Sec. 1605.)

In addition to load factors, a capacity reduction factor, ϕ , is used to adjust for the lack of perfect materials, strength, and size. The phi factor also varies for the stress considered, whether flexural or shear.

Design Parameters

The parameters for strength design are as follows:

1. The steel is at yield stress.
2. The masonry stress block is rectangular.
3. The masonry strain is limited to 0.003 in./in.
4. The steel ratio, p , is limited to 50% of the balanced reinforcing ratio, p_b , to ensure that a ductile mechanism forms prior to brittle, crushing behavior.

For out-of-plane forces the maximum steel ratio is limited to:

$$\rho_{\max} = \frac{\left[0.64f'_m \left(\frac{\epsilon_{mu}}{\epsilon_{mu} + 1.3\epsilon_y} \right) - \frac{N_u}{bd} \right]}{1.25f_y}$$

For in-plane forces the maximum steel ratio is limited to:

$$\rho_{\max} = \frac{\left[0.64f'_m \left(\frac{\epsilon_{mu}}{\epsilon_{mu} + 5\epsilon_y} \right) - \frac{N_u}{bd} \right]}{\left[1.25f_y \left(\frac{5\epsilon_y}{\epsilon_{mu} + 5\epsilon_y} \right) - \frac{1}{2} \left(\frac{\epsilon_{mu}}{\epsilon_{mu} + 5\epsilon_y} \right) \epsilon_{mu} E_s \right]}$$

FIGURE 32.13 Strain–stress distribution on a flexural member at balanced conditions.

Strength Design for Sections with Tension Steel Only

As stated above, the limits for flexural design using strength methods are that the stress in the steel is at yield strength and that the strain in the concrete masonry is at 0.0025 and 0.0035 for clay masonry. When these conditions occur at the same moment, the section is considered to be a balanced design. See Figure 32.13.

The depth to the neutral axis, c_b , for a balanced design for concrete masonry is:

$$c_b = \frac{0.0025}{0.0025 + f_y / E_s} d = \frac{72\,500}{72\,500 + f_y} d = 0.547d$$

For clay masonry:

$$C_b = \frac{0.0035}{0.0035 + f_y / E_s} d = \frac{101\,500}{101\,500 + f_y} d = 0.629d$$

Defining Terms

Allowable work stress design or elastic design — A technique based on and limiting the stress in the structural element to a value that is always in the elastic range.

Brick — Solid unit $\leq 25\%$ void; hollow unit $> 25\%$ and $< 75\%$ void.

Grout — Material to tie reinforcing steel and masonry units together to form a structural system.

Maximum usable strain — The limit of the masonry just before crushing.

Modular ratio — Ratio between the modulus of elasticity of steel to the modulus of elasticity of masonry.

Mortar — Plastic material between units in bed and head joints.

Steel ratio — Area of steel to area of masonry.

Strength design — A technique based on capacity of structural section considering the maximum strain in masonry, yield strength of steel, load factors for various loads considered, and phi factors for materials and workmanship.

Bulent A. Ovunc

University of Louisiana at Lafayette

The nonlinearity of a structure under external disturbances may be due to large deformations, which cause geometrical nonlinearity, and/or it may be due to stresses increasing beyond their proportional limits, thus causing material nonlinearity occurring within the entire or a part of the structure. The actual stress–strain variation is represented by continuous functions, depending on the material used. For beams, the nonlinear regions appearing in their spans are determined within the analysis. The dynamic analysis can be based on a linear acceleration approach and can be performed by either an incremental or an iterative process or by using an iterative process within each increment. It can be noticed that at a section, the axial, the shearing forces, the bending moment, and the axial transversal displacements and rotation are interrelated. The effect of the nonlinearities becomes infinitesimal, negligible, when the geometrical and material nonlinearities tend to zero.

33.1 Procedure of Analysis

In the analysis it is assumed that the material is homogeneous and isotropic and the strain variation over the cross-section is linear. The internal force and moments are determined from two different sources — the equilibrium of the infinitesimal element on the deformed configuration, which is related to the geometrical nonlinearity, and from the stress distribution over the cross-section, which is related to the material nonlinearity.

FIGURE 33.1 Axes systems in a frame.

33.2 Geometrical Behavior

The geometrical behavior of structures depends on the magnitudes of their deformations under external disturbances. The geometrical behavior is treated through three different axes systems. The joints of the structure are referred to by the Total Lagrangian axes system, XYZ. At an intermediate point within a member, the strains and the stresses are expressed with respect to the Eulerian axes system, x_e, y_e, z_e , whereas the displacements and rotations are expressed with respect to the Updated Lagrangian axes system, x_u, y_u, z_u . See Figure 33.1.

The abscissa along the Updated Lagrangian axes system, x_u, y_u, z_u (Figure 33.1), can be written in terms of the axial displacement $u()$, as

$$= y_u + u() \quad (33.1)$$

The point C is located on the neutral axis of the infinitesimal element CD, of length dy_u , on the undeformed configuration. The point A, at distance z from the point C, moves to a point A', on the deformed configuration C'D'. The point R' is the intersection of the lines passing through the cross-sections at C' and D'. Notice that the distances R'C', ρ' , and R'D', ρ'' are different than the radius of curvature ρ of the element C'D'. The point S' is the intersection of the lines perpendicular to the cross-sections at C' and D'.

The relations among the axial and shearing force $P(\xi)$, and $V(\xi)$ and the increment $dM/d\xi$ on bending moment are obtained from the equilibrium of the infinitesimal element C'D' on the deformed configuration. By considering the sum of the moments about points R' and S' and the sum of the forces about two axes, and by eliminating higher order differentials, one has

$$dM/d\xi = (1 + (w')^2)^{1/2} V(\xi) \quad (33.2)$$

$$dM/d\xi = -\rho dP/d\xi \quad (33.3)$$

$$dV/d\xi = (1/\rho)(1 + (w')^2)^{1/2} P(\xi) + (q_z w' + q_y)/(1 + (w')^2)^{1/2} \quad (33.4)$$

$$dP/d\xi = -(1/\rho)(1 + (w')^2)^{1/2} V(\xi) + (q_z - q_y w')/(1 + (w')^2)^{1/2} \quad (33.5)$$

where q_z and q_y are the distributed external loads on the infinitesimal element C'D' on the deformed configuration.

FIGURE 33.2 Infinitesimal element on deformed configuration.

For the dynamic analysis based on the continuous mass matrix method [Clough and Penzien, 1993; Ovunc, 1994],

$$q_z = m(d^2w/dt^2) \text{ and } q_y = m(d^2u/dt^2) \quad (33.6)$$

where m is the mass of the element per unit length.

The integration of the two simultaneous equations, Equation 33.4 and Equation 33.5, with $q_z = m(d^2w/dt^2)$ and $q_y = m(d^2u/dt^2)$ yields:

$$P(\xi) = ((1 + (w')^2)^{-1/2})[-C_1w' + C_2 - \xi Lm((d^2w/dt^2)w' + (d^2u/dt^2))] \quad (33.7)$$

$$V(\xi) = ((1 + (w')^2)^{-1/2})[C_1 + C_2w' - \xi Lm((d^2w/dt^2) - d^2u/dt^2)w'] \quad (33.8)$$

so that the increment $dM/d\xi$ on the bending moment [Equation (33.2)] can be obtained as

$$dM/d\xi = [C_1 + C_2w' - \xi Lm((d^2w/dt^2) - (d^2u/dt^2)w')] \quad (33.9)$$

If it is assumed that the inertia forces on the member are zero ($q_z = q_y = 0$), the above equations related to the geometrical behavior can be written as

$$dM/d\xi = [C_1 + C_2w'] \quad (33.10)$$

$$P(\xi) = ((1 + (w')^2)^{-1/2})[-C_1w' + C_2] \quad (33.11)$$

$$V(\xi) = ((1 + (w')^2)^{-1/2})[C_1 + C_2w'\xi] \quad (33.12)$$

The relation between the internal axial force $P(\xi)$, and shearing force $V(\xi)$ [Equation (33.11) and Equation (33.12)] can be obtained as

$$P^2 + V^2 = C^2 \quad (33.13)$$

where C is constant.

FIGURE 33.3 $\sigma - \epsilon$ diagram for steel.

FIGURE 33.4 Hognestad $\sigma - \epsilon$ diagram for concrete.

The relations from Equation 33.2 to Equation 33.5 show that the internal axial force $P(\xi)$, shearing force $V(\xi)$, and bending moment $M(\xi)$ are interrelated. Similarly, the axial displacement $u(\xi)$ and the transversal displacement $w(\xi)$ are also interrelated. All the above relations are related to the geometrical behavior.

33.3 Material Behavior

Material behavior depends on the variation of the stresses along the cross-section of a member. Under external disturbances, the stress in a member may vary from linear to nonlinear elastic to plastic stages. The variation of the stress versus the strain is expressed by a continuous function, corresponding to the characteristics of the material. Thus the normal stress σ_z at a distance z from the neutral axis of a section of a ductile material subjected to axial force and bending moment is expressed as [Ovunc, 1992] (Figure 33.3)

$$\sigma_z = a_\sigma \tanh(\alpha + \beta z) [1 + (\beta z)^2 / (3 \cosh^2(\alpha + \beta z))] \quad (33.14)$$

where $\alpha = (1/(c_\sigma L))(du/d\xi)$, $\beta = v\gamma$, $v = h/(2c_\sigma)$, $\gamma = d^2w/d\xi^2$, and a_σ and c_σ are related to the material properties.

For materials such as concrete, the expression of the stress can be approximated as (Figure 33.4)

$$\sigma_z = a_\sigma \tanh(\alpha + \beta z) [1 + (\beta z)/(2 \cosh^2(\alpha + \beta z))] \quad (33.14')$$

Additional terms can be introduced in the expression of the stress to improve the accuracy,

$$\sigma_z = a_\sigma \tanh(\alpha + \beta z) [1 + (\beta z)^2 / (3 \cosh^2(\alpha + \beta z)) - (\alpha + \beta z)^2 / (\cosh^4(\alpha + \beta z))] \quad (33.14'')$$

but they complicate the manipulation in the derivation.

Successive Loading and Unloading

During successive loading and unloading, the stress–strain variation can be divided into four phases to describe the behavior of the material (Figure 33.5):

- Phase I** — The stress–strain diagram is linear up to the proportional limit. The difference between the actual and the present study is negligible.
- Phase II** — Between proportional and yield limits, the idealized stress–strain diagram is still linear. But in the present study, the stress–strain diagram exhibits nonlinearity.
- Phase III** — The yield limit does not exist for an assumed linear stress–strain diagram, where the stress increases up to failure without any change in the stiffness of the member. The yield limit exists in the stress–strain diagrams of the idealized case and present study.

FIGURE 33.5 Successive loading and unloading.

Phase IV — During unloading, the stresses and strains decrease. For the decrease in stress, the stress–strain diagram is linear and parallel to the linear part of the loading diagram in all three cases. For the decrease beyond the lower proportional limit, the stress–strain variations in all the three cases are similar to their respective loading diagrams.

Stress Resultants

The axial force, $P(\xi)$, and the bending moment, $M(\xi)$, at an arbitrary section ξ are determined as the resultants of the stress over the cross-section, as

$$P(\xi) = a_{\sigma}(bh/3)\tanh\alpha[(2/v\gamma)\tanh(v\gamma) + 1 - \tanh\alpha\tanh(v\gamma) + 3v\gamma\tanh(v\gamma)] \quad (33.15)$$

$$M(\xi) = a_{\sigma}(bh/4)[\tanh(v\gamma) - v\gamma/3][1 - \tanh^2\alpha - \tanh^2(v\gamma)] \quad (33.16)$$

and the increment of the bending moment as

$$dM/d\xi = a_{\sigma}(bh^2/6)vw''''[1 - \tanh^2(v\gamma))(1 + v\gamma\tanh v\gamma) + \tanh^2\alpha] \quad (33.16')$$

where $v = h/(2c_{\sigma})$ and $\gamma = d^2w/d\xi^2$.

For frames with material nonlinearity, the resisting axial force, $P(\xi)$, and the bending moment, $M(\xi)$, are no longer independent functions. The effect of the deflection $w(\xi)$ on the axial force $P(\xi)$ and the effect of the axial displacement $u(\xi)$ on the bending moment $M(\xi)$ can be seen from their expressions.

33.4 Equations of Motion

Herein, in the derivation of equations of motion, the inertia forces on the members are assumed to be zero ($q_z = q_y = 0$). Then the equations of motion are determined by equating the expressions of internal forces $P(\xi)$ and $V(\xi)$ and moment $dM/d\xi$, obtained from the geometrical behavior [Equation (33.10), Equation (33.11)], to those obtained from the material behavior [Equation (33.15) and Equation (33.16')]

$$a_{\sigma}(bh^2/6)vw''''[1 - \tanh^2(v\gamma))(1 + v\gamma\tanh v\gamma) + \tanh^2\alpha] - [C_1 + C_2w'] = 0 \quad (33.17)$$

$$a_{\sigma}(bh/3)\tanh\alpha[(2/v\gamma)\tanh(v\gamma) + 1 - \tanh\alpha\tanh(v\gamma) + 3v\gamma\tanh(v\gamma)] - ((1 + (w')^2)^{-1/2})[-C_1w' + C_2] = 0 \quad (33.18)$$

The axial and transversal displacements $u(\xi)$ and $w(\xi)$, respectively, will be determined from the two differential equations above [Equation (33.17) and Equation (33.18)].

Equation of Motion without the Effect of Member Axial Force

Considering the equation of motion [Equation (33.17)] and eliminating the effect of axial force (assuming $\alpha = 0$), one has

$$a_{\sigma}(bh^2/6)v w''''(1 - \tanh^2(v\gamma))(1 + v\gamma \tanh v\gamma) - (C_1 + C_2 w') = 0 \quad (33.19)$$

or, differentiating once more with respect to ξ and neglecting $(w'')^2$ second order differential, one has

$$w^{iv} (1 + v\gamma \tanh v\gamma) - C w'' \cosh(v\gamma) = 0 \quad (33.20)$$

Various numerical integration methods can be used to generate the vector of the nonlinear member end reactions $\{f_{nl}\}$.

33.5 Linearization of the Moment and Force Displacement Relationships

To simplify the determination of displacements through the differential equation [Equation (33.20)], approximate methods can be used. As an approximate method, the expression of bending moment $M(\xi)$ [Equation 33.16] can be approximated by multiplying and dividing by $v\gamma$, thus one has

$$M(\xi) = v\gamma([a_{\sigma}(bh/4)[[\tanh(v\gamma)/(v\gamma) - 1/3][1 - \tanh^2(v\gamma)]] \quad (33.21)$$

where γ appearing out of the bracket, say γ_{lin} , is

$$\gamma_{lin} = (d^2/d\xi^2) (N_1(\eta) N_2(\eta) N_3(\eta) N_4(\eta)) \}^T \{d_{ben}\}$$

and $\eta = \xi/l$; $N_i(\eta)$ is the shape function and $\{d_{ben}\}$ is the vector of member end displacements and rotations.

γ appearing within the parenthesis of bending moment, $M(\xi)$, is the summation of the displacements and rotations up to the present iteration or increment.

The shearing force–displacement relation is linearized similarly, as

$$V(\xi) = dM(\xi)/d\xi = (v\gamma')a_{\sigma}(bh/6)(1 - \tanh^2(v\gamma))(1 + v\gamma \tanh(v\gamma)) \quad (33.22)$$

γ' appearing out of the bracket can be assumed, as it is in linear analysis, obtained from the shape function, for the present increment or iteration

$$\gamma' = d^3 w/d\xi^3 = (12\eta/l^3 6\eta/l^2 - 12\eta/l^3 6\eta/l^2) \{d_{ben}\}$$

γ appearing within the parenthesis of the shearing force, $V(\xi)$, is the summation of the displacements and rotations up to the present iteration or increment.

Substituting the linear expressions of the parameters γ and γ' into the expressions of $M(\xi)$ and $V(\xi)$ provides the linearized expressions. Thus one has

$$M(\xi) = EI [[\tanh(v\gamma)/(v\gamma) - 1/3][1 - \tanh^2(v\gamma)]] ((-6 + 12\eta)/l^2 (-4 + 6\eta)/l (6 - 12\eta)/l^2 (-2 + 6\eta)/l) \{d_{ben}\} \quad (33.23)$$

$$V(\gamma) = EI (1 - \tanh^2(v\gamma))(1 + v\gamma \tanh(v\gamma)) (12/l^3 6\eta/l^2 - 12/l^3 6\eta/l^2) \{d_{ben}\} \quad (33.24)$$

where E and I are the Young's modulus and the moment of inertia of the cross-section.

Then, the equation of motion for the frame can be written as

$$([M]\{D(t)\} + [C]\{D(t)\} + [K_{nl}]\{D(t)\} = \{F(t)\} \quad (33.25)$$

where $[M]$, $[C]$, and $[K_{nl}]$ are the mass, damping, and nonlinear stiffness matrices for the frame, obtained from those of the members, respectively, and $\{D(t)\}$ and $\{F(t)\}$ are the displacements, including the rotations, and external forces, including the moments, at the joints of the frame.

Trusses

For trusses, the geometrical and material behaviors provide the equation of motion as

$$P(y) = a_c b h \tanh \alpha$$

where $\alpha = (1/(c_\sigma L))(du/d\xi)$, $u(\xi) = d_1 + (d_2 - d_1) \xi/L_{def}$, d_1 and d_2 are the end axial displacements at the fore and aft joints of the member with respect to the updated Lagrangian axis systems, and L_{def} is the deformed length of the member.

The linearization and the generation of the equation of motion are obtained in a similar manner to that for frames.

33.6 Consistent and Lumped Mass Matrix Methods

In the consistent and lumped mass matrix methods, the same steps as in the continuous mass matrix method are used by making the required assumptions related to their derivations.

33.7 Practical Applications

A two-span truss subjected to a suddenly applied constant load is considered as an example. The data on the geometry, material properties, external loading history, and the time steps are the same as given in Mondkar and Powell [Mondkar and Powell, 1977] (Figure 33.6).

Mondkar and Powell assumed Ramberg–Osgood continuous stress–strain variation. Their nonlinear analysis is based on Newmark's constant acceleration method. The variation of the vertical displacement

FIGURE 33.6 Truss under suddenly applied constant load P .

FIGURE 33.7 Linear and nonlinear responses of two-span truss under axial force $P = 10$ kips.

w , at the point of application of the external load P , versus the time steps is plotted in Figure 33.7. The diagrams include the linear and nonlinear responses under the Mondkar and Powell assumption and in the present study. The displacements for the linear responses using the Mondkar and Powell method and the present study have small differences up to the maximum amplitude. Beyond this point, the differences become larger. The displacements under the present study are larger than those obtained by the Mondkar and Powell assumption.

A comparison of linear and nonlinear dynamic displacements using two different external loads is shown in Figure 33.8. It can be noticed that the natural circular frequency for nonlinear response (ω_{NL}) is smaller than the natural frequency for linear response (ω_N). For external loads $P = 10$ k, the nonlinear displacement (w_{NL}) increases to infinity, showing the instability of the truss under $P = 10$ k. Since the members 7, 9, and 10, all of which are connected to the same joint, exhibit stresses at or beyond their the yield limit, local instability occurs.

FIGURE 33.8 Comparisons of linear and nonlinear displacements under axial forces, $P = 5$ kips and $P = 10$ kips.

Defining Terms

Linear behavior — In a system, the relation between the strain or deformation and the stress or applied load is linear.

Elastic behavior — A system is elastic if it returns to its original shape when the load acting on it is removed.

Materially linear behavior — If the variation of stress versus the strain is linear within the material.

Geometrically linear behavior — If the variation of the deformation versus the applied load is linear.

Plastic behavior — If, in a system, the strain or deformation increases when the stress or applied load remains at a constant limit value.

Stability — The strength to stand or endure.

Scour of Bridge Foundations

- 34.1 Total Scour
- 34.2 Long-Term Aggradation or Degradation
- 34.3 General Scour
- 34.4 Contraction Scour
- 34.5 Local Scour at Bridge Piers
Pier Scour Armoring Factor K_{45} • K_W Correction Factor for
Very Wide Piers
- 34.6 Local Scour at Complex Piers
- 34.7 Local Scour at Abutments

E. V. Richardson
Ayres Associates

Scour is the engineering term for the erosive action of flowing water, excavating and carrying away material from the bed and banks of streams and from around the piers and abutments of bridges. Scour is the most common cause of bridge failures. This chapter gives the methods and equations recommended by the U.S. Federal Highway Administration (FHWA) for the analysis and design of bridge foundations to be safe from scour. The recommendations are given in three Hydraulic Engineering Circulars (HEC-18 [Richardson and Davis, 2001], HEC 20 [Lagasse et al., 2001], and HEC 23 [Lagasse et al., 2001]) and one Hydraulic Design Series (HDS-6) [Richardson et al., 2001].

34.1 Total Scour

All streambed materials will scour. Only the rates of scour differ. Sand- and gravel-bed materials reach maximum scour depths in hours, whereas cohesive clays may take days or many storm cycles to reach maximum scour depths. However, ultimate scour in cohesive clays will be as deep as scour in sand-bed streams [Briaud et al., 1999]. Limestone and granite rock are very scour resistant (years). The total scour methods and equations given in this chapter predict maximum scour. Under some circumstances, taking the time rate of scour of clays into account may be appropriate. Briaud et al. [1999, 2001] describe equipment and methods to determine the time rate of scour in clay bed materials. Total scour at a highway crossing is comprised of three components:

1. Long-term aggradation or degradation of the river bed
2. General scour at the bridge (contraction of the flow or other flow conditions)
3. Local scour at the piers or abutments

In addition, **lateral migration** of the stream must be assessed when evaluating total scour at bridge piers and abutments.

These three scour components are considered to be independent of each other and are added to obtain the total scour at a pier or abutment. Considering the components independent and additive adds some conservatism to the design. Total scour is determined using a design discharge. For streams and rivers the discharge for the 20-, 50-, or 100-return period is used depending on the class of road. For bridges crossing tidal waterways, the discharge is determined using the return period of the storm surge elevation and area of the waterway.

34.2 Long-Term Aggradation or Degradation

The streambed at a bridge crossing may be aggrading, degrading, or in relative equilibrium. Aggradation involves the deposition of sediment under the bridge, whereas degradation is the lowering of the streambed under the bridge due to a deficit in sediment supply from upstream. These long-term bed elevation changes may be the natural trend of the stream or the result of some modification to the stream or watershed. Long-term aggradation and degradation do not include the cutting and filling of the streambed in the vicinity of the bridge that might occur during a runoff event (general and local scour). If the stream is aggrading, the increase in streambed elevation is not considered in the total scour. But if the stream is degrading, the estimated decrease in elevation of the streambed is included in the total scour. The engineer must assess the present state of the stream and watershed and then evaluate potential future changes in the river system. From this assessment, the long-term streambed changes are estimated.

Factors that affect long-term bed elevation changes are dams and reservoirs (up- or downstream of the bridge), changes in watershed land use (urbanization, deforestation, etc.), channelization, cutoffs of meander bends (natural or manmade), changes in the downstream channel base level (control), gravel mining from the streambed, diversion of water into or out of the stream, natural lowering of the fluvial system, movement of a bend and bridge location with respect to stream planform, and stream movement in relation to the crossing. To assess long-term bed elevation changes, a three-level fluvial system approach can be used. It consists of:

1. A qualitative determination using general geomorphic and river mechanics relationships
2. An engineering geomorphic analysis using established qualitative and quantitative relationships to estimate elevation changes resulting from various scenarios of future conditions
3. Computations using physical process computer models such as BRI-STARS [Molinas, 1990], HEC 6 [USACE, 1993], and SAM [USACE, 1988; Ayres, 2003]

The three-level approach is described in greater detail in FHWA publications HEC 20 [Lagasse et al., 2001], and HDS-6 [Richardson et al., 2001]. Available bridge inspection records, gaging station records, aerial photographs, available maps, and interviews with people knowledgeable of the stream are valuable for the analysis.

34.3 General Scour

General scour is a lowering of the streambed across the waterway at the bridge. This lowering may be uniform across the bed or it may be deeper in some parts of the cross-section. General scour is different from long-term degradation in that general scour may be cyclic and/or related to the passing of a flood. That is, the streambed lowers on the rising limb of a flood and fills on the falling limb. General scour may result from contraction of the flow or from other general scour conditions, such as flow around a bend, variable downstream control, junction of two streams, etc. Contraction scour occurs when the area of the bridge opening is smaller than the flow area of the upstream channel or channel and flood plain. Equations are given in the next section or using sediment transport computer models (see [Chapter 97](#), Sedimentation).

34.4 Contraction Scour

Contraction may be live-bed or clear-water scour. Live-bed contraction scour occurs at a bridge when there is transport of bed material in the upstream reach into the bridge cross-section. With live-bed contraction scour, the area of the contracted section that is scoured increases until, in the limit, the transport of sediment out of the contracted section equals the sediment transported in. Clear-water contraction scour occurs when (1) there is no bed material transport from the upstream reach into the downstream reach or (2) the material being transported in the upstream reach is transported through the downstream reach mostly in suspension and at less than capacity of the flow. With clear-water contraction scour, the area of the contracted section increases until, in the limit, the velocity of the flow (V) or the shear stress (τ_o) on the bed is equal to the critical velocity (V_c) or critical shear stress (τ_c) of a certain particle size (D) in the bed material. Normally, for both live-bed and clear-water scour, the width of the contracted section is constrained, and depth increases until the limiting conditions are reached.

Live-bed contraction scour depths may be limited by sediment transport into the bridge section or by armoring of the bed by large sediment particles in the bed material. Therefore, contraction scour at a bridge can be determined by calculating the scour depths using both the clear-water and live-bed contraction scour equations and using the smaller of the two depths.

Also, to determine if the contraction scour is live bed or clear water, calculate the critical velocity for beginning of motion V_c of the D_{50} size of the bed material being considered and compare it to the mean velocity V of the flow in the main channel or overbank area upstream of the bridge opening. If the critical velocity of the bed material is larger than the mean velocity ($V_c > V$), then clear-water contraction scour will exist. If the critical velocity is less than the mean velocity ($V_c < V$), then live-bed contraction scour will exist.

There are four conditions (cases) of contraction scour at bridge sites depending on the type of contraction and whether overbank flow or relief bridges exist. Regardless of the case, contraction scour is evaluated using two basic equations: (1) the live-bed scour equation and (2) the clear-water scour equation. The four conditions (cases) of contraction scour are:

Case 1. Overbank flow on a floodplain is being forced back into the main channel by the approaches to the bridge. Case 1 conditions include:

- A. The river channel width becomes narrower either due to the bridge abutments projecting into the channel or the bridge being located at a narrowing reach of the river.
- B. No contraction of the main channel occurs, but the overbank flow area is completely obstructed by an embankment
- C. Abutments are set back from the stream channel.

Case 2. Flow is confined to the main channel (i.e., no overbank flow is present).

Case 3. A relief bridge exists in the overbank area with little or no bed material transport.

Case 4. A relief bridge exists over a secondary stream in the overbank area with bed material transport (similar to Case 1).

Live-bed contraction scour depth is calculated using the following modified version of Laursen's [1960] equation for live-bed scour at a long contraction.

$$\frac{y_2}{y_1} = \left(\frac{Q_2}{Q_1} \right)^{6/7} \left(\frac{W_1}{W_2} \right)^{k_1} \quad (34.1)$$

$$y_s = y_2 - y_o = (\text{average contraction scour depth}) \quad (34.2)$$

where y_1 = average depth in the upstream main channel, m (ft); y_2 = average depth in the contracted section, m (ft); y_o = existing depth of flow in the contracted section before scour, m (ft); Q_1 = flow in the upstream channel transporting sediment, m^3/sec (ft^3/sec); Q_2 = flow in the contracted channel, m^3/sec

FIGURE 34.1 Fall velocity of sand-sized particles with specific gravity of 2.65.

sec (ft³/sec); W_1 = bottom width of the upstream main channel, m (ft); W_2 = bottom width of the main channel in the contracted section less pier width (s), m (ft); and k_1 = exponent determined below.

| V_s/ω | k_1 | Mode of Bed Material Transport |
|--------------|-------|---|
| <0.50 | 0.59 | Mostly contact bed material discharge |
| 0.50 to 2.0 | 0.64 | Some suspended bed material discharge |
| >2.0 | 0.69 | Mostly suspended bed material discharge |

$V_* = (\tau_o/\rho)^{1/2} = (gy_1 S_1)^2$, shear velocity in the upstream section, m/sec (ft/sec); ω = fall velocity of bed material based on the D_{50} , m/sec (Figure 34.1), for fall velocity in English units (ft/sec) multiply in m/sec by 3.28; g = acceleration of gravity, 9.81 m/sec² (32.2 ft/sec²); S_1 = slope of energy grade line of main channel, m/m (ft/ft); τ_o = shear stress on the bed, Pa (N/m²) (lb/ft²); ρ = density of water, 1000 kg/m³ (1.94 slugs/ft³).

Notes

Q_2 may be the total flow going through the bridge opening as in Cases 1a and 1b. It is not the total flow for Case 1c. For Case 1c, contraction scour must be computed separately for the main channel and the left and/or right overbank areas.

Q_1 is the flow in the main channel upstream of the bridge, not including overbank flows.

Clear-water contraction scour depth is calculated using an equation based on a development suggested by Laursen. The equation is:

$$y_2 = \left[\frac{K_u Q^2}{D_m^{2/3} W^2} \right]^{3/7} \quad (34.3)$$

$$y_s = y_2 - y_o = (\text{average contraction scour depth}) \quad (34.4)$$

where y_2 = average equilibrium depth in the contracted section after contraction scour, m (ft); Q = discharge through the bridge or on the set-back overbank area at the bridge associated with the width W , m³/sec (ft³/sec); D_m = diameter of the smallest nontransportable particle in the bed material (1.25 D_{50}) in the contracted section, m (ft); D_{50} = median diameter of bed material, m (ft); W = bottom width of the contracted section less pier widths, m (ft); y_o = average existing depth in the contracted section, m (ft); $K_u = 0.025$ SI units; $K_u = 0.0077$ English units.

For stratified bed material, the depth of scour can be determined by using the clear-water scour equation sequentially with successive D_m of the bed material layers.

FIGURE 34.2 Common pier shapes [Source: Richardson, E. V. and Davis, S. R. 2001. *Evaluating Scour at Bridges, Forth Edition*. HEC 18, Pub. No. FHWA-NHI 01-001, FHWA, Washington, D.C.].

34.5 Local Scour at Bridge Piers

To determine maximum local pier scour, an equation based on an equation developed at Colorado State University [Richardson et al., 2001] is recommended for both live-bed and clear-water pier scour in HEC 18 [Richardson and Davis, 2001]. The recommendation is based on a study by Jones [1983] and a comparison by Mueller [1996] of 22 scour equations using field data collected by the U.S. Geological Survey. The data included 384 field measurements of scour at 56 bridges. The equation is:

$$\frac{y_s}{y_1} = 2.0 K_1 K_2 K_3 K_4 K_w \left(\frac{a}{y_1} \right)^{0.65} Fr_1^{0.43} \quad (34.5)$$

where y_s = Scour depth, m (ft), y_1 = Flow depth directly upstream of the pier, m (ft), K_1 = Correction factor for pier nose shape from Figure 34.2 and Table 34.1, K_2 = Correction factor for angle of attack of flow from Equation 34.6, K_3 = Correction factor for bed condition from Table 34.3, K_4 = Correction factor for armoring by bed material size, K_w = Correction factor for pier width from Equations 34.7 and Equation 34.8, a = Pier width, m (ft), L = Length of pier, m (ft), Fr_1 = Froude Number directly upstream of the pier = $V_1/(gy_1)^{1/2}$, V_1 = Mean velocity of flow directly upstream of the pier, m/sec (ft/sec), g = Acceleration of gravity (9.81 m/sec²) (32.2 ft/sec²)

$$K_2 = (\cos \theta + L/a \sin \theta)^{0.65} \quad (34.6)$$

If L/a is larger than 12, use $L/a = 12$ as a maximum.

Table 34.2 illustrates the magnitude of the effect of the angle of attack on local pier scour.

TABLE 34.1 Correction Factor, K_1 , for Pier Nose Shape

| Shape of Pier Nose | K_1 |
|------------------------|-------|
| (a) Square nose | 1.1 |
| (b) Round nose | 1.0 |
| (c) Circular cylinder | 1.0 |
| (d) Group of cylinders | 1.0 |
| (e) Sharp nose | 0.9 |

TABLE 34.2 Correction Factor, K_2 , for Angle of Attack, θ , of the Flow

| Angle | $L/a = 4$ | $L/a = 8$ | $L/a = 12$ |
|-------|-----------|-----------|------------|
| 0 | 1.0 | 1.0 | 1.0 |
| 15 | 1.5 | 2.0 | 2.5 |
| 30 | 2.0 | 2.75 | 3.5 |
| 45 | 2.3 | 3.3 | 4.3 |
| 90 | 2.5 | 3.9 | 5.0 |

Note: Angle = skew angle of flow; L = length of pier, m.

TABLE 34.3 Increase in Equilibrium Pier Scour Depths, K_3 , for Bed Condition

| Bed Condition | Dune Height, m | K_3 |
|-----------------------------|------------------|------------|
| Clear-water scour | N/A | 1.1 |
| Plane bed and antidune flow | N/A | 1.1 |
| Small dunes | $3 > H \geq 0.6$ | 1.1 |
| Medium dunes | $9 > H \geq 3$ | 1.2 to 1.1 |
| Large dunes | $H \geq 9$ | 1.3 |

Notes

For angles of attack up to 5 degrees use the pier nose shape correction factor K_1 . For greater angles, K_2 dominates and K_1 should be considered as 1.0. K_2 should be applied using the effective length L of the pier actually subjected to the angle of attack of the flow. Plane-bed and/or antidune flow conditions are typical for most bridges over sand bed streams for the flood frequencies employed in scour design. Large dunes exist during flood flow on very large rivers, such as the Mississippi. Smaller streams with a dune bed configuration at flood flow will have smaller dunes. Piers set close to abutments (for example at the toe of a spill through abutment) must be carefully evaluated for the angle of attack and velocity of the flow coming around the abutment.

Pier Scour Armoring Factor K_4

Richardson, using the U. S. Geological Survey field data of 384 measurements at 56 bridges [Landers et al., 1999] and Mueller and Jones [1999] studies, developed the following for K_4 :

- The minimum value of K_4 is 0.4.
- For $D_{50} < 2.0$ mm, $K_4 = 1.0$;
- For $D_{95} < 20.0$ mm, $K_4 = 1.0$;
- For $V_1 < V_{icD35}$, $K_4 = 0.4$.
- For $V_1 > V_{icD35}$, $K_4 = (1 - V_{icD35}/V_1)^{0.43}$. (34.7)

where V_{icD_x} = the approach velocity (m/sec or ft/sec) required to initiate scour at the pier for the grain size D_x (m or ft).

$$V_{icD35} = 0.645 \left(\frac{D_{35}}{a} \right)^{0.053} V_{cD35} \tag{34.8}$$

where V_{cD35} = the critical velocity (m/sec or ft/sec) for incipient motion for the grain size D_{35} (m or ft).

$$V_{cD35} = K_u \gamma_1^{1/6} D_{35}^{1/3} \tag{34.9}$$

where γ_1 = depth of flow just upstream of the pier, excluding local scour, m (ft); V_1 = velocity of the approach flow just upstream of the pier, m/sec (ft/sec); D_x = grain size for which x percent of the bed material is finer, m (ft); $K_u = 6.19$ SI units; and $K_u = 11.17$ English units.

D_{35} may be calculated using the following equation:

$$D_{35} = \frac{D_{50}}{\left(\frac{D_{84}}{D_{16}} \right)^{0.1925}} \tag{34.10}$$

If D_{84} and/or D_{16} are not measured, then take $D_{35} = 0.8 D_{50}$.

FIGURE 34.3 Multiple columns skewed to the flow [Source: Richardson, E. V. and Davis, S. R. 2001. *Evaluating Scour at Bridges, Fourth Edition*. HEC 18, Pub. No. FHWA-NHI 01-001, FHWA, Washington, D.C.).

K_w Correction Factor for Very Wide Piers

Johnson and Torrico [1994] suggest the following equations for a K_w factor to wide piers in shallow flow. The correction factor should be applied when the ratio of depth of flow (y) to pier width (a) is less than 0.8 ($y/a < 0.8$); the ratio of pier width (a) to the median diameter of the bed material (D_{50}) is greater than 50 ($a/D_{50} > 50$); and the Froude number of the flow is subcritical.

$$K_w = 2.58 \left(\frac{y}{a} \right)^{0.34} Fr_1^{0.65} \quad \text{for } V/V_c < 1 \quad (34.11)$$

$$K_w = 1.0 \left(\frac{y}{a} \right)^{0.13} Fr_1^{0.25} \quad \text{for } V/V_c \geq 1 \quad (34.12)$$

Care should be used in applying K_w because it is based on limited data from flume experiments. Its use should take into consideration traffic volume, class and importance of the highway, cost of a failure (potential loss of lives and dollars), and the change in cost that would occur if the K_w factor is used.

With **multiple columns** skewed to the flow (Figure 34.3) and spaced less than five pier diameters apart, the pier width “ a ” is a composite width of all the columns in a single bent with no space between. This composite pier width would be used in Equation 34.6 to determine K_2 in the pier scour equation. If the multiple columns are spaced five diameters or greater apart and debris is not a problem, the scour depth is taken as 1.2 times the local scour of a single column.

Pressure flow scour occurs when flow under a bridge is in contact with the underside of the bridge. The bridge may or may not be submerged. If the bridge is entirely submerged, the resulting flow is a complex combination of the plunging flow under the bridge (orifice flow) and flow over the bridge (weir flow). Pier scour with pressure flow is a combination of vertical deck contraction scour and local pier scour, which are additive [Jones et al., 1996 and Arneson and Abt, 1999]. To determine scour depths for a bridge, the reader is referred to the publications of Jones et al. [1996], Arneson and Abt [1999], and Richardson and Davis [2001].

Debris lodged on a pier can increase local scour at a pier. The scour depth can be estimated by assuming that the pier width is larger than the actual width. For additional discussion, see HEC-20 [Lagasse et al., 2001], and HEC 18 [Richardson and Davis, 2001],

34.6 Local Scour at Complex Piers

Most determinations of local pier scour depths have focused on piers with single substructural elements. In the general case, the flow could be obstructed by three substructure elements, which include the pier

stem, the pile cap or footing, and the pile group. Based on research by Jones and Sheppard [2000], Richardson and Jones determined methods and equations to determine scour depths for complex pier foundations, which are given in HEC 18 (Richardson and Davis, 2001). **Physical model** studies are still recommended for complex piers with unusual features such as staggered or unevenly spaced piles or for major bridges where conservative scour estimates are not economically acceptable. However, the methods presented in HEC18 provide a good estimate of scour for a variety of complex pier situations.

34.7 Local Scour at Abutments

The flow obstructed by the abutment and approach highway embankment forms two erosion potentials. One is a horizontal vortex starting at the upstream end of the abutment and running along the toe of the abutment, and the other is a vertical wake vortex at the downstream end of the abutment. Research has only developed equations to predict scour depths caused by the horizontal vortex.. There are three general shapes of abutments:

1. Spill-through abutments
2. Vertical walls without wing walls
3. Vertical-wall abutments with wing walls

These shapes have varying angles to the flow. Maximum depth of scour from the horizontal vortex for spill-through abutments is 55% of that for vertical-wall abutments. Similarly, scour depths at vertical wall abutments with wingwalls is 82% of the scour of vertical wall abutments without wingwalls.

Almost all equations in the literature use the abutment and roadway approach length instead of the intercepted flow as one of the variables. This approach results in excessively conservative estimates of scour depth. Richardson and Richardson [1993] pointed this out in a discussion of Melville's [1992] paper. They stated, "The reason the equations in the literature predict excessively conservative abutment scour depths for the field situation is that, in the laboratory flume, the discharge intercepted by the abutment is directly related to the abutment length; whereas, in the field, this is rarely the case."

Because available equations do not estimate reliable abutment scour depths for the horizontal vortex, engineering judgment is required in designing foundations for abutments. As a minimum, abutment foundations should be designed assuming no ground support (lateral or vertical) as a result of soil loss from long-term degradation, stream instability, and contraction scour. The abutment should be protected from local scour using riprap and/or guide banks. Guidelines for the design of riprap and guide banks are given in HEC-23 [Lagasse et al., 2001]. HEC 18 [Richardson and Davis, 2001] gives two equations to provide guidance in the design of abutment foundations.

To protect the abutment and approach roadway from scour by the wake vortex, several states use a 15-meter (50-ft) guide bank extending from the downstream corner of the abutment. Otherwise, the downstream abutment and approach should be protected with riprap or other forms of bank protection.

Defining Terms

Bed form — A relief feature on the bed of a stream, such as dunes, plane bed, or antidunes. Also called *bed configuration* [Simons and Richardson, 1963; Richardson et al., 2001].

Bed material — Material found on the bed of a stream. May be transported in contact with the bed or in suspension.

Critical shear stress — The minimum amount of shear (force) exerted by the flow on a particle or group of particles that is required to initiate particle motion.

Discharge — Time rate of the movement of a quantity of water or sediment passing a given cross-section of a stream or river.

Geomorphology — The branch of physiography and geology that deals with the general configuration (form) of the earth's surface and the changes that take place as the result of the forces of nature.

Hydraulic radius — The cross-sectional area of a stream, divided by its wetted perimeter. Equals the depth of flow when the width is larger than ten times depth.

Median diameter — The particle diameter at which 50% of a sample's particles are coarser and 50% are finer (D_{50}).

Shear stress, tractive force — The force or drag on the channel boundaries that is caused by the flowing water. For uniform flow, shear stress is equal to the unit weight of water times the hydraulic radius times the slope. Usually expressed as force per unit area.

Shear velocity — The square root of the shear stress divided by the mass density of water, in units of velocity.

Slope — Fall per unit length of the channel bottom, water surface, or energy grade line.

Purdue University, Emeritus

A fluid is a substance that cannot sustain shear stress while at rest; even a small shear stress causes a continuous rate of angular deformation within a fluid. Under typical conditions liquids and gases behave as fluids. Under extreme conditions, solids may exhibit fluid characteristics, as in the “flow” of ice in a glacier.

Fluids are characterized by the relationship between applied shear stress and rate of angular deformation (*shear rate*). **Newtonian fluids** obey a simple linear relationship. For parallel flow this may be expressed as $\tau_{yx} = \mu \, du/dy$, where τ_{yx} is shear stress applied in the direction of the velocity, y is distance perpendicular to velocity, μ is dynamic viscosity or simply **viscosity**, and du/dy is rate of angular deformation. Most gases and many liquids — such as water, gasoline, and other pure substances — are closely approximated by the Newtonian fluid model.

Viscosity depends primarily on temperature at moderate pressures. Viscosity decreases sharply with increasing temperature for liquids and increases slightly for gases. At extremely high pressures, viscosities of liquids may increase significantly.

Fluid systems are commonly encountered in engineering practice. Transportation vehicles of all types — whether immersed or floating — experience viscous and pressure drag forces caused by fluid flow around the vehicle. Pipeline transportation and human circulation are fluid systems, as are convection heating and ventilating systems.

35.1 Fundamentals of Incompressible Fluid Flow

This section covers incompressible fluid flow. *Density* is defined as mass per unit volume and denoted by ρ ; fluids with constant density are *incompressible*. Liquids are nearly incompressible. Gases are compressible, but gas flow may be treated as incompressible when the maximum speed is less than one-third the speed of sound.

The objective of fluid flow analysis is to predict the pressure drop and pumping power for internal flow through conduits and the forces and moments on bodies in external flow. In principle this may be accomplished if the three components of velocity and the pressure are known. In practice it is often

impossible to solve problems analytically; in these cases it is necessary to rely upon experimental data from tests of models and model systems.

This section covers fundamentals of incompressible fluid mechanics. First, fluids without relative motion are considered. Details of flow fields are then considered. Dimensional analysis to help simplify design of experiments and presentation of experimental data is then treated, followed by applications of the results.

The basic equations used to analyze fluid flows are conservation of mass, Newton's second law of motion (linear momentum), and the first law of thermodynamics. These equations are derived in mechanics and physics for application to fixed masses. Special forms of the equations are required to analyze moving fluids.

A *system* is defined as a fixed mass of fluid. A *control volume* is an arbitrary boundary defined in the flow field to identify a region in space. Fluid may flow through the control volume, and exchanges of heat and work with the surroundings may occur.

The best system or control volume size for analysis depends on the information sought. Integral control volumes are used to obtain overall information such as thrust of a jet engine or force exerted by a liquid jet on a surface. Differential systems and control volumes are used to obtain detailed information about flow fields, such as point-by-point variation of velocity.

For analysis, the fluid is assumed to be a *continuum*; individual molecules are not considered. Fluid velocity is a vector that varies continuously throughout the flow; the velocity field is a vector field. It is possible to resolve the velocity into scalar components. Thus $\vec{V} = u\hat{i} + v\hat{j} + w\hat{k}$, where \vec{V} is the velocity vector of the *fluid particle* (small volume of fluid surrounding point xyz); u , v , and w are scalar components of velocity; and \hat{i} , \hat{j} , \hat{k} are unit vectors in the x , y , and z directions, respectively.

In the most general case, velocity is a function of three space coordinates and time, $\vec{V} = \vec{V}(x, y, z, t)$. For steady flow there is no time dependence. The number of space coordinates defines the dimensions of the flow field; $\vec{V} = \vec{V}(x)$ is a steady, one-dimensional flow field.

Stress is defined as the limiting value of force per unit area as the area is reduced to differential size. The simplest description of stress uses area elements having normals in the three coordinate directions; the infinitesimal force on each area element also may have three components. The notation τ_{yx} signifies a shear stress acting in the x direction on an area element with normal in the y direction. The *stress field* is the continuous distribution of stresses throughout the fluid; the stress field behaves as a second-order tensor.

35.2 Fluids without Relative Motion

In the absence of relative motion, no viscous stresses can be present within a fluid. The only surface stress is pressure, which acts against the surface of a fluid element. Pressure must vary continuously throughout the fluid, so it may be expanded in a Taylor series. Summing forces on an infinitesimal fluid element (Figure 35.1) leads to the expression

$$-\nabla p + \rho \vec{g} = \rho \vec{a} \quad (35.1)$$

This result shows that the *pressure gradient* ∇p is the negative of the net body force per unit volume. (When $\vec{a} = 0$ this is the *basic equation of fluid statics*.)

When the fluid is static or the acceleration field is known, Equation (35.1) may be solved for pressure distribution. This is done most easily by expanding the pressure gradient into components (most advanced mathematics books give the *del operator* ∇ in rectangular, cylindrical, and spherical coordinates).

35.3 Basic Equations in Integral Form for Control Volumes

To formulate the basic equations for control volume application requires a limiting process [Fox et al., 2004] or derivation of the Reynolds transport theorem [Fay, 1994]. The resulting relation between the system expression and control volume variables is

FIGURE 35.1 Differential fluid element showing pressure forces.

$$\left. \frac{dN}{dt} \right|_{\text{system}} = \frac{\partial}{\partial t} \int_{CV} \eta \rho dV + \int_{CS} \eta \rho \vec{V} \cdot d\vec{A} \quad (35.2)$$

To apply Equation (35.2), the system equation is formulated in terms of the rate of change of any extensive property N of the system; the corresponding intensive property is represented by η . The first integral in Equation (35.2) represents the quantity of N stored within the control volume; the second integral represents the net flux of N carried outward through the control surface.

Conservation of mass is obtained by substituting, for a system of constant mass, $dM/dt = 0$; the corresponding intensive property is “mass per unit mass,” so $\eta = 1$. Thus,

$$0 = \frac{\partial}{\partial t} \int_{CV} \rho dV + \int_{CS} \rho \vec{V} \cdot d\vec{A} \quad (35.3)$$

For incompressible flow, density cannot vary with time, so it is tempting to factor ρ from under the volume integral. However, parts of the control volume could be occupied by fluids having different densities at different times.

The momentum equation for control volumes is obtained by substituting the system form of Newton’s second law into the left side of Equation (35.2) and setting $\eta = \vec{V}$ on the right side:

$$\vec{F}_S + \vec{F}_B = \frac{\partial}{\partial t} \int_{CV} \vec{V} \rho dV + \int_{CS} \vec{V} \rho \vec{V} \cdot d\vec{A} \quad (35.4)$$

The left side of Equation (35.4) represents external surface and body forces acting *on* the control volume. The first integral represents the rate of change of linear momentum contained within the control volume. The second integral accounts for the net flux of linear momentum from the control surface. Equation (35.4) is a vector equation; each of its three components must be satisfied.

The first law of thermodynamics is obtained by substituting the rate form of the system equation into Equation (35.2). The result is the scalar equation

$$\dot{Q} - \dot{W}_{\text{shaft}} = \frac{\partial}{\partial t} \int_{CV} e \rho dV + \int_{CS} \left(e + \frac{p}{\rho} \right) \rho \vec{V} \cdot d\vec{A} \quad (35.5)$$

In Equation (35.5) the intensive property stored energy $e = u + (V^2/2) + gz$ includes internal thermal energy u , kinetic energy $V^2/2$, and gravitational potential energy gz (all per unit mass). The rate of heat

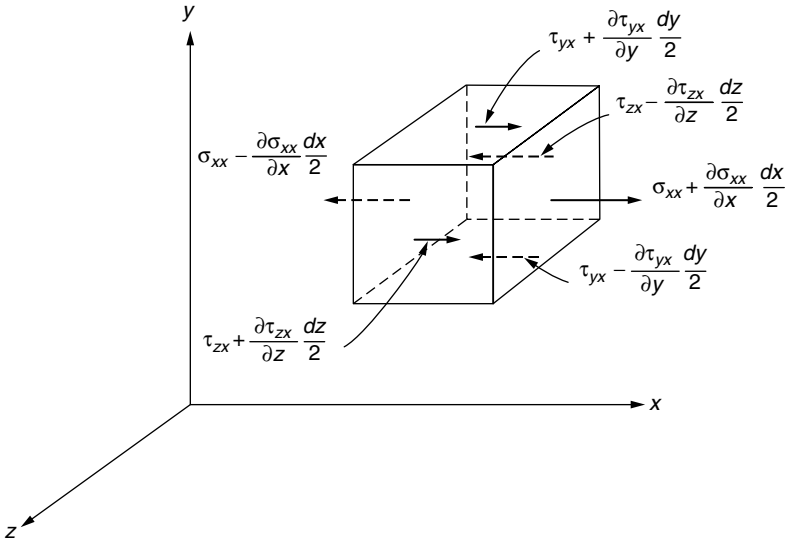

FIGURE 35.3 Differential fluid element showing stresses acting in the x direction.

Convective acceleration occurs when fluid particles are convected into regions of differing velocity; it may be nonzero even in a steady flow, such as steady flow through a nozzle. *Local acceleration* is caused by velocity variations with time; it is nonzero only for unsteady flow.

Forces acting on a fluid particle also may be obtained using the Taylor series expansion procedure. The results of expanding the stresses acting in the x direction on an infinitesimal fluid particle are shown in Figure 35.3.

Performing the same expansion in the other directions and collecting terms gives the *stress equations of motion*:

$$\rho g_x + \frac{\partial \sigma_{xx}}{\partial x} + \frac{\partial \tau_{yx}}{\partial y} + \frac{\partial \tau_{zx}}{\partial z} = \rho \left(u \frac{\partial u}{\partial x} + v \frac{\partial u}{\partial y} + w \frac{\partial u}{\partial z} + \frac{\partial u}{\partial t} \right) \quad (35.8a)$$

$$\rho g_y + \frac{\partial \tau_{xy}}{\partial x} + \frac{\partial \sigma_{yy}}{\partial y} + \frac{\partial \tau_{zy}}{\partial z} = \rho \left(u \frac{\partial v}{\partial x} + v \frac{\partial v}{\partial y} + w \frac{\partial v}{\partial z} + \frac{\partial v}{\partial t} \right) \quad (35.8b)$$

$$\rho g_z + \frac{\partial \tau_{xz}}{\partial x} + \frac{\partial \tau_{yz}}{\partial y} + \frac{\partial \sigma_{zz}}{\partial z} = \rho \left(u \frac{\partial w}{\partial x} + v \frac{\partial w}{\partial y} + w \frac{\partial w}{\partial z} + \frac{\partial w}{\partial t} \right) \quad (35.8c)$$

Before Equation (35.8a) through Equation (35.8c) may be used to solve for velocity, the stress field must be related to the velocity field. Details of this development are beyond the scope of this chapter, but are well covered by Sherman [1990]. For incompressible flow the stress components in rectangular coordinates are

$$\tau_{xy} = \tau_{yx} = \mu \left(\frac{\partial v}{\partial x} + \frac{\partial u}{\partial y} \right) \quad (35.9a)$$

$$\tau_{yz} = \tau_{zy} = \mu \left(\frac{\partial w}{\partial y} + \frac{\partial v}{\partial z} \right) \quad (35.9b)$$

$$\tau_{zx} = \tau_{xz} = \mu \left(\frac{\partial u}{\partial z} + \frac{\partial w}{\partial x} \right) \quad (35.9c)$$

$$\sigma_{xx} = -p - \frac{2}{3} \mu \nabla \cdot \vec{V} + 2\mu \frac{\partial u}{\partial x} \quad (35.9d)$$

$$\sigma_{yy} = -p - \frac{2}{3} \mu \nabla \cdot \vec{V} + 2\mu \frac{\partial v}{\partial y} \quad (35.9e)$$

$$\sigma_{zz} = -p - \frac{2}{3} \mu \nabla \cdot \vec{V} + 2\mu \frac{\partial w}{\partial z} \quad (35.9f)$$

Note that shear stresses on adjacent faces of a fluid element are equal but directed oppositely.

The final form of the momentum equation is obtained by substituting stresses from Equation (35.9) into Equation (35.8). The result is the *Navier–Stokes equations*:

$$\rho g_x - \frac{\partial p}{\partial x} + \mu \left(\frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} + \frac{\partial^2 u}{\partial z^2} \right) = \rho \left(u \frac{\partial u}{\partial x} + v \frac{\partial u}{\partial y} + w \frac{\partial u}{\partial z} + \frac{\partial u}{\partial t} \right) \quad (35.10a)$$

$$\rho g_y - \frac{\partial p}{\partial y} + \mu \left(\frac{\partial^2 v}{\partial x^2} + \frac{\partial^2 v}{\partial y^2} + \frac{\partial^2 v}{\partial z^2} \right) = \rho \left(u \frac{\partial v}{\partial x} + v \frac{\partial v}{\partial y} + w \frac{\partial v}{\partial z} + \frac{\partial v}{\partial t} \right) \quad (35.10b)$$

$$\rho g_z - \frac{\partial p}{\partial z} + \mu \left(\frac{\partial^2 w}{\partial x^2} + \frac{\partial^2 w}{\partial y^2} + \frac{\partial^2 w}{\partial z^2} \right) = \rho \left(u \frac{\partial w}{\partial x} + v \frac{\partial w}{\partial y} + w \frac{\partial w}{\partial z} + \frac{\partial w}{\partial t} \right) \quad (35.10c)$$

These second-order, nonlinear partial differential equations are the fundamental equations of motion for viscous incompressible fluids. The Navier–Stokes equations are extremely difficult to solve analytically; only a handful of exact solutions are known [Sherman, 1990]. Some simplified cases can be solved numerically using today’s advanced computers.

The Navier–Stokes equations also provide the starting point for stability analyses that predict the breakdown of laminar flow and the onset of turbulence.

35.5 Incompressible Inviscid Flow

All real fluids are viscous. However, in many situations it is reasonable to neglect viscous effects. Thus, it is useful to consider an incompressible *ideal fluid* with zero viscosity. When the fluid is inviscid there are no shear stresses; pressure is the only stress on a fluid particle.

The equations of motion for frictionless flow are called the *Euler equations*. They are obtained by substituting the acceleration of a fluid particle into Equation (35.1):

$$-\nabla p + \rho \vec{g} = \rho \frac{D \vec{V}}{Dt} \quad (35.11)$$

Equation (35.11) can be integrated to relate pressure, elevation, and velocity in a flowing fluid.

The Euler equations may be written in components using rectangular coordinates or using *streamline coordinates* defined along and normal to the flow streamlines. In streamline coordinates the components of the Euler equations are

$$\frac{\partial p}{\partial s} = -\rho V \frac{\partial V}{\partial s} \quad (\text{along a streamline}) \quad (35.12a)$$

$$\frac{\partial p}{\partial n} = \rho \frac{V^2}{R} \quad (\text{normal to a streamline}) \quad (35.12b)$$

Equation (35.12a) shows that, for frictionless flow, variations in pressure and velocity are opposite; pressure falls when velocity increases and vice versa. (Frictionless flow is an excellent model for accelerating flow; it must be used with caution for decelerating flow, in which viscous effects are likely to be important.)

Equation (35.12b) shows that pressure always increases in the direction outward from the center of curvature of streamlines. (The increasing pressure causes each fluid particle to follow a curved path along the curved streamline.) When streamlines are straight, the radius of curvature is infinite and pressure does not vary normal to the streamlines.

The *Bernoulli equation* is obtained when the Euler equation is integrated along a streamline for steady, incompressible flow without viscous effects:

$$\frac{p_1}{\rho} + \frac{V_1^2}{2} + gz_1 = \frac{p_2}{\rho} + \frac{V_2^2}{2} + gz_2 \quad (35.13)$$

The Bernoulli equation is one of the most useful equations in fluid mechanics, but it also is incorrectly applied frequently. The restrictions of steady, incompressible flow, along a streamline, without friction must be justified carefully each time the Bernoulli equation is used.

The Bernoulli equation may be used to predict pressure variations in external flow over objects and to design instrumentation for measuring pressure and velocity. *Stagnation pressure* is sensed by a total-head tube where $V = 0$. For this situation the Bernoulli equation reduces to

$$p_0 = p + \frac{1}{2}\rho V^2 \quad (35.14)$$

Equation (35.14) defines stagnation pressure p_0 as the sum of *static pressure* p and *dynamic pressure* $\frac{1}{2}\rho V^2$. A detailed discussion of fluid measurements is beyond the scope of this chapter, but these pressures can be measured using probes and a suitable instrument to sense pressure.

35.6 Dimensional Analysis and Similitude

Dimensional analysis is the process of combining key parameters of a flow situation into dimensionless groups. Several methods may be used to obtain the dimensionless groups [Fox et al., 2004], which reduce the number of variables needed to express the functional dependence of the results of an experiment or analysis. Thus, dimensionless groups simplify the presentation of data and permit analytical results to be generalized.

Each dimensionless group is a ratio of forces. Significant dimensionless groups in fluid mechanics include Reynolds number Re (ratio of inertia force to viscous force), pressure coefficient C_p (ratio of pressure force to inertia force), Froude number Fr (ratio of gravity force to inertia force), Weber number We (ratio of surface tension force to inertia force), and Mach number M (which may be interpreted as the ratio of inertia force to compressibility force).

Dynamic similarity occurs when ratios of all significant forces are the same between two flows. Dynamic similarity is required to scale model test results for use in prediction or design. Dynamic similarity is ensured for geometrically similar flows with corresponding flow patterns when all relevant dimensionless groups except one are duplicated between the two flows.

The basic differential equations also may be nondimensionalized to obtain dimensionless groups. Dynamic similarity is ensured when two flows are governed by the same differential equations with the same dimensionless coefficient values in the equations and boundary conditions. Strouhal number St is a frequency parameter that arises from boundary conditions for external flow with vortex shedding.

35.7 Internal Incompressible Viscous Flow

Laminar flow occurs at low Reynolds number; as Reynolds number increases, transition occurs and flow becomes turbulent. The numerical value corresponding to “low” Reynolds number depends on flow geometry. For circular pipes the Reynolds number at transition is $Re = \rho \bar{V}D / \mu \approx 2000$, where \bar{V} is the average velocity at any cross section. Transition Reynolds numbers for other geometries differ significantly.

Fully developed laminar flow cases in simple geometries can be solved by (1) using a differential control volume and Taylor series expansion to obtain an equation for shear stress variation or (2) reducing the Navier–Stokes equations to a simple form applicable to the flow field. Then the shear stress profile is integrated using appropriate boundary conditions to obtain the velocity profile. Once the velocity profile is obtained, volume flow rate, flow rate as a function of pressure drop, average velocity, and point(s) of maximum velocity can be found. Analyses of fully developed laminar flow cases are presented by Fox et al. [2004]; all known exact solutions of the Navier–Stokes equations are described in detail by Schlichting [1979] and White [1991].

Turbulent flow cannot be analyzed from first principles. Turbulence is characterized by velocity fluctuations that transport momentum across streamlines; no simple relationship exists between shear stress and strain rate in turbulent flow. Instantaneous properties cannot be predicted in a turbulent flow field; only average values can be calculated. For engineering analyses, turbulent flow is handled empirically using curve-fits to velocity profiles and experimentally determined loss coefficients.

Analysis of turbulent pipe flow is based on the first law of thermodynamics. Viscous friction causes irreversible conversion from mechanical energy to thermal energy. This conversion is regarded as a loss in mechanical energy called **head loss**:

$$\frac{p_1}{\rho} + \alpha_1 \frac{\bar{V}_1^2}{2} + gz_1 - \left(\frac{p_2}{\rho} + \alpha_2 \frac{\bar{V}_2^2}{2} + gz_2 \right) = h_{IT} \quad (35.15)$$

In Equation (35.15), total head loss h_{IT} is the difference between the mechanical energies at cross-sections 1 and 2; $\alpha \bar{V}^2/2$ is the kinetic energy flux (α is the *kinetic energy coefficient*).

To make calculations, total head loss is subdivided into “major” losses that occur in sections of constant area where flow is fully developed and “minor” losses in transitions such as entrances, fittings, valves, and exits. Major losses h_f in sections with fully developed flow are expressed in terms of the experimentally determined friction factor f :

$$h_f = f \frac{L}{D} \frac{\bar{V}^2}{2} \quad (35.16)$$

Friction factor is a function of Reynolds number Re and relative roughness e/D (equivalent roughness height e divided by tube diameter D). Results from numerous experiments were compiled and smooth curves fitted by Moody; the results are shown on the *Moody diagram* (Figure 35.4).

Minor loss data also are measured experimentally; minor losses h_{lm} may be expressed as:

$$h_{lm} = f \frac{L_e}{D} \frac{\bar{V}^2}{2} = K \frac{\bar{V}^2}{2} \quad (35.17)$$

Equivalent length ratios L_e/D and minor loss coefficients K are available from numerous sources. More details on computation of minor losses are in Chapter 40, “Valves.”

FIGURE 35.4 Moody diagram giving friction factors for pipe flow. (Source: Moody, L. F. 1944. *Trans. ASME*. 66(8):671–684. With permission.)

Computer programs that make calculations for pipe flow systems are commonly available. One such program accompanies the Fox et al. text [2004].

35.8 External Incompressible Viscous Flow

The **boundary layer** is the thin region near the surface of a body in which viscous effects are important. Boundary layers may be laminar or turbulent, depending on Reynolds number and factors such as pressure gradient, surface roughness, and heat transfer.

Basic characteristics of all laminar and turbulent boundary layers are present in developing flow over a flat plate in a semiinfinite fluid. The boundary layer is thin, so there is negligible disturbance of the inviscid flow outside the boundary layer; thus, the pressure gradient is close to zero for this flow field. *Transition* from laminar to turbulent boundary-layer flow on a flat plate occurs for Reynolds numbers above $Re = \rho Ux / \mu \approx 5 \cdot 10^5$; this usually is considered the transition Reynolds number for flat-plate flow. Transition may occur earlier if the surface is rough, if pressure rises in the flow direction, or if **separation** occurs. After transition, the turbulent boundary layer thickens more rapidly than the laminar boundary layer as a result of the increased shear stress on the surface beneath the turbulent boundary layer.

Bodies immersed in flowing fluids experience forces due to the shear stresses and pressure differences caused by the fluid motion. *Drag* is the force parallel to the flow direction and *lift* is the force perpendicular to the flow direction. *Streamlining* is the art of shaping a body to reduce the fluid dynamic drag force. Airfoils (and hydrofoils) are designed to produce lift in air (or water); they are streamlined to reduce drag and attain high lift/drag ratios.

In general, lift and drag cannot be predicted analytically, although progress continues on computational fluid dynamics (CFD) computer programs. For most engineering purposes, drag and lift are calculated from experimentally measured coefficients. The defining equations for drag and lift coefficients C_D and C_L are

$$F_D = C_D A \frac{1}{2} \rho V^2 \quad \text{and} \quad F_L = C_L A \frac{1}{2} \rho V^2 \quad (35.18)$$

where $\frac{1}{2} \rho V^2$ is the dynamic pressure and A is the area upon which each coefficient is based. Common practice is to base drag coefficients on projected frontal area and lift coefficients on projected *planform* area. See Fox et al. [2004] for more details.

Defining Terms

Boundary layer — The thin layer of fluid adjacent to a surface where viscous effects are important; outside the boundary layer viscous effects may be neglected.

Head loss — The irreversible conversion from mechanical to thermal energy resulting from viscous friction in pipe flow (expressed as energy per unit mass).

Newtonian fluid — A fluid characterized by a linear relationship between shear rate (rate of angular deformation) and shear stress.

Separation — Phenomenon that occurs when fluid layers adjacent to a solid surface are brought to rest and the boundary-layer flow departs from the surface contour, forming a relatively low-pressure *wake* region. Separation can occur only in an *adverse pressure gradient*, in which pressure increases in the flow direction.

Viscosity — The coefficient that relates rate of shearing strain to shear stress for a Newtonian fluid (also called *dynamic viscosity*).

36.1 Introduction

Compressible flow is defined as *variable density flow*; this is in contrast to incompressible flow, where the density is assumed to be constant throughout. The variation in density is mainly caused by variations in pressure and temperature. We sometimes call the study of such fluids in motion **gas dynamics**. Fluid compressibility is a very important consideration in modern engineering applications. Knowledge of compressible fluid flow theory is required in the design and operation of many devices commonly encountered in engineering practice. A few important examples are the external flow over modern high-speed aircrafts; internal flows through rocket, gas turbine, and reciprocating engines; flow through natural gas transmission pipelines; and flow in high-speed wind tunnels.

The variation of fluid density and other fluid properties for compressible flow gives rise to the occurrence of strange phenomena in compressible flow not found in incompressible flow. For example, with compressible flows we can have fluid deceleration in a convergent duct, fluid temperature decrease with heating, fluid acceleration due to friction, and discontinuous property changes in the flow.

There are many useful compressible flow references that the reader can consult, such as Anderson [2003], Oosthuizen and Carscallen [1997], Hodge and Koenig [1995], John [1984], and Zucrow and Hoffman [1976]. The objectives of this chapter are to primarily study compressibility effects by considering the steady, one-dimensional flow of an ideal gas. Although many real flows of engineering interest are more complex, these restrictions will allow us to concentrate on the effects of basic flow processes. Another aspect of this chapter is the consistent formulation of the equations in a form suitable for computer solution. The author and his associates have developed interactive software for the calculation of the properties of various compressible flows. The first version of the software called **COMPROP** was developed to accompany the textbook by Oosthuizen and Carscallen [1997]. A more recent version of the software called **COMPROP2** was developed to accompany the recent textbook by Anderson [2003]. For more detail about the development of **COMPROP2** and its capabilities see Tam et al. [2001].

36.2 The Mach Number and Flow Regimes

The single most important parameter in the analysis of the compressible fluids is the **Mach Number** (M), named after the nineteenth century Austrian physicist Ernst Mach. The Mach number (a dimensionless measure of compressibility) is defined as:

$$M = \frac{V}{a} \quad (36.1)$$

where V is the local flow velocity and a is the local **speed of sound** (the other common symbol used for the local speed of sound is “ c ”). For an ideal gas the speed of sound is given by [Anderson, 2003]:

$$a = \sqrt{\gamma R T} \quad (36.2)$$

where γ is the specific heat ratio ($= 1.4$ for air), R is the gas constant ($= 287$ J/kg·K for air), and T is the absolute fluid temperature. The speed of sound in a gas depends, therefore, only on the absolute temperature of the gas. For air at standard sea level conditions the speed sound is about 341 m/sec.

The Mach number can be used to characterize flow regimes as follows (the numerical values listed are only rough guides):

Incompressible flow — The Mach number is very small compared to unity ($M < 0.3$). For practical purposes the flow is treated as incompressible. For air at standard sea level conditions this assumption is good for local flow velocities of about 100 m/sec or less.

Subsonic flow — The Mach number is less than unity but large enough so that compressible flow effects are present ($0.3 < M < 1$).

Sonic flow — The Mach number is unity ($M = 1$). The significance of the point at which Mach number is equal to 1 will be demonstrated in upcoming sections.

Transonic flow — The Mach number is very close to unity ($0.8 < M < 1.2$). Modern aircrafts are mainly powered by gas turbine engines that involve transonic flows.

Supersonic flow — The Mach number is larger than unity ($M > 1$). For this flow, a shock wave is encountered. There are dramatic differences (physical and mathematical) between subsonic and supersonic flows, as will be discussed in the future sections.

Hypersonic flow — The Mach number is larger than five ($M > 5$). When a space shuttle reenters the earth’s atmosphere, the flow is hypersonic. At very high Mach numbers the flowfield becomes very hot and dissociation and ionization of gases take place. In these cases the assumption of an ideal gas is no longer valid, and the flow must be analyzed by the use of kinetic theory of gases rather than continuum mechanics.

In the development of the equations of the motion of a compressible fluid, much of the analysis will appear in terms of the Mach number.

36.3 Ideal Gas Relations

Before we can proceed with the development of the equations of the motion of a compressible flow, we need to become familiar with the ideal gas fluid we will be working with. The ideal gas property changes can be evaluated from the following **equation of state** for an ideal gas:

$$p = \rho R T \quad (36.3)$$

where p is the fluid absolute pressure, ρ is the fluid density, T is the fluid absolute temperature, and R is the gas constant ($= 287$ J/kg·K for air). The **gas constant**, R , represents a constant for each distinct ideal gas, where

$$R = \frac{\bar{R}}{M} \quad (36.4)$$

with this notation, \bar{R} is the universal gas constant (= 8314 J/kg·mol·K) and M is the molecular weight of the ideal gas (= 28.97 for air).

For an ideal gas, **internal energy**, u , and **enthalpy**, h , are considered to be functions of temperature only, and where the **specific heats at constant volume and pressure**, c_v and c_p , are also functions of temperature only. The changes in the internal energy and enthalpy of an ideal gas are computed for constant specific heats as:

$$u_2 - u_1 = c_v(T_2 - T_1) \quad (36.5)$$

$$h_2 - h_1 = c_p(T_2 - T_1) \quad (36.6)$$

For variable specific heats one must integrate $du = \int c_v dT$ and $dh = \int c_p dT$ or use the gas tables [Moran and Shapiro, 2000]. Most modern thermodynamics texts now contain software for evaluating properties of nonideal gases [Çengel and Boles, 2002].

From Equation (36.5) and Equation (36.6), we see that changes in internal energy and enthalpy are related to the changes in temperature by the values of c_v and c_p . We will now develop useful relations for determining c_v and c_p . From Equation (36.5), Equation (36.6), and the definition of enthalpy ($h = u + pv = u + RT$) it can be shown that [Moran and Shapiro, 2000]:

$$c_p - c_v = R \quad (36.7)$$

Equation (36.7) indicates that the difference between c_v and c_p is constant for each ideal gas regardless of temperature. Also $c_p > c_v$. If the **specific heat ratio**, γ , is defined as (the other common symbol used for specific heat ratio is “k”)

$$\gamma = \frac{c_p}{c_v} \quad (36.8)$$

then combining Equation (36.7) and Equation (36.8) leads to

$$c_p = \frac{\gamma R}{\gamma - 1} \quad (36.9)$$

and

$$c_v = \frac{R}{\gamma - 1} \quad (36.10)$$

For air at standard conditions, $c_p = 1005$ J/kg·K and $c_v = 718$ J/kg·K. Equation (36.9) and Equation (36.10) will be useful in our subsequent treatment of compressible flow.

For compressible flows, changes in the thermodynamic property **entropy**, s , are also important. From the first and the second laws of thermodynamics, it can be shown that the change in entropy of an ideal gas with constant specific heat values (c_v and c_p) can be obtained from [Anderson, 2003]:

$$s_2 - s_1 = c_p \ln \frac{T_2}{T_1} - R \ln \frac{p_2}{p_1} \quad (36.11)$$

and

$$s_2 - s_1 = c_v \ln \frac{T_2}{T_1} + R \ln \frac{v_2}{v_1} \quad (36.12)$$

For variable specific heats one must integrate $\int c_p dT$ and $\int c_v dT$ or use the gas tables [Moran and Shapiro, 2000]. Equation (36.11) and Equation (36.12) allow the calculation of the change in entropy of an ideal gas between two states with constant specific heat values in terms of either the temperature and pressure, or the temperature and specific volume. Note that entropy is a function of both T and p , or T and v but not temperature alone (unlike internal energy and enthalpy).

36.4 Isentropic Flow Relations

An adiabatic flow (no heat transfer) which is frictionless (ideal or reversible) is referred to as **isentropic** (constant entropy) flow. Such flow does not occur in nature. However, the actual changes experienced by the large regions of the compressible flow field are often well approximated by this process. This is the case in internal flows such as for nozzles and external flows such as around an airfoil. In the regions adjacent to the nozzle walls or the airfoil surface, a thin boundary layer is formed and isentropic flow approximation fails. In this region flow is not adiabatic and reversible which causes the entropy to increase in the boundary layer.

Important relations for an isentropic flow of an ideal gas with constant c_v and c_p can be obtained directly from Equation (36.11) and Equation (36.12) by setting the left-hand side of these equations to zero ($s_2 = s_1$)

$$\frac{p_2}{p_1} = \left(\frac{\rho_2}{\rho_1} \right)^\gamma = \left(\frac{T_2}{T_1} \right)^{\gamma/(\gamma-1)} \quad (36.13)$$

Equation (36.13) relates absolute pressure, density, and absolute temperature for an isentropic process, and is very frequently used in the analysis of compressible flows.

36.5 Stagnation State and Properties

Stagnation state is defined as a state that would be reached by a fluid if it were brought to rest isentropically (reversibly and adiabatically) and without work. Figure 36.1 shows a stagnation point in compressible flow. The properties at the stagnation state are referred to as **stagnation properties** (or total properties). The stagnation state and the stagnation properties are designated by the subscript 0 (or t). Stagnation properties are very useful and are used as a reference state for compressible flows.

Consider the steady flow of a fluid through a duct such as a nozzle, diffuser, or some other flow passage where the flow takes place adiabatically and with no shaft or electrical work. Assuming the fluid experi-

FIGURE 36.1 Stagnation point.

ences little or no change in its elevation and its potential energy, the energy equation between any two points in the flow for this single-stream steady-flow system reduces to

$$h_1 + \frac{V_1^2}{2} = h_2 + \frac{V_2^2}{2} \quad (36.14)$$

In Equation (36.14), if we let one of the points to be stagnation point ($V = 0$), then

$$h_0 = h + \frac{V^2}{2} \quad (36.15)$$

where h_0 is the **stagnation enthalpy** and h is the **static enthalpy** of the fluid. Combining Equation (36.14) and Equation (36.15)

$$h_{01} = h_{02} \quad (36.16)$$

That is, in the absence of any heat and work interactions and any changes in potential energy, the stagnation enthalpy of a fluid remains constant during a steady-flow process. Flows through nozzles and diffusers usually satisfy these conditions, and any increase (or decrease) in fluid velocity in these devices will create an equivalent decrease (or increase) in the static enthalpy of the fluid.

Frequently, there is difficulty in understanding the difference between stagnation and static properties. Stagnation properties are those properties experienced by a fixed observer, the fluid being brought to rest at the observer ($V = 0$). **Static properties** are those properties experienced by an observer moving with the same velocity as the stream. The difference between the static and stagnation properties is due to the velocity (or kinetic energy) of the flow, see Equation (36.15). We may regard the stagnation conditions as local fluid properties. Aside from analytical convenience, the definition of the stagnation state is useful experimentally, since stagnation temperature, T_0 , and stagnation pressure, p_0 , are relatively easily measured. It is usually much more convenient to measure stagnation temperature T_0 than the static temperature T .

36.6 Stagnation Property Relations

Recall the definition of stagnation enthalpy given by Equation (36.15), for an ideal gas with constant specific heats, its static and stagnation enthalpies can be replaced by $c_p T$ or $c_p T_0$, respectively,

$$c_p T_0 = c_p T + \frac{V^2}{2}$$

or

$$T_0 = T + \frac{V^2}{2c_p} \quad (36.17)$$

In Equation (36.17), the **stagnation temperature**, T_0 , represents the temperature an ideal gas will attain when it is brought to rest adiabatically. The term $V^2/2c_p$ corresponds to the temperature rise during such a process and is called the **dynamic temperature** (or impact temperature rise). Note that for low-speed flows, the stagnation and static temperatures are typically the same. But for high-speed flows, the stagnation temperature (measured by a stationary probe, for example) may be significantly higher than the static temperature of the fluid.

Introducing Equation (36.1) for M and Equation (36.9) for c_p into Equation (36.17) we obtain

$$\frac{T_0}{T} = \left(1 + \frac{\gamma - 1}{2} M^2\right) \quad (36.18)$$

Equation (36.18) gives the ratio of the stagnation to static temperature at a point in a flow as a function of the Mach number at that point. Equation (36.17) and Equation (36.18) are valid for any adiabatic flow whether thermodynamically reversible or not. They are, therefore, valid across a shock wave which is irreversible.

The ratio of the **stagnation pressure** to static pressure is obtained by substituting Equation (36.18) into the isentropic relation for pressure given by Equation (36.13) and letting state 2 be the stagnation state:

$$\frac{p_0}{p} = \left(\frac{T_0}{T}\right)^{\gamma/(\gamma-1)} = \left(1 + \frac{\gamma - 1}{2} M^2\right)^{\gamma/(\gamma-1)} \quad (36.19)$$

The ratio of the **stagnation density** to static density is obtained by substituting Equation (36.18) into the isentropic relation for density given by Equation (36.13) and letting state 2 be the stagnation state:

$$\frac{\rho_0}{\rho} = \left(\frac{T_0}{T}\right)^{1/(\gamma-1)} = \left(1 + \frac{\gamma - 1}{2} M^2\right)^{1/(\gamma-1)} \quad (36.20)$$

Equation (36.19) and Equation (36.20) give the ratios of stagnation to static pressure and density, respectively, at a point in the flow field as a function of the Mach number at that point.

Equation (36.18), Equation (36.19), and Equation (36.20) provide important relations for stagnation properties and are usually tabulated as a function of Mach number M for $\gamma = 1.4$ (corresponds to air at standard conditions) in most standard compressible flow (gas dynamics) textbooks [Anderson, 2003; John, 1984; Zucrow and Hoffman, 1976]. Figure 36.2 was developed using **COMP2** [Tam et al., 2001] and shows the variation of these stagnation properties as a function of Mach number for $\gamma = 1.4$. It is important to note that the *local* value of stagnation property depends only upon the local value of the static property and the local Mach number and is independent of the flow process. Equation (36.18), Equation (36.19), and Equation (36.20) may be used to determine these local stagnation values, even for nonisentropic flow, assuming that the local static property and local Mach number are known. These equations also allow us to relate stagnation properties between any two points (say points 1 and 2) in the compressible flowfield. For example, if the actual flow between points 1 and 2 in the flowfield is reversible and adiabatic (isentropic), then T_0 , p_0 , and ρ_0 have constant values at every point in the

FIGURE 36.2 Stagnation property ratios for an ideal gas with $\gamma = 1.4$.

FIGURE 36.3 Converging–diverging nozzle.

flowfield. On the other hand, if the flow is irreversible and adiabatic, then only T_0 will remain constant at every point in the flow. However, for the case where the actual flow is irreversible and nonadiabatic, none of the stagnation properties stay constant between points 1 and 2 in the flowfield ($T_{01} \neq T_{02}$, $p_{01} \neq p_{02}$, and $\rho_{01} \neq \rho_{02}$).

36.7 Isentropic Flow with Area Changes

Nozzles are flow passages which accelerate the fluid to higher speeds. **Diffusers** accomplish the opposite, that is, they are used to decelerate the flow to lower speeds. These devices are quite common in gas turbines, rockets, and flow metering devices. In **incompressible flow** ($\rho = \text{constant}$), the volumetric flow rate (product of flow velocity, V , and the cross-sectional area, A) is constant. Thus, any passage which converges (causes A to decrease in the flow direction) is a nozzle, and any diverging passage (causes A to increase in the flow direction) is a diffuser. In fact, in any subsonic flow ($M < 1$), a converging channel accelerates and a diverging channel decelerates the flow. As will be shown in this section, just the opposite is true in supersonic flow ($M > 1$).

For the converging–diverging nozzle shown in Figure 36.3, the conservation of mass (continuity) under steady state conditions for this one-dimensional flow can be written as

$$\dot{m} = \rho VA = \text{constant} \tag{36.21}$$

The above equation can be used to relate the mass flow rate (\dot{m}) at different sections of the channel. Taking the logarithm of Equation (36.21) and then differentiating the resulting equation, we get

$$\frac{d\rho}{\rho} + \frac{dA}{A} + \frac{dV}{V} = 0 \tag{36.22}$$

The differential form of the frictionless momentum equation for our steady one-dimensional flow is

$$dp + \rho V dV = 0 \tag{36.23}$$

Equation (36.23) could have also been obtained from the steady one-dimensional energy equation for an isentropic flow with no work interactions and no potential energy. Combining Equation (36.23) with Equation (36.22) and introducing the definition of Mach number, Equation (36.1), one can obtain

$$\frac{dA}{A} = -\frac{dV}{V} \left(1 - \frac{V^2}{dp/d\rho} \right) = -\frac{dV}{V} \left(1 - \frac{V^2}{a^2} \right)$$

or

$$\frac{dA}{dV} = \frac{A}{V} (M^2 - 1) \tag{36.24}$$

FIGURE 36.4 Area and velocity changes for subsonic and supersonic gas flow.

TABLE 36.1 Variation of Flow Properties in Converging or Diverging Channels

| Type of Flow Passage | M | dA | dM | dV | dρ | dT | dρ |
|--------------------------------|----|----|----|----|----|----|----|
| Subsonic converging nozzle | <1 | - | + | + | - | - | - |
| Subsonic diverging diffuser | <1 | + | - | - | + | + | + |
| Supersonic converging diffuser | >1 | - | - | - | + | + | + |
| Supersonic diverging nozzle | >1 | + | + | + | - | - | - |

where in the above equation for an isentropic flow, the speed of sound can be expressed as $a = \sqrt{dp/d\rho}$ [John, 1984]. Inspection of Equation (36.24), without actually solving it, shows a fascinating aspect of compressible flow. As mentioned at the beginning of this section, property changes are of opposite sign for subsonic and supersonic flow. This is because of the term $(M^2 - 1)$ in Equation (36.24). There are four combinations of area change and Mach number summarized in Figure 36.4. The variation of velocity, pressure, temperature, and density in converging–diverging channels in both subsonic and supersonic flow is tabulated in Table 36.1.

Equation (36.24) and Figure 36.4 have many ramifications. For $M = 1$ (sonic flow), Equation (36.24) yields $dA/dV = 0$. Mathematically this result suggests that the area associated with sonic flow ($M = 1$) is either a minimum or a maximum amount. The minimum in area is the only physically realistic solution. A convergent–divergent channel involves a minimum area (see Figure 36.3). These results indicate that the sonic condition ($M = 1$) can occur in a converging–diverging duct at the minimum area location, often referred to as the **throat** of a converging–diverging channel. Therefore, for the steady flow of an ideal gas to expand isentropically from subsonic to supersonic speeds, a convergent–divergent channel must be used. This is why rocket engines, in order to expand the exhaust gases to high-velocity, supersonic speeds, use a large bell-shaped exhaust nozzle. Conversely, for an ideal gas to compress isentropically from supersonic to subsonic speeds, it must also flow through a convergent–divergent channel, with a throat where $M = 1$ occurs.

The Mach number–area variation in a nozzle can be determined by combining the continuity relation [Equation (36.21)] with the ideal gas and isentropic flow relations. For this purpose, equate the mass flow rate at any section of the nozzle in Figure 36.3 to the mass flow rate under sonic conditions (at the throat, the flow is sonic and the conditions are denoted by an asterisk and are referred to as **critical conditions**):

$$\rho V A = \rho^* V^* A^*$$

or

$$\frac{A}{A^*} = \frac{\rho^* V^*}{\rho V} = \frac{\rho^* M^* a^*}{\rho M a} = \frac{1}{M} \left(\frac{\rho^*}{\rho_0} \right) \left(\frac{\rho_0}{\rho} \right) \sqrt{\frac{T^*/T_0}{T/T_0}} \quad (36.25)$$

FIGURE 36.5 Variation of A/A^* with Mach number in isentropic flow for $\gamma = 1.4$.

where from Equation (36.2), $a = \sqrt{\gamma RT}$, and at the throat, the area of the throat is A^* and $M^* = 1$ ($V^* = a^* = \sqrt{\gamma RT^*}$), and for an isentropic flow ρ_0 and T_0 is constant throughout the flow. Substituting Equation (36.18) and Equation (36.20) into Equation (36.25) and recognizing that the **critical temperature ratio** (T^*/T_0) and the **critical density ratio** (ρ^*/ρ_0) is obtained from Equation (36.18) and Equation (36.20), respectively with $M = 1$, we obtain

$$\frac{A}{A^*} = \frac{1}{M} \left[\frac{2}{\gamma + 1} \left(1 + \frac{\gamma - 1}{2} M^2 \right) \right]^{\frac{\gamma + 1}{2(\gamma - 1)}} \quad (36.26)$$

Equation (36.26) and **COMPROM2** [Tam et al., 2001] were used to generate the plot of A/A^* shown in Figure 36.5 for $\gamma = 1.4$. Numerical values of A/A^* versus M are also usually tabulated alongside stagnation properties given by Equation (36.18) through Equation (36.20) in most standard compressible flow textbooks, see, for example, Anderson [2003]. As can be seen from Figure 36.5, for each value of A/A^* , there are two possible isentropic solutions, one subsonic and the other supersonic. For example, from Equation (36.26) with $\gamma = 1.4$ or Figure 36.5, with $A/A^* = 2$, $M = 0.3$ and also $M = 2.2$. The minimum area (throat) occurs at $M = 1$. This agrees with the results of Equation (36.24), illustrated in Figure 36.4. That is, to accelerate a slow moving fluid to supersonic velocities, a converging–diverging nozzle is needed.

Under steady state conditions, the **mass flow rate** through a nozzle can be calculated from Equation (36.21) expressed in terms of M and the stagnation properties T_0 and ρ_0 from Equation (36.18) and Equation (36.19) as:

$$\dot{m} = \rho AV = \left(\frac{P}{RT} \right) A (M \sqrt{\gamma RT}) = PAM \sqrt{\frac{\gamma}{RT}} = \frac{\gamma P_0 AM}{\sqrt{\gamma RT_0}} \left(1 + \frac{\gamma - 1}{2} M^2 \right)^{-\frac{(\gamma + 1)}{2(\gamma - 1)}} \quad (36.27)$$

Thus the mass flow rate of a particular fluid through a nozzle is a function of the stagnation properties of a fluid, the flow area, and the Mach number. The above relationship is valid at any location along the length of the nozzle.

For a specified flow area A and stagnation properties T_0 and ρ_0 , the **maximum mass flow rate** through a nozzle can be determined by differentiating Equation (36.27) with respect to M and setting the result equal to zero. It yields $M = 1$. As discussed above, the only location in a nozzle where $M = 1$ is at the throat (minimum flow area). Therefore, the maximum possible mass flow passes through a nozzle when its throat is at the critical or sonic condition. The nozzle is then said to be **choked** and can carry no additional mass flow unless the throat is widened. If the throat is constricted further, the mass flow rate through the nozzle must decrease. We can obtain an expression for the maximum mass flow rate by substituting $M = 1$ in Equation (36.27):

FIGURE 36.6 Stationary normal shock wave.

$$\dot{m}^* = \dot{m}_{\max} = \gamma \left(\frac{2}{\gamma + 1} \right)^{\frac{\gamma + 1}{2(\gamma - 1)}} \frac{P_0 A^*}{\sqrt{\gamma R T_0}} \quad (36.28)$$

Thus, for isentropic flow of a particular ideal gas through a nozzle, the maximum mass flow rate possible with a given throat area is fixed by the stagnation pressure and temperature of the inlet flow.

36.8 Normal and Oblique Shock Waves

When the flow velocity exceeds the speed of sound ($M > 1$), adjustments in the flow often take place through abrupt discontinuous surfaces called **shock waves**. This is one of the most interesting and unique phenomena that occurs in supersonic flow. A shock wave can be considered as a discontinuity in the properties of the flowfield. The process is irreversible. A shock wave is extremely thin, usually only a few molecular mean free paths thick (for air $\approx 10^{-5}$ cm). A shock wave is, in general, curved. However, many shock waves that occur in practical situations are straight, being either at right angles to the flow path (termed a **normal shock**) or at an angle to the flow path (termed an **oblique shock**). In case of a normal shock, the velocities both ahead (i.e., upstream) of the shock and after (i.e., downstream) the shock are at right angles to the shock wave. However, in the case of an oblique shock there is a change in the flow direction across the shock.

Attention will be given first to the changes that occur through a stationary normal shock. Fluid crossing a normal shock experiences a sudden increase in pressure, temperature, and density, accompanied by a sudden decrease in velocity from a supersonic flow to a subsonic flow. Consider an ideal gas flowing in a duct as shown in Figure 36.6. For steady state flow through a stationary normal shock, with no direction change, area change (shock is very thin), heat transfer (shock is adiabatic), or work done, the mass (continuity), momentum, and energy equations are:

Mass: $\rho_1 V_1 = \rho_2 V_2 \quad (36.29)$

Momentum: $p_1 - p_2 = \rho_1 V_1 (V_2 - V_1) \quad (36.30)$

Energy: $T_{01} = T_1 + \frac{V_1^2}{2c_p} = T_2 + \frac{V_2^2}{2c_p} = T_{02} \quad (36.31)$

These equations, together with the definition of Mach number, Equation (36.1), the equation for speed of sound, Equation (36.2), the equation of state, Equation (36.3), and the equation for stagnation temperature, Equation (36.18), will yield two solutions. One solution, which is trivial, states that there is no change and hence no shock wave. The other solution, which corresponds to the change across a stationary normal shock wave, can be expressed in terms of the upstream Mach number:

$$M_2^2 = \frac{(\gamma - 1)M_1^2 + 2}{2\gamma M_1^2 - (\gamma - 1)} \quad (36.32)$$

$$\frac{p_2}{p_1} = \frac{2\gamma M_1^2 - (\gamma - 1)}{(\gamma + 1)} \quad (36.33)$$

$$\frac{p_{02}}{p_{01}} = \left[\frac{(\gamma + 1)M_1^2}{2 + (\gamma - 1)M_1^2} \right]^{\gamma/(\gamma - 1)} \left[\frac{\gamma + 1}{2\gamma M_1^2 - (\gamma - 1)} \right]^{1/(\gamma - 1)} \quad (36.34)$$

$$\frac{T_2}{T_1} = [2 + (\gamma - 1)M_1^2] \frac{2\gamma M_1^2 - (\gamma - 1)}{(\gamma + 1)^2 M_1^2} \quad (36.35)$$

$$\frac{p_2}{\rho_1} = \frac{V_1}{V_2} = \frac{(\gamma + 1)M_1^2}{2 + (\gamma - 1)M_1^2} \quad (36.36)$$

The variations of p_2/p_1 , ρ_2/ρ_1 , T_2/T_1 , p_{02}/p_{01} , and M_2 with M_1 as obtained from Equation (36.32) through Equation (36.36) and **COMPROM2** [Tam et al., 2001] are plotted in Figure 36.7 for $\gamma = 1.4$, and they are normally tabulated in standard compressible flow texts in “Normal Shock Tables,” see, for example, Oosthuizen and Carscallen [1997]. From Figure 36.7 we can see that rather large losses of stagnation pressure occur across the normal shock. For an adiabatic process (flow across the normal shock is adiabatic but irreversible), the stagnation pressure represents a measure of available energy of the flow in a given state. A decrease in stagnation pressure, or increase in entropy ($s_2 > s_1$), represents an energy dissipation or **loss of available energy**. The increase in entropy across the normal shock can be related to the stagnation pressure ratio across the shock by substituting Equation (36.18) and Equation (36.19) in Equation (36.11) and recognizing that stagnation temperature remains constant across the normal shock, [see energy Equation (36.31)]. The result is:

$$s_2 - s_1 = -R \ln \frac{p_{02}}{p_{01}} \quad (36.37)$$

FIGURE 36.7 Variation of flow properties across a stationary normal shock wave for $\gamma = 1.4$.

From the second law of thermodynamics we must have $s_2 > s_1$. In order to minimize the loss of available energy across a normal shock, we need to have a small change in the stagnation pressure across the normal shock. Examination of Figure 36.7 shows that in order for this to happen the Mach number at the upstream of the normal shock (M_1) must be near unity.

If a plane shock is not perpendicular to the flow but inclined at an angle (termed an oblique shock), the shock will cause the fluid passing through it to change direction, in addition to increasing its pressure, temperature, and density, and decreasing its velocity. An oblique shock is illustrated in Figure 36.8; in this case the fluid flow is deflected through an angle δ , called the **deflection angle**. The angle θ shown in the figure is referred to as the **shock or wave angle** and the subscripts n and t indicate directions normal and tangent to the shock, respectively. The conservation of mass, momentum, and energy equations for the indicated control volume, see Figure 36.8, are:

$$\text{Mass:} \quad \rho_1 V_{1n} = \rho_2 V_{2n} \quad (36.38)$$

$$\text{Momentum:} \quad p_1 - p_2 = \rho_2 V_{2n}^2 - \rho_1 V_{1n}^2 \quad (\text{normal to the shock}) \quad (36.39)$$

$$0 = \rho_1 V_{1n} (V_{2t} - V_{1t}) \quad \text{or} \quad V_{2t} = V_{1t} \quad (\text{tangent to the shock}) \quad (36.40)$$

$$\text{Energy:} \quad T_{01} = T_1 + \frac{V_{1n}^2}{2c_p} = T_2 + \frac{V_{2n}^2}{2c_p} = T_{02} \quad (36.41)$$

Since the conservation equations [Equation (36.38), Equation (36.39), and Equation (36.41)] for the oblique shock contain only the normal component of the velocity, they are identical to the normal shock conservation equations [Equation (36.29) through Equation (36.31)]. In other words, an oblique shock acts as a normal shock for the component normal to the shock, while the tangential velocity remains unchanged, [Equation (36.40)]. This fact permits the use of normal shock equations to calculate oblique shock parameters. To use normal shock equations for oblique shock calculations, in normal shock equations replace M_1 by M_{1n} and M_2 by M_{2n} where $M_{1n} = M_1 \sin \theta$ and $M_{2n} = M_2 \sin(\theta - \delta)$. Equations for M_{1n} and M_{2n} are dependent on δ and their values cannot be determined until the deflection angle is obtained. However, δ is a unique function of M_1 and θ . From the geometry of Figure 36.8 and some trigonometric manipulation, the following $\delta - \theta - M$ relationship can be obtained:

$$\tan \delta = \frac{2 \cot \theta (M_1^2 \sin^2 \theta - 1)}{2 + M_1^2 (\gamma + \cos 2\theta)} \quad (36.42)$$

Equation (36.42) specifies δ as a unique function of M_1 and θ . This relation is vital to the analysis of oblique shocks. The results obtained from Equation (36.42) are usually presented in the form of a graph as shown in Figure 36.9. Detailed oblique shock graphs (at times referred to as oblique shock charts) may be found in Oosthuizen and Carscallen [1997]. These charts along with the modified form of the normal shock equations are used for determination of the oblique shock properties. Figure 36.9 is a plot of shock angle versus deflection angle, with the upstream Mach number as a parameter. It is interesting

FIGURE 36.8 Oblique shock wave.

FIGURE 36.9 Oblique shock angle versus deflection angle and upstream Mach number for $\gamma = 1.4$.

to note that in the oblique shock figures, for a given initial Mach number (M_1) and a given deflection angle (δ), there are either two solutions (solid line and the dashed line in the figure) or none at all. Figure 36.9 shows that for a given M_1 (in this case $M_1 = 2.0$), a **maximum deflection angle** (δ_{\max}) can be found (in this case $\delta_{\max} = 23^\circ$). This maximum varies from 0° at $M_1 = 1$ to about 45° as $M_1 \rightarrow \infty$. If δ_{\max} is exceeded, the shock detaches, that is, moves ahead of the turning surface and becomes curved. For such a case, no solution exists on the oblique shock figures. In case of the attached shock, where two solutions are possible, the **weak shock** solution (solid line in Figure 36.9) is most common. A weak shock is the solution farthest removed from the normal shock case.

36.9 Rayleigh Flow

Ideal gas flow in a constant area duct with heating or cooling (stagnation temperature change) and without friction is referred to as **Rayleigh flow**. Heat can be added or removed to the gas by heat exchange through the duct walls, by radiative heat transfer, by combustion, or by evaporation and condensation. Although the frictionless (inviscid) assumption may appear unrealistic, Rayleigh flow is nevertheless useful for the analysis of jet engine combustors and flowing gaseous lasers. In these devices, the heat addition process dominates the viscous effects.

The conservation equations for the Rayleigh flow combined with the equation of state, the Mach number equation, and the definitions of the stagnation temperature and pressure, leads to the following equations; a complete analysis is given in Anderson [2003]:

$$\frac{T_0}{T_0^*} = \frac{(\gamma+1)M^2}{(1+\gamma M^2)^2} [2+(\gamma-1)M^2] \quad (36.43)$$

$$\frac{T}{T^*} = \frac{(1+\gamma)^2 M^2}{(1+\gamma M^2)^2} \quad (36.44)$$

$$\frac{p}{p^*} = \frac{(1+\gamma)}{(1+\gamma M^2)} \quad (36.45)$$

$$\frac{P_0}{P_0^*} = \left(\frac{1+\gamma}{1+\gamma M^2} \right) \left[\frac{2+(\gamma-1)M^2}{\gamma+1} \right]^{\gamma/(\gamma-1)} \quad (36.46)$$

For convenience of calculation, in Equation (36.43) through Equation (36.46) sonic flow has been used as a reference condition, where the superscript asterisk (*) signifies properties at $M = 1$. In this way, the fluid properties for Rayleigh flow have been presented as a function of a single variable, the local Mach number. Equation (36.43) through Equation (36.46) and **COMPROM2** [Tam et al., 2001] were used to

FIGURE 36.10 Rayleigh flow property variations with Mach number for $\gamma = 1.4$.

generate Figure 36.10 for $\gamma = 1.4$. These property variations are also normally tabulated in standard compressible flow texts in “Rayleigh Flow Tables,” see, for example, John [1984]. Note that for a given flow no matter what the local flow properties are, the reference sonic conditions (the starred quantities) are constant values. Given particular inlet conditions to the duct (T_{01} , p_{01} , M_1) and \dot{q} (the rate of heat transfer per unit mass of the flowing fluid), we can obtain the duct exit conditions after a given change in stagnation temperature (heating or cooling) as follows: The value of inlet Mach number (M_1) fixes the value of T_{01}/T_{01}^* from Equation (36.43) and thus the value of T_{01}^* , since we know T_{01} . The exit state T_{02}/T_{01}^* can then be determined from the following conservation of energy equation for this flow (for a given value of c_p or γ):

$$c_p(T_2 - T_1) + \frac{1}{2}(V_2^2 - V_1^2) = \dot{q} = c_p(T_{02} - T_{01}) = c_p\Delta T_0$$

or

$$\frac{T_{02}}{T_{01}^*} = \frac{T_{01}}{T_{01}^*} + \frac{\dot{q}}{c_p T_{01}^*} \quad (36.47)$$

By the value of T_{02}/T_{01}^* , then M_2 , T/T^* , p_2/p^* , and p_{02}/p_{01}^* are all fixed from Equation (36.43) through Equation (36.46).

Referring to Figure 36.10 and comparing the flow properties with the T_0/T_{01}^* curve, several interesting facts about Rayleigh flow are evident. Considering the case of heating (increasing T_0/T_{01}^*), we notice that the increase in the stagnation temperature drives the Mach number toward unity for both subsonic and supersonic flow. After the Mach number has reached the sonic condition ($M = 1$), any further increase in heating (increase in stagnation temperature) is possible only if the initial conditions at the inlet of the duct are changed. Therefore, a maximum amount of heat can be added to flow in a duct, this maximum is determined by the attainment of Mach 1. Thus, flow in a duct can be choked by heat addition. In this case flow is referred to as **thermally choked**. Another interesting observation from Figure 36.10 is

that the stagnation pressure always decreases for heat addition to the stream. Hence, combustion will cause a loss in stagnation pressure. Conversely, cooling tends to increase the stagnation pressure.

36.10 Fanno Flow

Flow of an ideal gas through a constant-area adiabatic duct with wall friction is referred to as **Fanno flow**. In effect, this is similar to a Moody-type pipe flow but with large changes in kinetic energy, enthalpy, and pressure in the flow.

The conservation equations for the Fanno flow combined with the definition of friction factor, equation of state, the Mach number equation, and the definitions of the stagnation temperature and pressure, leads to the following equations; a complete analysis is given in Anderson [2003]:

$$\frac{4f}{D} L^* = \left(\frac{1-M^2}{\gamma M^2} \right) + \frac{\gamma+1}{2\gamma} \ln \left[\frac{(\gamma+1)M^2}{2+(\gamma-1)M^2} \right] \quad (36.48)$$

$$\frac{T}{T^*} = \frac{(\gamma+1)}{2+(\gamma-1)M^2} \quad (36.49)$$

$$\frac{p}{p^*} = \frac{1}{M} \left[\frac{(\gamma+1)}{2+(\gamma-1)M^2} \right]^{\frac{1}{2}} \quad (36.50)$$

$$\frac{p_0}{p_0^*} = \frac{1}{M} \left[\frac{2+(\gamma-1)M^2}{(\gamma+1)} \right]^{\frac{(\gamma+1)}{2(\gamma-1)}} \quad (36.51)$$

Analogous to our discussion of Rayleigh flow, in Equation (36.48) through Equation (36.51) sonic flow ($M = 1$) has been used as a reference condition, where the flow properties are denoted by T^* , p^* , and p_0^* . L^* is defined as the length of the duct necessary to change the Mach number of the flow from M to unity and f is an average friction factor. Equations (36.48) through Equation (36.51) and **COMPROP2** [Tam et al., 2001] were used to generate Figure 36.11 for $\gamma = 1.4$. These equations are also normally tabulated in standard compressible flow texts in “Fanno Flow Tables,” see, for example, John [1984].

Consider a duct of given cross-sectional area and variable length. If the inlet, mass flow rate, and average friction factor are fixed, there is a maximum length of the duct that can transmit the flow. Since the Mach number is unity at the duct exit in that case, the length is designated L^* and the flow is said to be **friction-choked**. In other words, friction always derives the Mach number toward unity, decelerating a supersonic flow and accelerating a subsonic flow. From Equation (36.48) we can see that at any point in the duct (say point 1), the variable fL^*/D depends only on the Mach number at that point (M_1) and γ . Since the diameter (D) is constant and f is assumed constant, then at some other point (say 2) a distance L ($L < L^*$) downstream from point 1, we have

$$\left(\frac{4f}{D} L^* \right)_2 = \left(\frac{4f}{D} L^* \right)_1 - \left(\frac{4f}{D} L \right) \quad (36.52)$$

From Equation (36.52), we can determine M_2 . If in a given situation M_2 was fixed, then Equation (36.52) can be rearranged to determine the length of duct required (L) for Mach number M_1 to change to Mach number M_2 .

FIGURE 36.11 Fanno flow property variations with Mach number for $\gamma = 1.4$.

Defining Terms

Compressible flow — Flow in which the fluid density varies.

Isentropic flow — An adiabatic flow (no heat transfer) which is frictionless (ideal or reversible). For this flow the entropy is constant.

Stagnation state — A state that would be reached by a fluid if it were brought to rest isentropically (reversibly and adiabatically) and without work. The properties at the stagnation state are referred to as **stagnation properties** (or total properties).

Shock wave — A fully developed compression wave of large amplitude, across which density, pressure, temperature, and particle velocity change drastically. A shock wave is, in general, curved. However, many shock waves that occur in practical situations are straight, being either at right angles to the flow path (termed a **normal shock**) or at an angle to the flow path (termed an **oblique shock**).

Rayleigh flow — An idealized type of gas flow in which heat transfer may occur, satisfying the assumptions that the flow takes place in constant-area cross-section and is frictionless and steady, that the gas is ideal and has constant specific heat, that the composition of the gas does not change, and that there are no devices in the system that deliver or receive mechanical work.

Fanno flow — An ideal flow used to study the flow of fluids in long pipes; the flow obeys the same simplifying assumptions as Rayleigh flow except that the assumption there is no friction is replaced by the requirement the flow be adiabatic.

Rheology may be defined as the study of the deformation and flow of matter under the influence of imposed stresses. In Newtonian fluids the stress varies linearly with the strain (or deformation) rate at constant temperature, with the constant of proportionality being the viscosity. All fluids that do not follow this simple behavior are classified as non-Newtonian. The practicing engineer is often concerned with characterizing the rheological behavior of fluids by means of rheological material functions in well-defined simple flows. This enables development of a constitutive equation that is the relationship between the stress tensor and the rate of deformation tensor. Such an equation should, in principle, enable characterization of the fluid structure and calculation of the fluid stresses for the kinematics of interest, which could involve a complex time-dependent velocity field. A physical restriction on constitutive equations, one which translates into a mathematical requirement, is that they must satisfy the principle of **material objectivity** — that is, they should be independent of the reference frame used to describe the fluid motion. An important consequence of this constraint is that all scalars associated with material functions should depend on **invariants** of the associated tensors. The following section is concerned with the rheological description and characterization of incompressible non-Newtonian liquids. A concise historical perspective on the evolution of the discipline is given in Doraiswamy [2002].

37.1 Kinematics, Flow Classification, and Material Functions

It is convenient to use two reference flows — simple shear flow and simple elongational flow — as a practical basis for evaluation of complex situations. The associated material functions in steady flow are the most widely used in rheological characterization of fluids. The kinematics of a flow field may be defined in terms of the fluid velocity field or in terms of particle displacements. It is usually more convenient to work with the deformation rate tensor $\dot{\gamma}_{ij}$, which, in Cartesian coordinates x_i , is related to the velocity gradient tensor v_{ij} as follows:

$$\dot{\gamma}_{ij} = v_{ij} + v_{ji} = \frac{\partial v_i}{\partial x_j} + \frac{\partial v_j}{\partial x_i} \quad (37.1)$$

It is often useful to isolate the rotational component of the fluid motion, which is defined by the vorticity tensor:

$$\omega_{ij} = \frac{\partial v_i}{\partial x_j} - \frac{\partial v_j}{\partial x_i} \quad (37.2)$$

The deformation rate tensor $\dot{\gamma}_{ij}$ is a function only of the present time t — that is, $\dot{\gamma}_{ij} = \dot{\gamma}_{ij}(t)$. It is valid for arbitrarily large deformations since it does not depend on past times t' . If the kinematics are to be described using deformations instead of deformation rates, it is necessary to consider a spatial reference state at a past time t' . The infinitesimal strain tensor $\gamma_{ij}(t, t')$, which is a measure of the strain at time t relative to the reference state at time t' , is related to the deformation rate tensor $\dot{\gamma}_{ij}(t)$ by a simple integration $\gamma_{ij}(t, t') = \int_{t'}^t \dot{\gamma}_{ij}(t'') dt''$ only in the limit of vanishingly small deformations. For finite deformations $\gamma_{ij}(t, t')$ violates the principle of material objectivity, and appropriate frame invariant measures of strain need to be defined; these are described later in the section on integral constitutive equations.

A **homogeneous flow field** is one in which the velocity gradient is constant at all points. In simple shear flow there is a nonzero component of velocity in only one direction. In a Cartesian (x, y, z) coordinate system the velocity field is defined by $v_x = \dot{\gamma}y, v_y = v_z = 0$. The scalar $\dot{\gamma}$ is termed the *shear rate* and, for the most general situation, is related to the magnitude of the second invariant of $\dot{\gamma}_{ij}$ by $\dot{\gamma} = (II_{\dot{\gamma}})^{1/2}$. The stress tensor τ_{ij} and the deformation rate tensor $\dot{\gamma}_{ij}$ enable definition of three independent material functions that are sufficient to characterize simple shear flow:

$$\eta(\dot{\gamma}) = \frac{\tau_{xy}}{\dot{\gamma}}, \quad \Psi_1(\dot{\gamma}) = \frac{(\tau_{xx} - \tau_{yy})}{\dot{\gamma}^2}, \quad \text{and} \quad \Psi_2(\dot{\gamma}) = \frac{(\tau_{yy} - \tau_{zz})}{\dot{\gamma}^2} \quad (37.3)$$

where $\eta(\dot{\gamma})$ is the shear viscosity and Ψ_1 and Ψ_2 are the first and second normal stress coefficients, respectively. Unlike most non-Newtonian systems, Newtonian fluids do not display stresses normal to the shear stress, and the coefficients Ψ_1 and Ψ_2 are therefore zero. The SI units of viscosity are Pascal seconds (1 Pa · s = 10 p) and of the normal stress coefficients are Pa · s².

For dilute solutions it is useful to define the intrinsic viscosity $[\eta]$ (which has dimensions of reciprocal concentration) as follows:

$$[\eta] = \lim_{c \rightarrow 0} \frac{\eta - \eta_s}{c\eta_s} \quad (37.4)$$

where η_s is the solvent viscosity and c is the mass concentration of the solute. At very low shear rates, the intrinsic viscosity approaches a limiting value $[\eta]_0$ known as the zero-shear rate intrinsic viscosity.

Extensional flow is defined kinematically by a rate of deformation tensor that has only diagonal components. The most common extensional flow is the simple uniaxial extension, for which the velocity field has the form $v_x = -1/2 \dot{\epsilon}x$, $v_y = -1/2 \dot{\epsilon}y$, and $v_z = +\dot{\epsilon}z$ in Cartesian coordinates. It is approximated by the stretching of a filament by forces exerted at both ends. The scalar coefficient $\dot{\epsilon}$ is called the principal extension rate. This flow is completely characterized by a single material function, the elongational (or extensional) viscosity $\bar{\eta}$, which, for typical non-Newtonian systems (such as polymer melts), can be several orders of magnitude higher than the shear viscosity η :

$$\bar{\eta}(\dot{\epsilon}) = \frac{(\tau_{zz} - \tau_{xx})}{\dot{\epsilon}} = \frac{(\tau_{zz} - \tau_{yy})}{\dot{\epsilon}} \quad (37.5)$$

The extensional viscosity has a value three times that of the shear viscosity for a Newtonian fluid (called the Trouton relation).

Viscometric and steady extensional flows are motions of constant strain rate history in which the material properties are independent of time (although they usually have a strong dependence on strain rate). Time-dependent material properties are required for describing non-Newtonian behavior because the effect of past deformations (varying strain history) on the structure of the fluid (and consequently the stress) cannot be ignored.

A class of transient shearing flows that is widely used in rheological measurements is small-amplitude oscillatory shear flow, in which the stresses and material properties depend on time (or frequency). These involve measurement of the stress response of a fluid to an imposed sinusoidal shearing strain or shear rate of the form $\dot{\gamma}_{xy} = \gamma_0 \omega \cos \omega t$, where γ_0 , ω , and t are the maximum imposed amplitude, the frequency, and the time, respectively. The shear stress response is then given by

$$\tau_{xy} = \gamma_0 G'(\omega) \sin \omega t + \gamma_0 G''(\omega) \cos \omega t \quad (37.6)$$

which provides a definition of the storage modulus, $G'(\omega)$, and the loss modulus, $G''(\omega)$ (or the analogous dynamic viscosity functions: $\eta' = G'' / \omega$ and $\eta'' = G' / \omega$). For a purely elastic material the loss modulus G'' is zero, and for a purely viscous material the storage modulus G' is zero. The SI units of the elastic moduli are Pascals.

Another commonly used time-dependent material property is the relaxation modulus $G(t, \gamma_0)$, which involves measurement of the shear stress relaxation of a material after the sudden imposition of a step strain, γ_0 . It is more suited to describing solid-like materials than liquid-like materials and is defined by $G(t, \gamma_0) = \tau_{xy} / \gamma_0$.

For stress growth upon inception of steady shear flow defined by

$$\begin{aligned} \dot{\gamma}_{xy} &= 0, & t < 0 \\ &= \dot{\gamma}_0, & t \geq 0 \end{aligned} \quad (37.7)$$

the associated material functions are

$$\eta^+(t, \dot{\gamma}_0) = \frac{\tau_{xy}}{\dot{\gamma}}, \quad \Psi_1^+(t, \dot{\gamma}_0) = \frac{(\tau_{xx} - \tau_{yy})}{\dot{\gamma}_0^2}, \quad \text{and} \quad \Psi_2^+(t, \dot{\gamma}_0) = \frac{(\tau_{yy} - \tau_{zz})}{\dot{\gamma}_0^2} \quad (37.8)$$

where the plus sign indicates that the shear rate is applied at positive times. The inverse experiment is stress relaxation after cessation of steady shear flow defined by

$$\begin{aligned} \dot{\gamma}_{xy} &= \dot{\gamma}_0, & t < 0 \\ &= 0, & t \geq 0 \end{aligned} \quad (37.9)$$

in which the material functions can be defined in a similar manner:

$$\eta^-(t, \dot{\gamma}_0) = \frac{\tau_{xy}}{\dot{\gamma}}, \quad \Psi_1^-(t, \dot{\gamma}_0) = \frac{(\tau_{xx} - \tau_{yy})}{\dot{\gamma}_0^2}, \quad \text{and} \quad \Psi_2^-(t, \dot{\gamma}_0) = \frac{(\tau_{yy} - \tau_{zz})}{\dot{\gamma}_0^2} \quad (37.10)$$

Analogous transient quantities, $\bar{\eta}^+(t, \dot{\epsilon}_0)$ and $\bar{\eta}^-(t, \dot{\epsilon}_0)$, can be defined for the stress growth or inception of simple extensional flow with an elongation rate $\dot{\epsilon}_0$

$$\bar{\eta}^+(t, \dot{\epsilon}_0) \quad \text{or} \quad \bar{\eta}^-(t, \dot{\epsilon}_0) = \frac{\tau_{zz} - \tau_{xx}}{\dot{\epsilon}_0} \quad (37.11)$$

All the above properties become independent of the imposed strain in the limit of zero strain (that is, as $\gamma_o \rightarrow 0$, $\dot{\gamma}_o \rightarrow 0$, or $\dot{\epsilon}_o \rightarrow 0$), in which case the material functions depend only on the time. The behavior in the limit of small deformations is termed *linear viscoelasticity* and the related material properties are defined appropriately, for example, $G(t) = G(t, \gamma_o)_{\gamma_o \rightarrow 0}$. Linear viscoelasticity reveals information about material behavior in the unstrained state in which the molecular conformations and entanglements have their equilibrium values and is used more for material characterization and quality control applications than for process modeling.

In addition to the kinematics, the material properties depend on the chemical constitution of the fluid (e.g., molecular weight, molecular weight distribution, polymer branching) and the physical state of the fluid (typically measured by the temperature and concentration); consequently, they have great utility in characterization and processing operations. Some of the more commonly used correlations for material functions are discussed later. The experimental science of determining rheological material properties such as those considered in this section is termed **rheometry**; further details are provided in Dealy [1982, 1994].

37.2 Fluids

Non-Newtonian fluids may be broadly classified by their ability to retain the memory of a past deformation (which is usually reflected in a time dependence of the material properties). Fluids that display memory effects usually exhibit elasticity. A fluid is identified as viscoelastic if the stresses in it persist after the deformation has ceased (typically manifested in the decay of the shear stress and primary normal stress difference after cessation of steady shear flow). The duration of time over which appreciable stresses persist after cessation of deformation gives an estimate of the relaxation time λ of the material. A dimensionless group commonly used for evaluating the role of fluid viscoelasticity is the Deborah number, De , defined by

$$De = \frac{\lambda}{T} \quad (37.12)$$

where λ is the relaxation time for the fluid (which can be estimated experimentally using an appropriate constitutive equation) and T is the characteristic time constant for the process of interest. Low values of the Deborah number therefore correspond to fluid-like behavior and high values to solid-like behavior.

The non-Newtonian materials most often encountered by the engineer are polymer melts, polymer solutions, and multiphase systems. Polymer melts and solutions are usually viscoelastic, that is, they are capable of storing elastic energy. Their viscosity–shear rate behavior typically exhibits a constant “zero shear rate viscosity” at low shear rates, followed by a shear thinning region where the viscosity decreases with shear rate. Unlike that of polymer solutions, the viscosity of melts rarely exhibits a second plateau — the infinite-shear viscosity — at the highest shear rates typically used in measurements. Also, melts usually display much higher viscosities than solutions. It is often convenient to classify solutions into dilute and concentrated systems; in the former, unlike the latter, the individual polymer chains rarely overlap. Based on simple scaling arguments it is usually assumed that the dilute solution regime ends when $[\eta]_c \sim 1$, where c is the polymer concentration (typically 5% by weight). The source of elasticity differs between melts and solutions. In polymer solutions elasticity is mainly associated with changes in the orientation and configuration of molecules as a result of polymer–solvent interactions. In the case of polymer melts (or concentrated solutions) it is the result of mobility constraints imposed by polymer–polymer interactions. Not all fluids that retain a memory of past deformations exhibit elasticity and, in some cases (typically in concentrated suspensions), time-dependent rheological properties may be related to changes in fluid structure that are purely dissipative, as in thixotropic and rheopectic fluids. Under steady shear conditions, the viscosity decreases with time for thixotropic fluids, whereas it increases with time for rheopectic fluids. Suspensions also frequently display “yield behavior,” that is, they do not

TABLE 37.1 Common Generalized Newtonian Fluids Described by the Function $\eta(\dot{\gamma})$ or $\eta(\tau)$

| Model | Equation | Comments |
|---------------------------------------|--|--|
| Power-law model (Ostwald–de Waele) | $\eta = K\dot{\gamma}^{n-1}$ $K = \text{consistency index}$ $n = \text{power law index}$ | For “pseudoplastic” liquids, $n < 1$ For “dilatant” liquids, $n > 1$ |
| Carreau | $\frac{\eta - \eta_\infty}{\eta_0 - \eta_\infty} = [1 + (\lambda\dot{\gamma})^2]^{(n-1)/2}$ $\eta_0 = \text{zero shear viscosity}$ $\eta_\infty = \text{infinite shear viscosity}$ | Describes smooth transition from η_0 to η_∞ typically observed in polymer solutions. |
| Bingham | $\eta = \infty, \quad \tau \leq \tau_y$ $\eta = \mu_0 + \frac{\tau_y}{\dot{\gamma}}, \quad \tau \geq \tau_y$ $\tau_y = \text{yield stress}$ $\mu_0 = \text{viscosity}$ | Describes yield behavior typically observed in suspensions. |
| Herschel–Bulkley | $\eta = \infty, \quad \tau \leq \tau_y$ $\eta = \frac{\tau_y}{\dot{\gamma}} + K\dot{\gamma}^{n-1}, \quad \tau \geq \tau_y$ | Describes behavior of shear-thinning suspensions. |
| Ellis | $\frac{\eta_0}{\eta} = 1 + \left(\frac{\tau}{\tau_{1/2}} \right)^{\alpha-1}$ $\tau_{1/2} = \text{value of } \tau \text{ at which } \eta = \eta_0 / 2$ | Predicts zero-shear viscosity but difficult to use since it is not explicit in shear rate. |

Note: All scalar stresses refer to the magnitude or second invariant of the stress tensor τ_{ij} .

flow unless a critical (or yield) stress is applied. A number of equations describing the yield behavior of suspensions are included in Table 37.1. At low volume fractions (<5%), the viscosity η_{sp} of a rigid suspension of spheres is related to the viscosity of the suspending fluid η_s by the Einstein equation:

$$\eta_{sp} = \eta_s(1 + 2.5\phi) \quad (37.13)$$

where ϕ is the volume fraction. At higher concentrations the empirical Maron-Pierce equation is useful for estimating the viscosity of suspensions of rigid particles of narrow size distribution in viscous fluids at low deformation rates:

$$\eta_{sp} = \frac{\eta_s}{(1 - \phi/A)^2} \quad (37.14)$$

The empirical constant A may be loosely identified with the maximum packing fraction for the particulate system. It has a value of 0.68 for smooth spheres and may be approximated by the expression $A = 0.54 - 0.013a$ for aspect ratio a in the range $6 < a < 30$. The distribution of particle sizes has little effect on suspension viscosity when the volumetric loading of solids is below 20%; at higher concentration levels the effects are very pronounced. In general, the addition of suspended solids increases the shear thinning as one moves into the shear-thinning range of deformation rates and the importance of elasticity appears to decrease with increased solids content. The rheology of spherical and anisotropic suspensions (with and without Brownian motion) is discussed by Gupta [1994].

For multiphase systems comprising fluid drops in a suspending liquid at low deformation rates and volume fractions, the Taylor analogue to the Einstein equation may be used:

$$\eta_{sp} = \eta_s \left(1 + \frac{1+2.5r}{1+r} \phi \right) \quad (37.15)$$

where r is the ratio of the viscosity of the disperse phase to that of the continuous phase. Few generalizations can be made about blends of immiscible deformable systems in view of complications arising due to droplet breakup, coalescence, and morphology effects; further details are provided in Han [1981].

The rheology of a variety of complex materials such as polymeric liquid crystals, fiber suspensions, foams and powders is discussed in Gupta [2000] and Larson [1999].

37.3 Constitutive Equations

No single constitutive equation is suitable for all purposes and the selection of one depends on the particular situation concerned. The form of the equation will reflect the type of flow (e.g., shear or elongation), the type of material (e.g., melt, concentrated solution or dilute solution), the solution scheme (differential or integral model) best suited to the problem of interest, and the particular situation to be portrayed (stress overshoot, flow instability, die-swell, etc.). The basic assumption of all constitutive equations is that the stress at any location and at any time in the flowing fluid depends on the entire flow history of the fluid element occupying that material point only (and not of adjacent elements). Constitutive equations may be broadly classified into rate (or differential) equations and integral equations (although many of the nonlinear differential forms may also have an equivalent integral expression). The development and use of a number of commonly used differential and integral models have been described by Astarita and Marrucci [1974], Bird et al. [1987a], and Larson [1988].

For a Newtonian fluid the scalar fluid viscosity η is defined by:

$$\tau_{ij} = \eta \dot{\gamma}_{ij} \quad (37.16)$$

A generalized Newtonian fluid is described by a constitutive equation in which the viscosity is only a function of the magnitude of the second invariant of the stress or the shear rate. Common empiricisms for the function $\eta(\dot{\gamma})$ or $\eta(\tau)$ (where τ is the magnitude or second invariant of τ_{ij}) are summarized in Table 37.1. The generalized Newtonian fluid is best suited to describing steady state shear flows or small deviations from such flows as long as the Deborah number is sufficiently low. Like the Newtonian fluid, it cannot describe normal stress effects or time-dependent elastic effects. In elongational flows and in rapidly changing flows, the generalized Newtonian models should not be used.

Linear viscoelasticity is primarily concerned with the description of fluid deformations that are very small or very slow. The theory of linear viscoelasticity does not satisfy the principle of frame invariance except in the zero deformation limit. Differential formulations of linear viscoelastic models combine classical ideas of Hookean solids and Newtonian fluids and are represented by the Maxwell model,

$$\tau_{ij} + \lambda_1 \frac{\partial \tau_{ij}}{\partial t} = \eta_o \dot{\gamma}_{ij} \quad (37.17)$$

and the Jeffreys model,

$$\tau_{ij} + \lambda_1 \frac{\partial \tau_{ij}}{\partial t} = \eta_o \left(\dot{\gamma}_{ij} + \lambda_2 \frac{\partial \dot{\gamma}_{ij}}{\partial t} \right) \quad (37.18)$$

in which λ_1 and λ_2 are the relaxation time and the retardation time, respectively. The most general linear viscoelastic model, which includes both the above forms, is the generalized Maxwell model. It is conve-

TABLE 37.2 Common Constitutive Equations Included in the Eight-Constant Oldroyd Model

| Model Name | λ_1 | λ_2 | Time Constants | | | | λ_6 | λ_7 |
|-------------------------|-------------|-------------|----------------|--------------|-------------|---|-------------|-------------|
| | | | λ_3 | λ_4 | λ_5 | | | |
| Oldroyd six-constant | | | | | | 0 | 0 | |
| Oldroyd four-constant | | | 0 | 0 | | 0 | 0 | |

| Second-order fluid | 0 | | 0 | | 0 | 0 | 0 | |
| Upper convected Maxwell | | 0 | 0 | 0 | 0 | 0 | 0 | |

niently represented in an integral form (which can therefore accommodate an infinite number of time constants) and is given by:

$$\tau_{ij} = \int_{-\infty}^t G(t-t') \dot{\gamma}_{ij}(t') dt' = \int_{-\infty}^t M(t-t') \gamma_{ij}(t, t') dt' \quad (37.19)$$

in which $G(t-t')$ is the relaxation modulus and $M(t-t') = dG(t-t')/dt'$ is the memory function. Various relationships between linear viscoelastic properties and material structure are provided by Ferry [1980].

The difference between the various nonlinear viscoelastic equations based on continuum mechanics are due primarily to the types of time derivative that arise as a result of rewriting them in an appropriate reference frame in order to make them objective. One of the most general frame invariant differential formulations for the stress tensor τ_{ij} is the eight-constant Oldroyd model, which may be expressed by the following equation:

$$\begin{aligned} \tau_{ij} + \lambda_1 \frac{D}{Dt} \tau_{ij} + \frac{\lambda_3}{2} (\dot{\gamma}_{ik} \tau_{kj} \dot{\gamma}_{kj}) + \frac{\lambda_5}{2} \tau_{kk} \dot{\gamma}_{ij} + \frac{\lambda_6}{2} \tau_{kk} \dot{\gamma}_{ij} \delta_{ij} \\ = \eta_0 \left[\dot{\gamma}_{ij} + \lambda_2 \frac{D}{Dt} \tau_{ij} + \lambda_4 \dot{\gamma}_{ik} \dot{\gamma}_{kj} + \frac{\lambda_7}{2} \dot{\gamma}_{ij} \dot{\gamma}_{ji} \delta_{ij} \right] \end{aligned} \quad (37.20)$$

where D/Dt is the corotational or Jaumann time derivative defined by:

$$\frac{D}{Dt} \tau_{ij} = \frac{\partial \tau_{ij}}{\partial t} + v_i \frac{d\tau_{ij}}{dx_i} + \frac{1}{2} (\omega_{ik} \tau_{kj} - \tau_{ik} \omega_{kj}) \quad (37.21)$$

The eight-constant Oldroyd model includes a number of common differential models, some of which are summarized in Table 37.2 [Bird et al., 1987a]. The steady material functions for the various models can be obtained by assigning relevant values of the constants from Table 37.2 into the following expressions [Bird et al., 1987a]:

$$\frac{\eta}{\eta_0} = \frac{1 + [\lambda_2(\lambda_3 + \lambda_5) + \lambda_4(\lambda_1 - \lambda_3 - \lambda_5) + \lambda_7(\lambda_1 - \lambda_3 - \frac{3}{2}\lambda_5)] \dot{\gamma}^2}{1 + [\lambda_1(\lambda_3 + \lambda_5) + \lambda_3(\lambda_1 - \lambda_3 - \lambda_5) + \lambda_6(\lambda_1 - \lambda_3 - \frac{3}{2}\lambda_5)] \dot{\gamma}^2} \quad (37.22)$$

$$\frac{\Psi_1}{2\eta_0\lambda_1} = \frac{\eta(\dot{\gamma})}{\eta_0} - \frac{\lambda_2}{\lambda_1} \quad (37.23)$$

$$\frac{\Psi_2}{2\eta_o\lambda_1} = \frac{\Psi_1}{2\eta_o\lambda_1} + \frac{(\lambda_1 - \lambda_3)\eta(\dot{\gamma})}{\lambda_1\eta_o} - \frac{(\lambda_2 - \lambda_4)}{\lambda_1} \quad (37.24)$$

$$\frac{\bar{\eta}}{3\eta_o} = \frac{1 - (\lambda_2 - \lambda_4)\dot{\epsilon} + (\frac{3}{2}\lambda_5 - \lambda_1 + \lambda_3)(2\lambda_2 - 2\lambda_4 - 3\lambda_7)\dot{\epsilon}^2}{1 - (\lambda_1 - \lambda_3)\dot{\epsilon} + (\frac{3}{2}\lambda_5 - \lambda_1 + \lambda_3)(2\lambda_1 - 2\lambda_3 - 3\lambda_6)\dot{\epsilon}^2} \quad (37.25)$$

The Oldroyd eight-parameter model illustrates how the number of constants becomes prohibitively large if only frame invariance considerations are used to formulate constitutive equations based purely on continuum mechanics considerations. It provides useful qualitative descriptions but is not quantitatively accurate. Care must be exercised in using the Oldroyd models in elongational flows since the elongational viscosity can become infinite if the parameters are not chosen carefully. Various empirical differential models have also been suggested. The White–Metzner model, for example, is obtained by making the relaxation time and the viscosity in the upper convected Maxwell model functions of the shear rate. It is useful in describing flows where the coupling of shear thinning and elasticity is significant. The Giesekus model can be obtained from molecular arguments and, unlike the Oldroyd model, is quadratic in stress. Although the model is considerably more difficult to use, it predicts decreasing viscosity and normal stress coefficients with increasing shear rate and a finite second normal stress coefficient. Differential constitutive equations are often the most convenient and practical way to determine the role of viscoelasticity in real-world systems. They are best suited to describing flows in which both shearing and extension are involved or shearing flows in which normal stresses are important.

A major advantage of integral formulations is that they are usually explicit in stress. The integral constitutive equations are conveniently represented in terms of a finite strain tensor and not the velocity field that has been considered so far. The infinitesimal strain tensor γ_{ij} described earlier is valid only for vanishingly small displacements. In order to describe the strain or displacement for finite deformations, it is necessary to consider a reference configuration. If a particle occupies position x_i at time t and position x'_i at past time t' , specification of the displacement functions $x_i(x'_i, t', t)$ or $x'_i(x_i, t, t')$ is equivalent to specifying the velocity field. This enables definition of the displacement gradient tensor Δ_{ij} and the inverse displacement gradient tensor Δ_{ij}^{-1} given by:

$$\Delta_{ij}(x_p, t, t') = \frac{\partial x'_i}{\partial x_j} \quad (37.26)$$

and

$$\Delta_{ij}^{-1}(x_p, t, t') = \frac{\partial x_i}{\partial x'_j} \quad (37.27)$$

The principle of material objectivity then permits definition of finite strain tensors called the *Cauchy strain tensor*, c_{ij} , and the *Finger strain tensor*, f_{ij} , in terms of displacement gradients rather than the velocity field:

$$c_{ij} = \Delta_{ki}\Delta_{kj} \quad (37.28)$$

$$f_{ij} = \Delta_{ik}^{-1}\Delta_{jk}^{-1} \quad (37.29)$$

Both c_{ij} and f_{ij} describe material deformation independent of superimposed rigid rotations and reduce to the unit tensor in the undeformed state. Since rheology is concerned with deviations from the

undeformed state, it is sometimes more convenient to work with the relative Cauchy strain tensor C_{ij} and the relative Finger strain tensor F_{ij} , defined as follows:

$$C_{ij} = c_{ij} - \delta_{ij} = \Delta_{ki} \Delta_{kj} - \delta_{ij} \quad (37.30)$$

$$F_{ij} = \delta_{ij} - f_{ij} = \delta_{ij} - \Delta_{ik}^{-1} \Delta_{jk}^{-1} \quad (37.31)$$

Any of the finite strain tensors (f_{ij} , c_{ij} , F_{ij} , C_{ij}) or an appropriate combination of these can be used in integral formulations since they are all frame invariant measures of the fluid strain at time t' relative to that at the time t .

The most general formulation for stress, which contains a number of constitutive equations, is the memory integral expansion in which the stress is expressed as a functional of the strain history [Bird et al., 1987a]. It is obtained by integration over all past times t' following the particle that ends up at position x at present time t :

$$\begin{aligned} \tau_{ij}(x_p, t) = & \int_{-\infty}^t M_I(t-t') F'_{ij} dt' \\ & + \int_{-\infty}^t \int_{-\infty}^t M_{II}(t-t', t-t'') (F'_{ik} F'_{kj} + F'_{ik} F'_{kj}) dt' dt'' + \dots \end{aligned} \quad (37.32)$$

where $F'_{ij} = F_{ij}(x_p, t, t')$, $F'_{kj} = F_{ij}(x_p, t, t')$, and M_I, M_{II}, \dots are kernel functions that account for memory effects. The single integral forms are the most practical and are obtained by setting all higher-dimensional integrals equal to zero. The most popular empirical integral model is the factorized K-BKZ (Kaye-Bernstein, Kearsley, Zapas) model given by:

$$\tau_{ij}(x_p, t) = \int_{-\infty}^t M(t-t') \left[\frac{\partial W}{\partial I_f} F'_{ij}(x_p, t, t') + \frac{\partial W}{\partial I_c} C'_{ij}(x_p, t, t') \right] dt' \quad (37.33)$$

in which $M(t-t') (\equiv M_I)$ is the linear viscoelastic memory function defined in Equation (37.19), $C'_{ij} = C_{ij}(x_p, t, t')$, and $W(I_f, I_c)$ is a potential function that needs to be experimentally determined; it is a function of the two strain invariants $I_f = f_{ii}$ and $I_c = c_{ii}$. The K-BKZ equation, which is based on rubber elasticity theory and makes no molecular assumptions, quantitatively describes important rheological phenomena such as stress growth and relaxation. The Lodge constitutive equation (which is the integral equivalent of the upper convected Maxwell model) is a special case of the K-BKZ equation and is obtained by setting $W = I_c$:

$$\tau_{ij}(x_p, t) = \int_{-\infty}^t M(t-t') C'_{ij}(x_p, t, t') dt' \quad (37.34)$$

In the limit of vanishingly small displacements, the general linear viscoelastic model [Equation (37.19)] is obtained from Equation (37.34) by setting C_{ij} equal to the infinitesimal strain tensor, γ_{ij} . Integral models provide a framework for including a wide class of nonlinear viscoelastic behavior. By selecting suitable empirical forms for the kernel functions, they enable description of fluid rheology using a small finite number of constants; these have the advantage of having physical meaning and can be determined from rheometric experiments. Quantitative determination of the kernel functions is, however, a nontrivial problem.

In addition to the continuum models described above, constitutive equations based on molecular theories (which result in integral forms similar to those discussed) have also been proposed. Most of these models can be classified in one of the following categories:

1. Bead-spring or random coil theories for dilute polymer solutions
2. Hydrodynamic interaction theories for moderately concentrated solutions that account for the indirect drag that one part of a polymer chain exerts on another through the solvent
3. Molecular entanglement, network, or reptation theories for concentrated solutions and melts

Although molecular models have considerable potential for material characterization and rheological flow modeling, their applicability is restricted at this time. Bird et al. [1987b] have covered such constitutive equations in great detail.

37.4 Some Useful Correlations for Material Functions

Correlations for and between the material functions are very useful in order to enable quick estimates of material properties; they are often used for material characterization and process control applications. The more commonly used correlations are described below (further details on correlations and parameter values are summarized in van Krevelen and Hoftyzer [1976], Graessley [1974], and Bird et al. [1987a]).

Equivalence of Dynamic and Steady Shear Properties

The Cox–Merz empiricism predicts that the magnitude of the complex viscosity ($|\eta^*|$) is equal to that of the viscosity at equal values of the frequency and shear rate. That is,

$$\eta(\dot{\gamma}) = |\eta^*(\omega)|_{\omega=\dot{\gamma}} = (\sqrt{\eta'(\omega)^2 + \eta''(\omega)^2})_{\omega=\dot{\gamma}} \quad (37.35)$$

Laun's rule is another useful correlation for predicting the first normal stress difference from dynamic data:

$$\Psi_1 = \frac{2\eta''(\omega)}{\omega} \left[1 + \left(\frac{\eta''}{\eta'} \right)^{0.7} \right]_{\omega=\dot{\gamma}} \quad (37.36)$$

For highly filled suspensions (~70%) that exhibit a yield stress, shear thinning, and a recoverable strain, the so-called Rutgers–Delaware rule predicts that the complex viscosity vs. maximum (or effective) shear rate ($\gamma_m \omega$) is identical to the steady shear rate vs. shear rate [Doraiswamy et al., 1991]; γ_m is the strain amplitude.

Dependence of Viscosity on Temperature

If $\eta_o(T)$ is the zero-shear viscosity at the desired temperature T , and $\eta_o(T_o)$ the zero shear viscosity at an arbitrary reference temperature T_o , a shift factor a_T may be approximated as follows:

$$a_T = \frac{\eta_o(T)T_o\rho_o}{\eta_o(T_o)T\rho} \cong \frac{\eta_o(T)}{\eta_o(T_o)} \quad (37.37)$$

where ρ and ρ_o are the densities at the temperatures T and T_o , respectively. An Arrhenius-type equation is often used to determine the temperature dependence of a_T as long as the temperature is at least 100 K above the glass transition temperature, T_g :

$$a_T = \exp \left[\frac{\Delta E}{R} \left(\frac{1}{T} - \frac{1}{T_o} \right) \right] \quad (37.38)$$

where ΔE is the activation energy and R is the Boltzmann constant. For typical polymer melts $\Delta E/R$ is ~ 5000 K. For temperatures between T_g and $T_g + 100$, the Williams–Landel–Ferry expression can be used to estimate a_T :

$$\log a_T = \frac{-c_1^\circ(T - T_o)}{c_2^\circ + (T - T_o)} \quad (37.39)$$

If T_o is taken to be the glass-transition temperature, the following values can be used for quick estimates: $c_1^\circ = 17.44$ and $c_2^\circ = 51.6$ K.

The time–temperature superposition principle states that varying the temperature at fixed shear rate (or time) is equivalent to varying the shear rate at fixed temperature. By defining a reduced viscosity η_r and a reduced shear rate $\dot{\gamma}_r$ as follows:

$$\eta_r = \eta(\dot{\gamma}, T) \frac{\eta_o(T_o)}{\eta_o(T)} \cong \frac{\eta(\dot{\gamma}_r, T)}{a_T}; \quad \dot{\gamma}_r = a_T \dot{\gamma} \quad (37.40)$$

it is possible to reduce viscosity data at different temperatures and shear rates to a single master curve, provided the different isotherms are of similar shape [Bird et al., 1987a]. This approach enables extending the shear rate range of an available experimental configuration for obtaining viscometric data. Analogous procedures can be used for other material properties.

Dependence of Viscosity on Molecular Weight and Concentration

Molecular weights of polymers can be determined using solution viscosity measurements. At very low concentration or in the zero concentration limit, the intrinsic viscosity of linear, monodisperse solutions of polymers is related to the molecular weight, M , by the Mark–Houwink equation:

$$[\eta]_o = KM^a \quad (37.41)$$

where K and a are functions of the polymer, solvent, and temperature; their values are available in the literature (e.g., van Krevelen and Hoftyzer [1976]). A typical value for a is 0.7. At higher concentrations ($c > 1/[\eta]_o$), for which overlap between neighboring molecules becomes significant, the viscosity scales as the product cM . Finally, for pure melts and highly concentrated solutions beyond a critical molecular weight (typically in the range 2000–50,000), entanglements between molecules become significant and the zero shear melt viscosity is given by:

$$\eta_o = KM^{3.4} \quad (37.42)$$

For narrow distributions M can be approximated by M_w . For broad distributions, the viscosity depends on a molecular weight average between M_w and the next higher average (z average). If branching is present, M_w is replaced by gM_w , where g is a branching index.

37.5 Rheological Measurements

A detailed discussion of rheometric techniques is beyond the scope of this article; more in-depth discussions are given in Barnes et al. [1989], Gupta [2000], Dealy [1982], and Collyer and Clegg [1998], which provide original references to many of the techniques discussed. The last book also includes some relatively uncommon approaches for rheological measurements such as large-amplitude oscillatory shear and hole pressure measurements for normal stress differences. The reader is referred to these same references for a discussion of linear viscoelastic property measurements.

Key issues that need to be considered in rheometer selection are:

1. Type of flow field (shear vs extension; non-homogeneity of the deformation rate)
2. Deformation rate range
3. Stress range
4. Transient measurements (dynamic vs steady state properties)
5. Largest size of the discrete phase
6. Viscous heating
7. Elasticity effects

Slip effects are a common occurrence in the handling of suspensions and emulsions and can be accounted for by appropriate analysis of data. Roughening the surfaces of the liquid–fixture interface is the preferred experimental route to overcoming this problem. Changes in structure during measurement (thixotropic effects) can also become a critical factor especially for concentrated suspensions and emulsions.

Shear Viscosity

The most common instruments for measuring shear viscosity are as follows:

Capillary Viscometers

The sample is pushed through a capillary using a piston or pressurized reservoir under controlled temperature conditions. The key advantages are the ease of sample loading, wide ranges of temperature and shear rates, and convenient examination of the extruded sample for texture analysis and elasticity (die swell) effects. The main disadvantages are the corrections that have to be made for shear rate variation across the capillary diameter, entrance flow, and capillary end effects. In order to avoid entrance effects, it is recommended that the ratio of the reservoir diameter to the capillary diameter be at least 10, while a capillary aspect ratio of at least 50 is usually sufficient to make end effects negligible; the so-called Bagley correction is needed for end effects with short capillaries. The adiabatic temperature rise at high shear rates can be quite large for viscous materials, and appropriate corrections need to be made; it is worth noting that the maximum adiabatic temperature rise takes place a short distance away from the wall rather than at the maximum shear at the wall. Slip effects can also become significant in some systems and are manifested by a dependence of viscosity on capillary diameter. The flow rate Q is determined as a function of the pressure drop ΔP in order to determine the viscosity $\eta(\dot{\gamma})$ as a function of shear rate $\dot{\gamma}$. If R is the tube radius and L the length, the wall shear stress is given by

$$\tau_w = \Delta P \frac{R}{2L} \quad (37.43)$$

and the wall shear rate by

$$\dot{\gamma}_w = \frac{4Q}{\pi R^3} \left(\frac{3}{4} + \frac{1}{4} \frac{d \ln Q}{d \ln \tau_w} \right) \quad (37.44)$$

The viscosity is then easily found to be

$$\eta = \frac{\tau_w}{\dot{\gamma}} \quad (37.45)$$

Equation 37.44 is the famous Weissenberg–Rabinowitsch–Mooney equation, which enables determination of the local or true value of the shear rate from the average or “apparent shear rate” $4Q/\pi R^3$.

For a power-law fluid, Equation (34.44) takes the form

$$\dot{\gamma}_w = \frac{4Q}{\pi R^3} \left(\frac{3n+1}{4n} \right) \quad (37.46)$$

where $n = d \log \tau / d \log \dot{\gamma}$. For the special case of a Newtonian liquid where n equals unity, Equation 37.43 through Equation 37.46 yield the well-known Hagen–Poiseuille equation

$$\eta = \frac{\pi \Delta P R^4}{8 L Q} \quad (37.47)$$

The Bagley correction e to the wall shear stress for end effects is expressed as a multiple of the tube aspect ratio L/R and is obtained by extrapolating pressure drop–tube aspect ratio data at constant shear rate (or R) to zero pressure drop:

$$e = \frac{1}{2} \frac{\Delta P}{\tau_w} - \frac{L}{R} \quad (37.48)$$

The flow rate capacity for gas-pressure–driven instruments and the force transducer load for plunger-driven instruments typically set a limit of 10^6 l/sec for the maximum shear rate in the capillary rheometer. Viscous heating effects and extruded flow instabilities such as melt fracture are other major factors that set an upper bound on operation. Drip effects for gas-pressure–driven units and plunger-piston friction effects typically set a lower limit of 1 l/sec for the reliably attainable shear rate in the capillary device.

Most commercial capillary units are plunger-driven though gas-pressure–driven devices operating at pressures up to 200 Mpa are also available. Some capillary units have pressure transducers mounted just downstream of the entrance so that related pressure losses do not need to be accounted for.

An important variation of the capillary device is the slit rheometer where ultra-high shear rates (up to 10^6 l/sec) can be obtained under effectively isothermal conditions; slit rheometers have also been used to make measurements of the first normal stress difference for shear flow.

Coaxial Cylindrical Viscometers

Measuring viscosity using Couette-type rheometers involves filling the annular space between two concentric cylinders with the liquid and measuring the torque on the outer (or inner) cylinder while the inner (or outer) cylinder is rotated at a constant speed. In other versions of the device, one cylinder is held stationary while the other is rotated under the influence of a constant torque; the rotational speed is then measured using some form of tachometer. Such units can also be used for dynamic measurements, in which case the constant rotational speed is replaced by oscillation at a fixed frequency and small amplitude. Wide gap and infinite gap variations are also possible in order to handle suspensions and emulsions, though convenient analyses are available only for power-law fluids.

The main advantages are the effectively constant shear rate in the gap if the annulus is small (R_o/R_i = radius of outer cylinder/radius of inner cylinder < 1.03), the ability to collect data at low shear rates because of the large surface area, and the relative ease of calibration. Disadvantages are sample loading and viscous heating for viscous materials and “climbing” of polymer solutions up the inner cylinder due to normal stresses. Secondary flows and turbulence effects are additional factors for low-viscosity

fluids. The shear stress τ and shear rate $\dot{\gamma}$ at any radius r are related to the torque M by the following equations:

$$\tau(r) = \frac{T}{2\pi r^2 h} \quad R_i \leq r \leq R_o \quad (37.49)$$

$$R_i \leq r \leq R_o \quad \dot{\gamma} \leq \dot{\gamma} \leq \dot{\gamma}_o \quad (37.50)$$

where h is the immersed length of the cylinder and ω the angular frequency. For very narrow gaps,

$$\dot{\gamma}(r) = \frac{\omega R_i}{(R_o - R_i)} \quad (37.51)$$

An end correction is needed when the extra torque required to account for additional drag at the bottom surface is significant and is avoided by using a very large immersion length or shaping the bottom of the inner cylinder to resemble an inverted cone. The typical range of these devices is 10^{-2} to 10^2 l/sec and is limited by the sensitivity of the torque measurement device.

A useful practical variation of the Couette device is the Brookfield viscometer, which comprises a cylindrical spindle rotating in ~ 500 ml of fluid. It is driven by a synchronous motor through a calibrated spring and the deflection of the latter serves as an empirical measure of the “viscosity” for many commercial situations.

Cone-and-Plate Viscometers

The fluid is sandwiched between a flat, circular plate and a linearly concentric cone; the former is truncated to avoid physical contact. The two are rotated relative to each other and the torque T is measured to attain a constant angular velocity ω . The typical plate radius R is a few centimeters while the cone angle θ is a couple of degrees. The downward normal force F needed to keep the relative positions of the two geometries constant is also measured. The key advantage of this rheometer is the constant shear rate throughout the fluid which also therefore enables accurate transient measurements such as dynamic properties. The device lends itself well to disposable fixtures and consequently measurements on reacting systems such as gels. Additional advantages include the small sample size and the ease of loading and cleaning. A number of limitations need to be considered. Secondary flows, centrifugal effects, and elastic instabilities become significant at high shear rates. Free surface distortion can affect the measurements as can sample drying at the outer edge; the latter problem is usually circumvented by coating the rim with a thin oil or using a solvent trap. Accurate positioning of the plates is a requirement that makes the device relatively expensive and complicated to operate.

The relevant equations for the cone-and-plate rheometer are:

$$\tau = \frac{3T}{2\pi R^3} \quad (37.52)$$

$$\dot{\gamma} = \frac{\omega}{\alpha} \quad (37.53)$$

$$N_1 = \frac{2F}{\pi R^2} \quad (37.54)$$

$$T_{\theta\theta} = -p_a + N_2 + (N_1 + 2N_2) \ln \frac{r}{R} \quad (37.55)$$

where α is the cone angle in radians, p_a is the atmospheric pressure, $T_{\theta\theta}$ is the total stress exerted by the fluid normal to the plate surface, and the subscripts on T represent the θ direction in a spherical coordinate system. Determination of N_1 permits determination of N_2 through Equation (37.55) in principle if $T_{\theta\theta}$ can be determined; measurement of the latter is usually not practical to a sufficient level of accuracy.

If ω is made to depend on time, the previous set of equations still holds true for T and N ; appropriate time-dependent material properties can be determined for oscillatory flow, stress growth, and relaxation. It is worth noting many modern rheometers are operated in a constant stress mode so that the shear rate becomes the dependent variable; such devices lend themselves very well to measurement of creep properties and yield stresses if present.

The cone-and-plate rheometer can be used over a wide range of shear rates varying from 10^{-6} to 10^3 l/sec. It is especially well suited to measuring the viscosity of highly viscous fluids at low shear rates and is often used to generate zero shear viscosity data for polymer melts and concentrated solutions. The typical frequency range for oscillatory measurements is 10^{-2} to 10^2 rad/sec. One of the most widely used commercial instruments is the Rheometrics unit (now owned by TA Instruments), which permits torque measurements from 0.1 to 2000 g-cm and normal forces from 0.1 to 2000 g; a special feature of the device is the so-called "force rebalance transducer," which prevents axial separation of the plates during rotation due to normal stresses.

Parallel-Plate Viscometers

Coaxial parallel disks are preferred to the cone-and-plate geometry when particles are involved whose size is comparable to the distance between the truncated cone and the plate. Other advantages are that sample preparation is easy when the initial material is a solid, and large torque readings are obtained for small amplitude oscillatory flow when the gap spacing is large. Unlike the cone-and-plate system, however, the stress and shear rates vary with radial position, and this complicates data analysis. The shear stress and shear rate at the edge of the disks (i.e., at $r = R$) are given by:

$$\dot{\gamma}(R) = \frac{\omega R}{h} \quad (37.56)$$

$$\tau(R) = \frac{3T}{2\pi R^3} \left[1 + \frac{1}{3} \frac{d \ln T}{d \ln \dot{\gamma}} \right] \quad (37.57)$$

$$N_1(R) - N_2(R) = \frac{2F}{\pi R^2} \left[1 + \frac{1}{2} \frac{d \ln F}{d \ln \dot{\gamma}(R)} \right] \quad (37.58)$$

where h is the gap separation. In order to determine the shear stress or normal stress at a particular shear rate, torque and normal force results are needed over a range of rim shear rates to enable differentiation of the data. The correction is seen to be analogous to the Weissenberg–Rabinowitsch–Mooney equation for tube flow. The parallel plate setup lends itself to ultra-high shear rate viscometry when sample size limitations do not permit capillary measurements. Use of very fine gaps ($< 50 \mu$) helps overcome viscous heating problems due to the advantageous scaling of surface area with volume (gap size) and also centrifugal effects (due to the inverse scale of surface tension forces with gap size). However, care needs to be taken to account for surface nonuniformity effects and secondary flows using an appropriate calibration fluid.

The parallel-plate device enables direct determination of the dynamic moduli from measurement of the torque amplitude and the difference with the angular deformation, provided the entire sample is within the linear viscoelastic region. The unit can also be operated in the "eccentric rotating disk" mode for estimation of the dynamic properties. An offset between the axes of the two disks induces an eccentric oscillatory motion when the disks are rotated in opposing directions; an analysis of the flow field yields G' and G'' .

Other instruments that are used in special situations and deserve brief mention are sliding plate, torque, and squeeze flow viscometers. The sliding plate rheometer is used to measure large, transient deformations at very high shear rates, while most rheometers are used for steady-state measurement at low shear rates; the sample is typically sandwiched between two horizontal plates and is sheared by moving one plate relative to the other. Edge, friction, and gap variation effects are typically overcome by using specially designed transducers. Torque rheometers comprise two irregularly shaped screw-type mixing elements in a heated mixing chamber shaped like a figure eight. The torque needed to turn the rollers in opposing directions and the temperature are measured as a function of time and rotation speed. Although the flow field is nonhomogeneous, the torque can be approximated by the following expression if appropriate approximations are made:

$$T = C(n)N^n \quad (37.59)$$

where the constant C depends on the mixer geometry and power law index, and N is the rotation speed in revolutions per minute. Also, since the viscosity varies linearly with torque, the temperature dependence of the viscosity can also be obtained from the data. One of the most commonly used torque rheometers is the one made by C.W. Brabender. The squeeze flow rheometer consists of two parallel, coaxial disks that are made to approach each other at constant velocity so that the liquid contained in the gap is forced out. The applied force is measured as a function of time in constant velocity experiments or the plate separation 2H as a function of time in constant force experiments. These units are relatively simple to operate and enable handling of materials prone to fracture; squeeze flow also simulates compression molding. The main problem with these units is that the flow is time dependent and nonhomogeneous and is neither purely shear nor extensional. Also, for rapid squeeze flow, elasticity effects need to be considered. The relevant equation for power-law fluids with consistency index K and power-law index n is:

$$F = \frac{-dH}{dt} \left[\frac{2n+1}{2n} \right] \frac{\pi K}{H^{2n+1}} \frac{R^{n+3}}{(n+3)} \quad (37.60)$$

which for the special case of Newtonian fluids, where K is the viscosity and n is unity, reduces to the well known Stefan equation.

Extensional Viscometers

Measurement of extensional properties remains a daunting task because of problems related to the difficulty in clamping the test material (for mobile fluids) and applying a controlled stretch rate for a sufficient length of time to attain steady state (for both mobile and rigid materials), Extensional rheometers are broadly classified as constant-stress or constant-stretch-rate units; it is usually found that steady state is attained faster in the constant-stress mode. Some of the key categories are listed below:

Mechanical Stretching Extensiometers

These devices are usually restricted to relatively immobile systems. In these devices one end of a cylindrical sample is attached to a force transducer, and the other end is drawn out such that either the stretch rate or stress is constant. For constant stretch rate, the length L varies with time t as per the following equation:

$$\epsilon = \ln \frac{L}{L_0} = \dot{\epsilon} t \quad (37.61)$$

where L_0 is the initial length and ϵ is the so-called Hencky extensional strain. The applied force is scaled with the cross-sectional area as it decreases for constant-stress devices. It is important that the experiment be carried out in an inert liquid to avoid gravitational effects and to maintain constant temperature. A major constraint is the difficulty in attaining steady state which typically corresponds to a Hencky strain of 7 or a thousand-fold increase in specimen length.

An important practical variation on this unit is the Meissner apparatus, which uses toothed wheels to stretch a constant length of sample at a constant angular velocity and a deflection transducer that measures the force needed to keep the sample length constant. Another version due to Sridhar and coworkers is the use of coaxial disks to draw the sandwiched sample apart and then determine the extensional viscosity from the measured force on the disks (using a transducer) and the filament profile (using high-resolution optics). The maximum stretch rate attained in such units is typically 1 l/sec, which is several orders of magnitude lower than those encountered in industry. Nonetheless, properties at low extension rates provide valuable insights into the origins of material properties and the development of constitutive equations.

Fiber Spinning

In this device, a pressurizing unit pumps molten polymer through a circular die and the exiting strand is pulled downwards at constant velocity using two counter-rotating knurled wheels; the drawdown force is measured using an appropriate type of transducer, and the spinline profile is determined optically. The system is usually enclosed in an isothermal chamber. In a constant pull-down velocity experiment, if it is assumed that the velocity is uniform over the cross-section, the local stretch rate can be determined from the flow rate and the diameter profile; the local liquid stress is determined from a momentum balance. The same concept is also applicable to mobile solutions which, in the unit developed by Ferguson and Hudson, involves stretching of the fluid jet emerging from a nozzle using a rotating drum and measuring the tensile force through the deflection of a thin-walled entrance tube; the analysis is similar except that fluid inertia and air drag effects do not become negligible.

A useful variation of the fiber spinning device due to Gupta and Sridhar generates stretch rates up to 1000 l/sec and involves measurement of the pressure decrease in a closed reservoir on application of suction to steady flow of exiting liquid through a capillary; the pressure decrease is related to the tensile stress and the stretch rate is determined from the spinline profile. An extension of this approach (developed by Agarwal and Gupta), which enables stretching of low viscosity and low elasticity liquids as well as miniaturization, employs intrinsic viscosity-type measuring instruments.

The determination of a true extensional viscosity is a difficult proposition in these flows due to:

1. The inherent transient nature of the process since each fluid element experiences a range of stretch rates as it moves down the spin line
2. The considerable sensitivity of the material properties to the previous history for viscoelastic properties

From a practical viewpoint, one may define an apparent extensional viscosity as the ratio of the instantaneous extensional stress to the instantaneous stretch rate. This ratio provides a convenient measure of fluid resistance to extensional deformation and may be used for parameter determination in constitutive models, which in turn may be used to simulate the processes of interest.

Converging Flow

The increase in average velocity as a liquid flows through a conical channel imparts an extensional component to the flow field. The relative amounts of shear and extension depend on the channel geometry, flow rate, fluid properties, and wall slip. According to the Cogswell analysis, the average net extensional stress in the entry region σ_E and the average stretch rate $\dot{\epsilon}_E$ are given by

$$\sigma_E = \left(\frac{3}{8}\right)(n+1)P_{\text{ent}} \quad (37.62)$$

and

$$\dot{\epsilon}_E = \frac{4\tau\dot{\gamma}}{3(n+1)P_{\text{ent}}} \quad (37.63)$$

where Q is the flow rate, n is the power-law index for shear flow, τ is the shear stress at a shear rate $\dot{\gamma}$ ($= 4Q/\pi R^3$) and P_{ent} is the total pressure drop across the abrupt contraction between two points where the flow is fully developed less the value for fully developed Poiseuille flow.

An analogous situation occurs in the entrance region from a reservoir to a capillary as measured through the Bagley correction e , which is a measure of extensional viscosity effects.

Some other extensional rheometers are the open-syphon technique, in which liquid is sucked up from a reservoir into a capillary and the downward pull is measured; lubricated flows, in which low-viscosity Newtonian fluids are used at the walls of test sections designed to induce pure steady extensional flow; and the opposed-nozzle extensometer due to Fuller, which involves application of a suction to fluid between two opposing nozzles to generate extension and then measuring the resulting torque on one of the nozzles that is mounted on a knife edge.

Defining Terms

Invariants of tensors — A second-order tensor T_{ij} having three scalar invariants that are independent of the coordinate system to which the components of T_{ij} are referred. They are $I_T = T_{ij}T_{ij}$, $II_T = T_{ij}T_{jk}T_{ki}$ and $III_T = T_{ij}T_{jk}T_{ki}$.

Material objectivity — A principle that requires that the rheological description of a material should be independent of the reference frame used to describe the fluid motion.

Relaxation time — The duration of time over which appreciable stresses persist after cessation of deformation in a fluid (e.g., the characteristic time constant for exponential decay of stress).

Rheometry — The experimental science of determining rheological material properties.

Viscometric flow — A flow field in which the deformation as seen by a fluid element is indistinguishable from simple shear flow.

Airfoils/Wings

Bruce R. Munson

Iowa State University

Dennis J. Cronin

Iowa State University

38.1 Nomenclature

38.2 Airfoil Shapes

38.3 Lift and Drag Characteristics for Airfoils

38.4 Lift and Drag of Wings

A simplified sketch of a wing is shown in [Figure 38.1](#). An **airfoil** is any cross-section of the wing made by a plane parallel to the xz plane. The airfoil size and shape usually vary along the span.

Airfoils and wings are designed to generate a lift force, L , normal to the free stream flow that is considerably larger than the drag force, D , parallel to the free stream flow. The lift and drag are strongly dependent on the geometry (shape, size, orientation to the flow) of the wing and the speed at which it flies, V_∞ , as well as other parameters, including the density, ρ ; viscosity, μ ; and speed of sound, a , of the air. The following sections discuss some properties of airfoils and wings.

38.1 Nomenclature

The shape, size, and orientation of an airfoil can be given in terms of the following parameters ([Figure 38.2](#)): the **chord** length, c , the chord line that connects the leading and trailing edges; the **angle of attack**, α , relative to the free stream velocity, V_∞ ; the mean **camber** line that is halfway between the upper and lower surfaces; and the thickness distribution, t , which is the distance between the upper and lower surfaces perpendicular to the camber line.

Various classes of airfoils have been developed over the years. These include the classic National Advisory Committee for Aeronautics four-, five-, and six-digit series airfoils (for example, the NACA 2412 airfoil used on the Cessna 150 or the NACA 64A109 used on the Gates Learjet [Anderson, 1991]) as well as numerous other modern airfoils [Hubin, 1992].

Performance characteristics of wings are normally given in terms of the dimensionless **lift coefficient** and **drag coefficient**,

$$C_L = \frac{L}{q_\infty S} \quad (38.1)$$

$$C_D = \frac{D}{q_\infty S} \quad (38.2)$$

where $q_\infty = \frac{1}{2}\rho V_\infty^2$ is the **dynamic pressure** and S is the planform area of the wing. The planform area is the area seen by looking into the wing from above: the span times the chord for a rectangular wing.

FIGURE 38.1 Wing geometry.

FIGURE 38.2 Airfoil geometry.

Typical characteristics for lift and drag coefficients as a function of the angle of attack are shown in [Figure 38.3](#). An efficient wing has a large lift-to-drag ratio — that is, a large C_L/C_D .

As the angle of attack is increased from small values, the lift coefficient increases nearly linearly with α . At larger angles, there is a sudden decrease in lift and a large increase in drag. This condition indicates that the wing has stalled. The airflow has separated from the upper surface, and an area of reverse flow exists ([Figure 38.3](#)). **Stall** is a manifestation of boundary layer separation. This complex phenomenon is a result of viscous effects within a thin air layer (the boundary layer) near the upper surface of the wing in which viscous effects are important [Schlichting, 1979].

In addition to knowing the lift and drag for an airfoil, it is often necessary to know the location where these forces act. This location, the **center of pressure**, is important in determining the moments that tend to pitch the nose of the airplane up or down. Such information is often given in terms of a **moment coefficient**,

$$C_M = \frac{M}{q_0 S c} \quad (38.3)$$

where M is the moment of the lift and drag forces about some specified point, often the leading edge.

For a given geometry, the lift and drag coefficients and the center of pressure (or moment coefficient) may depend on the flight speed and properties of the air. This dependence can be characterized in terms

FIGURE 38.3 Typical lift and drag coefficients as a function of angle of attack.

of the Reynolds number based on chord length, $Re = \rho V_o c / \mu$, and the Mach number, $Ma = V_o / a$. For modern commercial aircraft, the Reynolds number is typically on the order of millions (10^6). Mach numbers range from less than 1 (subsonic flight) to greater than 1 (supersonic flight).

38.2 Airfoil Shapes

As shown in Figure 38.4, typical airfoil shapes have changed over the years in response to changes in flight requirements and because of increased knowledge of flow properties. Early airplanes used thin airfoils (maximum thickness 6 to 8% of the chord length), with only slight camber [Figure 38.4(a)]. Subsequently, thicker (12 to 18% maximum thickness) airfoils were developed and used successfully on a variety of low-speed aircraft [Figure 38.4(b) and Figure 38.4(c)].

A relatively recent development (ca. 1970s) has been design and construction of laminar flow airfoils that have smaller drag than previously obtainable [(Figure 38.4(d)]. This has resulted from new airfoil shapes and smooth surface construction that allow the flow over most of the airfoil to remain laminar rather than become turbulent. The performance of such airfoils can be quite sensitive to surface roughness (e.g., insects, ice, and rain) and Reynolds number effects.

With the advent of commercial and business jet aircraft, it became necessary to develop airfoils that operate properly at Mach numbers close to unity. Since air, in general, accelerates as it passes around an airfoil, the flow may be locally supersonic near portions of the upper surface, even though the flight speed is subsonic. Such supersonic flow can cause shock waves (discontinuities in the flow) that degrade

FIGURE 38.4 Various airfoil shapes.

FIGURE 38.5 Typical pressure distribution on an airfoil.

airfoil performance. Airfoils have been developed (denoted *supercritical airfoils*) to minimize the effect of the shock wave in this locally supersonic region [Figure 38.4(e)].

Certain flow phenomena, such as shock waves, occur in supersonic flight that do not occur for subsonic flight [Anderson, 1991]. The result is that supersonic airfoils tend to be thinner and sharper than those for subsonic flight [see Figure 38.4(f)].

38.3 Lift and Drag Characteristics for Airfoils

Lift and drag forces on airfoils are the result of pressure and viscous forces that the air imposes on the airfoil surfaces. Pressure is the dominant factor that produces lift. A typical pressure distribution is shown in Figure 38.5. In simplistic terms, the air travels faster over the upper surface than it does over the lower surface. Hence, from **Bernoulli's principle** for steady flow, the pressure on the upper surface is lower than that on the bottom surface.

For an unstalled airfoil, most of the drag is due to viscous forces. This skin friction drag is a result of the shear stress distribution on the airfoil. For a stalled airfoil, pressure forces contribute significantly to the drag.

For a two-dimensional body such as an airfoil (a wing of infinite span), the section lift, drag, and moment coefficients (about a defined point) are based on the lift, drag, and moment per unit span, L' [force/length], D' [force/length], and M' [force · length/length], respectively. That is,

$$c_l = \frac{L'}{q_o c} \quad (38.4)$$

$$c_d = \frac{D'}{q_o c} \quad (38.5)$$

$$c_m = \frac{M'}{q_o c^2} \quad (38.6)$$

For most airfoils, the lift coefficient is nearly linear with the angle of attack up to the stall angle. According to simple airfoil theory [and verified by experiment (Figure 38.6)], the lift-curve slope, $dc_l / d\alpha$, is approximately equal to 2π and α in radians (or $dc_l / d\alpha = 0.1096 \text{ deg}^{-1}$ when α is in degrees) [Anderson, 1991].

For symmetrical (no camber) airfoils, zero angle of attack produces zero lift; for airfoils with camber, the zero-lift condition ($\alpha = \alpha_{0L}$) occurs at nonzero angle of attack (Figure 38.6).

The maximum lift coefficient for an airfoil ($c_l = c_{l,\max}$) is typically on the order of unity and occurs at the critical angle of attack ($\alpha = \alpha_{CR}$) (Figure 38.3). That is, the lift generated per unit span is on the

FIGURE 38.6 Effect of camber on airfoil lift coefficient.

FIGURE 38.7 Effect of flaps on airfoil lift coefficient.

order of the dynamic pressure times the planform area: $L' = c_l q_o c \approx q_o c$. The drag coefficient, on the other hand, is on the order of 0.01. Hence, the maximum lift-to-drag ratio is on the order of 100.

As illustrated in Figure 38.7, the airfoil geometry may be altered by using movable trailing or leading edge **flaps**. Such devices can significantly improve low-speed (i.e., landing or takeoff) performance by increasing the maximum lift coefficient, thereby reducing the required landing or takeoff speed.

38.4 Lift and Drag of Wings

All wings have a finite span, b , with two wing tips. The flow near the tips can greatly influence the flow characteristics over the entire wing. Hence, a wing has different lift and drag coefficients than those for the corresponding airfoil. That is, the lift and drag coefficients for a wing are a function of the aspect ratio, $AR = b^2/S$. For a wing of rectangular planform (i.e., constant chord), the aspect ratio is simply b/c .

Because of the pressure difference between the lower and upper surfaces of a wing, the air tends to “leak” around the wing tips (bottom to top) and produce a swirling flow — the trailing or wing tip vortices shown in Figure 38.8. This swirl interacts with the flow over the entire length of the wing, thereby affecting its lift and drag. The trailing vortices create a flow that makes it appear as though the wing were flying at an angle of attack different from the actual angle. This effect produces additional drag termed the *induced drag*.

As shown by theory and experiment [Anderson, 1991], the larger the aspect ratio is, the larger the lift coefficient and the smaller the drag coefficient (Figure 38.9). A wing with an infinite

FIGURE 38.8 Trailing vortex.

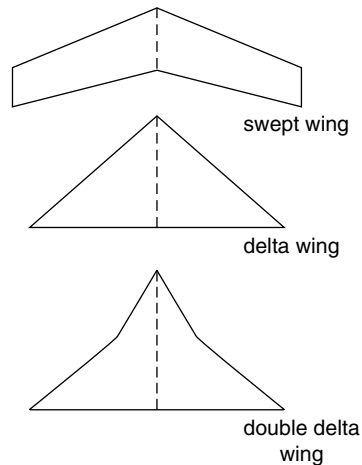

FIGURE 38.9 Lift coefficient as a function of aspect ratio. **FIGURE 38.10** Various wing planforms.

aspect ratio would have the properties of its airfoil section. Very efficient flyers (i.e., soaring birds and sailplanes) have long, slender (large AR) wings.

For many wings, the chord length decreases from the wing root (next to the aircraft body) to the wing tip. In addition, the shape of the airfoil section may change from root to tip, as may the local angle of attack (i.e., the wing may have some “twist” to it).

Many modern high-speed wings are swept back with a V-shaped planform; others are delta wings with a triangular planform (Figure 38.10). Such designs take advantage of characteristics associated with high-speed compressible flow [Anderson, 1990].

Although tunnel tests of model airfoils and wings still provide valuable (and sometimes unexpected) information, modern computational fluid dynamic (CFD) techniques are widely used. Techniques involving paneling methods, finite elements, boundary elements, finite differences, and viscous-inviscid interaction are among the powerful tools currently available to the aerodynamicist [Moran, 1984].

Defining Terms

Airfoil — The cross-section of a wing, front to back.

Angle of attack — The angle between the line connecting the leading and trailing edges of an airfoil and the free stream velocity.

Bernoulli’s principle — Conservation of energy principle that states that an increase in flow speed is accompanied by a decrease in pressure and vice versa.

Camber — Maximum distance between the chord line and the camber line.

Center of pressure — Point of application of the lift and drag forces.

Chord — Distance between the leading and trailing edges of an airfoil.

Dynamic pressure — Pressure increase resulting from the conversion of kinetic energy into pressure.

Flaps — Leading and trailing edge devices used to modify the geometry of an airfoil.

Lift and drag coefficients — Lift and drag made dimensionless by dynamic pressure and wing area.

Moment coefficient — Pitching moment made dimensionless by dynamic pressure, wing area, and chord length.

Planform — Shape of a wing as viewed from directly above it.

Span — Distance between the tips of a wing.

Stall — Sudden decrease in lift as angle of attack is increased to the point where flow separation occurs.

39.1 Theoretical Boundary Layers

39.2 Reynolds Similarity in Test Data

39.3 Friction in Pipes

39.4 Noncircular Channel

39.5 Example Solutions

39.1 Theoretical Boundary Layers

In a simple model of a solid, material deformation is proportional to the strain. In a simple model of a fluid, the deformation is proportional to the rate of strain or the change in velocity over a small distance. The mathematical term describing this phenomenon is the last term in the following boundary layer equation:

$$\rho \left[\frac{\delta u}{\delta t} + u \frac{\delta u}{\delta x} + v \frac{\delta u}{\delta y} \right] = -\frac{\delta p}{\delta x} + \frac{\delta}{\delta y} \left(\mu \frac{\delta u}{\delta y} \right) \quad (39.1)$$

where u is the velocity in the x direction as a function of x , y , and t . The values ρ and μ are the density and dynamic viscosity for the fluid, respectively. This equation is good for all situations with no pressure (P) change present in the direction normal to the wall.

The left-hand side of Equation (39.1) represents time kinetic energy in flow. The pressure term is a potential energy term. The rate of strain term that represents this energy dissipates through viscous losses. When the dissipation term is significant compared to the others, a boundary layer must be considered as part of the flow analysis.

For a straight-channel, steady (not time-dependent) flow, Equation (39.1) becomes

$$\mu \frac{d^2 u}{dy^2} = \frac{dp}{dx} \quad (39.2)$$

which has the solution

$$u = -\frac{1}{2\mu} \frac{dp}{dx} (D^2 - y^2) \quad (39.3)$$

where d is the distance toward the wall measured from the centerline and the velocity u is zero at the walls. This velocity equation is parabola. Note that when $y = D$, Equation (39.3) becomes

$$u_{cl} = -\frac{D^2}{2\mu} \frac{dp}{dx} \quad (39.4)$$

Thus, if the pressure loss over a distance X is measured along with the centerline velocity (u_{cl}), the viscosity can be determined. Similarly, if the velocity is known at the centerline, the pressure loss per unit length can be calculated.

39.2 Reynolds Similarity in Test Data

As a boundary layer develops, it starts in a smooth, or laminar, state. Downstream, it transforms into a turbulent state, where the flow is irregular and contains eddies. Various physical conditions, such as wall or surface roughness or upstream turbulence, will affect the speed of this transition. In smooth-walled pipes, laminar flow occurs for Reynolds numbers (Re) of less than 2000, with fully developed turbulence for Re greater than 4000. The Reynolds number is a dimensionless number developed from dynamic similarity principles that represents the ratio of the magnitudes of the inertia forces to the friction forces in the fluid.

$$\text{Re} = \frac{\text{inertia force}}{\text{friction force}}$$

where inertia force $= \rho V_c^2 L_c^2$ and friction force $= \mu V_c L_c^2$. Then,

$$\text{Re} = \frac{\rho V_c L_c}{\mu} = \frac{V_c L_c}{\nu} \quad (39.5)$$

where V_c and L_c are characteristic or representative velocities and lengths, respectively. For a pipe or similar narrow channel, L_c is the internal diameter (ID) of the pipe and V_c is the average or bulk velocity obtained by dividing the mass flow rate (M) by the cross-sectional area and density of the fluid:

$$V_c = \frac{M}{\rho A} \quad (39.6)$$

Using the Reynolds number as a similarity parameter, test data can be correlated into generalized charts for frictional losses.

For the flat plate (Figure 39.1) case, V_c is taken as the free stream velocity outside the boundary layer, and L_c is the length measured along the wall standing from the leading edge.

39.3 Friction in Pipes

The energy equation for steady flow between any two points in a pipe can be written as

$$\frac{V_2^2 - V_1^2}{2g} + \frac{P_2 - P_1}{\rho g} + Z_2 - Z_1 - h_f = 0 \quad (39.7)$$

where h_f is a head loss due to friction. This equation neglects other minor losses (such as elbows, valves, exit and entrance losses, and bends). It is useful to define the head loss in terms of a friction factor (f) such that this nondimensional friction factor (f), known as the Darcy friction factor, can be determined experimentally as a function of the dimensionless Reynolds numbers and a relative roughness parameter ϵ/D , as shown in Figure 39.2. Rough factors, ϵ , are given in Table 39.1.

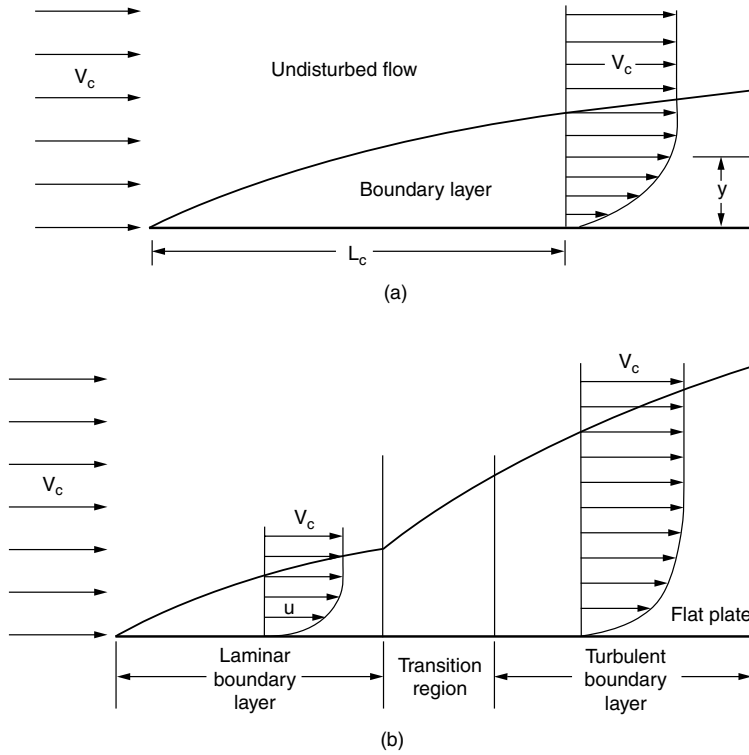

FIGURE 39.1 (a) Boundary layer along a smooth plane. (b) Laminar and turbulent boundary layers along a smooth, flat plate. (Vertical scales greatly enlarged.)

FIGURE 39.2 Friction factors for commercial pipe. (Source: Moody, L. F. 1944. Friction factors for pipe flow. *Trans. ASME*. 66:672. With permission.)

TABLE 39.1 Roughness

| Surface | ϵ , ft | ϵ , m |
|---|---------------------|---------------------|
| Glass, plastic | Smooth | Smooth |
| Drawn tubing | $5 \cdot 10^{-6}$ | $1.5 \cdot 10^{-6}$ |
| Commercial steel, wrought iron or aluminum sheet | $1.5 \cdot 10^{-4}$ | $4.6 \cdot 10^{-5}$ |
| Galvanized iron | $5 \cdot 10^{-4}$ | $1.2 \cdot 10^{-4}$ |
| Cast iron | $8.5 \cdot 10^{-4}$ | $2.4 \cdot 10^{-4}$ |
| Concrete pipe | $4 \cdot 10^{-3}$ | $1.2 \cdot 10^{-3}$ |
| Riveted steel pipe | .01 | .003 |
| Wood | .001 | .0003 |

There are two equations that describe the data shown in [Figure 39.2](#). The first is the laminar line. For laminar flow in pipes with Re less than 2000, it can be shown through analysis that

$$f = \frac{64}{Re} \quad (39.8)$$

The second is the Colebrook equation [Colebrook, 1938]:

$$\frac{1}{\sqrt{f}} = -2 \log_{10} \left[\frac{\epsilon/D}{3.7} + \frac{2.51}{Re\sqrt{f}} \right] \quad (39.9)$$

which describes the turbulent region. Note that, as the roughness ϵ approaches zero, we obtain the smooth pipeline and the equation becomes

$$\frac{1}{\sqrt{f}} = 2 \log_{10} \left[\frac{Re\sqrt{f}}{2.51} \right] \quad (39.10)$$

For fully developed turbulence, the Re approaches zero and the Colebrook equation simplifies to

$$\frac{1}{\sqrt{f}} = 2 \log_{10} \left[\frac{3.7}{\epsilon/D} \right] \quad (39.11)$$

For turbulent flows in closed conduits with noncircular cross-sections, a modified form of Darcy's equation may be used to evaluate the friction loss:

$$h_f = f \left(\frac{L}{D} \right) \left(\frac{v^2}{2g} \right)$$

where D is the diameter of the circular conduit.

39.4 Noncircular Channel

In the case of noncircular cross-sections, a new term, R , is introduced to replace diameter D . R is defined as hydraulic radius, which is the ratio of the cross-sectional area to the wetted perimeter (WP) of the noncircular flow section.

$$R = \frac{A}{WP}$$

For a circular pipe of diameter D the hydraulic radius R is

$$R = \frac{A}{WP} = \frac{\pi D^2 / 4}{\pi D} = \frac{D}{4}$$

or $D = 4R$. Substitution of $4R$ for D in Darcy's equation yields

$$h_f = \left(\frac{L}{4R} \right) \left(\frac{v^2}{2g} \right)$$

The Reynolds number can be modified as

$$Re = \frac{v(4R)\rho}{\mu} \quad \text{or} \quad Re = \frac{v(4R)}{\nu}$$

39.5 Example Solutions

Example 39.1

Refer to [Figure 39.3](#). Water at 50°C is flowing at a rate of $0.07 \text{ m}^3/\text{sec}$. The pipeline is steel and has an inside diameter of 0.19 m . The length of the pipeline is 900 m . Assume the kinematic viscosity (ν) is $5.48 \cdot 10^{-7} \text{ m}^2/\text{sec}$. Find the power input to the pump if its efficiency is 82% ; neglect minor losses.

Given information is as follows:

$$Q = 0.07 \text{ m}^3/\text{s}; \quad L = 900 \text{ m}; \quad T = 50^\circ\text{C}$$

$$\Delta Z = 15 \text{ m}; \quad \nu = 5.48 \cdot 10^{-7} \text{ m}^2/\text{s}; \quad D = 0.2 \text{ m}$$

$$\gamma \text{ at } 50^\circ\text{C} = 9.69 \text{ kN/m}^3$$

Find power input to pump.

FIGURE 39.3 Pipeline in Example 39.1.

Solution

First, determine the Reynolds number:

$$\begin{aligned} \text{Re} &= \frac{vD}{\nu}; \quad v = \frac{Q}{A} \\ \text{Re} &= \frac{4Q}{\pi D \nu} = \frac{4(0.07)}{\pi(0.2)(5.48 \cdot 10^{-7})} \\ &= 8.13 \cdot 10^5 \end{aligned}$$

Second, determine ε/D ratio and friction factor f . Roughness (ε) for steel pipe = $4.6 \cdot 10^{-5}$ m.

$$\frac{\varepsilon}{D} = \frac{4.6 \cdot 10^{-5} \text{ m}}{0.19 \text{ m}} = 0.000242$$

From Moody's diagram with values of N_R and ε/D , $f = 0.0151$.

Next, determine head loss due to friction:

$$\begin{aligned} h_f &= 0.0151 \left(\frac{L}{D} \right) \left(\frac{v^2}{2g} \right); \quad v = \frac{Q}{A} \\ h_f &= 0.0151 \frac{8LQ^2}{\pi^2 g D^5} \\ &= 0.0151 \frac{8(900)(0.07)^2}{\pi^2 (9.81)(0.02)^5} \\ &= 0.0151 \frac{35.28}{0.031} = 17.2 \text{ m} \end{aligned}$$

Finally, determine power input into pump:

$$\begin{aligned} P_A &= h_A \gamma Q = 17.2 \left(9.69 \frac{\text{kN}}{\text{m}^3} \right) \left(0.07 \frac{\text{m}^3}{\text{s}} \right) \\ &= 11.67 \frac{\text{kN} \cdot \text{m}}{\text{s}} = 11.67 \text{ kW} \end{aligned}$$

$$e_p = \frac{P_A}{P_I}$$

e_p = Pump efficiency

P_A = Power delivered to fluid

P_I = Power input into pump

$$P_I = \frac{P_A}{e_p} = \frac{11.67 \text{ kW}}{0.82} = 14.23 \text{ kW}$$

FIGURE 39.4 Duct in Example 39.2.

TABLE 39.2 Dynamic Viscosity of Liquids (μ) (mPa · sec)

| Liquid | -25°C | 0°C | 25°C | 50°C | 75°C | 100°C |
|------------------|-------|-------|-------|-------|-------|-------|
| Water | | 1.793 | 0.890 | 0.547 | 0.378 | |
| Mercury | | | 1.526 | 1.402 | 1.312 | |
| Methanol | 1.258 | 0.793 | 0.544 | | | |
| Isobutyl acetate | | | 0.676 | 0.493 | 0.370 | 0.286 |

Example 39.2

Air with a specific weight of 12.5 N/m^3 and dynamic viscosity of $2.0 \cdot 10^{-5} \text{ N} \cdot \text{sec/m}^2$ flows through the shaded portion of the duct shown in Figure 39.4 at the rate of $0.04 \text{ m}^3/\text{sec}$. (See Table 39.2 or Figure 39.5 for dynamic viscosities of some common liquids.) Calculate the Reynolds number of the flow, given that $\gamma = 12.5 \text{ N/m}^3$, $\mu = 2.0 \cdot 10^{-5} \text{ N} \cdot \text{sec/m}^2$, $Q = 0.04 \text{ m}^3/\text{sec}$, and $L = 30 \text{ m}$.

Solution

$$\rho = \gamma/g = \frac{12.5 \text{ N/m}^3}{9.81 \text{ m/s}^2} = 1.27 \text{ N} \cdot \text{s}^2/\text{m}^4 \text{ or } \text{kg/m}^3$$

$$\begin{aligned} A(\text{shaded}) &= (0.05 \text{ m})^2 - \frac{\pi}{4}(0.025 \text{ m})^2 \\ &= 0.0025 \text{ m}^2 - 0.00049 \text{ m}^2 \\ &= 0.002 \text{ m}^2 \end{aligned}$$

$$\begin{aligned} \text{Wet parameter (WP)} &= 4(0.05 \text{ m}) + \pi(0.025 \text{ m}) \\ &= 0.2 \text{ m} + 0.0785 \text{ m} \\ &= 0.279 \text{ m} \end{aligned}$$

$$\begin{aligned} \text{Hydraulic radius (R)} &= \frac{A}{\text{WP}} \\ &= \frac{0.002 \text{ m}^2}{0.279 \text{ m}} \\ &= 0.00717 \text{ m} \end{aligned}$$

FIGURE 39.5 Absolute viscosity of common fluids at 1 atm. (Source: White, F. 1986. *Fluid Mechanics*, 2nd ed. McGraw-Hill, New York. With permission.)

$$v = \frac{Q}{A} = \frac{0.04 \text{ m}^3/\text{s}}{0.002 \text{ m}^2} = 20 \text{ m/s}$$

$$\text{Reynolds number (Re)} = \frac{4Rv\rho}{\mu}$$

$$N_R = \frac{4(0.00717 \text{ m})(20 \text{ m/s})(1.27 \text{ N}\cdot\text{s}/\text{m}^2)}{2.0 \cdot 10^{-5} \text{ N}\cdot\text{s}/\text{m}^2}$$

$$= 3.64 \cdot 10^4$$

Check Valve Types • Check Valve Selection

Valves are mechanical devices typically installed in pipelines to control flow or pressure. The valves provide control using a variable restriction created by a rotating plug or disc; a sliding sleeve or gate; or the pinching of a flexible membrane. Since valves can be vital to the successful operation of piping systems, care should be taken to ensure that the proper valve is selected and that it is operated correctly. If not properly selected and operated, valves can cause operational problems including poor control, excessive head loss, cavitation, and hydraulic transients. Such problems can lead to accelerated wear requiring repair or replacement of the valve and, in some cases, system failure.

This chapter discusses hydraulic characteristics and function of control valves, air release/vacuum breaking valves, and check valves. Control valves are used to control flow, pressure, liquid level, cavitation, and pressure transients. Hydraulic aspects of common types of control valves are discussed, including controllability, torque requirements, cavitation, hydraulic transients, and principles of valve selection. Air valves are designed to expel large amounts of air at low pressure during filling, release small amounts of pressurized air during system operation, and admit air when the pipe is drained to prevent excessive vacuum pressures and possible pipe collapse. Guidelines are provided for selecting the proper size, type, and location of air valves to protect pipelines. Common types of check valves are described and guidelines are offered for selecting the proper check valve for different systems.

40.1 Control Valves

Hydraulic selection criteria for control valves include controllability (i.e., flow and pressure drop characteristics), torque or thrust requirements for operator sizing, cavitation performance, velocity limits, and transients generated by valve operation. Other factors that influence valve selection and performance include valve installation (flow direction and orientation), effectiveness of seating, and the influence of disturbances generated upstream from the valve.

Valve Types

Butterfly valves are popular and suitable for a variety of valve applications. They come in a wide variety of body, disc, size, and seat designs. Details of their construction can have a significant effect on their performance, especially their seating ability and the magnitude of the operating torque. All butterfly

FIGURE 40.1 Metal seated butterfly valve cutaway (figure courtesy of FLOWSERVE).

FIGURE 40.2 Typical full-port, skirted cone valve (figure courtesy of Apco Valve and Primer).

valves have a disc that rotates 90° , creating two crescent-shaped openings that discharge parallel to the wall of the downstream pipe. However, there is a wide range in valve quality, cost, and performance. A well-engineered butterfly valve can provide excellent service for many years. One type of butterfly valve is illustrated in Figure 40.1.

Cone valves have a rotating conical plug that presents no obstruction to the flow when the plug is in the fully open position. In a partially open position, these valves have two crescent-shaped throttling ports in series. There are four classifications of cone valves: full-port, reduced-port, skirted, and unskirted. Full-port means that the hole through the conical plug is the same diameter as the inlet and outlet passages of the valve body, as shown in Figure 40.2. A reduced-port valve is fabricated with the plug diameter smaller than the valve diameter, and the valve body has reducers and expanders to transition between pipe and plug diameters. The term “skirted” means that the plug is, or has the appearance of being, solid and all of the water flows through the two crescent-shaped openings in series. An “unskirted” cone valve has a fabricated plug design that allows some of the water to flow around the plug (i.e., between the plug and valve body). This design is sometimes referred to as a skeleton cone valve. The flow around the plug causes the unskirted or skeleton cone valve to have significantly worse cavitation performance than the skirted design. For unseating, the plug is lifted prior to rotation. After rotating the plug to the closed position, the plug is lowered into the seat.

Ball valves have numerous designs. One style of ball valve has a solid spherical plug with a cylindrical hole forming the flow passage (much like a skirted cone valve), as shown in Figure 40.3. For full-port designs, the flow passage is the same diameter as the valve inlet/outlet diameter. For reduced-port designs, the flow passage through the ball has a smaller diameter than the nominal valve diameter; the valve body includes reducing and expanding sections. Both of these designs have two throttling ports in series and have flow characteristics similar to cone valves. Close machining tolerances are required for the seating surfaces because the spherically shaped plug rotates into and out of the seat. Another design uses a fabricated plug essentially made of two intersecting pipes, one closed and one open, as shown in Figure 40.4. Ball valves are available with either metal or soft seats.

Plug valves are similar to cone valves, in that they have a conical rotating plug. The flow passage through the plug is typically rectangular in shape rather than circular, as shown in Figure 40.5. The eccentric plug valve design contains a control element that looks much like the visor on a helmet. This type of valve has only one throttling port.

Globe valves vary in design more than most valves do. There are far too many variations to discuss them in any detail. The conventional globe valve has a single port with a plug that moves linearly, as shown in Figure 40.6. The flow is controlled by the linear movement of the plug, relative to the seat. The internals of globe valves can vary significantly. Recent developments include a variety of single and multistage trims that suppress cavitation but reduce flow capacity. One type of trim, shown in Figure

FIGURE 40.3 Full-port, skirted, ball valve cutaway (figure courtesy of FLOWSERVE).

FIGURE 40.4 Unskirted ball valve cutaway (figure courtesy of Apco Valve and Primer).

40.7, has a perforated cylinder, similar to that of the sleeve valve. Some designs use multiple concentric perforated sleeves to dissipate the energy in stages. Other styles, often referred to as *stack valves*, use both parallel and series flow passages which produce very high pressure drops while suppressing cavitation.

Gate valves have a variety of fabrication differences that influence their seating performance, but their flow characteristics are similar. They have a single or double seating surface, with either soft or metal seats. The movement of a flat plate passing in and out of the flow path controls the flow through a gate valve. For most designs, the gate is completely removed from the flow path when the valve is in the full-open position. In the partially open position, all gate valves have one crescent-shaped flow opening. Gate valves can be relatively inexpensive and generate little head loss in the full-open position. As a result, gate valves are commonly used as isolation valves. Gate valves are seldom used as control valves due to vibrations and poor cavitation performance at partial valve openings.

Sleeve valves are a relatively new valve style and are excellent for controlling flow and suppressing cavitation in systems with relatively high pressure drop requirements. One style is an in-line sleeve valve that consists of a stationary sleeve with numerous holes and an external traveling sleeve, which controls the number of holes exposed for flow passage. The size and spacing of the holes can be varied to provide a variety of flow characteristics and cavitation performance. For in-line sleeve valves, the jets discharge inward, forcing the cavitation to be concentrated at the center of the discharge pipe, away from the boundaries. For use at terminal structures, sleeve valves can also be designed with the jets discharging outward into a pipe or tank. Since the perforated sleeve functions much like a strainer, sleeve valves are limited to clean water systems.

FIGURE 40.5 Full-port, skirted, plug valve cutaway (figure courtesy of FLOWSERVE).

FIGURE 40.6 Globe valve cutaway. The flow through the valve is controlled by a disc, which moves vertically up and down (figure courtesy of CLA-VAL).

FIGURE 40.7 Globe valve cavitation trim. The figure illustrates flow passing through the trim and collecting in the center. Other trims/valves are designed for outward flow (figure courtesy of FLOWSERVE).

FIGURE 40.8 Free discharge fixed-cone (Howell–Bunger) valve (figure courtesy of Rodney Hunt).

Free-discharge, fixed-cone valves (Howell–Bunger) have a stationary cone, a traveling sleeve, and an optional discharge hood to direct the flow. A fixed-cone valve without a hood is shown in Figure 40.8. These valves are used for free-discharge releases at high pressure. Fixed-cone valves are commonly used in conjunction with low-level outlet works for dams. Since the high-velocity jet is fully aerated, cavitation is avoided. A dissipation pool is usually included to prevent erosion of the surrounding area by the jet. Care must be taken in designing the hood to limit back-splash and ensure that adequate air is supplied to prevent cavitation. Recent developments include discharge hoods designed to dissipate up to 95% of the jet's energy [Johnson et al., 2001].

For additional details about other types of control valves available in the industry and information on body styles, internal trim options, materials of construction, details on packing options, valve operators, etc., the reader is referred to Crane, 1979; Fisher, 2001; ISA, 1976; and Driskell, 1983.

Valve Coefficients

The relationship between flow and pressure drop at any valve opening can be expressed by a number of coefficients. The coefficients most commonly used are:

Discharge coefficient

$$C_d = \frac{V}{\sqrt{2\Delta P/\rho + V^2}} = \frac{V}{\sqrt{2g\Delta H + V^2}} \quad (40.1)$$

Loss coefficient

$$K = \frac{2\Delta P}{\rho V^2} = \frac{2g\Delta H}{V^2} \quad (40.2)$$

Flow coefficient

$$C_v = \frac{Q}{\sqrt{\Delta P/s.g.}} \quad (40.3)$$

Free-discharge coefficient

$$C_{df} = \frac{V}{\sqrt{2P_u/\rho + V^2}} = \frac{V}{\sqrt{2gH_u + V^2}} \quad (40.4)$$

V is the average velocity at the inlet to the valve; ρ is the fluid density; g is the acceleration due to gravity; ΔP and ΔH are the net pressure and head drop, respectively, across the valve; $s.g.$ is the specific gravity of the fluid; and P_u and H_u are the gage pressure and the pressure head, respectively, at the inlet to the valve.

A few comments about these coefficients might be helpful. With the exception of Equation 40.3, the coefficients are dimensionless (as long as consistent units for ΔH , ΔP , V , g , and ρ are used). In Equation 40.3, ΔP is in pounds per square inch (psi) and Q is in U.S. gallons per minute (gpm). This makes the numeric value of C_v a function of valve size. The value of C_v has physical significance. It represents the flow rate in gpm that a valve can pass with 1 psi pressure differential. C_v data can be scaled between geometrically similar valves of different sizes using Equation 40.5. (Note: For best accuracy, the inside diameter should be used rather than the nominal diameter.)

$$C_{v1} = C_{v2} \left(\frac{d_1}{d_2} \right)^2 \quad (40.5)$$

One disadvantage of using C_v to quantify discharge capacity stems from the fact that full-port ball, cone, and gate valves have almost no pressure drop when the valve is full open. Consequently, the value of C_v approaches infinity. In contrast, the C_d value will approach 1.0 as pressure drop goes to zero. C_d is also independent of valve size and varies between 0 and 1.0 for all types of valves. This makes it convenient to compare the relative capacity of different valves.

Equation 40.4 is the recommended definition of the discharge coefficient for free discharging valves. Equation 40.4 can also be applied to predict flow capacity for a valve that is operating in choking cavitation (ch) by replacing P_u with $P_{u(ch)}$, where $P_{u(ch)} = P_u + P_{\text{baro}} - P_{\text{vapor}}$.

Figure 40.9 shows representative discharge coefficient data for a full-port skirted cone valve, a butterfly valve, and a globe valve. The data are based on actual test data, but the values only apply to the valves

FIGURE 40.9 Discharge coefficient data for various types of control valves (data for demonstration purposes only).

tested and are not representative of all valves of the same type. When selecting a control valve for a particular application, it is necessary to obtain valve-specific performance data from the manufacturer. The data are presented only for illustration purposes.

The data in [Figure 40.9](#) illustrate characteristic differences between valves, however, one must use caution when interpreting relative values of the discharge coefficients. At full-open, the C_d for the cone valve is 2.5 times the C_d for the globe valve. That does not necessarily mean that the cone valve will have significantly greater flow capacity in all cases. The difference in flow capacity of the valves installed in identical systems depends on the system loss (i.e., friction and minor losses). For example, if the pipeline is very long, the flow will typically be controlled almost exclusively by friction, regardless of the type of control valve used. On the other hand, if the system is very short, the control valve will produce most of the energy loss. In low-friction systems, a cone valve will provide significantly more flow than a globe valve at the same valve opening.

Note that the C_d curves for the butterfly and globe valves in [Figure 40.9](#) flatten off near the full-open position. This means that they will not be able to provide good flow control beyond about 90% open. It is not uncommon for the C_d values for some butterfly valves to reach a maximum value at valve openings less than full-open. For the butterfly valve in [Figure 40.9](#), the flow will actually decrease as the valve opens the last 10%. This is not a desirable flow characteristic.

When selecting a control valve, it is necessary to analyze the valve's performance as a part of the piping system and not simply consider its characteristics ([Figure 40.9](#)) alone. It is often desirable to have the flow linearly reduced (linear valve) as the control valve is closed. The linearity of a valve, however, depends more on the system losses than it does on the type of valve. A linear valve installed in a short pipe, where friction and minor losses are small, will linearly reduce the flow as the valve closes. When installed in a high friction loss system, the same valve will not reduce the flow during the first 50 to 75% of its stroke. Valve and system interaction will also influence cavitation and transient problems.

Operating Torque

In addition to selecting a valve with the appropriate flow characteristics, it is also necessary to select the operator so the valve can be opened and closed under the most severe flow conditions expected. The four primary torques that typically affect rotary-actuated (or quarter-turn) valves are seating torque, bearing friction torque, packing friction torque, and hydrodynamic torque. These torque values must be experimentally determined.

Seating torque develops when the plug or disc moves in or out of the seat. A frictional force develops between the disc and the seat resulting in a torque on the valve shaft. For small valves with soft seats, the seating torque can be larger than all the other torques combined. **Bearing friction torque** is caused by the load placed on the bearing surface by the valve shaft when there is a pressure differential across the valve. Since the pressure drop significantly increases as a valve closes, the bearing torque is greatest at small openings. **Packing friction torque** is caused by the valve shaft rubbing against the packing material. The packing material is "packed" around the shaft to prevent leakage. Packing friction torque can be particularly troublesome because it can be modified in the field. If a packing leaks, the normal procedure is to tighten the packing until the leak stops. This can significantly increase the packing torque and may prevent the operator from opening the valve. Any time a packing is adjusted, the ability of the actuator to close the valve under all operating conditions should be confirmed.

Forces induced by the fluid flowing through the valve cause a **hydrodynamic torque**, which usually acts to close the valve. The magnitude of the torque varies with flow rate (or pressure drop) and valve opening. The valve opening, which corresponds to the maximum hydrodynamic torque value, is dependent upon both the valve design and system characteristics. The hydrodynamic forces should be evaluated over the entire valve operating range to identify the maximum operating torque.

Some rotary-actuated valves experience a torque reversal at large valve openings. At a point of torque reversal, the net torque is zero. If a valve operates at opening near a torque reversal, instabilities inherent in the flow will cause the disc to flutter. This can result in fatigue failure of the shaft and loosening or

FIGURE 40.10 Sample flow and torque coefficient data for a 24-in. butterfly valve (data for demonstration purposes only).

breaking of connections. Torque reversals should be avoided by limiting the maximum opening of the valve so it will not be exposed to torque reversals.

Another factor influencing the stability and magnitude of the hydrodynamic torque is the presence of a disturbance located just upstream from the valve (i.e., another valve, elbow, pump, etc.). Turbulence and nonuniform flow generated by a disturbance can increase both the average torque and the magnitude of torque fluctuations. This will increase the possibility of fatigue failure of the shaft and connections.

Torque is typically measured by flow testing the valve in a laboratory. A properly designed testing program can identify each component of the torque. Such test data must then be scaled to valves of different sizes. Scaling the seating and packing torques is difficult but the bearing and hydrodynamic torques can be scaled fairly accurately. Scaling the hydrodynamic torque can be done using one of two common torque coefficients, C_{tv} and C_{idP} defined as follows:

$$C_{tv} = \frac{T}{\rho d^3 V^2} \quad (40.6)$$

$$C_{idP} = \frac{T}{d^3 \Delta P} \quad (40.7)$$

where T is the hydrodynamic torque, ρ is the fluid density, d is the valve diameter, V is the fluid velocity, and ΔP is the net pressure differential across the valve. These coefficients are dimensionless and the standard sign convention is that a positive torque acts in the closing direction.

To illustrate how the maximum hydrodynamic torque value is determined and used, sample valve loss (K) and torque (C_{idP}) coefficient data for a 24-inch butterfly valve are presented in Figure 40.10. For this particular valve, the torque coefficient increases with valve opening up to approximately 86° and a torque reversal occurs at approximately 89.5°. The valve loss coefficient, on the other hand, consistently decreases with increasing valve opening. Per Equation 40.7, the hydrodynamic torque is dependent upon C_{idP} and ΔP . ΔP , like K , will increase with decreasing valve opening. As a result, the maximum torque will usually not occur at the valve opening with the highest C_{idP} value. Table 40.1 shows hydrodynamic torque data as a function of valve opening, based on the data presented in Figure 40.10. For this example, maximum torque occurs at 50° open. This analysis should be done for several system operating conditions (if there is more than one) to determine the maximum hydrodynamic torque that the valve will be subjected to. This torque would be added to the estimated torques for seating, packing, and bearing to obtain the required operator torque.

Cavitation

Cavitation is the process of rapid vaporization and condensation of a liquid, brought about by changes in either fluid temperature or pressure. When the process occurs at a constant pressure, due to an increase

Note: D (in.) = 24 (pipe and valve diameter), Area (square feet) = 3.14 (pipe and valve cross-sectional area), R = 0.016 (system resistance), Δz (ft) = 120 (upstream reservoir–downstream reservoir).

$$\text{System Equation: } \Delta z = (R + K_v) \frac{Q^2}{2g}$$

in temperature, it is referred to as boiling. When the process occurs at a constant temperature, due to a decrease in pressure, it is called cavitation. Cavitation occurs when small air voids, referred to as nuclei, are subjected to vapor pressure and grow rapidly by vaporization and then are subjected to high external pressure causing collapse. All liquids contain nuclei in the form of small free air bubbles and air pockets trapped on small debris particles. The low pressure necessary for the nuclei to grow into vapor cavities occurs in zones of high velocity/low pressure, and especially at the center of eddies generated by turbulence. The pressure at the center of the eddies is lower than the ambient fluid pressure due to their high rotational velocity. When the local pressure reaches vapor pressure, the small nuclei grow rapidly by vaporization of the liquid, causing the eddies to rapidly dissipate. This subjects the vapor cavity to the ambient pressure which is greater than vapor pressure. The cavity implodes and creates extremely high local pressures and micro jets that can damage solid surfaces. For a thorough treatment of cavitation, see Knapp et al., 1970 and Tullis, 1989.

A valve exposed to excessive cavitation can experience accelerated wear; generate excessive noise, vibrations, and head loss; and even lose capacity if subjected to choking cavitation. Figure 40.11 shows

FIGURE 40.11 Cavitation damage in a globe valve (view from the downstream end of the valve).

an example of valve body damage resulting from cavitation. The acceptable cavitation level for a valve in a given system varies with valve type, valve function, details of the piping layout, and duration of operation. There are at least three cavitation limits appropriate for valve operation. These are critical, incipient damage, and choking cavitation. Critical cavitation corresponds to the onset of noise and is appropriate as a design limit for valves that need to operate essentially free of cavitation. Incipient damage corresponds to onset of pitting (material removal). It is an appropriate design limit when significant noise and vibrations can be tolerated but no damage is desired. Choked flow, choking cavitation, or flashing represents the condition where the mean pressure downstream from the valve drops to vapor pressure and the flow is at its maximum for a given upstream pressure. Between incipient damage and choking cavitation, the erosion damage and vibration levels can be severe. Using choking as a design condition is appropriate for valves intended for intermittent use, such as a pressure relief valve, where cavitation damage can be tolerated for short periods of time. It should not be used for valves intended for long-term, damage-free operation.

One unfortunate misunderstanding about valve cavitation arises from the false teaching that cavitation begins when the mean downstream pressure approaches vapor pressure, i.e., when the valve starts to choke. Choking is, in fact, the final stage of cavitation — well beyond the point where damage begins. Promoting this incorrect definition of “onset of cavitation” has resulted in many valves suffering extensive damage.

A thorough cavitation analysis is an important part of valve selection. Detailed procedures for analyzing a valve for cavitation and making adjustments for size and pressure scale effects are available [Tullis, 1989, 1993]. However, the analysis cannot be done without experimental cavitation data. Cavitation data are available for only a few valves due to the limited amount of laboratory cavitation testing performed to date. The following example demonstrates the principles involved in evaluating the cavitation intensity for a valve operating under specific flow and pressure conditions. Consider a 6-in. diameter butterfly valve that is installed in a system and operated under the following flow conditions: $P_u = 44$ psi, $P_d = 20.8$ psi, and $Q = 1.29$ cubic feet per second (cfs). Assume that the barometric pressure is 12.2 psia and the vapor pressure is 1.16 psia. Assume that the 6-in. butterfly valve flow characteristics are described by the butterfly valve data presented in [Figure 40.9](#).

Determining the cavitation intensity of the valve requires comparing the value of the cavitation parameter Σ for the valve at system operating conditions to Σ values for the valve at different cavitation intensity levels (i.e., critical cavitation, incipient damage, and choking cavitation). Σ is defined as:

$$\Sigma = \frac{(P_d + P_b - P_v)}{(P_u - P_d)} \quad (40.8)$$

P_u and P_d are the pressures upstream and downstream from the valve, P_b is the barometric pressure, and P_v the absolute vapor pressure.

From Equation 40.1, $C_d = 0.111$, which corresponds to a valve opening of approximately 27%. From Equation 40.8, Σ for the system operating conditions is:

$$\Sigma_{sys} = \frac{(20.8 + 12.2 - 1.16)}{(44 - 20.8)} = 1.37$$

Values of Σ corresponding to critical cavitation, incipient damage, and choking cavitation for the same valve opening must be obtained from laboratory data. Assume the following laboratory data apply to the butterfly valve at 27% open:

$$\Sigma_{cr} = 1.7 \text{ (critical cavitation)}$$

$$\Sigma_{id} = 1.0 \text{ (incipient damage)}$$

$$\Sigma_{ch} = 0.4 \text{ (choking cavitation)}$$

Since Σ_{sys} 1.37 is between Σ_{cr} 1.7 and Σ_{id} 1.0, the valve will be operating with cavitation but not severe enough to cause cavitation damage. The specific values of the reference Σ data (critical, incipient damage, and choking) vary with valve opening and should be accounted for in the analysis process.

Several options are available for suppressing cavitation such as selecting the correct valve type and size, locating valves and/or orifices in series, using cavitation-resistant materials, and injecting air. A more thorough discussion on cavitation analysis is available [Tullis, 1989, 1993].

Control Valve Selection

Some systems contain hundreds of valves and it is not reasonable to suggest that all of them receive detailed engineering attention. One of the important components of good valve selection is identifying critical valves, meaning valves that need special analysis. Critical valves include valves that will be subjected to unusual operating conditions such as high pressure drop (potential cavitation problems) and valves required to provide accurate flow control over a wide range of flow rates. Critical valves also include valves that can generate hydraulic transients if closed too quickly. In general, critical valves are those valves whose function is vital to the successful operation of the system or whose failure can lead to serious consequences.

The following hydraulic performance criteria have been suggested for selecting flow control valves [Tullis, 1989]:

1. For systems where conserving head is important, control valves should not produce excessive pressure drop in the full-open position.
2. A control valve should control the flow over at least 50% of its movement. This means that when the valve is closed from 100 to 50% open, the flow should be reduced at least 5 to 10%.
3. The maximum flow and pressure drop should be limited so the operating torque does not exceed the capacity of the operator or valve shaft and connections.
4. The valve should not be subjected to excessive cavitation.
5. Pressure transients should not exceed the safe pressure limits of the system. This requires that the valve be sized to control the flow over most of its stroke and that the closure speed be controlled. It will often require a computer simulation of the system to determine the safe valve closing time. For details on transient analysis, see Wylie and Streeter, 1993; Tullis, 1989; BHRA, 2000; and IAHR, 2000.
6. Some valves should not be operated at small openings due to potential seat damage caused by high velocity jets, cavitation near the seat, and poor flow control.
7. Some valves should not be operated near full-open, where they may have poor flow control and/or experience torque reversals leading to fatigue failures.

40.2 Air Valves

There are three types of automatic air valves: air-vacuum valves, air release valves, and combination valves. The air-vacuum valve has a large orifice to expel and admit large quantities of air at low pressure when filling or draining a pipeline. These valves contain some type of float, which rises and seals the orifice as the valve body fills with water. Once the line is pressurized, the valve cannot reopen to remove air that may subsequently accumulate. If the pressure becomes negative because of a transient or when the pipe is drained, the float drops and admits air into the line.

Air-vacuum valves should be sized based on both air release and negative pressure relief (vacuum) requirements. The larger of the two valve sizes should be used. To size the air-vacuum valve for air release (pipeline filling), the water fill rate and the allowable pressure of the air inside the pipe are needed. When

filling a pipe, air released from an air valve can approach sonic velocity when the internal air pressure is approximately 7 psi. Filling rates should be controlled by the water inflow rate, not by restricting the air outflow rate. A typical safe fill rate is about 1 fps in the pipe. With the fill rate and allowable air pressure determined, the size of air-vacuum valve needed for air release can be selected using manufacturers' sizing charts.

The other criterion used to size an air-vacuum valve is pipe collapse. It is necessary to determine whether the pipe can collapse due to rapid draining from a major pipe rupture. If the pipe can collapse, the next step is to calculate the maximum draining rate and estimate the vacuum pressure the pipe can tolerate without collapse. Once those two pieces of information are determined, the air-vacuum valve can be sized using charts provided by the valve suppliers.

Since the draining rate of a ruptured pipe will typically exceed the "safe" filling rate, the size of air-vacuum valve determined for vacuum service will be larger than the valve size based on filling requirements. The larger size should be selected. There is no problem having an automatic air valve oversized for filling, provided that the water inflow rate is properly controlled.

Placement of the air-vacuum valves is critical. An analysis of the system is needed to determine where the valves should be located to protect the pipe. Generally, they are located at high points where the pipe begins its downward slope. When multiple air-vacuum valves are required at various locations along the pipe, each one must be sized independently based on a pipe rupture that will cause maximum flow in that reach of pipe.

In addition to air-vacuum valves, it is necessary to install air release valves. These valves contain a small orifice and are intended to release air that cannot be released by the air-vacuum valves during initial filling. The small orifice is controlled by a plunger attached to a float. As air accumulates in the valve body, the float drops and opens the orifice. As the air is expelled, the float rises due to buoyancy and closes off the orifice. These valves also release small amounts of pressurized air that accumulates during normal operation.

The air trapped during initial filling must be flushed to the air release valves. A flow rate equivalent to 3 to 5 fps is typically required to move pockets of trapped air to the air release valves. While doing this, the pressure in the pipeline should be kept at a minimum by controlling flow and pressure with the inlet and outlet valves.

The combination air valve has two orifices: a large one that functions as an air-vacuum valve and a small one that functions as an air release valve. The combination air valve can simply be two separate valves — one air-vacuum valve and one air release valve — or it can be one valve with both functions integrated into the design. The combination valve in Figure 40.12 is shown in the open position. As the water in the valve rises, the float will close both the air-vacuum and the air release valves. Positive line pressures will keep the air-vacuum valve closed due to the differential pressure force. As air accumulates in the valve, the float will drop, opening the small air release orifice and expelling the air. As the air is expelled, the float will rise and close the air release orifice. Pipelines almost always require both air-vacuum and air release valves because they serve different functions.

Locating air release and air-vacuum valves depends primarily on the pipe profile. Air valves are generally placed at high points or at regular intervals if there are no significant high points.

FIGURE 40.12 Combination air release and air-vacuum valve cutaway. Both the air-vacuum and air release are shown in the open position (figure used with permission from CLA-VAL).

The use of large diameter, manually operated air release valves should be avoided. If manual air valves are opened after the pipeline is pressurized, they will release huge quantities of air because the air will exit at sonic velocity. The rapid release of air causes the water to accelerate toward the air valve. When the water reaches the air valve, it will decelerate rapidly, creating a transient pressure rise that could rupture the pipeline. A similar problem occurs if a large pocket of air under high pressure is allowed to accumulate and then move through the pipe and is discharged through a control valve. To avoid both of these problems, the system should be designed to prevent the accumulation of significant amounts of air at high pressure.

40.3 Check Valves

Check Valve Types

The most common type of check valve is the **swing check**, as shown in Figure 40.13. It has a simple design, low-pressure drop at full open, and reliable sealing. It relies on gravity for valve closure, and sealing is accomplished between two flat surfaces (disc and seat). The clearances in the hinge pins and connections provide considerable freedom of movement, allowing the sealing surfaces to self-align. An advantage of a swing check, relative to other types of check valves, is that the disc will continue to seal properly with substantial wear of the hinge pin and/or connections. These valves are also relatively easy to repair, available in a wide range of sizes, and economical. The primary disadvantage of swing check valves is that they are typically the slowest closing of all the check valves due to the large mass of the disc and the long distance of travel from full open to the closed position. They are generally not appropriate for use in systems where rapid flow reversals occur. Excessive wear of the hinge pin and connections can eventually result in a valve failure.

Tilt disc check valves, like the one shown in Figure 40.14, have the hinge pin located in the flow stream, just above the centerline of the disc. They also depend on gravity for closure but close somewhat faster than swing check valves because of the shorter travel distance of the disc. Closer machining tolerances of the sealing surfaces are required, relative to the swing check, because the disc rotates into the seat. Consequently, even limited wear of the hinge pin or bushings can cause sealing problems. Due to the complexity of the sealing arrangement, field repairs to the seats are more difficult.

FIGURE 40.13 Schematic of typical swing check valve. The hatched disc shows the disc in the full-open position.

FIGURE 40.14 Schematic of typical tilt check valve. The right- and left-hand figures show the valve in the closed and open position, respectively.

FIGURE 40.15 Three different nozzle check valve styles (figures used with permission from ENERTECH).

The body and closing elements of **lift check valves** come in a variety of configurations. They are also called by a variety of names describing either the shape of the body or disc, such as piston, ball, y-pattern, etc. The body can have the inlet and outlet in-line, or the outlet can elbow down at an angle. The disc (closing element) is generally piston shaped. Lift checks generally have larger pressure drops due to the configuration of the body. Lift checks generally rely on both gravity and spring forces for closure. Speed of closure depends primarily on the restoring force of the spring.

The **double-door check valves** have two half discs that rely on a spring force for closure. They close quickly but can experience flutter problems if the approach flow is disturbed. Restricting the maximum opening of the discs reduces their sensitivity to flutter but increases pressure drop. A broken spring is the primary cause of valve failure for double-door check valves.

Nozzle check valves are streamlined, low-pressure drop, rapidly closing check valves. The seating surface is often an annular ring machined into the valve body. The closing element is a lightweight, spring-loaded circular disc or annular ring that moves parallel to the valve centerline. Three different styles of nozzle check valves are illustrated in [Figure 40.15](#). Because the seat diameter is large and the flow passage streamlined, a short stroke is sufficient to achieve full flow with limited pressure drop. The short stroke, the lightweight disc, and the restoring force of the spring result in a very fast disc closure. Nozzle check valves are fairly insensitive to upstream disturbances.

Check Valve Selection

The basic function of a check valve is to allow forward flow under normal conditions and avoid flow reversal, which can drain the pipe and cause reverse rotation of the pump. The characteristics of check valves, as suggested by Kalsi Engineering and Tullis Engineering Consultants, 1993, that should be considered during valve selection include:

1. Closure speed of check valves relative to the rate of flow reversal of the system
2. The stability of the disc and its sensitivity to upstream disturbances
3. The flow required to fully open and firmly backseat the disc
4. The pressure drop at maximum flow
5. Sealing effectiveness and ease of maintenance

Items 1 and 2 in this list are most important because they can lead to major system and valve failures. If a slow closing check valve is installed in a system where the flow reverses rapidly, high transient pressures can occur. Systems in which rapid flow reversals occur include parallel pumps and systems that have air chambers or surge tanks close to the check valve [Thorley, 1989]. The magnitude of the pressure rise is a function of how fast the valve disc closes relative to how fast the flow in the system reverses. Laboratory tests by the authors have shown an order-of-magnitude difference between the pressure rise caused by a swing check valve compared to a nozzle check valve subjected to the same rate of flow reversal.

Check valves subjected to continuous disc instability experience accelerated wear that can lead to failure. One example of such a failure was a swing check valve installed downstream from one of two parallel, high-pressure, booster pumps at an oil refinery. The unstable disc caused the hinge pin to wear and ultimately fail, detaching the disc from the valve body. This resulted in reverse flow that subjected the upstream pipe to excessive pressure and ruptured the pipe.

For valves installed in critical locations, it is especially important to consider disc stability when selecting the type and size of check valve. If there is a high probability of disc flutter, then a check valve that is less sensitive to flutter should be selected, such as a nozzle valve. If a swing or tilt disc check valve is selected, it should be sized small enough that the disc is held firmly against the full-open stop at normal flows. This is especially important when the valve is located immediately downstream from a disturbance.

41.1 Introduction

Pumps are devices that impart a pressure increase to a liquid. Fans are used to increase the velocity of a gas, but this is also accomplished through an increase in pressure. The pressure rise found in pumps can vary tremendously, and this is a very important design parameter along with the liquid flow rate. This pressure rise can range from simply increasing the elevation of the liquid to increasing the pressure by hundreds of atmospheres. Fan applications, on the other hand, generally deal with small pressure increases. In spite of this seemingly significant distinction between pumps and fans, there are many similarities in the fundamentals of certain types of these machines as well as with their application and theory of operation.

Pumps or fans can be used as a means of forcing flows into a region of interest or, alternatively, exhausting flows from a region of interest. For example, the inlet to an induced draft fan is attached to the region of interest. Forced draft fans are hooked with their exhaust side to the region of interest. Pumps are usually not denoted with this distinction except for vacuum pumps, which are always used to exhaust a fluid from a volume of interest.

The appropriate use of pumps and fans depends upon the satisfactory choice of device and the proper design and installation for the application. A check of sources of commercial equipment shows that many varieties of pumps and fans are available. Each of these has special characteristics that must be appreciated for achieving proper function. Preliminary design criteria for choosing among different types are given by Boehm [1987].

As is to be expected, wise applications of pumps and fans require knowledge of fluid flow fundamentals. Unless the fluid mechanics of a particular application is understood, the design could be less than desirable.

In this chapter, pump and fan types are briefly defined. In addition, typical application information is given. Also, some ideas from fluid mechanics that are especially relevant to pump and fan operation are reviewed. For more details on this latter topic, see the chapter of this book that discusses fluid mechanics fundamentals.

41.2 Pumps

Raising of water from wells and cisterns is the earliest form of pumping (a very detailed history of early applications is given by Ewbank [1842]). Modern applications are much broader, and these find a wide variety of machines in use. Modern pumps function on one of two principles. By far the majority of pump installations are of the *velocity head* type. In these devices, the pressure rise is achieved by giving the fluid movement. At the exit of the machine, this movement is translated into a pressure increase by slowing down the fluid. The other major type of pump is called *positive displacement*. These devices are designed to increase the pressure on the liquid while essentially trying to compress the volume. A categorization of pump types (with the exception of vacuum pumps) has been given by Krutzsch [1986], and an adaptation of this is shown below:

1. Velocity head
 - A. Centrifugal
 - i. Axial flow (single or multistage)
 - ii. Radial flow (single or double suction)
 - iii. Mixed flow (single or double suction)
 - iv. Peripheral (single or multistage)
 - B. Special effect
 - i. Gas lift
 - ii. Jet
 - iii. Hydraulic ram
 - iv. Electromagnetic
2. Positive displacement
 - A. Reciprocating
 - i. Piston, plunger
 - a. Direct acting (simplex or duplex)
 - b. Power (single or double acting, simplex, duplex, triplex, multiplex)
 - ii. Diaphragm (mechanically or fluid driven, simplex or multiplex)
 - B. Rotary
 - i. Single rotor (vane, piston, screw, flexible member, peristaltic)
 - ii. Multiple rotor (gear, lobe, screw, circumferential piston)

In the next sections, some of the more common pumps are described.

Centrifugal and Other Velocity-Head Pumps

Centrifugal pumps are used in more industrial applications than any other kind of pump. This is primarily because these pumps offer low initial and upkeep costs. Traditionally, pumps of this type have been limited to low-pressure-head applications, but modern pump designs have overcome this problem unless very high pressures are required. Some of the other good characteristics of these types of devices include smooth (nonpulsating) flow and the ability to tolerate nonflow conditions.

The most important parts of the centrifugal pump are the *impeller* and *volute*. An impeller can take on many forms, ranging from essentially a spinning disc to designs with elaborate vanes. The latter is usual. Impeller design tends to be unique to each manufacturer; a variety of designs are used for a range of applications. An example of an impeller is shown in Figure 41.1. This device imparts a radial velocity to the fluid that has entered the pump perpendicular to the impeller. The volute (there may be one or more) performs the function of slowing the fluid and increasing the pressure. A good discussion of centrifugal pumps is given by Lobanoff and Ross [1992].

The design of a pump and its performance are dependent upon a number of applicable variables. While these will be noted in more detail below, they include the pump operating speed, the flow rate,

FIGURE 41.1 A schematic of a centrifugal pump is shown. The liquid enters perpendicular to the figure, and a radial velocity is imparted by clockwise spin of the impeller.

and the developed head. Pump engineers generally combine these variables together into a parameter called the *specific speed*, N_s . This is given as

$$N_s = Q^{0.5}N/H^{0.75}$$

where Q = volume rate of flow, gpm; N = operating speed of pump, rpm; and H = pump head, ft.

Historically, the efficiency is related to this parameter in a general way, showing a maximum efficiency of over 90% at a specific speed of about 2500 and very high flow rates [Yedidiah, 1996]. For lower flows, the maximum efficiency is decreased and occurs at smaller values of N_s . Rishel [2000] reported on the results of a study of actual installations of “wire-to-water” efficiencies for pumps. These ranged from 20% for small systems (20 gpm) to 84% for systems at 2000 gpm. The head was varied in the study. A plot of the data he cited is given as Figure 41.2.

An important factor in the specification of a centrifugal pump is the casing orientation and type. For example, the pump can be oriented vertically or horizontally. Horizontal mounting is most common. Vertical pumps usually offer benefits related to ease of priming and reduction in required NPSH (see discussion below). This type also requires less floor space. Submersible and immersible pumps are always of the vertical type. Another design factor is the way the casing is split, and this has implications for ease of manufacture and repair. Casings that are split perpendicular to the shaft are called radially split, while those split parallel to the shaft axis are denoted as axially split. The latter can be horizontally split or vertically split. The number of stages in the pump greatly affects the pump-output characteristics. Several stages can be incorporated into the same casing, with an associated increase in pump output. Multistage pumps are often used for applications with total developed head over (about) 50 atm.

Whether or not a pump is self-priming can be important. By this it is meant that the impeller of the pump must be immersed in the fluid to be pumped. In general, a centrifugal pump cannot begin pumping

FIGURE 41.2 “Wire-to-water” efficiencies for centrifugal pumps are given based upon the data of Rishel [2000]. The head varies throughout the data within the range shown.

unless it is primed. If a centrifugal pump is filled with air when it is turned on, the initiation of pumping action may not be sufficient to bring the fluid into the pump. Pumps can be specified with features that minimize priming problems.

Although not only applicable to centrifugal pumps, a major application here is the use of a *variable speed drive* (VSD). In many situations, the design condition is not the only one at which the pump may have to operate. For example, if the flow decreases for some reason, the head would go up, and vice versa. This may cause problems with the particular pump installation. A VSD will allow these situations, as well as part load operation, to be accommodated. Without VSD, this would have been accomplished by mechanical devices to throttle the flow, for example. A VSD can greatly enhance the system operational efficiency.

There are other types of velocity-head pumps. *Gas lifts* accomplish a pumping action by a drag on gas bubbles that rise through a liquid.

Jet pumps (eductors) increase pressure by imparting momentum from a high-velocity liquid stream to a low-velocity or stagnant body of liquid. The resulting flow then goes through a diffuser to achieve an overall pressure increase. Related designs that use a gas or a vapor to impart the momentum are called *jet ejectors*. An excellent summary of these types of devices has been given by Power [1994]. In all cases where eductors or ejectors are used, a separate high-pressure fluid stream needs to be available to power the device.

Positive-Displacement Pumps

Positive-displacement pumps demonstrate high discharge pressures and low flow rates. Usually this is accomplished by some type of pulsating action. A piston pump is a classical example of a positive-displacement machine. Rotary pumps are one type of positive displacement device that does not impart pulsations to the exiting flow (a full description of these types of pumps is given by Turton [1994]). Several techniques are available for dealing with pulsating flows, including use of double-acting pumps (usually of the reciprocating type) and installation of pulsation dampeners.

Positive displacement pumps usually require special seals to contain the fluid. Costs are higher both initially and for maintenance compared to most pumps that operate on the velocity-head basis. Positive-displacement pumps demonstrate an efficiency that is nearly independent of flow rate, in contrast to the velocity-head type.

Reciprocating pumps offer very high efficiencies, reaching 90% in larger sizes. These types of pumps are more appropriate for pumping abrasive liquids (e.g., slurries) than are centrifugal pumps.

Piston pumps are commonly applied positive-displacement devices. The piston-cylinder arrangement is one that is familiar to most people who have ever used pumps. These pumps can be *single acting* or *double acting*. In the latter classification, the design is such that pumping takes place on both sides of the piston. Many application engineers recommend a maximum duty pressure of about 2000 psi. Higher pressures can be handled by a plunger-rod pump, where a plunger rod moves inside a pipe of the same diameter. Because fluctuations are inherent in most positive displacement devices, a pulsation dampener may have to be used [Vandall and Foerg, 1993].

A characteristic of positive displacement pumps that may be of value is that the output flow is proportional to pump speed. This allows this type of pump to be used for metering applications. Also, a positive aspect of these pumps is that they are self-priming, except at initial startup.

Very high head pressures (often damaging to the pump) can be developed in positive displacement pumps if the downstream flow is blocked. For this reason, a pressure-relief-valve bypass must always be used with positive displacement pumps. Some designers recommend a bypass even for centrifugal pumps.

Selecting a Pump Based upon Flow Considerations

Performance characteristics of the pump must be considered in system design. Simple diagrams of pump applications are shown in Figure 41.3. First consider the left-hand figure. This represents a flow circuit,

FIGURE 41.3 Typical pump applications, either in circuits or once-through arrangements, can be represented as combined fluid resistances as shown. The resistances are determined from fluid mechanics analyses.

and the pressure drops related to the piping, fittings, valves, and any other flow devices found in the circuit must be estimated using laws of fluid mechanics. Usually these resistances (pressure drops) are found to vary approximately with the square of the liquid flow rate.

Most pumps demonstrate a flow vs. pressure rise variation that is a positive value at zero flow and decreases to zero head at some larger flow. A variation typical of centrifugal pumps is shown on the left-hand side of Figure 41.4. One exception to this, and it is an important one related to these types of pumps, is the so-called “drooping head” behavior. In this situation, the head at zero flow is less than the heads that are achieved at small positive flows. This phenomenon is a result of high-efficiency design, and it is described in some detail by Paugh [1994].

Positive displacement pumps, as shown on the right-hand side of Figure 41.4, are an exception to this characteristic behavior in that these devices usually cannot tolerate a zero flow. An important aspect to note is that a closed system can presumably be pressurized by the pump to the detriment of the system and the pump.

The piping diagram shown on the right-hand side of Figure 41.3 is a once-through system, another frequently encountered installation. However, the leg of piping through “pressure drop 1” shown there can have some very important implications related to *net positive suction head*, often denoted as *NPSH*. In simple terms, *NPSH* indicates the difference between the local pressure and the thermodynamic saturation pressure at the fluid temperature. If $NPSH = 0$, the liquid can vaporize, and this can result in a variety of outcomes from noisy pump operation to outright failure of components. This condition is called *cavitation*, and it must be eliminated by proper design.

Cavitation, if it occurs, will first take place at the lowest pressure point within the piping arrangement. Often this point is located at, or inside, the inlet to the pump. Most manufacturers specify how much *NPSH* is required for satisfactory operation of their pumps. Hence, the *actual NPSH* (often times denoted as *NPSHA*) experienced by the pump must be larger than the manufacturer’s required *NPSH* (which may be called *NPSHR*).

If a design indicates insufficient *NPSH*, changes should be made in the system, possibly including alternative piping layout. This might include lowering the pump location relative to the feed, changing sizes of the inlet piping and fittings, or slowing of the pump speed. Some pumps have smaller *NPSH*

FIGURE 41.4 An overlay of the pump flow vs. head curve with the circuit piping characteristics gives the operating state of the circuit. A typical velocity–head pump characteristic is shown on the left, while a positive-displacement pump curve is shown on the right.

FIGURE 41.5 When selecting a pump for a given application, the starting point is a performance coverage map. From this, the model required to achieve a given performance can be selected. (Compliments of Goulds Pumps.)

requirements than others, and this might be a result of adding inducers to the inlet. Sometimes it is possible to cool the pump inlet fluid and this will increase the NPSHA. More extreme solutions could find a smaller pump installed prior to the inlet of the main pump whose purpose is to increase the NPSHA of the latter. Of course, if a pump is fed from a tank and vortices form there at typical flow conditions, this could greatly decrease the NPSHA beyond what would appear to be present.

Fluid properties can have a major impact on the choice of pump. One variable of concern is viscosity. This property can have high or extremely variable values in a given circuit. At the minimum, increases in viscosity will require more pumping power. But the value of the viscosity may influence the type of pump used. For viscosities up to slightly over 3000 cP, centrifugal pumps will work quite well. Rotary pumps can handle the less frequently encountered situations with considerably higher viscosities.

The manufacturer should be consulted for a map of operational information for a given pump. A typical set of these is shown in Figure 41.5 through Figure 41.7. This information will allow the designer to select a pump that satisfies the circuit operational requirements while meeting the necessary NPSH and most efficient operation criteria.

First consider Figure 41.5. This gives a map of overall performance for a given family of pumps. The specific operational ranges for each model with the family are shown. This range is due to use of various impeller sizes, pump speeds, and other design parameters in a particular configuration.

Once the general design conditions are located on the overall performance map, these will generally indicate a particular model for the application. This can then be used to determine the performance of the specific model. For example, if the design conditions had fallen in the range of model 1 1/2-2 - 10 3500 rpm, the details of this one would be examined. See Figure 41.6. Note the following generally typical characteristics of centrifugal pumps. The produced head decreases with increasing flow over the specific range for this pump. Larger diameter impellers are required to move to higher-level curves, and these conditions are associated with higher power requirements. NPSH requirements increase generally with increasing flow. Sometimes, manufacturers give this information as a simple function of flow, or this can be specified in more definitive terms as shown in Figure 41.6. Pumping efficiency curves are also shown. It is desirable to operate near the maximum values of efficiency if that can be accommodated between the design requirements and the characteristics of the specific pumps. This is a lower-flow pump, and,

FIGURE 41.6 Once the particular model of pump is determined (see Figure 41.5), the actual performance of that model can be examined from a plot of this type. This is given here for a particular speed. (Compliments of Goulds Pumps.)

FIGURE 41.7 Impeller speed for a given model will have an impact on the pump performance (compare to Figure 41.6). (Compliments of Goulds Pumps.)

FIGURE 41.8 Series and parallel operation of centrifugal pumps is possible. The resultant characteristics for two identical pumps are shown.

as was shown in Figure 41.2, this one demonstrates lower efficiencies than some larger units would be able to furnish within the same family of pumps.

Finally, consider Figure 41.7. This shows the impact of drive speed on the operation of the pump. Where Figure 41.6 was developed for a single speed, Figure 41.7 shows the effects of various speeds. Here the NPSH is shown as a simple function increasing with flow rate.

Several options are available to the designer for combining pumps in systems. Consider a comparison of the net effect between operating pumps in series or operating the same two pumps in parallel. Examples of this for pumps with characteristics like centrifugal units are shown in Figure 41.8. It is clear that one way to achieve high pumping pressures with centrifugal pumps is to place a number of units in series. This is a related effect to what is found in multistage designs.

41.3 Vacuum Pumps

When pressures significantly below atmospheric are required, a vacuum pump should be applied. In fact, vacuum is defined as being a pressure below the surrounding atmosphere. These pumps are often used to remove a vapor or a gas from within a volume of interest. If most of the vapor or gas is removed, this is often called a “hard” or “high” vacuum.

Even though the pressure differential across a vacuum pump is typically less than 1 atm, the small value of pressure at the inlet to the pump complicates the performance of the device. A resulting high-pressure ratio usually exists across a vacuum pump. Because of this factor, as well as the characteristics of gases and vapors as they become rarefied, a large amount of vacuum is usually accomplished by use of a sequence of vacuum pumps. To see how this is achieved, consider the general types of vacuum pumps available.

At coarse vacuums (not large pressure differences from atmospheric) a mechanical pump or blower might be used. These have designs that are very much like the other pump and fan systems discussed in this chapter.

At higher vacuums, a *vapor jet* (or *diffusion*) pump may find a cost-effective application. The basic idea behind this approach is a concept illuminated by kinetic theory: gases can be pumped by the molecular drag effect. A separate pumping fluid is used to remove the vapor/gas of interest. Devices built on this concept demonstrate high pumping speeds at low pressures.

Similar levels of vacuums as achieved by the diffusion pumps are also reached by *turbo* pumps. These latter devices use high-speed rotating machinery in several stages to accomplish the necessary evacuation.

Ion-getter and *sputter-ion pumps* are used for high- and ultrahigh-vacuum situations. In this approach, *gettering* is used, which denotes a concept where there is a chemical combination between a surface and the pumped gas. While many types of gettering materials are available, a commonly used one is titanium. When chemically active gas atoms strike a getter surface, stable, solid compounds are formed there.

To achieve high- or ultrahigh-vacuums, a series of these pumps might be used. At moderate vacuums, a *roughing* pump is a good choice. As the absolute pressure decreases, then a switch is made to another type of pump, say a cryopump or a diffusion pump. Finally, the very small pressures can then be reached

FIGURE 41.9 Approximate operational ranges where various types of vacuum pumps are most cost effective (in 1985 prices). Adapted from Hablani, M., 1997. *High-Vacuum Technology — A Practical Guide*, 2nd ed., Marcel Dekker, New York.

using a getter or ion pump. Approximate ranges for each of these pumps are shown in Figure 41.9. Figure 41.10 shows the performance range of various types of coarse vacuum pumps. These figures were developed from information given by Hablani [1997]. This text is an excellent source of information on all of these types of devices.

FIGURE 41.10 The operational ranges of coarse vacuum pumps are shown. Adapted from Hablani, M., 1997. *High-Vacuum Technology — A Practical Guide*, 2nd ed., Marcel Dekker, New York.

FIGURE 41.11 Shown are characteristics of a centrifugal fan. The drawbacks to operating away from optimal conditions are obvious from the efficiency variation.

41.4 Fans

As noted earlier, fans are devices that cause air to move. This definition is broad and can include a flapping palm branch, but the discussion here deals only with devices that impart air movement due to rotation of an impeller inside a fixed casing. In spite of this limiting definition, it includes a large variety of commercial designs.

Fans find application in many engineering systems. Along with chillers and boilers, they are the heart of heating, ventilating, and air conditioning (HVAC) systems. When large physical dimensions of a unit are not a design concern (usually the case), centrifugal fans are favored over axial flow units for HVAC applications. Many types of fans are found in power plants [Stultz and Kitto, 1992]. Very large fans are used to furnish air to the boiler as well to draw or force air through cooling towers and pollution control equipment. Electronic cooling finds applications for small units. Automobiles have several fans in them. Because of the great engineering importance of fans, several organizations publish rating and testing criteria (see, for example, [ASME, 1995]).

Generally, fans are classified according to how the air flows through the impeller. These flows may be axial (essentially a propeller in a duct), radial (conceptually much like the centrifugal pumps discussed earlier), mixed, and cross. While there are many other fan designations, all industrial units fall into one of these classifications. Mixed-flow fans are so named because both axial and radial flow occurs on the vanes. Casings for these devices are essentially like those for axial flow machines, but the inlet has a radial flow component. On cross-flow impellers, the gas traverses the blading twice.

Generic characteristics of fans are shown in [Figure 41.11](#). Since velocities can be high in fans, often both the total and the static pressure increases are considered. While both are not shown on this figure, the curves have similar variations. Of course the total ΔP is greater than the static value; the difference is the velocity head. This difference increases as the volume flow increases. At zero flow (the *shut-off point*), the static and total pressure difference values are the same. Efficiency variation shows a sharp optimum value at the design point. For this reason, it is critical that fan designs be carefully tuned to the required conditions.

A variety of vane types are found on fans, and the type of these is also used for fan classification. Axial fans usually have vanes of airfoil shape or vanes of uniform thickness. Some vane types that might be found on a centrifugal (radial flow) fan are shown in [Figure 41.12](#).

One aspect that is an issue in choosing fans for a particular application is fan efficiency. Typical efficiency comparisons of the effect of blade type on a centrifugal fan are shown in [Figure 41.13](#). Since velocities can be high, the value of aerodynamic design is clear. Weighing against this is increased cost.

FIGURE 41.12 A variety of vane types that might be used on a centrifugal fan are shown.

FIGURE 41.13 Efficiency variations with volume flow of centrifugal fans for a variety of vane types are shown.

An additional aspect that may be important in the choice of fans is noise generation. This may be most critical in HVAC applications. It is difficult to describe noise characteristics in brief terms because of the frequency-dependent nature of these phenomena. However, a comparison of specific sound power level (usually denoted by K_w) shows that backward-curved centrifugal fans with aerodynamic blades perform among the best designs. Details of noise characteristics are given elsewhere [ASHRAE, 1999].

While each type of fan has some specific qualities for certain applications, most installations use centrifugal (radial flow) fans. A primary exception is for very-high-flow, low-pressure-rise situations where axial (propeller) fans are used.

Similarities exist between fans and pumps because the fluid density essentially does not vary through either type of machine. Of course, in pumps this is because a liquid can be assumed to be incompressible. In fans, a gas (typically air) is moved with little pressure change. As a result, the gas density can be taken to be constant. Since most fans operate near atmospheric pressure, the ideal gas assumptions can be used in determining gas properties.

Flow control in fan applications, where needed, is a very important design concern. Methods for accomplishing this involve use of dampers (either on the inlet or on the outlet of the fan), variable pitch vanes, or variable speed control. Dampers are the least expensive to install but also the most inefficient in terms of energy use. Modern solid-state control for providing a variable frequency power to the drive motor is becoming the preferred control method, when a combination of initial and operating costs are considered.

Richard T. Lahey, Jr.

Rensselaer Polytechnic Institute

Multiphase flows occur in many cases of practical concern. In particular, important vapor/liquid and solid/fluid two-phase flows may occur in thermal energy production and utilization, chemical and food processing, environmental engineering, pharmaceutical manufacturing, petroleum production, and waste incineration technologies.

This chapter summarizes the essential features of two-phase flow and focuses on the engineering analysis of vapor/liquid systems. Readers interested in more in-depth treatment are referred to the work of Lahey [1992] and Roco [1993].

Two-phase flows are inherently more complicated than single-phase flows because the phases may separate and arrange themselves into distinct flow regimes. Moreover, the two phases normally do not travel at the same velocity, nor, in some situations, even in the same direction. As a consequence, important phenomena occur in two-phase flows that do not occur in single-phase flows.

The notation, conservation equations, and their associated closure relations will first be discussed. Next, flooding will be considered, and then the conservation equations will be used to analyze some situations of interest in two-phase flows.

42.1 Notation

The most important parameter that characterizes a two-phase flow is the so-called *local volume fraction* of phase k , $\alpha_k(x, t)$. This parameter is the time fraction that a probe at location x and time t will sense phase k during a measurement time T . That is,

$$\alpha_k = \sum_{i=1}^N \Delta t_i / T \quad (42.1)$$

The global volume fraction of phase k is the integral of the local volume fraction over the cross-sectional area (A_{xs}) of the conduit:

$$\langle \alpha_k \rangle = \iint_{A_{xs}} \alpha_k da / A_{xs} \quad (42.2)$$

By convention, in vapor/liquid two-phase flows, the volume fraction of the vapor phase, α_v , is called the *void fraction*, α .

Unlike single-phase flows, there are multiple velocities of interest in two-phase flows — in particular, the superficial velocity,

$$\langle \dot{j}_k \rangle = Q_k / A_{xs} \quad (42.3)$$

and the phasic velocity,

$$\langle u_k \rangle = Q_k / A_k = \langle \dot{j}_k \rangle / \langle \alpha_k \rangle \quad (42.4)$$

Also, the two phases normally do not travel with the same velocity. Indeed, in vapor/liquid systems, the vapor often travels faster than the liquid, giving rise to a local relative velocity (u_R),

$$u_R = u_v - u_l \quad (42.5a)$$

or slip ratio (S),

$$S = u_v / u_l \quad (42.5b)$$

The density of a two-phase mixture is given by

$$\langle \rho \rangle = \left[\iiint_{V_l} \rho_l dv + \iiint_{V_v} \rho_v dv \right] / (V_l + V_v) \quad (42.6a)$$

Thus, from Equation (42.2),

$$\langle \rho \rangle = \rho_l (1 - \langle \alpha \rangle) + \rho_v \langle \alpha \rangle \quad (42.6b)$$

42.2 Conservation Equations

Equations for the conservation of mass, momentum, and energy are needed to describe a flowing two-phase mixture. The appropriate one-dimensional, two-fluid (i.e., writing the conservation laws for each phase separately), and mixture conservation equations are described in the following sections. Let us consider the case of a vapor/liquid system, since this is the most complicated case.

Mass Conservation

For the vapor phase,

$$\frac{\partial}{\partial t} [\rho_v \langle \alpha \rangle A_{xs}] + \frac{\partial}{\partial z} [\rho_v \langle \alpha \rangle \langle u_v \rangle A_{xs}] = \Gamma A_{xs} \quad (42.7a)$$

For the liquid phase,

$$\frac{\partial}{\partial t}[\rho_l(1-\langle\alpha\rangle)A_{xs}] + \frac{\partial}{\partial z}[\rho_l(1-\langle\alpha\rangle)\langle u_l \rangle A_{xs}] = -\Gamma A_{xs} \quad (42.7b)$$

where Γ is the amount of liquid evaporated per unit volume per unit time.

Adding Equation (42.7a) and Equation (42.7b) together yields the one-dimensional mixture continuity equation,

$$\frac{\partial}{\partial t}[\langle\rho\rangle A_{xs}] + \frac{\partial}{\partial z}[GA_{xs}] = 0 \quad (42.8)$$

where the mass flux is given by

$$G \frac{\Delta}{A_{xs}} = \rho_v \langle\alpha\rangle \langle u_v \rangle + \rho_l(1-\langle\alpha\rangle)\langle u_l \rangle \quad (42.9)$$

Momentum Conservation

Let us now consider a typical flow regime in which the vapor phase does not wet the wall of the conduit. For this case we have for the vapor phase,

$$\begin{aligned} \frac{1}{g_c} \left[\frac{\partial}{\partial t}(\rho_v \langle\alpha\rangle \langle u_v \rangle) + \frac{1}{A_{xs}} \frac{\partial}{\partial z}(\rho_v \langle\alpha\rangle \langle u_v \rangle^2 A_{xs}) \right] \\ = -\langle\alpha\rangle \frac{\partial p}{\partial z} - \frac{g}{g_c} \rho_v \langle\alpha\rangle \sin\theta - \frac{\tau_i P_i}{A_{xs}} + \frac{\Gamma u_i}{g_c} \end{aligned} \quad (42.10a)$$

Similarly, for the liquid phase,

$$\begin{aligned} \frac{1}{g_c} \left[\frac{\partial}{\partial t}[\rho_l(1-\langle\alpha\rangle)\langle u_l \rangle] + \frac{1}{A_{xs}} \frac{\partial}{\partial z}[\rho_l(1-\langle\alpha\rangle)\langle u_l \rangle^2 A_{xs}] \right] \\ = -(1-\langle\alpha\rangle) \frac{\partial p}{\partial z} - \frac{g}{g_c} \rho_l(1-\langle\alpha\rangle) \sin\theta - \frac{\tau_w P_f}{A_{xs}} + \frac{\tau_i P_i}{A_{xs}} - \frac{\Gamma u_i}{g_c} \end{aligned} \quad (42.10b)$$

where the velocity of the vapor/liquid interface, u_i , the interfacial perimeter, P_i , and the interfacial shear stress, τ_i , must be constituted to achieve closure [Lahey and Drew, 1992].

Adding Equation (42.10a) and Equation (42.10b) and allowing for the possibility of N local losses, the one-dimensional mixture momentum equation can be written as

$$\begin{aligned} \frac{1}{g_c} \left[\frac{\partial G}{\partial t} + \frac{1}{A_{xs}} \frac{\partial}{\partial z}(G^2 A_{xs} / \langle\rho'\rangle) \right] = -\frac{\partial p}{\partial z} - \frac{g}{g_c} \langle\rho\rangle \sin\theta - \frac{\tau_w P_f}{A_{xs}} \\ - \sum_{i=1}^N K_i \frac{G^2 \delta(z-z_i) P_f}{2g_c \rho_l A_{xs}} \Phi(z) \end{aligned} \quad (42.11)$$

where $\delta(z)$ is the Dirac delta function $\langle\rho'\rangle$ in a two-phase "density" given by:

$$\langle \rho' \rangle = \left[\frac{(1 - \langle x \rangle)^2}{\rho_l (1 - \langle \alpha \rangle)} + \frac{\langle x \rangle^2}{\rho_v \langle \alpha \rangle} \right]^{-1} \quad (42.12)$$

and $\langle x \rangle$ is the flow quality. It should be noted that closure models for the wall shear, τ_w , will be discussed subsequently.

It is interesting to note that one can rearrange Equation (42.11) into drift-flux form [Lahey and Moody, 1993]:

$$\begin{aligned} \frac{1}{g_c} \left[\frac{\partial G}{\partial t} + \frac{1}{A_{xs}} \frac{\partial}{\partial z} \left(\frac{G^2 A_{xs}}{\langle \rho \rangle} \right) \right] = - \frac{\partial p}{\partial z} - \frac{g}{g_c} \langle \rho \rangle \sin \theta - \frac{\tau_w P_f}{A_{xs}} \\ - \frac{1}{g_c A_{xs}} \frac{\partial}{\partial z} \left[A_{xs} \left(\frac{\rho_l - \langle \rho \rangle}{\langle \rho \rangle - \rho_v} \right) \frac{\rho_l \rho_v}{\langle \rho \rangle} (V'_{gj})^2 \right] + \sum_{i=1}^N K_i \frac{G^2 \delta(z - z_i) P_f}{2g_c \rho_l A_{xs}} \Phi(z) \end{aligned} \quad (42.13)$$

where, as will be discussed subsequently, $V'_{gj} = V_{gj} + (C_0 - 1)\langle j \rangle$ is the generalized drift velocity.

Energy Conservation

For the vapor phase,

$$\begin{aligned} \frac{\partial}{\partial t} [\rho_v \langle \alpha \rangle (\langle e_v \rangle - p / J \rho_v) A_{xs}] + \frac{\partial}{\partial z} [\rho_v \langle u_v \rangle \langle \alpha \rangle A_{xs} \langle e_v \rangle] \\ = \Gamma A_{xs} e_{v_i} - p_i A_{xs} \frac{\partial \langle \alpha \rangle}{\partial t} + q''_v \langle \alpha \rangle A_{xs} - q''_i P_i \end{aligned} \quad (42.14a)$$

For the liquid phase,

$$\begin{aligned} \frac{\partial}{\partial t} [\rho_l (1 - \langle \alpha \rangle) (\langle e_l \rangle - p / J \rho_l) A_{xs}] + \frac{\partial}{\partial z} [\rho_l \langle u_l \rangle (1 - \langle \alpha \rangle) A_{xs} \langle \alpha \rangle] \\ = -\Gamma A_{xs} e_{l_i} + p_i A_{xs} \frac{\partial \langle \alpha \rangle}{\partial t} + q''_w P_H + q''_v (1 - \langle \alpha \rangle) A_{xs} + q''_i P \end{aligned} \quad (42.14b)$$

where:

$$\langle e_k \rangle \triangleq h_k + \frac{\langle u_k \rangle^2}{2g_c J} + \frac{gz \sin \theta}{g_c J} \quad (42.15)$$

As noted before, appropriate closure laws are needed for the specific phasic interfacial energy, e_{k_i} , heat fluxes, q''_{k_i} , the interfacial perimeter, P_i , and the volumetric heating rate, q''_k [Lahey and Drew, 1992]. Also, it is interesting to note that the interfacial jump condition gives

$$\Gamma = (q''_{v_i} - q''_{l_i}) P_i / A_{xs} h_{fg} \quad (42.16)$$

If we add Equation (42.14a) and Equation (42.14b), we obtain the mixture energy equation in the form

$$\frac{\partial}{\partial t}[\rho_l(1-\langle\alpha\rangle)\langle e_l\rangle - p/J\rho_l] + \rho_v\langle\alpha\rangle\langle e_v\rangle - p/J\rho_v]A_{xs} + \frac{\partial}{\partial t}[w_l\langle e_l\rangle + w_v\langle e_v\rangle] = q''_w A_{xs} + q''' A_{xs} \quad (42.17)$$

42.3 Closure

In order to be able to evaluate the conservation equations that describe two-phase flow we must first achieve closure by constituting all parameters in these equations in terms of their state variables.

In order to demonstrate the process, let us consider the mixture conservation equations, Equation (42.8), Equation (42.13), and Equation (42.17).

We can use the Zuber–Findly drift-flux model to relate the void fraction to the superficial velocities:

$$\langle\alpha\rangle = \frac{\langle j_v \rangle}{C_0 \langle j \rangle + V_{gj}} \quad (42.18)$$

where $\langle j \rangle \triangleq \langle j_v \rangle + \langle j_l \rangle$, C_0 is the void concentration parameter, and V_{gj} is the so-called *drift velocity*. Both of these drift-flux parameters are normally given by correlations that come from appropriate data [Chexal and Lellouche, 1986].

The wall shear, τ_w , is given by

$$\frac{\tau_w P_f}{A_{xs}} = \frac{f G^2 \phi_{l0}^2}{2g_c D_H \rho_l} \quad (42.19)$$

where ϕ_{l0}^2 is the two-phase friction pressure drop multiplier. It is just the ratio of the single-phase (liquid) to the two-phase density,

$$\phi_{l0}^2 = \rho_l / \rho_{2\phi} \quad (42.20)$$

For example, for homogeneous two-phase flow (in which the slip ratio, S , is unity) we have

$$\phi_{l0}^2 = \rho_l / \langle \rho_h \rangle = 1 + \frac{v_{fg}}{v_f} \langle x \rangle \quad (42.21)$$

For slip flows, empirical correlations, such as that of Martinelli–Nelson, shown in Figure 42.1, are often used.

For local losses (e.g., orifices, spacers, etc.) it is normal practice to assume a homogeneous multiplier; thus, as in Equation (42.21),

$$\Phi = 1 + \frac{v_{fg}}{v_f} \langle x \rangle \quad (42.22)$$

Figure 42.2 shows a typical pressure drop profile, which includes both local and distributed two-phase losses.

One of the interesting features of two-phase flows is that countercurrent flows may occur, in which the phases flow in different directions. In a vapor/liquid system this can lead to a countercurrent flow limitation (CCFL) or **flooding** condition.

FIGURE 42.1 Martinelli–Nelson two-phase friction multiplier for steam/water as a function of quality and pressure.

When flooding occurs in a vertical conduit, in which the liquid is flowing downward and the vapor upward, the liquid downflow will be limited by excessive friction at the vapor/liquid interface. A popular CCFL correlation is that of Wallis [1969],

$$\left(j_g^*\right)^{1/2} + \left(|j_f^*|\right)^{1/2} = C \quad (42.23)$$

where the square root of the phasic Froude number is given by

$$j_k^* = \frac{\langle j_k \rangle \rho_k^{1/2}}{[gD_H(\rho_l - \rho_v)]^{1/2}} \quad (42.24)$$

This CCFL correlation is known to work well in small-diameter conduits.

For large-diameter conduits the Kutateladze CCFL correlation works much better:

$$K_v^{1/2} + |K_l|^{1/2} = 1.79 \quad (42.25)$$

FIGURE 42.2 Two-phase pressure drop in an elbow.

where

$$K_k = \frac{\langle j_k \rangle \rho_k^{1/2}}{[\sigma g g_c (\rho_l - \rho_v)]^{1/4}} \quad (42.26)$$

A strategy for switching from one CCFL correlation to the other has been given by Henry et al. [1993] for various size conduits.

Figure 42.3 shows that both Equation (42.23) and Equation (42.25) imply that there will be no liquid downflow when the vapor upflow velocity (j_v) is large enough (i.e., at or above point 4).

Let us now use the conservation equations to analyze some two-phase flow phenomena of interest. For example, let us consider **critical flow** (i.e., the sonic discharge of a two-phase mixture).

For steady state conditions in which there are no local losses, Equation (42.11) can be expanded and rearranged to yield, for choked flow conditions,

$$-\frac{dp}{dz} = \frac{\frac{-G_c^2}{g_c A_{xs}} \frac{dA_{xs}}{dx} + \frac{g}{g_c} \langle \rho \rangle + \frac{\tau_w P_f}{A_{xs}}}{\left[1 + \frac{G_c^2}{g_c} \frac{d}{dp} \left(\frac{1}{\langle \rho' \rangle} \right) \right]} \quad (42.27)$$

FIGURE 42.3 Typical CCFL flooding locus.

Vanishing of the numerator determines where the choking plane will be (i.e., where the Mach number is unity), whereas vanishing of the denominator defines the local critical mass flux as

$$G_c = \left[-g_c \frac{dp}{d(1/\langle \rho' \rangle)} \right]^{1/2} \quad (42.28)$$

In order to proceed, we must know the local properties and the slip ratio (S). It can be shown [Lahey and Moody, 1993] that if the specific kinetic energy of the two-phase mixture is minimized we obtain $S = (\rho_l / \rho_v)^{1/3}$. Moreover, if an isotropic thermodynamic process is assumed through a converging nozzle, Figure 42.4 is obtained. This figure is very easy to use. For example, if the stagnation pressure (p_0) and enthalpy (h_0) upstream of the nozzle are 1000 psia and 800 Btu/lbm, respectively, the critical mass flux will be about $G_c = 3995$ lbm/sec-ft².

42.4 Two-Phase Instabilities

It is also significant to note that important static and dynamic instabilities may occur in two-phase flows. It can be shown [Lahey and Moody, 1993] that the criterion for the occurrence of an excursive instability is

$$\frac{\partial(\Delta p_{\text{system}})}{\partial w} > \frac{\partial(\Delta p_{\text{ext}})}{\partial w} \quad (42.29)$$

where the external (ext) pressure increase (Δp_{ext}) is normally due to a pump. Figure 42.5 shows that a two-phase system having a positive displacement pump (case 1) and a centrifugal pump with a steep pump/head curve (case 4) will be stable, whereas the cases of parallel channels (case 2) and a centrifugal pump with a relatively flat pump/head curve (case 3) are unstable and have multiple operating points.

If the state variables in the mixture conservation equations are perturbed (i.e., linearized) about a steady state,

$$\delta\varphi(\eta(t)) \triangleq \varphi(\eta(t)) - \varphi_0 = \left. \frac{\partial\varphi}{\partial\eta} \right|_0 \delta\eta \quad (42.30)$$

FIGURE 42.4 Maximum steam/water flow rate and local stagnation properties (Moody model).

and the resultant linear equations are combined and integrated in the axial (z) direction, then the so-called *characteristics equation* of a boiling (or condensing) system becomes [Lahey and Podowski, 1989]:

$$\delta(\Delta p_{1\phi}) + \delta(\Delta p_{2\phi}) = 0 \quad (42.31)$$

After Laplace-transforming Equation (42.31) — to convert it from the time domain to the frequency domain — we can apply Nyquist’s stability technique to determine whether or not density-wave oscillations (DWO) are expected. Significantly, DWO are the most important and prevalent dynamic oscillations that may occur in two-phase flows. For the parallel channel case shown schematically in Figure 42.6, we see that the system is marginally stable (i.e., the Nyquist locus of $\delta(\Delta p_{2\phi})/\delta(\Delta p_{1\phi})$ goes through the -1 point) and thus DWO are anticipated.

A stability map of boiling/condensing systems is often given in terms of the subcooling number (N_{sub}) and the phase change number (N_{pch}). A typical plot for a typical boiling water nuclear reactor (BWR/4) is given in Figure 42.7. It can be seen that, as the inlet subcooling is increased at a given power-to-flow ratio (i.e., for N_{pch} fixed), the system may go in and out of DWO.

42.5 Conclusion

This chapter summarizes some of the methods used in the analysis of two-phase flows. The emphasis has been on two-phase fluid mechanics, although phase change heat transfer is often also very important.

FIGURE 42.5 Excursive instability.

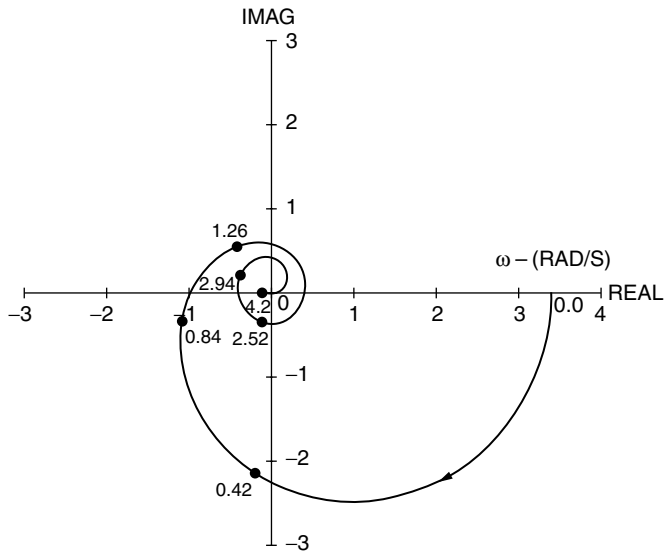

FIGURE 42.6 Nyquist plot for abnormal BWR/4 operating conditions (parallel channels).

FIGURE 42.7 Typical BWR/4 stability map ($K_{in} = 27.8$, $K_{exit} = 0.14$).

The literature associated with two-phase thermal hydraulics is vast; nevertheless, it is hoped that this chapter will provide a useful road map to this literature.

Defining Terms

Critical flow — A condition in which the two-phase mixture is flowing at the local sonic velocity.

Density — The mass per unit volume of the material in question (ρ).

Enthalpy — The internal energy per unit volume plus the related flow work (h).

Flooding — A countercurrent flow limitation due to the resistance induced by cocurrent vapor/liquid flow streams.

Flow area — The cross-sectional area through which the fluid flows (A_{xs}).

Flow rate — The mass flowing per unit time (w).

Phase — The various phases of a fluid are solid, liquid, and gas.

Void fraction — The local volume fraction of the dispersed vapor phase.

Volumetric flow rate — The volume flowing per unit time of phase k (Q_k).

Nomenclature

The fluid mixing process involves three different areas of viscosity which affect flow patterns and scaleup and two different scales within the fluid itself: **macro scale** and **micro scale**. Design questions come up with regard to the performance of mixing processes in a given volume. Consideration must be given to proper impeller and tank geometry as well as to the proper speed and power for the impeller. Similar considerations arise when it is desired to scale up or scale down, and this involves another set of mixing considerations.

If the fluid discharge from an impeller is measured with a device that has a high frequency response, one can track the velocity of the fluid as a function of time. The velocity at a given point in time can then be expressed as an average velocity (\bar{v}) plus a fluctuating component (v'). Average velocities can be integrated across the discharge of the impeller, and the pumping capacity normal to an arbitrary discharge plane can be calculated. This arbitrary discharge plane is often defined by the boundaries of the impeller blade diameter and height. Because there is no casing, however, an additional 10 to 20% of flow typically can be considered as the primary flow of an impeller.

The velocity gradients between the average velocities operate only on larger particles. Typically, these particles are greater than 1000 μm in size. This is not a precise definition, but it does give a feel for the magnitudes involved. This defines macro-scale mixing. In the turbulent region, these macro-scale fluctuations can also arise from the finite number of impeller blades passing a finite number of baffles. These set up velocity fluctuations that can also operate on the macro scale.

Smaller particles primarily see only the fluctuating velocity component. When the particle size is much less than 100 μm , the turbulent properties of the fluid become important. This is the definition of the boundary size for micro-scale mixing.

FIGURE 43.1 Typical velocity as a function of time for three different impellers, all at the same total pumping capacity. (Courtesy of LIGHTNIN.)

All of the power applied by a mixer to a fluid through the impeller appears as heat. The conversion of power to heat is through viscous shear and is 2542 Btu/h/hp. Viscous shear is present in turbulent flow only at the micro-scale level. As a result, the power per unit volume is a major component of the phenomenon of micro-scale mixing. At a 1 μm level, in fact, it does not matter what specific impeller design is used to apply the power.

Numerous experiments show that the power per unit volume in the zone of the impeller (which is about 5% of the total tank volume) is about 100 times higher than the power per unit volume in the rest of the vessel. Based on some reasonable assumptions about the fluid mechanics parameters, the root-mean-square (rms) velocity fluctuation in the zone of the impeller appears to be approximately 5 to 10 times higher than in the rest of the vessel. This conclusion has been verified by experimental measurements.

The ratio of the rms velocity fluctuation to the average velocity in the impeller zone is about 50% for many open impellers. If the rms velocity fluctuation is divided by the average velocity in the rest of the vessel, however, the ratio is on the order of 5 to 10%. This is also the ratio of rms velocity fluctuation to the mean velocity in pipeline flow. In micro-scale mixing, phenomena can occur in mixing tanks that do not occur in pipeline reactors. Whether this is good or bad depends upon the process requirements.

Figure 43.1 shows velocity versus time for three different impellers. The differences between the impellers are quite significant and can be important for mixing processes. All three impeller velocities are calculated for the same impeller flow, Q , and same diameter. The A310 (Figure 43.2) draws the least power and has the lowest velocity fluctuations. This gives the lowest micro-scale turbulence and shear rate. The A200 (Figure 43.3) displays increased velocity fluctuations and draws more power. The R100

FIGURE 43.2 Fluidfoil impeller (A310). (Courtesy of LIGHTNIN.)

FIGURE 43.3 Typical axial-flow turbine (A200). (Courtesy of LIGHTNIN.)

FIGURE 43.4 Radial-flow Rushton turbine (R100). (Courtesy of LIGHTNIN.)

(Figure 43.4) draws the most power and has the highest micro-scale shear rate. The proper impeller should be used for each individual process requirement.

The velocity spectra in the axial direction for the axial-flow impeller A200 are shown in Figure 43.5. A decibel correlation has been used in this figure because of its well-known applicability in mathematical modeling as well as the practicality of putting many orders of magnitude of data in a reasonably sized chart. Other spectra of importance are the power spectra (the square of the velocity) and the Reynolds stress (the product of the R and Z velocity components), which is a measure of the momentum at a point.

The ultimate question is this: How do all these phenomena apply to process design in mixing vessels? No one today is specifying mixers for industrial processes based on meeting criteria of this type. This is largely because processes are so complex that it is not possible to define the process requirements in terms of these fluid mechanics parameters. If the process results could be defined in terms of these parameters, sufficient information probably exists to permit the calculation of an approximate mixer design. It is important to continue studying fluid mechanics parameters in both mixing and pipeline reactors to establish what is required by different processes in fundamental terms.

One of the most practical recent results of these studies has been the ability to design pilot plant experiments (and, in many cases, plant-scale experiments) that can establish the sensitivity of a process to macro-scale mixing variables (as a function of power, pumping capacity, impeller diameter, impeller tip

FIGURE 43.5 Typical velocity spectrum as a function of fluctuation frequency. (Courtesy of LIGHTNIN.)

speeds, and macro-scale shear rates) in contrast to micro-scale mixing variables (which are relative to power per unit volume, rms velocity fluctuations, and some estimation of the size of the micro-scale eddies).

Another useful and interesting concept is the size of the eddies at which the power of an impeller is eventually dissipated. This concept utilizes the principles of **isotropic turbulence** developed by Komolgoroff. The calculations assume some reasonable approach to the degree of isotropic turbulence, and the estimates do give some idea as to how far down in the micro scale the power per unit volume can effectively reach. The equation is

$$L = (v^3 / \epsilon)^{1/4}$$

43.1 Scaleup/Scaledown

Two applications of scaleup frequently arise. One is building a model for pilot plant studies to develop an understanding of the process variables for an existing full-scale mixing installation. The other is taking a new process and studying it in the pilot plant to work out pertinent scaleup variables for a new mixing installation.

Because there are thousands of specific processes each year that involve mixing, there will be at least hundreds of different situations requiring a somewhat different pilot plant approach. Unfortunately, no set of rules states how to carry out studies for any specific program, but here are a few guidelines that can help one carry out a pilot plant program:

- For any given process, take a qualitative look at the possible role of fluid shear stresses. Try to consider pathways related to fluid shear stress that may affect the process. If none exist, then this extremely complex phenomenon can be dismissed and the process design can be based on such things as uniformity, circulation time, blend time, or velocity specifications. This is often the case in the blending of miscible fluids and the suspension of solids.
- If fluid shear stresses are likely to be involved in obtaining a process result, then one must qualitatively look at the scale at which the shear stresses influence the result. If the particles, bubbles, droplets, or fluid clumps are on the order of 1000 μm or larger, the variables are macro-scale, and average velocity at a point is the predominant variable.

When macro-scale variables are involved, every geometric design variable can affect the role of shear stresses. These variables can include power, impeller speed, impeller diameter, impeller blade shape, impeller blade width or height, thickness of the material used to make the impeller, number of blades, impeller location, baffle location, and number of impellers.

Micro-scale variables are involved when the particles, droplets, baffles, or fluid clumps are on the order of 100 μm or less. In this case, the critical parameters usually are power per unit volume, distribution of power per unit volume between the impeller and the rest of the tank, rms velocity fluctuation, energy spectra, dissipation length, the smallest micro-scale eddy size for the particular power level, and viscosity of the fluid.

- The overall circulating pattern, including the circulation time and the deviation of the circulation times, can never be neglected. No matter what else a mixer does, it must be able to circulate fluid throughout an entire vessel appropriately. If it cannot, then that mixer is not suited for the tank being considered.

43.2 Effect of the Circulation Time Spectrum and the Spectrum of Shear Rates on Ten Different Mixing Technologies

Gas-Liquid Dispersion

The macro-scale rate shear change affects the bubble size distribution in tanks of various sizes. As processes are scaled up, the linear, superficial gas velocity tends to be higher in the larger tank. This is

the major contributor to the energy input of the gas stream. If the power per unit volume put in by the mixer remains relatively constant, then small tanks have a different ratio of mixing energy to gas expansion energy, which affects the flow pattern and a variety of other fluid mechanics parameters. The large tank will tend to have a larger variation of the size distribution of bubbles than will the small tank.

This phenomenon is affected by the fact that the surface tension and viscosity vary all the way from a relatively pure liquid phase to all types of situations with dissolved chemicals, either electrolytes or nonelectrolytes, and other types of surface-active agents.

Gas–Liquid Mass Transfer

If we are concerned only with the total volumetric mass transfer rate, then we can achieve very similar $K_c a$ values in large tanks and in small tanks.

Blend time enters the picture primarily for other process steps immediately preceding or following the gas-liquid mass transfer step. Blending can play an important role in the total process, of which gas-liquid mass transfer is only one component.

Solids Suspension and Dispersion

Solids suspension is not usually affected by blend time or shear rate changes in the relatively low to medium solids concentration in the range from 0 to 40% by weight. However, as solids become more concentrated, the effect of solids concentration on the power required changes the criteria from the settling velocity of the individual particles in the mixture to the apparent viscosity of the more concentrated slurry. This means that we enter an area where the blending of non-Newtonian fluid regions, the shear rates, and circulation patterns play marked roles (see [Figure 43.6](#)).

The suspension of a single solid particle should depend primarily on the upward velocity at a given point and also should be affected by the uniformity of this velocity profile across the entire tank cross-section. There are upward velocities in the tank, and there also must be corresponding downward velocities. In addition to the effect of the upward velocity on a settling particle, there is also the random motion of the micro-scale environment, which does not affect large particles very much but is a major factor in the concentration and uniformity of particles in the transition and micro-scale range.

Using a draft tube in the tank for solids suspension introduces another, different set of variables. There are other relationships that are very much affected by scaleup in this type of process. Different scaleup problems exist depending on whether the impeller is pumping up or down within the draft tube.

If the process involves the dispersion of solids in a liquid, then we may either be concerned with breaking up agglomerates or possibly physically breaking or shattering particles that have a low cohesive

FIGURE 43.6 Effect of percent solids by weight and power required for uniformity and fluid motion. (Courtesy of LIGHTNIN.)

force between their components. Normally, we do not think of breaking ionic bonds with the shear rates available in mixing machinery.

If we know the shear stress required to break up a particle, we can determine the shear rate required of the machinery by various viscosities with the equation

$$\text{Shear stress} = \text{Viscosity} \times \text{Shear rate}$$

The shear rate available from various types of mixing and dispersion devices is known approximately, as is the range of viscosities in which they can operate. This makes the selection of the mixing equipment subject to calculation of the shear stress required for the viscosity to be used.

In the equation above, it is assumed that there is 100% transmission of the shear rate in the shear stress. However, with the slurry viscosity determined essentially by the properties of the slurry, at high slurry concentrations there is a slippage factor in which internal motion of particles in the fluids over and around each other can reduce the effective transmission of viscosity efficiencies from 100% to as low as 30%.

Animal cells in biotechnology do not normally have a tough skin as fungal cells do and are very sensitive to mixing effects. Many approaches have been tried to minimize the effect of increased shear rates on scaleup, and these include encapsulating the organism in or on micro particles and conditioning cells selectively to shear rates. In addition, traditional fermentation processes have maximum shear rate requirements in which cells become progressively more and more damaged until they become motile.

Solid–Liquid Mass Transfer

There is potentially a major effect of both shear rate and circulation time in these processes. The solids may be inorganic, in which case we are looking at the slip velocity of the particle and also whether we can break up agglomerates of particles, which may enhance mass transfer. When the particles become small enough, they tend to follow the flow pattern, so the slip velocity necessary to affect the mass transfer becomes less and available.

This shows that from the definition of off-bottom motion to complete uniformity, the effect of mixer power is much less than from going to on-bottom motion to off-bottom suspension. The initial increase in power causes more and more solids to become in active communication with the liquid and has a much greater mass transfer rate than that occurring above the power level for off-bottom suspension, in which slip velocity between the particles of fluid is the major contributor.

Since there may well be chemical or biological reactions happening on or in the solid phase, depending upon the size of the process participants, it may or may not be appropriate to consider macro- or micro-scale effects.

In the case of living organisms, their access to dissolved oxygen throughout the tank is of great concern. Large tanks in the fermentation industry often have a Z/T ratio of 2:1 to 4:1; thus, top to bottom blending can be a major factor. Some biological particles are facultative and can adapt and reestablish their metabolism at different dissolved oxygen levels. Other organisms are irreversibly destroyed by sufficient exposure to low dissolved oxygen levels.

Liquid–Liquid Emulsions

Almost every shear rate parameter we have affects liquid–liquid emulsion formation. Some of the effects are dependent upon whether the emulsion is both dispersing and coalescing in the tank, or whether there are sufficient stabilizers present to maintain the smallest droplet size produced for long periods of time. Blend time and the standard deviation of circulation times affect the length of time it takes for a particle to be exposed to the various levels of shear work and thus the time it takes to achieve the ultimate small particle size desired.

As an aside, when a large liquid droplet is broken up by shear stress, it tends to initially elongate into a dumbbell type of shape, which determines the particle size of the two large droplets formed. Then the neck in the center of the “dumbbell” may explode or shatter. This would give a debris of particle sizes that can be quite different from the two major particles produced.

Liquid–Liquid Extraction

If our main interest is in the total volumetric mass transfer between the liquids, the role of shear rate and blend time is relatively minor. However, if we are interested in the bubble size distribution — and we often are because that affects the settling time of an emulsion in a multistage cocurrent or counter-current extraction process — then the change in macro and micro rates on scaleup is a major factor. Blend time and circulation time are usually not major factors on scaleup.

Blending

If the blending process occurs between two or more fluids with relatively low viscosity such that the blending is not affected by fluid shear rates, then the difference in blend time and circulation between small and large tanks is the only factor involved. However, if the blending involves wide disparities in the density of viscosity and surface tension between the various phases, a certain level of shear rate may be required before blending can proceed to its ultimate degree of uniformity.

The role of viscosity is a major factor in going from the turbulent regime, through the transition region, into the viscous regime, and there is a change in the rate of energy dissipation discussed previously. The role of non-Newtonian viscosity is very strong since that tends to markedly change the influence of impellers and determines the appropriate geometry.

Another factor here is the relative increase in Reynolds number on scaleup. This means that we could have pilot plants, as well as the plant, running in the turbulent region. We could have the pilot plant running in the transition region and the plant in the turbulent, or the pilot plant could be in the viscous region while the plant is in the transition region. There is no apparent way to prevent this Reynolds number change upon scaleup. In reviewing the qualitative flow pattern in a pilot scale system, it should be realized that the flow pattern in the large tank will be at an apparently much lower viscosity and therefore at a much higher Reynolds number than is observed in the pilot plant. This means that the roles of tank shape, D/T ratio, baffles, and impeller locations can be based on different criteria in the plant size unit than in the pilot size unit under observation.

Chemical Reactions

Chemical reactions are influenced by the uniformity of concentration both at the feed point and in the rest of the tank and can be markedly affected by changes in overall blend time and circulation time as well as the micro-scale environment. It is possible to keep the ratio between the power per unit volume at the impeller and that in the rest of the tank relatively similar on scaleup, but much detail needs to be considered regarding the reaction conditions, particularly where selectivity is involved. This means that reactions can take different paths depending upon chemistry and fluid mechanics, and this is a major consideration in what should be examined. The method of introducing the reagent stream can be projected in several different ways depending upon the geometry of the impeller and the feed system.

Fluid Motion

Sometimes the specification is purely in terms of pumping capacity. Obviously, the change in volume and velocity relationships depends upon the size of the two- and three-dimensional area or volume involved. The impeller flow is treated in a head/flow concept, and the head required for various types of mixing systems can be calculated or estimated.

Heat Transfer

In general, the fluid mechanics of the film on the mixer side of the heat transfer surface is a function of what happens at that surface rather than the fluid mechanics around the impeller zone. The impeller provides flow largely across and adjacent to the heat transfer surface, and that is the major consideration of the heat transfer result obtained. Many of the correlations are in terms of traditional dimensionless groups in heat transfer, while the impeller performance is often expressed as the impeller Reynolds number.

43.3 Computational Fluid Dynamics

Several software programs available to model flow patterns of mixing tanks are available. They allow the prediction of flow patterns based on certain boundary conditions. The most reliable models use accurate fluid mechanics data generated for the impellers in question and a reasonable number of modeling cells to give the overall tank flow pattern. These flow patterns can give velocities, streamlines, and localized kinetic energy values for the system. Their main use at the present time is in examining the effect of changes in mixing variables based on adjustments to the mixing process. These programs can model velocity, shear rates, and kinetic energy but probably cannot adapt to the chemistry of diffusion or mass transfer kinetics of actual industrial processes at the present time.

Relatively uncomplicated transparent tank studies using tracer fluids or particles can also give a feel for the overall flow pattern. The time and expense of calculating these flow patterns with computational fluid dynamics should be considered in relation to their applicability to an actual industrial process. The future of computational fluid dynamics looks very encouraging, and a reasonable amount of time and effort placed in this regard can yield immediate results as well as the potential for future process evaluation.

Figure 43.7 through [Figure 43.9](#) show some approaches. Figure 43.7 shows velocity vectors for an A310 impeller. [Figure 43.8](#) shows contours of kinetic energy of turbulence. Figure 43.9 uses a particle trajectory approach with neutral buoyancy particles.

Numerical fluid mechanics can define many of the fluid mechanics parameters for an overall reactor system. Many of the models break the mixing tank up into small microcells. Suitable material and mass transfer balances between these cells throughout the reactor are then made. This can involve massive computational requirements. Programs are available that can give reasonably acceptable models of experimental data in mixing vessels. Modeling the three-dimensional aspect of a flow pattern in a mixing tank can require a large amount of computing power.

Fluid Measurement Techniques

S. A. Sherif

University of Florida, Gainesville

44.1 Fundamental Principles

44.2 Basic Equations

Differential Pressure Meters • Thermal Anemometers • Laser
Doppler Anemometers • Volume and Mass Flow Measurements

The subject of fluid measurements covers a broad spectrum of applications. Examples include wind-tunnel experiments, turbomachinery studies, water tunnel and flume investigations, erosion studies, and meteorological research, to name a few. Many wind-tunnel investigations call for determining forces on scale models of large systems. **Similarity analysis** is then performed to permit generalization of the experimental results obtained on the laboratory model. Techniques for measuring fluid flow parameters are extremely diverse and include thermal anemometers, laser velocimeters, volume and mass flow devices, flow visualization by direction injection, and optical diagnostics. Measurements can be carried out in liquids and gases, incompressible and compressible fluids, two-phase and single-phase flows, and Newtonian and **non-Newtonian fluids**. Types of quantities measured vary greatly and include velocity, temperature, turbulence, vorticity, Reynolds stresses, turbulent heat flux, higher-order turbulence moments, volume and mass flow rates, and differential pressure. Topics covered in this chapter will be limited to differential pressure measurements, thermal anemometry, laser velocimetry, and volume and mass flow measurements. Coverage of these topics will take the form of providing a summary of fundamental principles followed by a summary of the basic equations used.

44.1 Fundamental Principles

The purpose of this section is to provide an overview of the fundamental principles involved in fluid measurements employing the most common and widely used techniques. These techniques include using differential pressure-based instruments, hot-wire and hot-film anemometers, laser Doppler velocimeters, and volume and mass flow devices. These topics will be discussed in some detail in this section.

Differential pressures may be thought of as differences between time-averaged pressures at two points in a fluid flow or between a time-averaged and an instantaneous value of pressure evaluated at a point in the flow [Blake, 1983]. This type of measurement provides an alternative to **thermal anemometry** for determining velocity magnitude and direction as well as turbulence intensity of a fluid flow. The Pitot-static tube is one of the most reliable differential pressure probes for flow measurement (see [Figure 44.1](#)). Special forms of Preston tubes have been used for measurement of wall shear stress in boundary layers of smooth walls. Preston tubes are hypodermic needles that respond to the mean velocity profile in the vicinity of the wall.

FIGURE 44.1 Typical installation of a Pitot-static tube in a duct. (Source: Blake, W. K. 1983. Differential pressure measurement. In *Fluid Mechanics Measurements*, R. J. Goldstein, Ed., Hemisphere, Washington, DC. pp. 61–97. Reproduced with permission. All rights reserved.)

Thermal anemometry refers to the use of a wire or film sensor for velocity, temperature, concentration, and turbulence measurements. This technique started in the late 1800s in the form of employing home-made constant-current anemometers (CCA) for velocity measurement. Three categories of anemometers now exist. The constant-temperature anemometer (CTA) supplies a sensor with heating current that changes with the flow velocity to maintain constant sensor resistance. This type is primarily used for velocity, turbulence, Reynolds stress, and vorticity measurements. The constant-current anemometer, on the other hand, supplies a constant heating current to the sensor. This can either be used for velocity measurements or for temperature and temperature fluctuation measurements. This choice is dictated by the magnitude of the probe sensor current, where the probe sensitivity to velocity fluctuations diminishes for low values of current. The third type of anemometer is the pulsed wire anemometer, which is capable of measuring the fluid velocity by momentarily heating the sensor. This causes heating of the fluid around the sensor and a subsequent convection of that fluid segment downstream to a second wire that acts as a temperature sensor. The time of flight of the heated fluid segment is inversely proportional to the fluid velocity. Typical block diagrams representing the constant-temperature and constant-current anemometers are shown in [Figure 44.2](#) and [Figure 44.3](#), respectively. Thermal anemometers are always connected to a probe via a probe cable. The sensor of a typical probe can either be made of wire or film. Wire probes are made of tungsten or platinum and are about 1 mm long and 5 μm in diameter. Film probes, on the other hand, are made of nickel or platinum deposited in a thin layer onto a backing material (such as quartz) and connected to the anemometer employing leads attached to the ends of the film. A thin protective coating is usually deposited over the film to prevent damage by chemical reaction or abrasion. Typical thicknesses of film probes are 70 μm .

Laser Doppler anemometry (LDA), or laser Doppler velocimetry (LDV), deals with measuring fluid velocities and higher-order turbulence quantities by detecting the Doppler frequency shift of laser light that has been scattered by small particles moving with the fluid [Adrian, 1983]. Three different types of LDA optical systems exist. These are the reference-beam system, the dual-beam system, and the dual-scatter system. The dual-beam LDA produces two types of signals — coherent and incoherent. The coherent signal occurs when at least two particles simultaneously reside in the measurement volume.

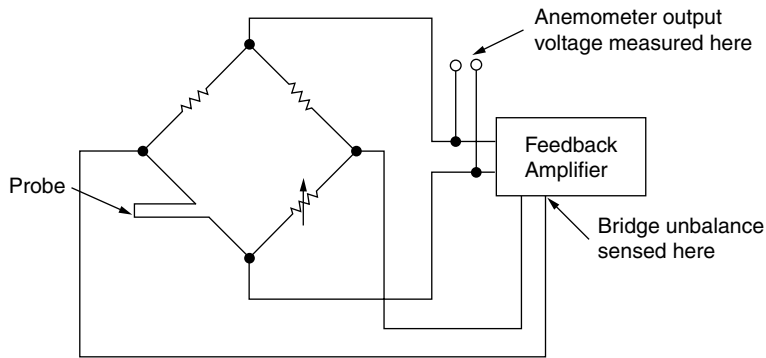

FIGURE 44.2 Block diagram of a constant-temperature anemometer.

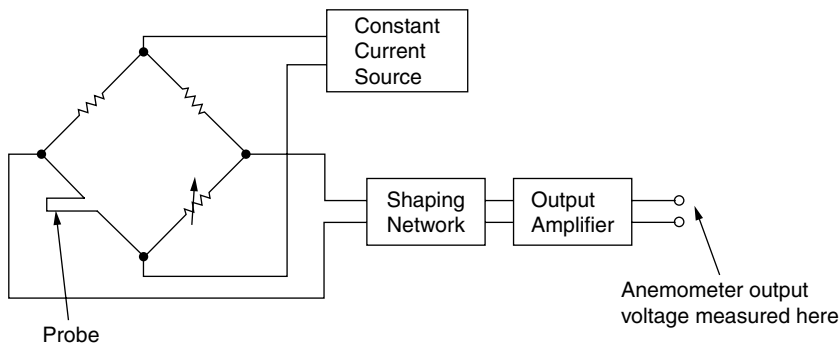

FIGURE 44.3 Block diagram of a constant-current anemometer.

The incoherent signal occurs when a single particle scatters two light waves, one from each illuminating beam. The reference-beam LDA mixes light scattered from an illuminating beam with a reference beam to detect the frequency difference. Both the reference-beam LDA and the dual-beam LDA have the disadvantage of having to satisfy a coherent aperture condition. The amplitude of the reference-beam Doppler signal is proportional to the square root of the reference-beam power, thus allowing an unlimited increase of the signal amplitude by the simple expedient of increasing the power. This feature is particularly useful when the scattered light flux is small compared to a background radiation level. A typical LDA system consists of a laser, a **beam waist adjuster**, a beamsplitter, a **bragg cell**, a backscatter section, a **photomultiplier tube**, photomultiplier optics, an interference filter, a **pinhole section**, a **beam translator**, a beam expander, and a front lens (see Figure 44.4). Other components include a **signal processor** and a **frequency tracker** or a **frequency counter**.

Fluid meters may be classified into those that determine fluid quantity and those that determine fluid flow rate. Quantity meter may be classified as weighing meters (such as weighers or tilting traps) or volumetric meters (such as calibrated tanks, reciprocating pistons, rotating disks and pistons, sliding and rotating vanes, gear and lobed impellers, bellows, and liquid sealed drums). Rate meters, on the other hand, can be classified as differential pressure meters (such as orifice, venturi, nozzle, centrifugal, Pitot-tube, or linear resistance meters), momentum meters (such as turbine, propeller, or cup anemometers), variable-area meters (such as gate, cones, floats-in-tubes, or slotted cylinder and piston meters), force meters (such as target or hydrometric pendulum meters), thermal meters (such as hot-wire and hot-film anemometers), fluid surface height or head meters (such as weirs and flumes), and miscellaneous meters (such as electromagnetic, tracers, acoustic, vortex-shedding, laser, and Coriolis meters) [Mattingly, 1983].

A typical orifice meter (see Figure 44.5) consists of four parts:

FIGURE 44.4 Typical laser Doppler anemometer system. (Courtesy of Dantec Measurement Technology A/S.)

FIGURE 44.5 Orifice meter. (Source: Mattingly, G. E. 1983. Volume flow measurements. In *Fluid Mechanics Measurements*, R. J. Goldstein, Ed., Hemisphere, Washington, DC. pp. 245–306. Reproduced with permission. All rights reserved.)

1. The upstream section including flow-conditioning devices
2. The orifice fixture and plate assembly
3. The downstream meter-tube section
4. The secondary element (not shown)

A venturi tube typically has a shape that closely approximates the streamline pattern of the flow through a reduced cross-sectional area (see [Figure 44.6](#)). Elbow meters are considered nonintrusive since they do

FIGURE 44.6 Venturi tube. (Source: Mattingly, G. E. 1983. Volume flow measurements. In *Fluid Mechanics Measurements*, R. J. Goldstein, Ed., Hemisphere, Washington, DC. pp. 245–306. Reproduced with permission. All rights reserved.)

not interfere with the flow pattern in the pipe and do not introduce structural elements in the flow [Mattingly, 1983]. Laminar flow meters are based on establishing laminar flow between the pressure taps and using the laminar flow rate relationships through a tube of a known area and with a specified pressure drop across its length. Turbine meters enable the fluid flow to spin a propeller wheel whose angular speed is related to the average flow rate in the duct. The angular speed is typically detected by the passage of the blade tips past a coil pickup in the pipe. Rotameters are vertically installed devices that operate by balancing the upward fluid drag on the float with the weight of the float in the upwardly diverging tube (see Figure 44.7). Appropriate choice of the configuration of the metering tube can allow the position of the float to be linearly proportional to the flow rate. Target meters (see Figure 44.8) operate on the principle that the average flow rate in a pipe flow is related to the fluid drag on a disk supported in the pipe. The fluid drag can be measured using secondary devices such as strain gauges and fluid-activated bellows. Target meters are particularly useful in flow metering applications involving dirty fluids so long as the suspended particles do not alter the critical geometrical arrangement. Thermal flow meters operate on the principle of sensing the increase in fluid temperature between two thermometers placed in the flow when heat is added between the thermometers. Thermal flow meters may be made to be nonintrusive and are also capable of operating on the basis of cooling rather than heating.

44.2 Basic Equations

Differential Pressure Meters

The velocity in a one-dimensional laminar flow using a Pitot tube may be expressed as

FIGURE 44.7 Rotameter. (Source: Mattingly, G. E. 1983. Volume flow measurements. In *Fluid Mechanics Measurements*, R. J. Goldstein, Ed., Hemisphere, Washington, DC. pp. 245–306. Reproduced with permission. All rights reserved.)

FIGURE 44.8 Target meter. (Source: Mattingly, G. E. 1983. Volume flow measurements. In *Fluid Mechanics Measurements*, R. J. Goldstein, Ed., Hemisphere, Washington, DC. pp. 245–306. Reproduced with permission. All rights reserved.)

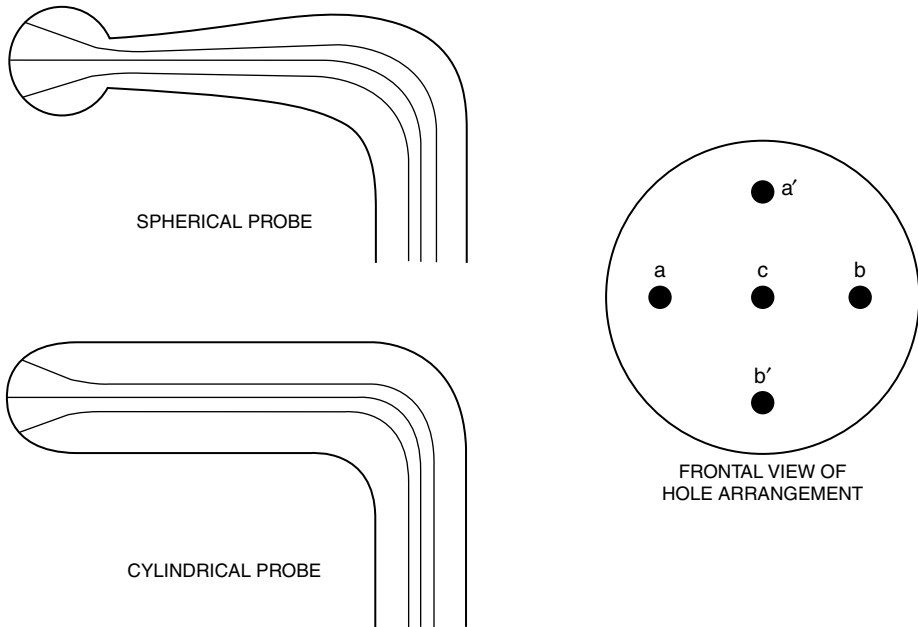

FIGURE 44.9 Some five-hole Pitot-tube geometries. (Source: Blake, W. K. 1983. Differential pressure measurement. In *Fluid Mechanics Measurements*, R. J. Goldstein, Ed., Hemisphere, Washington, DC. pp. 61–97. Reproduced with permission. All rights reserved.)

$$U = \sqrt{\frac{2(p_T - p_s)}{\rho}} \quad (44.1)$$

The most widely used method for measuring mean velocity in multidimensional flows is a five-hole pressure probe, which is a streamlined axisymmetric body that points into the flow (see Figure 44.9). The vector decomposition of the flow velocity U , which is incident on the five pressure taps a , b , c , a' , and b' of a spherical probe, is shown in Figure 44.10. Pien [1958] has shown the following:

$$\frac{p_a - p_b}{2p_c - p_a - p_b} = \frac{\sin 2\alpha}{1 - \cos 2\alpha} \tan 2\beta_h \quad (44.2)$$

$$\frac{p_a - p_b}{\frac{1}{2}\rho V_h^2} = \frac{9}{4} \sin 2\alpha \sin 2\beta_h \quad (44.3)$$

Thermal Anemometers

The overheat ratio and resistance difference ratio may be expressed as

$$a_1 = \frac{R_s}{R_f} \quad \text{and} \quad a_2 = \frac{R_s - R_f}{R_f} \quad (44.4)$$

The yaw, pitch, and roll sensitivities (Figure 44.11) may be expressed by the partial derivatives $\partial E/\partial\theta$, $\partial E/\partial\phi$, and $\partial E/\partial\psi$, respectively. The effective cooling velocity, on the other hand, may be expressed in either of the following forms:

FIGURE 44.10 Vector decomposition of hole geometry and flow direction for spherical-head Pitot tube. (Source: Blake, W. K. 1983. Differential pressure measurement. In *Fluid Mechanics Measurements*, R. J. Goldstein, Ed., Hemisphere, Washington, DC. pp. 61–97. Reproduced with permission. All rights reserved.)

FIGURE 44.11 Yaw and pitch angles of a standard hot-wire probe.

$$U_{\text{eff}}^2 = U_x^2 + k^2 U_y^2 + h^2 U_z^2 \quad (44.5)$$

$$U_{\text{eff}}^2 = U^2 (\cos^2 \theta \cos^2 \phi + k^2 \sin^2 \theta \cos^2 \phi + h^2 \sin^2 \phi) \quad (44.6)$$

The resistance–temperature relationships may be expressed by

$$R = \rho_r \frac{l}{A} \quad \text{and} \quad R_s = R_o [1 + \alpha(T_s - T_o) + \alpha_1(T_s - T_o)^2 + \dots] \quad (44.7)$$

where $\alpha = 3.5 \cdot 10^{-3} \text{ } ^\circ\text{C}^{-1}$ and $\alpha_1 = -5.5 \cdot 10^{-7} \text{ } ^\circ\text{C}^{-2}$ for platinum and $\alpha = 5.2 \cdot 10^{-3} \text{ } ^\circ\text{C}^{-1}$ and $\alpha_1 = 7.0 \cdot 10^{-7} \text{ } ^\circ\text{C}^{-2}$ for tungsten.

A number of cooling laws are commonly used in thermal anemometry. The most common of these cooling laws is King's [1914]:

$$\frac{I^2 R_s}{T_s - T_f} = A_o + B_o \sqrt{\text{Re}} \quad (44.8)$$

Siddall and Davies [1972] expressed King's law in a modified form given by

$$E_b^2 = A + BU^{0.5} + CU \quad (44.9)$$

where $A = 1.273$, $B = 0.860$, and $C = -0.017$. Collis and Williams [1959], on the other hand, derived the following cooling law:

$$\text{Nu} \left(\frac{T_m}{T_f} \right)^{-0.17} = A_1 + B_1 \text{Re}^{n_1} \quad (44.10)$$

where A_1 , B_1 , and n_1 take the values 0.24, 0.56, and 0.45, respectively, when the Reynolds number is between 0.02 and 44, while their values become 0, 0.48, and 0.51, respectively, for a Reynolds number larger than 44 and smaller than 140. The quantity T_m is the arithmetic average of \bar{T}_s and T_f .

Kramer's cooling law [Hinze, 1959] can be expressed by

$$\text{Nu} = 0.42\text{Pr}^{0.20} + 0.57\text{Pr}^{0.33}\text{Re}^{0.50} \quad (44.11)$$

This equation is valid over the Reynolds number range of $0.1 < \text{Re} < 10,000$. Other cooling laws include that of Van der Hegge Zijnen [1956], who derived the following equation:

$$\text{Nu} = 0.38\text{Pr}^{0.2} + (0.56\text{Re}^{0.5} + 0.001\text{Re})\text{Pr}^{0.333} \quad (44.12)$$

The effect of ambient temperature changes may be expressed in terms of the velocity and temperature sensitivities as follows:

$$e_s = S_{\text{vel}}U + S_{\text{temp}}t_f \quad (44.13)$$

$$S_{\text{vel}} = \left\{ \frac{n_1 \pi k_o R_s}{2^{1.97} \bar{E}_s \bar{U} T_o^{0.80}} \left[\frac{\rho_o \bar{U} d}{\mu_o} (2T_o)^{1.76} \right]^{n_1} B_1 \right\} \cdot \frac{(T_s + \bar{T}_f)^{0.97-1.76n_1} (T_s - \bar{T}_f)}{\bar{T}_f^{0.17}} \quad (44.14)$$

$$S_{\text{temp}} = -\frac{1}{2} \left\{ \frac{1.76n_1 \pi k_o R_s}{2^{0.97} \bar{E}_s T_o^{0.80}} \left[\frac{\rho_o \bar{U} d}{\mu_o} (2T_o)^{1.76} \right]^{n_1} \cdot B_1 \frac{T_s - \bar{T}_f}{\bar{T}_f^{0.17} (T_s + \bar{T}_f)^{0.03+1.76n_1}} \right. \\ \left. \cdot \bar{E}_s \left(\frac{0.17}{\bar{T}_f} + \frac{1}{T_s - \bar{T}_f} - \frac{0.97}{T_s + \bar{T}_f} \right) \right\} \quad (44.15)$$

The corrected bridge voltage is:

$$E_{bc} \simeq E_b \left[1 - \frac{T_{01} - T_{02}}{2(T_s - T_{01})} \right] \quad (44.16)$$

The frequency response of a constant-current anemometer may be expressed by the following differential equation:

$$\begin{aligned} \frac{dr_s}{dt} + \frac{\alpha R_o}{\rho c A l} \left\{ \frac{\pi l k_f}{\alpha R_o} \left[0.42 \text{Pr}^{0.20} + 0.57 \text{Pr}^{0.33} \left(\frac{\bar{U}d}{\nu} \right)^{0.5} \right] - \bar{I}^2 \right\} r_s \\ = \left(\frac{\pi k_f}{2 \rho c A \bar{U}} \right) 0.57 \text{Pr}^{0.33} \left(\frac{\bar{U}d}{\nu} \right)^{0.5} (\bar{R}_s - R_f) u \end{aligned} \quad (44.17)$$

whose time constant is

$$\tau_{cca} = \frac{\rho c A l (\bar{R}_s - R_f)}{\bar{I}^2 \alpha R_f R_o} \quad (44.18)$$

while the frequency response of a constant-temperature anemometer may be expressed by the following equation:

$$\frac{di_s}{dt} + \frac{\alpha R_o \bar{I}_s^2 [2g\bar{R}_s(\bar{R}_s - R_f) + R_f^2]}{\rho c A l (\bar{R}_s - R_f)} i_s = 0.57 \text{Pr}^{0.33} \sqrt{\frac{\bar{U}d}{\nu}} \frac{\pi l k_f (\bar{R}_s - R_f)}{2 \alpha R_o \bar{U}} u \quad (44.19)$$

whose time constant is

$$\tau_{cta} = \frac{\rho c A l (\bar{R}_s - R_f)}{\alpha R_o \bar{I}_s^2 [2g\bar{R}_s(\bar{R}_s - R_f) + R_f^2]} \quad (44.20)$$

The mean velocity vector may be computed using the following set of equations:

$$U_{\text{eff}_x}^2 = U^2 (\cos^2 \alpha + k^2 \sin^2 \alpha) \quad (44.21)$$

$$U_{\text{eff}_y}^2 = U^2 (\cos^2 \beta + k^2 \sin^2 \beta) \quad (44.22)$$

$$U_{\text{eff}_z}^2 = U^2 (\cos^2 \gamma + k^2 \sin^2 \gamma) \quad (44.23)$$

$$\cos \alpha = \frac{1}{U} \sqrt{\frac{U_{\text{eff}_x}^2 - k^2 U^2}{1 - k^2}} \quad (44.24)$$

$$\cos \beta = \frac{1}{U} \sqrt{\frac{U_{\text{eff}_y}^2 - k^2 U^2}{1 - k^2}} \quad (44.25)$$

$$\cos \gamma = \frac{1}{U} \sqrt{\frac{U_{\text{eff}_z}^2 - k^2 U^2}{1 - k^2}} \quad (44.26)$$

$$\cos^2 \alpha + \cos^2 \beta + \cos^2 \gamma = 1 \quad (44.27)$$

$$U = \sqrt{\frac{U_{\text{eff}_x}^2 + U_{\text{eff}_y}^2 + U_{\text{eff}_z}^2}{1 + 2k^2}} \quad (44.28)$$

Laser Doppler Anemometers

The Doppler frequency may be expressed in terms of half the angle between two identical laser beams with frequency f (wavelength λ) and the flow velocity component V_θ perpendicular to the two-beam bisector, as follows:

$$f_D = \frac{2 \sin \theta}{\lambda} V_\theta \quad (44.29)$$

A major advantage of this equation is the fact that it is linear and does not contain any undetermined constants, thus eliminating the need for calibration. The width of the measuring volume may be expressed in terms of the transmitting length focal distance, f_T , and the diameter of the beam waist before the transmitting lens, D :

$$d = \frac{4 f_T \lambda}{\pi D} \quad (44.30)$$

The length and height, on the other hand, may be expressed by

$$l = \frac{d}{\sin \theta} \quad \text{and} \quad h = \frac{d}{\cos \theta} \quad (44.31)$$

The spacing of the nearly parallel fringes (produced by the interference of the two light beams in the measuring volume) as well as the number of fringes can be expressed by

$$\delta = \frac{\lambda}{2 \sin \theta} \quad \text{and} \quad n = \frac{4 \Delta}{\pi D} \quad (44.32)$$

The Doppler frequency can be determined using frequency counters that time a fixed number, N , of zero crossings. This allows computing of the particle velocity by simply using the following relationship:

$$V_\theta = \frac{N \delta}{\Delta t} \quad (44.33)$$

Frequency counters are extremely accurate and have a wide dynamic range; however, their output is provided at irregular intervals. This necessitates using special statistical procedures to perform proper counting. Furthermore, the performance of frequency counters may be compromised at higher particle concentrations, when multiple particles are likely to coexist in the measuring volume.

Volume and Mass Flow Measurements

Tanks may be used to determine the flow rate for steady liquid flows by measuring the mass of liquid collected in a known period of time. For gas volume flow rate measurements, compressibility must be taken into account. Positive displacement flow meters may be used for specialized applications.

Volume or mass flow measurements may also be performed using restriction flow meters for flow in ducts. This may include flow nozzles, orifice plates, and venturis. These restriction flow meters typically produce a differential pressure across the meter.

The equations describing the ideal performance characteristics of differential pressure meters for incompressible fluids can be expressed by

$$V_2 = \left[\frac{2g(p_1 - p_2)}{\xi(1 - \beta^4)} \right]^{1/2} \quad \text{and} \quad \dot{M}_I = A_2 \left[\frac{2\rho(p_1 - p_2)}{(1 - \beta^4)} \right]^{1/2} \quad (44.34)$$

where the quantity $1/\bar{A}(1 - \beta^4)$ is a velocity correction factor, while β is the ratio of restriction hole to pipe diameter.

The corresponding equations for compressible fluids are:

$$V_2 = \left[\frac{2\gamma p_1 (1 - r^{1-1/\gamma})}{(\gamma - 1)\rho_1 (1 - \beta^4 r^{2/\gamma})} \right]^{1/2} \quad \text{and} \quad (44.35)$$

$$\dot{M}_I = \frac{A_2 p_1}{T_1^{1/2}} \left[\frac{r^{2/\gamma} (r^{2/\gamma} - r^{1+1/\gamma})}{1 - \beta^4 r^{2/\gamma}} \right]^{1/2} \left(\frac{g}{R \gamma - 1} \right)^{1/2}$$

The equations describing the performance of a real compressible orifice flow, on the other hand, are:

$$\dot{Q}_h = C' \sqrt{h_w p_f} \quad \text{and} \quad C' = F_b F_r Y F_{pg} F_{tb} F_{tf} F_{fg} F_{pv} F_m F_a F_\ell \quad (44.36)$$

The differential pressure across a paddle-type orifice plate is related to the fluid flow rate by

$$\dot{Q} = A_2 C_D \left[\frac{2\Delta p}{\rho(1 - \beta^4)} \right]^{1/4} \quad (44.37)$$

The orifice plate may be clamped between pipe flanges. Its main advantages include simplicity and low cost. Disadvantages include its limited capacity and a high permanent head loss due to uncontrolled expansion downstream from the metering element.

Venturi meters can also be used to perform volume or mass flow measurements. They are typically made from castings machine to close tolerances. As a consequence, they are generally bulky, heavy, and expensive.

Defining Terms

Beam translator — Used in LDV systems to adjust the intersection angle by reducing the standard beam distance.

Beam waist adjuster — Used in LDV systems with long focal lengths to optimize the fringe pattern quality in the measuring volume.

Bragg cell — A module in LDV systems capable of providing a positive or negative optical frequency shift of the laser light.

- Frequency tracker** — A device capable of measuring the instantaneous frequency of the LDV signal. Two types of trackers are used in LDV: the phase-locked loop (PLL) and the frequency-locked loop (FLL).
- Frequency counter** — A device used in LDV systems capable of measuring the frequency of a signal by accurately timing the duration of an integral number of cycles of the signal.
- Non-Newtonian fluids** — Fluids in which the coefficient of viscosity is not independent of the velocity gradient.
- Photomultiplier tube (PMT)** — A device in LDV systems capable of using the photoelectric effect, wherein photons striking a coating of photoemissive material on the photocathode cause electrons to be emitted from the material.
- Pinhole translator** — Used in LDV backscatter measurements. The device can image the measuring volume on a pinhole, thereby constituting an efficient additional spatial filter, thus eliminating undesirable reflections from window surfaces and walls in the vicinity of the measuring volume.
- Signal processor** — A device in LDV systems designed to measure the Doppler frequency in addition to any other relevant data coming from the photomultiplier tube (PMT) signal.
- Similarity analysis** — One of the most powerful tools in fluid mechanics, which permits a wide generalization of experimental results.
- Thermal anemometer** — A device that measures fluid velocity by sensing the changes in heat transfer from a small electrically heated sensor exposed to the fluid flow.

The Steady-State Model • The Transient Model

45.1 System Analysis

The first law of thermodynamics is frequently called the conservation of energy (actually mass-energy), as it represents a compilation of all the energy transfers across the boundary of a thermodynamic system as the system undergoes a process. Energy transfers are of two forms, work and heat. Both work and heat are transient quantities, not possessed by a system, and both are boundary phenomena, that is, observed only in crossing a system boundary. In addition, both are path functions; that is, they are dependent on the path of the process followed by the change in state of the system. Work and heat differ in that work can always be identified as the equivalent of a force acting through a related displacement, while heat is energy transfer due to a temperature gradient or difference, from higher to lower temperature.

One common type of work is that done at a movable boundary, such as shown in Figure 45.1. The boundary-movement work equals the external force times the distance through which it acts, so that for a quasiequilibrium process in which the forces are always balanced, the work for a process between states 1 and 2 is given by the expression

$${}_1W_2 = \int_1^2 \delta W = \int_1^2 P dV \quad (45.1)$$

such that the work is equal to the area under the curve on the P–V diagram shown in Figure 45.1.

Systems in which other driving forces and their associated displacements are present result in corresponding quasiequilibrium work transfers that are the product of the force and displacement, in a manner equivalent to the compressible-substance boundary movement work of Equation 45.1. For any of these work modes, the quasiequilibrium process is an idealized model of a real process (which occurs at a finite rate because of a finite gradient in the driving force). It nevertheless is a useful model against which to compare the real process.

By convention, heat transfer to the system from its surroundings is taken as positive (heat transfer from the system therefore is negative), and work done by the system on its surroundings is positive (work done on the system is negative). For a process in which the system proceeds from initial state 1 to final state 2, the change in total energy E possessed by the system is given as

FIGURE 45.1 Boundary movement work. (Source: Sonntag, R. E., Borgnakke, C., and van Wylen, G. J. 2003. *Fundamentals of Thermodynamics*, 6th ed., John Wiley & Sons, Inc.)

$$E_2 - E_1 = {}_1Q_2 - {}_1W_2 \quad (45.2)$$

The total energy can be divided into the part that depends only on the thermodynamic state, the internal energy U , and the part that depends on the system's motion (kinetic energy KE) and position with respect to the chosen coordinate frame (potential energy PE), such that at any state,

$$E = U + KE + PE \quad (45.3)$$

In many applications, changes in the system kinetic energy and potential energy are negligibly small by comparison with the other energy terms in the first law.

For a constant-pressure process with boundary movement work and no changes in kinetic and potential energies, the first law can be written as

$$\begin{aligned} {}_1Q_2 &= U_2 - U_1 + P(V_2 - V_1) \\ &= (U_2 + P_2V_2) - (U_1 + P_1V_1) = H_2 - H_1 \end{aligned} \quad (45.4)$$

in which H is the property termed enthalpy.

Consider a process involving a single phase (either solid, liquid, or vapor), with possible boundary-movement work, as given by Equation 45.1. Any heat transferred to the system will then be associated with a temperature change. The specific heat is defined as the amount of heat transfer required to change a unit mass by a unit temperature change. If this process occurs at constant volume, there will be no work, and the heat transfer equals the internal energy change. If the process occurs at constant pressure, then the heat transfer, from Equation 45.4, equals the enthalpy change. Thus, there are two specific heats, which become

$$C_v = \frac{1}{m} \left(\frac{\partial U}{\partial T} \right)_v = \left(\frac{\partial u}{\partial T} \right)_v; \quad C_p = \frac{1}{m} \left(\frac{\partial H}{\partial T} \right)_p = \left(\frac{\partial h}{\partial T} \right)_p \quad (45.5)$$

The specific heat is a property that can be measured, or more precisely, can be calculated from quantities that can be measured. The specific heat can then be used to calculate internal energy or enthalpy changes. In the case of solids or liquids, the energy and enthalpy depend primarily on temperature and not very much on pressure or specific volume. For an ideal gas, a very low-density gas following the equation of state

$$Pv = RT \quad (45.6)$$

FIGURE 45.2 Ideal gas specific heats. (Source: Sonntag, R. E., Borgnakke, C., and van Wylen, G. J. 2003. *Fundamentals of Thermodynamics*, 6th ed., John Wiley & Sons, Inc.)

these properties depend only on temperature, and not at all on P or v. Therefore, the expressions in Equation 45.5 can be used to calculate changes in u or h as

$$u_2 - u_1 = \int_1^2 C_{v0} dT; \quad h_2 - h_1 = \int_1^2 C_{p0} dT \quad (45.7)$$

The subscript 0 is included to denote that these are the specific heats for the ideal gas model. In order to integrate these expressions, it is necessary to know the dependence of specific heat on temperature. These are commonly calculated from statistical thermodynamics and tabulated as functions of temperature. Values for several common gases are shown in Figure 45.2.

For real gases or liquids, internal energy and enthalpy dependency on pressure can be calculated using an equation of state. The changes between phases, for example, between liquid and vapor at the same temperature, can be determined using thermodynamic relations. These real properties can then all be tabulated in tables of thermodynamic properties, many of which exist in the literature.

45.2 Control Volume Analysis

In many thermodynamic applications, it is often convenient to adopt a different perspective concerning the first-law analysis. Such cases involve the analysis of a device or machine through which mass is flowing. It is then appropriate to consider a certain region in space, a control volume, and to analyze the energy being transported across its surfaces by virtue of the mass flows, in addition to the heat and work transfers. Whenever a mass δm_i flows into the control volume during the time interval δt , it is necessarily pushed into it by the mass behind it. Similarly, a mass δm_e flowing out of the control volume during δt has to push other mass out of the way. Both cases involve a local boundary movement work $Pv \delta m$, which must be included along with the other energy terms in the first law. For convenience, the Pv term is added to the u term for the mass flow terms, with their sum being the enthalpy. The complete first law for a control volume analysis, represented on a rate basis, is then

$$\dot{Q}_{cv} + \sum \dot{m}_i (h_i + KE_i + PE_i) = \frac{dE_{cv}}{dt} + \sum \dot{m}_e (h_e + KE_e + PE_e) + \dot{W}_{cv} \quad (45.8)$$

The summation signs on the flow terms entering and exiting the control volume are included to allow for the possibility of more than one flow stream. Note that the total energy contained inside the control volume at any instant of time, E_{cv} , can be expressed in terms of the internal energy as in Equation 45.3.

The general expression of the first law for a control volume should be accompanied by the corresponding conservation of mass, which is

$$\frac{dm_{cv}}{dt} + \sum \dot{m}_e - \sum \dot{m}_i = 0 \quad (45.9)$$

The Steady-State Model

Two model processes are commonly utilized in control volume analysis in thermodynamics. The first is the steady-state model. In this case, all states, flow rates, and energy transfers are steady with time. While the state inside the control volume is nonuniform, varying from place to place, it is everywhere steady with time. Therefore, for the steady-state model,

$$\frac{dm_{cv}}{dt} = 0; \quad \frac{dE_{cv}}{dt} = 0 \quad (45.10)$$

these terms drop from Equation 45.8 and Equation 45.9, and everything else is steady, or independent of time. The resulting expressions are very useful in describing the steady long-term operation of a machine or other flow device but of course would not describe the transient startup or shutdown of such a device. The above expressions describing the steady-state model imply that the control volume remains rigid, such that the work rate (or power) term in the first law may include shaft work or electrical work, but not boundary movement work.

There are many common examples of steady-state model applications. One is a heat exchanger, in which a flowing fluid is heated or cooled in a process that is considered to be constant pressure (in the actual case, there will be a small pressure drop due to friction of the flowing fluid at the walls of the pipe). This process may involve a single phase, gas or liquid, or it may involve a change of phase — liquid to vapor in a boiler, or vapor to liquid in a condenser. Another example of a steady-state process is a nozzle, in which a fluid is expanded in a device that is contoured such that the velocity increases as the pressure is dropping. The opposite flow process is a diffuser, in which the device is contoured such that the pressure increases as the velocity is decreasing along the flow path. Still another example is a throttle, in which the fluid flows through a restriction such that the enthalpy remains essentially constant, a conclusion reached because all the other terms in the first law are negligibly small or zero. Note that in all four of these examples of steady-state processes, the flow device includes no moving parts and no work is associated with the process. A turbine, or other flow-expansion machine, is a device built for the purpose of producing a shaft output power, this at the expense of the pressure of the fluid. The opposite device is a compressor (gas) or pump (liquid), the purpose of which is to increase the pressure of a fluid through the input of shaft work.

Several flow devices may be coupled together for a special purpose, such as the heat engine, or power plant. A particular example involving **cogeneration** is shown in [Figure 45.3](#). High-pressure liquid water enters the steam generator, in which the water is boiled and also superheated. The vapor enters the high-pressure turbine, where it is expanded to an intermediate pressure and temperature. At this state, part of the steam is extracted and used for a specific thermal process, such as space heating. The remainder of the steam is expanded in the low-pressure turbine, producing more shaft-power output. Steam exiting the turbine is condensed to liquid, pumped to the intermediate pressure, and mixed with the condensate from the thermal process steam. All the liquid is then pumped back to the high pressure, completing the cycle and returning to the steam generator. Only a small amount of shaft power is required to pump the liquid in the two pumps in comparison to that produced in the turbine. The net difference represents a large useful power output that may be used to drive other devices, such as a generator to produce electrical power.

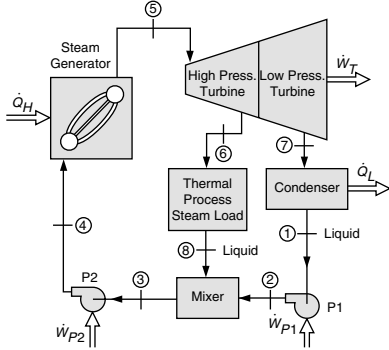

FIGURE 45.3 Cogeneration of steam and power. (Source: Sonntag, R. E., Borgnakke, C., and van Wylen, G. J. 2003. *Fundamentals of Thermodynamics*, 6th ed., John Wiley & Sons, Inc.)

FIGURE 45.4 Combined cycle power system. (Source: Sonntag, R. E., Borgnakke, C., and van Wylen, G. J. 2003. *Fundamentals of Thermodynamics*, 6th ed., John Wiley & Sons, Inc.)

To improve overall thermal efficiency of a power plant, and thereby conserve energy resources, two different heat engines may be compounded together, such as in the **combined cycle** shown in Figure 45.4. In this application, the source of heat supply to the steam turbine power plant cycle is the waste heat from a higher-operating temperature gas turbine engine. In the latter, ambient air is compressed to a high pressure in the compressor, after which it enters a burner (represented in the figure as a heater) along with fuel. The combustion products enter the turbine at high temperature and are expanded to ambient pressure, producing a large power output, a portion of which is used to drive the compressor. The products exiting the gas turbine are still at a high enough temperature to serve as the heat source for the steam turbine cycle. The gas turbine cycle may be referred to as a topping cycle for the steam power plant.

Another common example of coupling several flow devices is the heat pump, or refrigerator, shown in Figure 45.5. Low-temperature vapor enters the compressor at 1 and is compressed to a high pressure and temperature, exiting at 2. This vapor is then condensed to liquid at 3, after which the liquid is throttled to low pressure and temperature. The working fluid, part liquid and part vapor at 4, now enters the evaporator, in which the remaining liquid is boiled, completing the cycle to state 1. When the reason for building this unit is to keep the cold space at a temperature below the ambient, the quantity of interest is \dot{Q}_L , and the machine is called a refrigerator. Likewise, when the reason for building the unit is to keep the warm space at a temperature above the ambient, the quantity of interest is \dot{Q}_H , and the machine is called a heat pump.

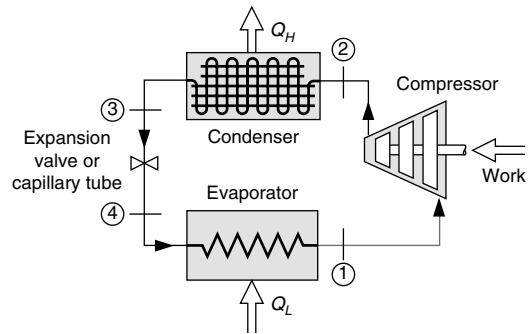

FIGURE 45.5 Refrigeration cycle. (Source: Sonntag, R. E., Borgnakke, C., and van Wylen, G. J. 2003. *Fundamentals of Thermodynamics*, 6th ed., John Wiley & Sons, Inc.)

The Transient Model

The second model in common use in control volume analysis in thermodynamics concerns the analysis of unsteady-rate processes. This model is termed the transient model. Equation 45.8 and Equation 45.9

are integrated over the time of the process, during which the state inside the control volume changes, as do the mass flow rates and energy transfer quantities. It is necessary to assume that the state on each flow area is steady, however, in order that the flow terms can be integrated without detailed knowledge of the rate of change of state and flow rate change. The integrated expressions for this model are

$$Q_{cv} + \sum m_i(h_i + KE_i + PE_i) = (E_2 - E_1)_{cv} + \sum m_e(h_e + KE_e + PE_e) + W_{cv} \quad (45.11)$$

$$(m_2 - m_1)_{cv} + \sum m_e - \sum m_i = 0 \quad (45.12)$$

The transient model is useful in describing the overall changes in such processes as the filling of vessels with a fluid, gas or liquid, or the opposite process, the discharge of a fluid from a vessel over a period of time.

Defining Terms

Cogeneration — The generation of steam in a steam generator (boiler) for the dual purpose of producing shaft power output from a turbine and also for use in a specific thermal process load, such as space heating or for a particular industrial process.

Combined Cycle — Combination of heat-engine power cycles for the purpose of utilizing the waste heat from the higher-operating-temperature cycle as the supply of energy to drive the other cycle. The result is an increase in thermal efficiency as compared with the use of a single cycle because of the increased power output from the same heat source input.

 - Direction and Feasibility of Processes • Process Efficiency • Exergy Analysis

Noam Lior

University of Pennsylvania

Thermodynamics is founded on a number of axioms, laws that have not been proven in a general sense but seem to agree with all of the experimental observations of natural phenomena conducted so far. Most commonly, these axioms are formulated under the names of the first, second, third, and zeroth laws of thermodynamics, but other axiomatic definitions have been formulated and shown to be equally successful [see Callen, 1985].

The first law of thermodynamics is a statement of energy conservation, mathematically providing an energy-accounting equation useful in the analysis of **thermodynamic systems** and generally enlightening us about energy conservation and the axiom that, as far as energy is concerned, one cannot get something for nothing. It does not, however, provide guidance about the directions and limitations of the work, heat, and other energy conversion interactions in the process under consideration. For example, the assignment of an amount of heat (positive or negative) in a first law equation is not conditioned on whether that amount of heat is delivered from a low-temperature source to a high-temperature one or vice versa; heat, work, and other forms of energy are treated as having the same thermodynamic quality, and there is no restriction on how much of the heat input could be converted into work as long as overall energy conservation is maintained. The second law provides these types of guidance and thus more strongly distinguishes thermodynamics from its subset branches of physics, such as mechanics.

Several competing statements and practical corollaries of the second law have been developed over the years. They are all consistent with each other. Those that have more rigor and generality are also typically somewhat more obscure to the practitioner, whereas those that are stated in simpler and more practical terms, though still correct, do not encompass all possible processes.

The best known statement of the second law is the Kelvin–Planck one: “It is impossible to construct an engine that, operating in a **cycle**, will produce no effect other than the extraction of heat from a single **reservoir** and the performance of an equivalent amount of work.” If such an engine, depicted in [Figure 46.1\(a\)](#), would be feasible, the produced work could then be returned to the reservoir. As a consequence of these operations, the reservoir, originally in equilibrium, is now in a new state, whereas the engine

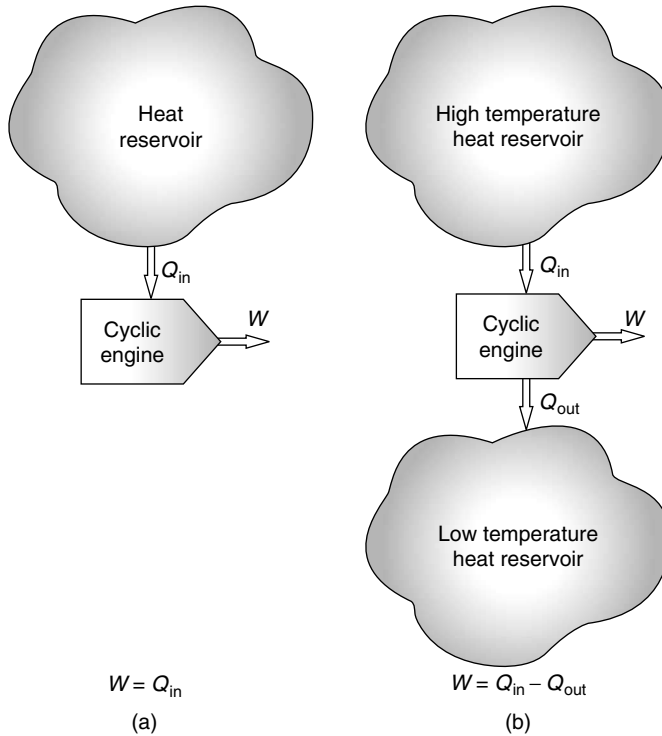

FIGURE 46.1 Comparison of power cycles (a) disallowed and (b) allowed by the second law: (a) a perpetual motion machine of the second kind (PMM2); (b) allowed power cycle.

(being cyclic) and the environment have not changed. Since a system in equilibrium (here the reservoir) can only be disequilibrated as a result of a change in its environment, the only way to satisfy the second law is by denying the possibility of a so-called *perpetual motion machine of the second kind* (PMM2) that, after having been started, produces work continuously without any net investment of energy. Rephrased, the Kelvin–Planck form of the second law thus states that a PMM2 is impossible, and, most notably, that a given quantity of heat cannot fully be converted to work: the heat-to-work conversion efficiency is always lower than 100%. Strikingly, no thermodynamic efficiency restriction exists in the opposite direction of the process: work energy can be fully converted into heat.

A work-producing cyclical engine that does not defy that second law is depicted in Figure 46.1(b). Besides making work, it has an effect of rejecting a portion of the heat gained from the heat source reservoir to a heat sink reservoir. This heat rejection causes an equivalent reduction of the amount of work produced, as dictated by the first law.

Another useful statement of the second law was made by Clausius: “It is impossible to construct a device that operates in a cycle and produces no effect other than the transfer of heat from a region of lower temperature to a region of higher temperature.” If such a device, depicted in Figure 46.2(a), would be feasible, it would allow the transfer of heat from colder to warmer regions without any investment of work. Combined with the cycle of Figure 46.1(b), it would then:

1. Allow the operation of a perpetual motion machine
2. Allow the operation of refrigerators that require no work investment, and
3. Defy the empirical laws of heat transfer, which insist that heat is transferred only down the temperature gradient — from hot to cold regions — and not in the opposite direction

A cooling cycle that does not defy the second law is depicted in Figure 46.2(b). In addition to cooling (taking heat from) the lower-temperature reservoir and delivering that amount of heat to the higher-

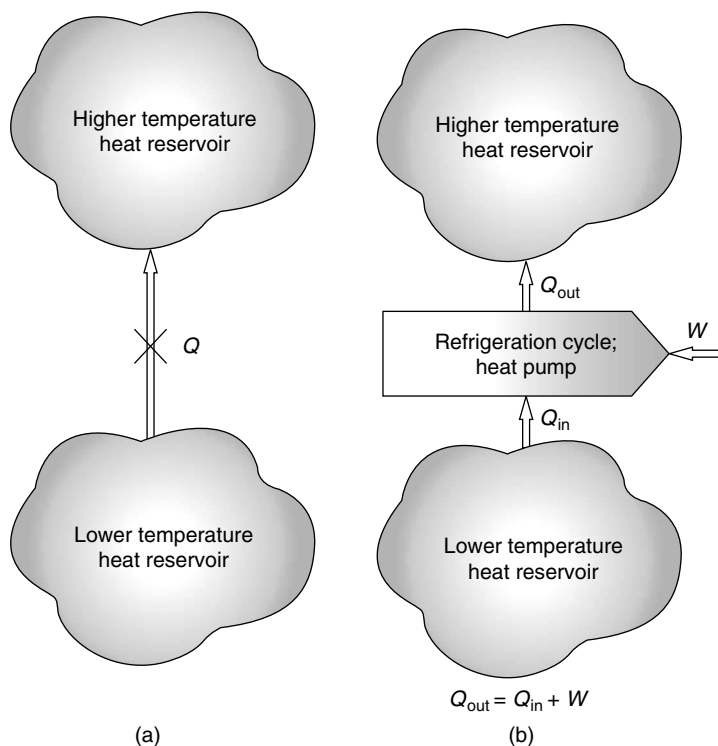

FIGURE 46.2 Comparison of conditions under which heat flow from low temperature to a higher temperature is (a) disallowed and (b) allowed by the second law: (a) heat flow from low to high temperature disallowed by the second law if the system environment does not change; (b) heat flow from low to high temperature allowed by the second law if work is supplied from the environment.

temperature reservoir, it has an effect of requiring some work from the outside, with an equivalent increase in the amount of heat delivered to the high-temperature reservoir, as dictated by the first law.

Two of the most rigorous statements of the second law are given as follows. Carathéodory proposed that “In the neighborhood of a **state** of a system there are states the system cannot reach through **adiabatic** processes” [Hatsopoulos and Keenan, 1965]. Furthermore, “A system having specified allowed states and an upper bound in volume can reach from any given state a **stable state** and leave no net effect on the **environment**” [Hatsopoulos and Keenan, 1965]. As explained already, it can be proven that these statements of the second law are fully consistent with the previous ones, in essence pronouncing axiomatically here that *stable equilibrium states exist*. A rudimentary exposition of the link between this statement and the impossibility of a PMM2 has been given in the preceding, and further clarification is available in the cited references.

46.1 Reversibility

After the disturbing second law statement that heat cannot fully be converted into work, the next logical question concerns the maximal efficiency of such energy conversion. It is obvious from the first law, and even just from operational considerations, that the most efficient heat-to-work conversion process is one that incurs minimal diversions of energy into paths that do not eventually produce work. In a generalized heat-to-work conversion process such as that in Figure 46.1(b), its components are two heat reservoirs at different temperatures, some type of device that produces work when interacting with these two heat reservoirs, and a sink for the produced work. It involves two heat transfer processes (one from the hot reservoir to the device, and one from the device to the cold reservoir), some heat-to-work conversion

process inside the device, and a work transfer process from the device to the work sink. Losses in the amount of energy available for work production occur in practice in each of these processes. The most obvious from operational experience is the loss due to possible friction in the device, in the transfer from it to the work-sink, and in any fluid flow associated with the process. Friction converts work into heat and thus diminishes the net amount of work produced. From another vantage point, the force used to overcome friction could have been used to produce work.

Many other phenomena, somewhat less operationally apparent, may also cause such losses. For example, it is easy to show that any heat transfer across a finite temperature difference causes a loss in the ability to produce work: if, as illustrated in Figure 46.3(a), the device producing work W is at the temperature T_d , where $T_c < T_d < T_h$, one could have conceivably incorporated an additional heat-to-work conversion device between each of the two heat reservoirs and the original device, as shown in Figure 46.3(b), and produced more work ($W + W_h + W_c$) than the system shown in Figure 46.3(b). These losses approach zero when the temperature differences between the heat reservoirs and the respective regions of the device with which they have a heat interaction also approach zero.

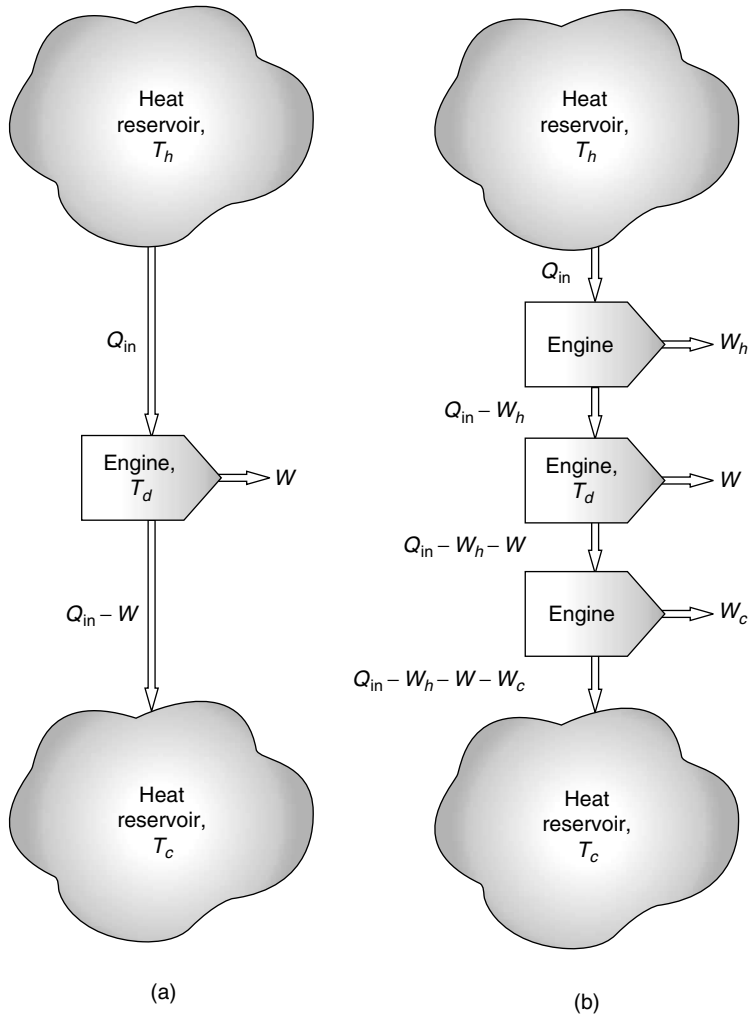

FIGURE 46.3 Power production with reservoir-engine heat transfer across finite temperature differences, $T_c < T_d < T_h$: (a) work produced is only W ; (b) work produced is $W + W_h + W_c$.

FIGURE 46.4 Illustration of the approach to reversibility: (a) abrupt expansion with no weight raise, no useful work production (highly irreversible process); (b) gradual expansion with weight raise, some useful work production (more reversible process).

Having established that temperature difference (or more strictly, temperature gradient) is a thermodynamic driving potential for work production, one can easily recognize that there are other thermodynamic potentials for work production, such as pressure gradients (piston engines and turbines, for example), concentration gradients (batteries and fuel cells), and electric potential gradients (electric motors). Analogous to the arguments presented for losses due to finite temperature differences, it is easy to recognize that similar losses occur due to phenomena such as unrestrained expansion, the mixing of two different substances, the diffusion of a single substance in a mixture across a finite concentration difference, and the passage of current across an electric potential gradient, all when unaccompanied by commensurate production of work.

It is interesting to note that the work-production losses due to all of these processes approach zero if the respective thermodynamic driving potentials approach zero. Furthermore, processes that proceed toward the new equilibrium state due to the influence of a succession of such infinitesimally small driving potentials can in the limit also be reversed in direction without any residual change in the system and its environment. A good example is a frictionless system in which some amount of gas confined in a cylinder is held at a pressure larger than the ambient pressure by means of a piston loaded down with a weight, as shown in Figure 46.4(a). To simplify the example, let us also assume that the system is originally at ambient temperature and that it is perfectly thermally insulated from the environment. Let us judge the ability of the system to do work by the height that it can lift some weight. If the weight is effortlessly slid to the side (in a direction perpendicular to gravity), the piston would pop up to the new force equilibrium state, under which the gas has expanded to a higher volume and lower pressure and temperature, but since the weight has remained at its original level the system has performed no useful work. The reversal of the process to bring the system *and the environment* to their original condition cannot be done, because work would have to be supplied for that purpose from the environment, thus changing its original state. This is an example of a process at its worst — producing no useful work and characterized

by a large (finite) driving force and by irreversibility. Some engineering ingenuity can improve the situation vastly, in the extreme by replacing the single weight with a very large number of small weights having the same total mass as the original single weight, say a pile of fine sand grains [Figure 46.4(b)]. Now we effortlessly slide one grain to the side, resulting in a very small rise of the piston and the production of some useful work through the consequent raising of the sand pile *sans* one grain. Removing one grain after another in the same fashion until the last grain is removed and the piston rests at the same equilibrium height as it did in the previously described worthless process will, as seems obvious, produce the most useful work given the original thermodynamic driving force. Furthermore, since the movements of the piston are infinitesimally small, one could, without any residual effect on the environment, slide each lifted grain of sand back onto the piston slightly to recompress the gas and move the piston down a little to the position it has occupied before its incremental rise.

Generalizing, then, reversibility is synonymous with highest potential for producing useful work, and the degree of process inefficiency is proportional to its degree of irreversibility. The example also illustrates the practical impossibility of fully reversible processes: the production of a finite amount of work at this maximal efficiency would either take forever or take an infinite number of such pistons, each lifting one grain at the same time (and frictionlessly at that). Practical processes are thus always a compromise between efficiency, rate, and amount of equipment needed.

46.2 Entropy

Like volume, temperature, pressure, and energy, entropy is a property characterizing thermodynamic systems. Unlike the other properties, it is not operationally and intuitively understood by novices, a situation not made simpler by the various approaches to its fundamental definition and by its increasing cavalier metaphysical application to fields as disparate as information theory, social science, economics, religion, and philosophy. Let us begin with the fundamental, prosaic definition of entropy, S , as

$$dS = \left(\frac{\delta Q}{T} \right)_{\text{rev}} \quad (46.1)$$

showing that the differential change in entropy, dS , in a process is equal to the ratio of the differential amount of heat interaction, δQ , that takes place if the process is reversible and the absolute temperature, T , during that process. For a finite-extent process between thermodynamic states 1 and 2, Equation (46.1) can be integrated to give

$$S_2 - S_1 = \int_1^2 \left(\frac{\delta Q}{T} \right)_{\text{rev}} \quad (46.2)$$

It is noteworthy here that, since entropy is a property and thus uniquely defined at states 1 and 2, the entropy change between these two states is always the same, whether the process is reversible or irreversible.

Entropy values of various materials are available in the literature: most books on thermodynamics and chemical and mechanical engineering handbooks include values of the entropy as a function of temperature and pressure; an extensive source for gas properties particularly related to high-temperature processes are the JANAF tables [Stull and Prophet, 1971]. The entropy values are given based on a common (but somewhat arbitrary) reference state, and its units are typically kJ/kg K, Btu/lb R, or kJ/kmol K if a molar basis is used. Although not used much in engineering practice, the fundamental reference state of entropy is 0 K, where according to the third law of thermodynamics the entropy tends to 0.

If the process between states 1 and 2 is irreversible, then

$$\left(\frac{\delta Q}{T} \right)_{\text{irrev}} \neq \left(\frac{\delta Q}{T} \right)_{\text{rev}} \quad (46.3)$$

and it can be shown by using the second law that

$$S_2 - S_1 \geq \int_1^2 \left(\frac{\delta Q}{T} \right) \quad (46.4)$$

where the equality sign applies to reversible processes and the inequality to irreversible ones. Consequently, it can also be shown for isolated systems (i.e., those having no interactions with their environment) that

$$dS_{\text{isolated system}} \geq 0 \quad (46.5)$$

where again the equality sign applies to reversible processes and the inequality to irreversible ones. Since a thermodynamic system and its environment together form an isolated system by definition, Equation (46.5) also states that the sum of the entropy changes of the system and the environment is ≥ 0 .

In another axiomatic approach to thermodynamics [Callen, 1985], the existence of the entropy property is introduced as an axiom and not as a derived property defined by Equation (46.1). It is basically postulated that, out of all the new equilibrium states that the system may attain at the end of a process, the one that has the maximal entropy will be realized. Equation (46.1) and other more familiar consequences of entropy are then derived as corollaries of this maximum postulate.

Equation (46.5) and the other attributes of entropy lead to several eminent mathematical, physical, and other consequences. Mathematically, the inequality Equation (46.5) indicates that many solutions may exist, which are bounded by the equality limit. In other words, out of all the new states 2 that an isolated system starting from state 1 can reach, only those at which the system entropy is larger are allowed; a unique (but practically unreachable) state 2 can be reached with no entropy change if the process is reversible. Also as a mathematical consequence, the entropy maximum principle allows the establishment of the following equations,

$$dS = 0 \quad \text{and} \quad d^2S < 0 \quad \text{at state 2} \quad (46.6)$$

which then can be used in calculating the nature of the new equilibrium state.

Among the physical consequences, the reversible isentropic process provides a unique limit on process path, which also results in maximal efficiency. Also, the fact that the entropy of real isolated systems always rises provides guidance about which new states may be reached and which may not. Through some operational arguments, but primarily by using statistical mechanics on the molecular level, entropy was shown to be a measure of disorder. This supports the observation that isolated systems undergoing any process become less orderly; mess increases unless an external agent is employed to make order, all consistent with the entropy increase law. Profoundly, entropy is thus regarded to be the scientific indicator of the direction of time — “the arrow of time,” after Eddington. The inevitable increase of disorder/entropy with time has led to deeper questions about the origin of the world and indeed of time itself, about the future of the universe in which disorder continuously grows, perhaps to a state of utter disorder (i.e., death), and has raised much philosophical discourse related to these issues. Significant attempts have been made to relate entropy and the second law to almost any human endeavor, including communications, economics, politics, social science, and religion (Bazarov [1964] and Georgescu-Roegen [1971], among many), not always in a scientifically convincing manner.

46.3 The Second Law for Bulk Flow

Based on Equation (46.4), the entropy of a fixed amount of mass (which, by definition, does not give mass to its environment or receive any from it) receiving an amount δQ of heat from a heat reservoir will change as

FIGURE 46.5 Entropy accounting for a control volume.

$$dS \geq \frac{\delta Q}{T} \quad (46.7)$$

The amount of entropy produced in the mass due to reversible heat transfer from the reservoir is $\delta Q/T$, and, according to the second law as expressed by Equation (46.4) and Equation (46.5), the amount of entropy produced due to the inevitable internal process irreversibilities, σ , is

$$\sigma \equiv dS - \frac{\delta Q}{T} \geq 0 \quad (46.8)$$

Addressing a transient and more general case, shown in Figure 46.5, the rate of entropy generation due to irreversibilities ($\dot{\sigma}$) in a given control volume that has (1) work, heat (\dot{Q}), and diffusion (mass transfer) interactions of k species with its environment, and (2) bulk molar flows (\dot{N} , moles/unit time) incoming (subscript i) and exiting (subscript e), can be expressed by simple entropy accounting as

$$\dot{\sigma} = \frac{dS_{cv}}{dt} - \sum_j \frac{\dot{Q}_j}{T_j} - \sum_i \left(\sum_k \dot{N}_k s_k \right)_i + \sum_e \left(\sum_k \dot{N}_k s_k \right)_e - \sum_k (\dot{N}_{k,e} - \dot{N}_{k,i}) s_{o,k} \geq 0 \quad (46.9)$$

where t is time, dS_{cv}/dt is the rate of entropy accumulation in the control volume, subscript j is the number of heat interactions with the environment, s is the specific molar entropy (entropy per mole), and subscript o refers to the conditions of this environment. Equation (46.9) expresses the fact that the entropy of this control volume changes due to heat interactions with its environment, due to the transport of entropy with entering and exiting bulk and diffusional mass flows, and due to internal irreversibilities (work interactions do not change the entropy).

46.4 Applications

Direction and Feasibility of Processes

Compliance with the second law is one of the criteria applied to examine the feasibility of proposed processes and patents. For example, we will examine such compliance for a steady-state combustion process in which it is proposed that methane preheated to 80°C be burned with 20% excess air preheated to 200°C in a leak-tight well-insulated atmospheric-pressure combustor. Since the combustor is isolated from its environment, compliance with the second law will be inspected by calculating the entropy change in the reaction

TABLE 46.1 Analysis of a Methane Combustion Reaction

| | Moles n_i | $y_i; p_i$ atm | T K | s kJ/kmol $\cdot K$ | s_o kJ/kmol $\cdot K$ | $h_o = h(T_o, p_o)$ kJ/kmol | $h(T, p)$ kJ/kmol | a_{ch} kJ/kmol | a kJ/kmol | $n_i a$ kJ/kmol CH ₄ |

| Σ_{products} | 12.424 | 1.0000 | | | | | | | | 642,281 |

Note: Dead state: $p_o = 1$ atm, $T_o = 298$ K; atmospheric composition (molar fractions): N₂ = 0.7567, O₂ = 0.2035, H₂O = 0.0303, CO₂ = 0.0003.

where it may be noted that the number of moles of air was adjusted to reflect 20% excess air and that the excess oxygen and all of the nitrogen are assumed to emerge from the combustor unreacted. The entropy change can be expressed by using Equation (46.9), which for this problem is reduced to

$$\sigma = \sum_p n_p s_p - \sum_r n_r s_r \tag{46.11}$$

where the subscripts p and r refer to the reaction products and reactants, respectively, n_i is the number of moles of species i , evident from Equation (46.10), and s_i is the molar entropy of species i , to be found from the literature based on the temperature and partial pressure.

The calculation procedure is outlined in Table 46.1, and further detail can be found in several of the references, such as Howell and Buckius [1992]. The partial pressures of the participating species are easily determined from the molar composition shown in Equation (46.10). The temperature of the reactants is given, and that of the reaction products exiting the combustor, T_p , is calculated from the first law, where the enthalpies of the species, which are primarily dependent on the temperature, are obtained from reference tables or correlations. In this case it is found that $T_p = 2241$ K. Based on this information, the entropies of the species are either found in the literature or calculated from available correlations or gas state equations. The results are listed in Table 46.1, which contains, besides the entropy values, additional information that will be used in another example later.

Application of these results to Equation (46.11) gives

$$\begin{aligned} \sigma &= [1(316.2) + 0.4(273.1) + 9.024(256.1) + 2(270.3)] \\ &\quad - [1(213.5) + 2.4(232.6) + 9.024(207.8)] \\ &= 630.2 \text{ kJ}/(\text{kmol} \cdot \text{K}) > 0 \end{aligned} \tag{46.12}$$

thus proving compliance of the proposed reaction with the second law and not denying its feasibility. It may be noted that such compliance is a necessary but not always sufficient condition for proving actual process feasibility; additional conditions, such as the existence of a spark in this example, may also be needed.

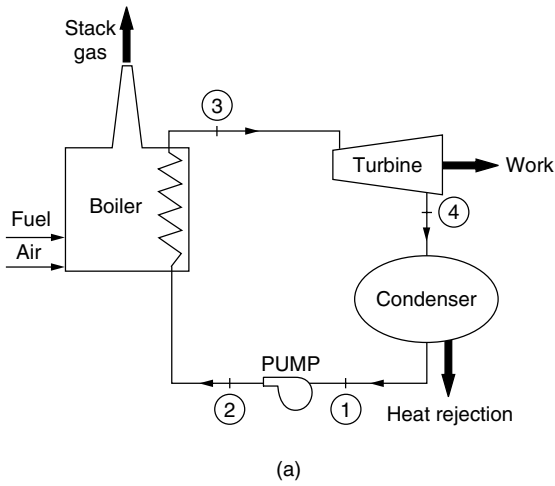

FIGURE 46.6 The Rankine cycle example: (a) the Rankine power cycle; (b) temperature-entropy diagram of the Rankine cycle.

Process Efficiency

Since reversible (isentropic for isolated systems) processes have maximal work-producing efficiency, they are often used as the basis for comparison in the definition of real process efficiencies, defined for work-producing processes (turbines, engines, etc.) as

$$\eta_{is} \equiv \frac{W_p}{W_{p,is}} \quad (46.13)$$

where η_{is} is the so-called “isentropic efficiency,” subscript p refers to the work produced, and p , is to the work that would have been produced if the process was isentropic. For work-consuming processes (such as pumps, fans, etc.), the isentropic efficiency is defined as

$$\eta_{is} \equiv \frac{W_{c,is}}{W_c} \quad (46.14)$$

where subscript c refers to the work consumed in the process and c , is to the work that would have been consumed if the process was isentropic.

For example, the isentropic efficiency of the turbine in the simple Rankine cycle shown in Figure 46.6(a) and qualitatively charted on the temperature-entropy (T - S) diagram of Figure 46.6(b), in which superheated steam expands from the pressure $p_3 = 350$ kPa to the condenser pressure $p_4 = 7$ kPa, would be calculated using Equation (46.11) as follows. If the expansion from p_3 to p_4 could have been performed isentropically (i.e., reversibly in this case), the turbine would have produced the maximal amount of work, with the expansion of the steam terminating on the intersection points 4_s of the p_4 isobar and the isentrope descending vertically from point 3, with $s_{4_s} = s_3$. Having thus the values of s_{4_s} and p_4 allows the determination of the **enthalpy**, h_{4_s} , shown in Table 46.2 (only the parameters in bold in this table would be addressed in this example). Assuming that the differences between the inlet-to-exit (states 3 and 4 in Figure 46.6) elevations and kinetic energies of the steam are negligible compared to the respective enthalpy difference and that the turbine does not exchange heat with its environment, the isentropic work $W_{p,is}$ can be calculated from the first law equation for the turbine control volume, reduced to

TABLE 46.2 Data for Figure 46.6

| State | p , kPa | T , K | s , kJ/kg · K | h , kJ/kg | a , kJ/kg | h , kJ/kg fuel | a , kJ/kg fuel |

| The Fuel, Air, and Stack Gas | | | | | | | |
| 5 | 101 | 298.15 | HHV = 50,019.00 | $a_{\text{fuel}} = 51,792.00$ | | 50,019.0 | 51,792.0 |
| 6 | 101 | 298.15 | 6.6999 | 299.03 | -0.70 | 6158.1 | -14.4 |
| 7 | 101 | 423.15 | 7.3388 | 459.81 | 79.40 | 9929.0 | 1714.5 |

Note: Dead state: $p_o = 1$ atm, $T_o = 298$ K. Atmospheric composition (molar fractions): $N_2 = 0.7567$, $O_2 = 0.2035$, $H_2O = 0.0303$, $CO_2 = 0.0003$.

$$W_{p, \text{is}} = h_3 - h_{4_s} \tag{46.15}$$

In actuality the expansion is irreversible. The second law tells us that the entropy in the process will increase, with the expansion terminating on the same isobar p_4 , but at a point 4 where $s_4 > s_3 = s_{4_s}$, which is indeed true in this example, as shown in Table 46.2. The work produced in this process, W_p , is again calculated from the first law:

$$W_p = h_3 - h_4 \tag{46.16}$$

Using Equation (46.13) and the enthalpy values listed in Table 46.2, the isentropic efficiency in this example is

$$\eta_{\text{is}} = \frac{h_3 - h_4}{h_3 - h_{4_s}} = \frac{35060 - 26761}{35060 - 25735} = 0.89 \tag{46.17}$$

Although not shown here, the data in Figure 46.6 include calculations assuming that the isentropic efficiency of the pump is 0.7. State 2_s in Figure 46.6(b) would have been reached if the pumping process starting from state 1 was isentropic; using Equation (46.14) and the given isentropic efficiency of the pump allows the determination of state 2 attained by the real process (note that states 2_s, 2, and 3 are here all on the same 350 kPa isobar), where s_2 is therefore greater than s_1 .

Although isentropic efficiencies as defined here have a reasonable rationale and are used widely, important issue has been taken with their fundamental usefulness. Using Figure 46.6(b), it can be argued that a better definition of such efficiency (to be named effectiveness, ϵ) would be given if the work W_p actually produced, say in the expansion 3–4, $(W_{p,3-4})_{\text{actual}}$ [the same as the W_p used in Equation (46.14)], was compared with the work that would have been produced if the expansion from 3 to 4 was reversible $[(W_{p,3-4})_{\text{reversible}}]$,

$$\epsilon = \frac{(W_{p,3-4})_{\text{actual}}}{(W_{p,3-4})_{\text{reversible}}} \tag{46.18}$$

rather than comparing it to work that would have been obtained in the isentropic expansion ending at a state 4_s, which does not actually exist in the real process. An example of a deficiency of the isentropic

efficiency (η_{is}) compared with the effectiveness (ϵ) is that it does not give credit to the fact that the steam exiting the turbine at state 4 has a higher temperature than if it had exited at state 4_s, and thus has the potential to perform more work. This is especially poignant when, as usual, additional stages of reheat and expansion are present in the plant. This reasoning and further comments on effectiveness are given in the following section.

Exergy Analysis

Based on the second law statement that only a fraction of heat energy can be converted into work, a very important application of the second law is the analysis of the potential of energy to perform useful work, that is, the examination of the “quality” of energy. To lay the grounds for such analysis, let us address for simplicity a steady flow and state open-flow system such as depicted in Figure 46.5, neglecting any potential and kinetic energy effects. The amount of work produced by the system is from the first law of thermodynamics,

$$W = \sum_i h_i m_i - \sum_e m_e h_e + \sum_j Q_j \quad (46.19)$$

where h is the specific enthalpy of each incoming or exiting stream of matter m .

As explained earlier, the maximal amount of work would be produced if the process is reversible, in which case entropy generation due to process irreversibilities (σ) is zero (although entropy change of the system due to the heat interactions Q_j at the respective temperatures T_j is nonzero). Multiplying the steady-state form of Equation (46.10) by some constant temperature T (to give it energy units) and subtracting it from Equation (46.19) yields

$$W_{\text{rev}} = \left(\sum_i m_i h_i - \sum_e m_e h_e \right) - T \left(\sum_i m_i s_i - \sum_e m_e s_e \right) + \sum_j Q_j \left(1 - \frac{T}{T_j} \right) \quad (46.20)$$

As can be seen from this equation, the reversible work output in the process $i \rightarrow e$ would be further maximized if the temperature at which the heat interaction occurs, T , would be the lowest practically applicable in the considered system, say T_o , yielding an expression for the maximal work output potential of the system, as

$$W_{\text{max}i \rightarrow e} = \sum_i m_i (h_i - T_o s_i) - \sum_e m_e (h_e - T_o s_e) + \sum_j Q_j \left(1 - \frac{T_o}{T_j} \right) \quad (46.21)$$

The term $(h - T_o s)$ appearing at the right side of this equation is thus the measure of a system’s potential to perform useful work and therefore of great thermodynamics significance. Composed of thermodynamic properties at a state and of the constant T_o , it is also a thermodynamic property at that state. This term is called the flow *exergy* or flow *availability function*, b :

$$b \equiv h - T_o s \quad (46.22)$$

Further examination of Equation (46.22) shows that a system at state i would produce the maximal useful work when the new equilibrium state e is identical to the ambient conditions o , since at that state all the driving forces of the system — such as temperature, concentration, and pressure differences — are zero and the system cannot by itself produce any more useful work. The maximal work output, assuming mass conservation, is then

$$W_{\max,i \rightarrow o} = \sum_i m_i [(h_i - h_o) - T_o(s_i - s_o)] \quad (46.23)$$

The term $[(h - h_o) - T_o(s - s_o)]$ is also a property and is the measure of a system's potential to perform useful work between any given state and the so-called "dead state," at which the system can undergo no further spontaneous processes. This term is called *flow exergy* or *flow availability*, a :

$$a \equiv (h - h_o) - T_o(s - s_o) \quad (46.24)$$

Since enthalpy is the measure of the energy in flow systems, examination of Equation (46.21) through Equation (46.24) shows clearly that the portion of the energy h that cannot be converted to useful work is the product $T_o s$.

The last term on the right side of Equation (46.21) is the exergy of the heat sources Q_j , at the respective temperatures T_j , exchanging heat with the considered thermodynamic system. The form of this term is the Carnot cycle work output between T_j and the dead state temperature T_o , which indeed would produce the maximal work and is thus also the exergy of these heat sources by definition. Shaft and other mechanical power, and electric power, are pure exergy.

Turning now to real, irreversible steady state processes, their exergy accounting equation — developed using Equation (46.9), Equation (46.21), and Equation (46.24) — is

$$W = \sum_j Q_j \left(1 - \frac{T_o}{T_j} \right) + \sum_i m_i a_i - \sum_e m_e a_e - T_o \sigma \quad (46.25)$$

where the work output of the process in this control volume is, in the order of terms on the right side of the equation, produced due to (1) heat interactions Q_j at the respective temperatures T_j with the control volume, and (2) and (3) the difference between the exergies flowing in and exiting the control volume, and is diminished by (4) the entropy generation due to process irreversibilities. This last term, $T_o \sigma$, amounts to the difference between the maximal work that could have been produced in a reversible process [Equation (46.21) and Equation (46.24)] and the amount produced in the actual irreversible process [Equation (46.25)]. It is called the *irreversibility* (I) or *lost work* of the process.

Beyond exergy changes due to temperature and pressure driving forces, multicomponent systems also experience exergy changes due to component mixing, phase change, and chemical reactions. It was found convenient to separate the exergy expression into its "physical" (a_{ph}) and "chemical" (a_{ch}) constituents,

$$a = a_{ph} + a_{ch} \quad (46.26)$$

where the *physical exergy* is the maximal work obtainable in a reversible physical process by a system initially at T and p and finally at the dead state T_o , p_o , and the *chemical exergy* is the maximal work obtainable from a system at dead state conditions T_o , p_o , initially at some species composition and finally at the dead state composition (such as the datum level composition of the environment). The total flow exergy, showing the thermal, mechanical, and chemical flow exergy components (segregated by the double brackets) is

$$a = [(h - h_o) - T_o(s - s_o)] (\text{thermal}) + \left[\frac{\mathbf{v}^2}{2} + gz \right] (\text{mechanical}) + \left[\sum_k x_k (\mu_k^\circ - \mu_{o,k}) \right] (\text{chemical}) \quad (46.27)$$

where \mathbf{v} is the flow velocity, g is the gravitational acceleration, z is the flow elevation above a zero reference level, x_k is the molar fraction of species k in the mixture, μ_k° is the **chemical potential** of species k at T_o and p_o , and $\mu_{k,o}$ is the chemical potential of species k at the system dead state defined by T_o , p_o , and the dead state composition.

The general transient exergy accounting equation that includes both physical and chemical exergy is

$$\begin{aligned} \frac{dA_{cv}}{dt} (\text{rate of exergy storage}) &= \sum_j \left(1 - \frac{T_o}{T_j}\right) \dot{Q}_j - \left(\dot{W}_{cv} - p_o \frac{dV_{cv}}{dt}\right) + \sum_i \dot{m}_i a_i \\ &\quad - \sum_e \dot{m}_e a_e (\text{rates of exergy transfer}) \\ &\quad - \dot{I}_{cv} (\text{rate of exergy destruction}) \end{aligned} \quad (46.28)$$

where A_{cv} is the exergy of the control volume, \dot{W}_{cv} is the work performed by the control volume, $p_o (dV_{cv}/dt)$ is the work due to the transient volume change of the control volume, a_i and a_e are the total flow exergies composed of both the physical and chemical components, and $\dot{I}_{cv} (\equiv T_o \dot{\sigma})$ is the irreversibility, that is, the rate of exergy destruction. A more detailed breakdown of exergy, in differential equation form, is given in Dunbar et al. [1992].

For a *closed system* (i.e., one that does not exchange mass with its environment but can have work and heat interactions with it) at a state defined by the specific internal energy u , specific volume v , and specific entropy s , the expression for the exergy, a° , is

$$a^\circ = \left(u + \frac{\mathbf{v}^2}{2} + gz - u_o \right) + p_o (v - v_o) - T_o (s - s_o) \quad (46.29)$$

Selection of the dead state for evaluating exergy is based on the specific application considered. Thus, for example, the dead state for the analysis of a water-cooled power plant operating at a certain geographic location should consist of the cooling water temperature and the ambient atmospheric pressure and composition, all at that location. Much work has been performed in defining “universal” dead states for processes and materials [Szargut et al., 1988].

Example — Exergy Analysis of a Power Plant

To demonstrate the calculation procedure and the benefits of exergy analysis, we will perform such an analysis on the simple Rankine cycle described in [Figure 46.6](#). The fuel used in the boiler is methane, undergoing the same combustion reaction as described in Equation (46.10). Both fuel and air enter the boiler at 25°C, 1 atm, and the combustion products exit the stack at 150°C.

Addressing the steam/water (single component) Rankine cycle loop first, the values of p , T , s , and h are already available from the example given and are listed in [Table 46.2](#). Given the dead state conditions listed under the table, the flow exergy (a) per kg of the water and steam is calculated from Equation (46.24) and listed in the table column to the left of the vertical dividing line.

The three bottom rows of the table list the properties of the inflowing fuel and air and of the stack exhaust gas. The enthalpy of the fuel is its higher heating value (HHV), which, along with exergy, is obtained from fuel property tables [Szargut et al., 1988; Howell and Buckius, 1992; Moran and Shapiro, 1992]. The specific flow exergy values of the air and stack gas are calculated from Equation (46.28) (with negligible kinetic and potential energy components) and listed to the left of the vertical dividing line.

It is sensible to analyze the power system based on the fuel energy and exergy input, in other words, to determine how this fuel input is distributed among the different system components and pro-

FIGURE 46.7 Energy and exergy breakdown for the Rankine power cycle example.

cesses. To that end we determine, per unit mass of fuel, the mass of cycle steam [here found to be 13.8 (kg steam)/(kg fuel) by applying the energy conservation equation to the boiler] and the mass of air and stack gas [20.6 (kg air)/(kg fuel) and 21.6 (kg exhaust gas)/(kg fuel) by applying Equation (46.10)]. These results are listed in the last two columns of the table.

Examination of the results is encouraged, and some of the most important ones, which describe the fuel energy and exergy distribution among the different system components/processes, are shown in Figure 46.7. *Energy* analysis indicates that the major energy loss, 70%, is due to the heat rejected in the condenser. Examination of the *exergy* analysis chart shows, however, that this large energy loss amounts to only 3% of the fuel exergy, and even complete elimination of the condenser heat rejection (if it were at all feasible) would increase the cycle efficiency by only three percentage points. Of course, this is because the heat rejected in the condenser is at a low temperature, only slightly elevated above that of the ambient, and thus has commensurately little potential to perform work despite its large energy. Another very significant difference is the fact that the exergy analysis identifies the major losses, 69%, to be in the boiler, due to the combustion and gas-to-steam/water heat transfer processes, whereas the energy analysis associates no loss to these processes. Finally, the exergy analysis attributes much less loss to the stack gas than the energy analysis does. Notably, the turbine output has almost the same percentage in both analyses, which is because the output is shaft power (i.e., pure exergy), and the HHV and exergy of the fuel are nearly identical. In conclusion, it is only exergy analysis that can correctly identify and evaluate the losses (irreversibilities) that diminish the ability of processes to perform useful work.

Example — Exergy Analysis of a Combustion Process

The methane combustor analyzed earlier, for which the data are given in Table 46.1, has a 100% energy efficiency because its enclosure is adiabatic and impermeable, as can also be ascertained by performing a first law energy conservation check using the data in Table 46.1. The intuitive implication of this result is that the combustor is thus perhaps “ideal” and requires no further technological improvement. It is interesting therefore to examine the effect that it has on the potential of the invested consumables (i.e., the fuel and other reactants) on producing useful work. The flow exergy a and the chemical exergy a_{ch} are calculated by using Equation (46.27), and property values from gas tables or correlations given in the literature, with the dead state (including the atmospheric composition) described at the bottom of Table 46.1. The calculation results are summarized in Table 46.1, showing, first, that the total exergy of the combustion products (642 281 kJ/mmol CH_4) is

only 78.4% of the original exergy of the reactants (818 984 kJ/kmol CH₄) that they possessed prior to combustion. This combustion process, although ideal from the energy standpoint, destroyed 21.6% of the original exergy. Practical combustion processes destroy even more exergy and are typically the largest cause for the lost work (irreversibility) in current-day fossil fuel power plants. Whereas energy (first law) analysis identified this process as “ideal,” exergy analysis was unique in its ability to recognize and quantify this power production efficiency loss, which we can subsequently attempt to reduce. More information on this approach and the reasons for combustion irreversibility can be found in Dunbar and Lior [1994].

Examination of Table 46.1 also shows that the exergy of the fuel is dominant among the reactants and that the chemical exergy, a_{ch} , is small relative to the overall exergy.

These examples have clearly demonstrated the unique role and importance of second law analysis. Integration of such analysis with conventional first law (energy) analysis is necessary and increasingly seen in practice [cf. Bejan, 1988; Moran and Shapiro, 1992].

Defining Terms

Adiabatic — A process or surface allowing only work interactions. Since most introductory thermodynamics texts consider only work and heat interactions, *adiabatic* is most often interpreted as a process or surface allowing no heat interactions.

Chemical potential — A potential given by $\mu_k \equiv h_k - Ts_k$, where h_k and s_k are, respectively, the enthalpy and entropy of the species k , and T is the temperature.

Cycle — A series of processes that bring a thermodynamic system back to its original state.

Enthalpy — Given by $h \equiv u + pv$, where u is the internal energy, p is the pressure, and v is the specific volume.

Environment — The environment of a thermodynamic system consists of everything outside of that system that could conceivably have some influence on it.

Equilibrium — A state in which all of the properties of a system that is not subjected to interactions do not change with time. Equilibrium states may be of various types: stable, neutral, metastable, and unstable.

Heat reservoir — A system in a stable equilibrium state such that, when subjected to finite heat interactions, its temperature remains constant. Although this is just a concept for simplifying the exposition of thermodynamics, the atmosphere, oceans, lakes, and rivers were often considered as practical examples of such a reservoir. It is noteworthy that the large and ever-increasing magnitudes of human-made heat interactions with these natural elements now invalidate their definition as “heat reservoirs” in this thermodynamic sense, because these interactions in fact change their temperature and cause increasingly adverse environmental effects.

Stable state — A system is in a stable state (or stable equilibrium state) if a finite change of state of the system cannot occur without leaving a corresponding finite change in the state of the environment. In other words a finite external influence would be needed to budge a system out of its stable state; small natural pulses and fluctuations would not suffice.

State — The state of a thermodynamic system is defined by all of the properties of the system, such as pressure, temperature, volume, composition, and so forth. A system returns to the same state when all the properties attain their original values.

Thermodynamic system — A thermodynamic system is whatever we enclose for the purpose of a study by a well-defined surface, which may be either material or imaginary and which can be isolated from everything else (i.e., from the “environment”).

The Thermodynamics of Solutions

Stanley I. Sandler
University of Delaware

Hasan Orbey
Deceased

- 47.1 Fundamentals
Real Liquid Mixtures — Excess Property Description • Real
Mixtures — Equation of State Description • Solutions in the
Solid Phase
- 47.2 Applications

It is important to know the thermodynamic properties of mixtures to be able to predict phase behavior such as vapor–liquid, liquid–liquid, vapor–liquid–liquid, and solid–liquid equilibria necessary to design separation and purification processes, to predict when a mixture will boil or will precipitate, and to estimate the equilibrium extents of homogeneous and heterogeneous chemical reactions. Also, mixture enthalpies are needed to design heat exchange equipment and entropies for compressor calculations.

47.1 Fundamentals

There are a collection of thermodynamic properties that describe a pure fluid such as the state variables temperature T and pressure P , and the system-intensive variables, specific volume (that is, the volume per mole of substance) v , specific internal energy u , specific enthalpy h , specific entropy s , specific Helmholtz energy a , and specific Gibbs energy g . The thermodynamics of mixtures would be relatively simple if, for any specific pure fluid thermodynamic variable Θ , the corresponding mixture property Θ_{mix} at the same temperature and pressure was

$$\Theta_{\text{mix}}(T, P, x_i) = \sum_i x_i \Theta_i(T, P) \quad (47.1)$$

where the subscripts i and mix indicate the property of pure component i and the mixture, respectively, and x_i is the mole fraction of species i . However, Equation (47.1) is not generally valid for several reasons. First, for the entropy and properties that depend on the entropy (such as the Gibbs energy $g = h - Ts$ and the Helmholtz energy $a = u - Ts$) an additional term arises because at constant temperature and pressure the volume available to a molecule of species i changes in the mixing process from the pure component volume $n_i v_i$ to the total volume of the mixture $n_i v_{\text{mix}}$. For a mixture of ideal gases $v_i = v_{\text{mix}} = RT/P$, and the additional term that appears is as follows:

$$\begin{aligned}
s_{\text{mix}}^{IG}(T, P, x_i) &= \sum_i x_i s_i^{IG}(T, P) - R \sum_i x_i \ln x_i \\
g_{\text{mix}}^{IG}(T, P, x_i) &= \sum_i x_i g_i^{IG}(T, P) + RT \sum_i x_i \ln x_i \\
a_{\text{mix}}^{IG}(T, P, x_i) &= \sum_i x_i a_i^{IG}(T, P) + RT \sum_i x_i \ln x_i
\end{aligned} \tag{47.2}$$

The simplest liquid mixture is an ideal mixture (denoted by the superscript *IM*) for which Equation (47.1) is valid for the internal energy and volume *at all temperatures and pressures*, that is,

$$\begin{aligned}
v_{\text{mix}}^{IM}(T, P, x_i) &= \sum_i x_i v_i(T, P) \\
h_{\text{mix}}^{IM}(T, P, x_i) &= \sum_i x_i h_i(T, P)
\end{aligned} \tag{47.3}$$

In this case, one can show [Sandler, 1999] that for an ideal mixture

$$\begin{aligned}
s_{\text{mix}}^{IM}(T, P, x_i) &= \sum_i x_i s_i(T, P) - R \sum_i x_i \ln x_i \\
g_{\text{mix}}^{IM}(T, P, x_i) &= \sum_i x_i g_i(T, P) + RT \sum_i x_i \ln x_i \\
a_{\text{mix}}^{IM}(T, P, x_i) &= \sum_i x_i a_i(T, P) + RT \sum_i x_i \ln x_i
\end{aligned} \tag{47.4}$$

Although Equation (47.4) is similar to Equation (47.2), there is an important difference. Here, the pure component and mixture properties are those of the real liquid at the temperature and pressure of the mixture, not those of ideal gases.

Equation (47.2) may not apply to real gases because they are not ideal gases. Also, Equation (47.4) does not apply to most liquid mixtures since Equation (47.3) is not, in general, valid. Another difficulty that arises is that at the temperature and pressure of interest, the pure components may not exist in the same state of aggregation as the mixture. An example of this is a mixture containing a dissolved gas or dissolved solid in a liquid.

To describe the thermodynamic behavior of a condensed phase (liquid or solid), either an excess property model or equation-of-state model may be used, depending on the mixture. For a vapor mixture, an equation of state is generally used. Both these descriptions are reviewed below.

Real Liquid Mixtures — Excess Property Description

For a liquid mixture formed by mixing pure liquids at constant temperature and pressure the following description is used:

$$\Theta_{\text{mix}}(T, P, x_i) = \Theta_{\text{mix}}^{IM}(T, P, x_i) + \Theta^{EX}(T, P, x_i) \tag{47.5}$$

Here, $\Theta^{EX}(T, P, x_i)$ is the additional change in the thermodynamic property when mixing the pure components above that on forming an ideal mixture. This excess thermodynamic property change on mixing is a function of temperature, pressure, and mixture composition. Expressions for several thermodynamic properties of real mixtures are given below:

$$\begin{aligned}
v_{\text{mix}}(T, P, x_i) &= \sum_i x_i v_i(T, P) + v^{\text{EX}}(T, P, x_i) \\
u_{\text{mix}}(T, P, x_i) &= \sum_i x_i u_i(T, P) + u^{\text{EX}}(T, P, x_i) \\
s_{\text{mix}}(T, P, x_i) &= \sum_i x_i s_i(T, P) - R \sum_i x_i \ln x_i + s^{\text{EX}}(T, P, x_i) \\
g_{\text{mix}}(T, P, x_i) &= \sum_i x_i g_i(T, P) + RT \sum_i x_i \ln x_i + g^{\text{EX}}(T, P, x_i) \\
a_{\text{mix}}(T, P, x_i) &= \sum_i x_i a_i(T, P) + RT \sum_i x_i \ln x_i + a^{\text{EX}}(T, P, x_i)
\end{aligned} \tag{47.6}$$

An important concept in mixture solution thermodynamics is the partial molar property $\bar{\Theta}_i(T, P, x_i)$, defined as follows:

$$\bar{\Theta}_i(T, P, x_i) = \left(\frac{\partial n_i \Theta_{\text{mix}}}{\partial n_i} \right)_{T, P, n_j \neq i} \tag{47.7}$$

Any solution property that is linear and homogeneous in the number of moles is related to its partial molar properties as follows [Van Ness, 1964]:

$$\Theta_{\text{mix}}(T, P, x_i) = \sum_i x_i \bar{\Theta}_i(T, P, x_i) \tag{47.8}$$

Also, from Equation (47.6),

$$\bar{\Theta}_i(T, P, x_i) = \bar{\Theta}_i^{\text{IM}}(T, P, x_i) + \bar{\Theta}_i^{\text{EX}}(T, P, x_i) \tag{47.9}$$

From this we have, as examples,

$$\begin{aligned}
\bar{v}_i(T, P, x_i) &= v_i(T, P) + \bar{v}_i^{\text{EX}}(T, P, x_i) \\
\bar{u}_i(T, P, x_i) &= u_i(T, P) + \bar{u}_i^{\text{EX}}(T, P, x_i) \\
\bar{s}_i(T, P, x_i) &= s_i(T, P) - R \ln x_i + \bar{s}_i^{\text{EX}}(T, P, x_i) \\
\bar{g}_i(T, P, x_i) &= g_i(T, P) + RT \ln x_i + \bar{g}_i^{\text{EX}}(T, P, x_i)
\end{aligned} \tag{47.10}$$

By definition, all excess properties must vanish in the limit of a pure component. Generally, a species excess partial molar property has its largest value when that species is at infinite dilution.

Several other thermodynamic variables of special interest are the chemical potential, μ_i ,

$$\begin{aligned}
\mu_i(T, P, x_i) &= \mu_i^\circ(T, P) + RT \ln x_i(T, P, x_i) + \bar{g}_i^{\text{EX}}(T, P, x_i) \\
&= \mu_i^\circ(T, P) + RT \ln x_i \gamma_i(T, P, x_i)
\end{aligned} \tag{47.11}$$

the activity, a_i ,

$$a_i(T, P, x_i) = \exp\left(\frac{\mu_i - \mu_i^o}{RT}\right) \quad (47.12)$$

the activity coefficient, γ_i ,

$$\gamma_i(T, P, x_i) = \exp\left(\frac{\bar{g}_i^{EX}(T, P, x_i)}{RT}\right) \quad (47.13)$$

the fugacity, f_i ,

$$RT \ln \left(\frac{\hat{f}_i(T, P, x_i)}{\hat{f}_i^o(T, P)} \right) = \mu_i(T, P, x_i) - \mu_i^o(T, P) \quad (47.14)$$

and the fugacity coefficient, $\hat{\phi}_i$,

$$\hat{\phi}_i(T, P, x_i) = \frac{\hat{f}_i}{x_i P} \quad (47.15)$$

In the definitions above, μ_i^o is the chemical potential of pure species i at the temperature, pressure, and state of aggregation of the mixture, and f_i^o is its fugacity in that state; this pure component state is referred to as the standard state for the component. Also, $\gamma_i(x_i \rightarrow 1) = 1$. If the pure species does not exist in the same state of aggregation as the mixture, as with a gas or solid dissolved in a liquid solvent, then other standard states are chosen. For example, if a hypothetical pure component state is chosen as the standard state with properties extrapolated based on the behavior of the component at infinite dilution, then

$$\mu_i(T, P, x_i) = \mu_i^*(T, P) + RT \ln(x_i \gamma_i^*) \quad (47.16)$$

where μ_i^* is the chemical potential in this so-called Henry's law standard state and γ_i^* is an activity coefficient defined so that $\gamma_i^*(T, P, x_i \rightarrow 0) = 1$. Another choice for the standard state of such components is the hypothetical ideal 1 molal solution, which is commonly used for electrolytes and other compounds.

The excess properties have generally been determined by experiment and then fitted to algebraic equations. These equations must satisfy the boundary condition of vanishing in the limit of a mixture going to a pure component. That is, in a binary mixture, $\Theta^{EX}(T, P, x_i)$ must go to zero as either $x_1 \rightarrow 1$ or $x_2 \rightarrow 1$. One solution model of historical interest is the strictly regular solution model, for which $u^{EX} = g^{EX} = x_1 x_2 \omega$ and $s^{EX} = 0$, where, from simple molecular theory, ω is the exchange energy that is the net difference on interchanging molecules between the pure species and the mixture. Another model is the athermal solution model, for which there is no excess internal energy change of mixing — that is, $u^{EX} = 0$ — but there is an excess entropy change so that $g^{EX} = -Ts^{EX}$. Most excess property models currently in use are a combination of an athermal part to account for the entropy change on mixing and a modified regular solution part to account for energy change on mixing. Several excess property models are listed in Table 47.1. There are also excess property models that are predictive (instead of merely correlative), such as the UNIFAC and ASOG models. These are described in detail elsewhere [Fredenslund et al. 1977; Sandler, 1999].

Because the electrostatic interactions between charged particles are so much stronger and longer range than between neutral molecules, electrolyte solutions are very nonideal. Consequently, specialized models, generally based on generalized Debye–Hückel theory, are used for electrolyte solutions [Sandler, 1999].

TABLE 47.1 Excess Gibbs Energy and Activity Coefficient Models*The two-constant Margules equation*

$$g^{EX} = x_1 x_2 \{A + B(x_1 - x_2)\}$$

which leads to

$$RT \ln \gamma_1 = \alpha_1 x_2^2 + \beta_1 x_2^3 \quad \text{and} \quad RT \ln \gamma_2 = \alpha_2 x_1^2 + \beta_2 x_1^3$$

with $\alpha_i = A + 3(-1)^{i+1}B$ and $\beta_i = 4(-1)^i B$.*The van Laar model*

$$g^{EX} = x_1 x_2 \frac{2a q_1 q_2}{x_1 q_1 + x_2 q_2}$$

which leads to

$$\ln \gamma_1 = \frac{\alpha}{\left[1 + \frac{\alpha x_1}{\beta x_2}\right]^2} \quad \text{and} \quad \ln \gamma_2 = \frac{\beta}{\left[1 + \frac{\beta x_2}{\alpha x_1}\right]^2}$$

with $\alpha = 2q_1 a$ and $\beta = 2q_2 a$.*The nonrandom two-liquid (NRTL) model*

$$\frac{g^{EX}}{RT} = x_1 x_2 \left(\frac{\tau_{21} G_{21}}{x_1 + x_2 G_{21}} + \frac{\tau_{12} G_{12}}{x_2 + x_1 G_{12}} \right)$$

which leads to

$$\ln \gamma_1 = x_2^2 \left[\tau_{21} \left(\frac{G_{21}}{x_1 + x_2 G_{21}} \right)^2 + \frac{\tau_{12} G_{12}}{(x_2 + x_1 G_{12})^2} \right]$$

and

$$\ln \gamma_2 = x_1^2 \left[\tau_{12} \left(\frac{G_{12}}{x_1 G_{12} + x_2} \right)^2 + \frac{\tau_{21} G_{21}}{(x_1 + x_2 G_{12})^2} \right]$$

with $\ln G_{12} = -\alpha \tau_{12}$ and $\ln G_{21} = -\alpha \tau_{21}$.*The Flory-Huggins model* (for polymer solutions)

$$\frac{g^{EX}}{RT} = x_1 \ln \frac{\phi_1}{x_1} + x_2 \ln \frac{\phi_2}{x_2} + \chi(x_1 + m x_2) \phi_1 \phi_2$$

which leads to

$$\ln \gamma_1 = \ln \frac{\phi_1}{x_1} + \left(1 - \frac{1}{m}\right) \phi_2 + \chi \phi_2^2 \quad \text{and} \quad \ln \gamma_2 = \ln \frac{\phi_2}{x_2} + (m-1) \phi_1 + \chi \phi_1^2$$

with $\phi_1 = x_1 / (x_1 + m x_2)$ and $\phi_2 = m x_2 / (x_1 + m x_2)$.

Real Mixtures — Equation of State Description

Whereas the excess property description is used for the thermodynamic description of solids and liquids, a volumetric equation of state is typically used for vapor mixtures and may be used for liquid mixtures

of hydrocarbons (including with light gases). The simplest volumetric equation of state is the ideal gas (which may be applicable only at low pressures):

$$P = \frac{RT}{v} \quad (47.17)$$

where R is the gas constant. The first equation of state that qualitatively described both vapors and liquids was that of van der Waals [1890]:

$$P = \frac{RT}{v-b} - \frac{a}{v^2} \quad (47.18)$$

Here b is interpreted as the hard-core volume of the molecules, and a is a parameter that represents the strength of the attractive interaction energy. Consequently, the first term results from molecular repulsions, and the second term from attractions. Many equations of state now used have this same structure, such as the Redlich–Kwong and Peng–Robinson equations:

$$P = \frac{RT}{v-b} - \frac{a(T)}{v(v+b)} \quad P = \frac{RT}{v-b} - \frac{a(T)}{v(v+b)+b(v-b)} \quad (47.19)$$

where the a parameter has been made a function of temperature to better describe the pure component vapor pressure.

In order to apply equations of state developed for pure components to mixtures, expressions are needed that relate the mixture parameters, such as a and b above, to those of the pure fluids. This is done using mixing and combining rules. The simplest mixing rules are those of van der Waals:

$$a_{\text{mix}} = \sum_i \sum_j x_i x_j a_{ij} \quad \text{and} \quad b_{\text{mix}} = \sum_i \sum_j x_i x_j b_{ij} \quad (47.20)$$

The most commonly used combining rules are

$$b_{ij} = \frac{1}{2}(b_{ii} + b_{jj}) \quad \text{and} \quad a_{ij} = \sqrt{a_{ii} a_{jj}} (1 - k_{ij}) \quad (47.21)$$

where a_{ii} and b_{ii} are pure component equation of state parameters and k_{ij} is an adjustable parameter. These mixing rules are applied to vapor and liquid mixtures of hydrocarbons, including light gases; more complicated rules that combine equations of state and activity coefficient models are needed for the accurate description of mixtures containing polar compounds. A recent review of equations of state and their mixing and combining rules can be found in Sandler [1994].

Once the volumetric equation of state for a mixture has been specified, the fugacity of each species in the mixture can be computed using the rigorous thermodynamic relation

$$\begin{aligned} RT \ln \hat{\phi}_i(T, P, x_i) &= \int_0^P \left(\bar{v}_i - \frac{RT}{P} \right) dP \\ &= \int_V^\infty \left[\left(\frac{\partial P}{\partial n_i} \right)_{T, V, n_j \neq i} - \frac{RT}{V} \right] dV - RT \ln Z \end{aligned} \quad (47.22)$$

Here, $Z = Pv/RT$ is the compressibility factor, \bar{v}_i is partial molar volume of component as calculated from an equation of state, V is total volume, and n is the number of moles. The analytic expressions specific to various equations of state and their mixing rules can be found in Sandler [1999].

Solutions in the Solid Phase

Various solid solutions are encountered in engineering applications. In some cases, pure solids can exist in more than one form (for example, sulfur in rhombic and monoclinic allotropic forms, or carbon in diamond and in graphite forms), with each phase exhibiting different physical characteristics. In such cases, equilibrium may exist between the pure solid phases. Solids may also form compounds, and solutions of these compounds are common in metallurgical applications. These phenomena are beyond the scope of this chapter and the reader is referred to other sources [Gaskell, 1981; Kyle, 1992; Sandler, 1999].

47.2 Applications

The fundamental principle of equilibrium between two phases in contact is that the temperature, pressure, and chemical potentials of each species must be identical in both phases. This principle results in the following relation for vapor–liquid equilibrium [Sandler, 1999] of mixtures of condensible liquids when one of the activity coefficient models discussed earlier is used for the liquid phase:

$$x_i \gamma_i(T, P, x_i) \hat{f}_i^o(T, P, x_i) = y_i \hat{\phi}_i(T, P, y_i) P \quad (47.23)$$

To use this equation, an appropriate reference state for the liquid phase must be selected, which dictates the term \hat{f}_i^o , and the fugacity coefficient in the gas phase, $\hat{\phi}_i$, is evaluated from an equation of state. If the liquid phase is ideal ($\gamma_i = 1$ and $\hat{f}_i^o = P_i^{\text{vap}}$, which is the pure component vapor pressure) and the gas phase is an ideal gas mixture, the well-known Raoult's law is obtained:

$$x_i P_i^{\text{vap}} = y_i P \quad \text{and} \quad \sum_i x_i P_i^{\text{vap}} = P \quad (47.24)$$

For liquid–liquid phase separation the equilibrium relation is

$$x_i^{\text{I}} \gamma(T, x_i^{\text{I}}) = x_i^{\text{II}} \gamma(T, x_i^{\text{II}}) \quad (47.25)$$

where I and II refer to the coexisting equilibrium liquid phases. This equation has to be solved for each species, with activity coefficients obtained from the models above.

In the case where both phases can be described by an equation of state, the equation of vapor–liquid equilibrium is

$$x_i \hat{\phi}_i^{\text{L}}(T, P, x_i) = y_i \hat{\phi}_i^{\text{V}}(T, P, y_i) \quad (47.26)$$

where the fugacity coefficient of each species in each phase is calculated from Equation (47.22) and an equation of state. Note that a cubic equation of state such as Equation (47.19) may have three roots for the volume or compressibility factor at the pressure of interest and at temperatures below the critical temperature. In this case, the smallest root and the liquid compositions are used for the evaluation of the liquid phase fugacity coefficients, and the largest volume root and the vapor phase compositions are used for the calculation of the vapor phase fugacity coefficients.

In most phase equilibrium calculations, the compositions of both phases are not known in advance, so regardless of whether the activity coefficient or equation of state description is used, the solution must be found by iteration. Detailed discussions of the application of equations of state and activity coefficient

models to phase equilibrium problems, and the algorithms used in their solution, can be found in Chapter 49 and in thermodynamics textbooks [e.g., Kyle, 1992; Chapter 8 of Sandler, 1999]. Calculations of equilibria of solids with solids, liquids, or vapors are important for heterogeneous chemical reactions, precipitation from solutions, and metallurgical applications. These cases are beyond the scope of this chapter and can be found elsewhere [Kyle, 1992; Gaskell, 1981; Sandler, 1999].

Defining Terms

Activity coefficient, γ_i — A term that accounts for the nonideality of a liquid mixture; related to the excess partial molar Gibbs energy.

Athermal solution — A mixture in which the excess internal energy of mixing is zero.

Chemical potential, μ_i — Equal to the partial molar Gibbs energy.

Equation of state — An equation relating the volume, temperature, and pressure of a pure fluid or mixture.

Excess property, $\Theta^{EX}(T, P, x_i)$ — The additional change in a thermodynamic property on forming a mixture from the pure components above that on forming an ideal mixture.

Fugacity, f_i , and fugacity coefficient, $\hat{\phi}_i$ — Terms related to the partial molar Gibbs energy or chemical potential that are computed from an equation of state.

Mixing rule — Equations to compute the parameters in a mixture equation of state from those for the pure components.

Partial molar property, $\bar{\Theta}_i(T, P, x_i)$ — The contribution to a thermodynamic property of a mixture made by adding a small amount on component i , reported on a molar basis.

Regular solution — A mixture in which the excess entropy of mixing is zero.

William B. Krantz
University of Colorado

In writing this brief overview it was necessary to focus on those aspects of the thermodynamics of surfaces that are of considerable importance in engineering applications and that could be summarized well in this compact format. We begin by considering the basic concepts of the interface as a surface, curvature, and the generalized Gibbs phase rule. The generalized first law of thermodynamics is then stated, which forms the basis for subsequent considerations of work done on or by interfaces. The implications of surface curvature on capillary pressure, vapor pressure and solubility, and phase transition temperature are reviewed. Adsorption at interfaces is then considered with a brief introduction to surface equations of state. The first law is then used to introduce the subjects of wettability, adhesion, and contact angles. Unfortunately, space does not permit reviewing adequately other important areas involving the thermodynamics of surfaces, such as electrical aspects of surface chemistry, nucleation and growth phenomena, colloids, emulsions, foams, aerosols, and thin films. An excellent overview of these and other topics in surface science is provided in Adamson [1990].

48.1 Basic Concepts

The Interface

Two bulk phases in contact will be separated by a thin region within which the intensive thermodynamic properties change continuously from those of the one phase to those of the other. Since this region is typically only a few nanometers thick, we replace it with a surface whose thermodynamic properties are assigned to conserve the extensive thermodynamic properties of the overall system composed of the interface and the two bulk phases, which now are assumed to maintain their bulk properties up to the dividing surface. There are several conventions used to locate the dividing plane, henceforth to be

referred to as the *interface*; however, the interfacial intensive thermodynamic properties are independent of its location.

An interface can exist between a liquid and a gas (L/G interface), two liquid phases (L/L), a liquid and a solid (L/S), a gas and a solid (G/S), or two solid phases (S/S). Interfaces between fluid phases frequently can be assumed to be at equilibrium. However, interfaces formed with a solid phase often cannot be described by equilibrium thermodynamics, owing to slow diffusion in solids.

Curvature

The interface between two fluids takes on solidlike properties in that it can sustain a state of stress characterized by the *surface tension*. Consequently, a pressure drop can be sustained across curved interfaces, which increases with their curvature. The latter is uniquely defined at a point on the interface by the curvatures in two mutually perpendicular directions. The curvature C of an interface in a given plane is defined by

$$C \equiv \bar{n} \cdot \frac{d\bar{t}}{ds} \quad (48.1)$$

where \bar{n} and \bar{t} are the normal and tangential unit vectors at a point and s is the arc length along the curved interface. For a curved surface described in rectangular Cartesian coordinates by $y = y(x, z)$, Equation (48.1) implies the following for the curvatures in the yx and yz planes:

$$C_{xy} = \frac{y_{xx}}{(1 + y_x^2)^{3/2}} \quad (48.2)$$

$$C_{zy} = \frac{y_{zz}}{(1 + y_z^2)^{3/2}} \quad (48.3)$$

where y_c and y_{cc} denote the first and second partial derivatives of y with respect to c ($c = x$ or z). For axisymmetric bodies the two curvatures C_1 and C_2 can be represented solely in terms of y_x and y_{xx} :

$$C_1 = \frac{y_{xx}}{(1 + y_x^2)^{3/2}} \quad (48.4)$$

$$C_2 = \frac{y_x}{x(1 + y_x^2)^{1/2}} \quad (48.5)$$

Let us determine the curvature of a sphere of radius r defined by $x^2 + y^2 + z^2 = r^2$. Equation (48.4) and Equation (48.5) then give $C_1 = C_2 = -r^{-1}$; that is, the curvature is equal to the reciprocal of the radius of the sphere. The negative sign follows the convention that the curvature is viewed as if one is looking at the surface down the y axis. The curvature is positive when viewed from the concave side (e.g., interior of the sphere) and negative when viewed from the convex side.

The Gibbs Phase Rule

The Gibbs phase rule specifies the number of thermodynamic intensive variables f required to uniquely determine the thermodynamic state of the system. The phase rule is derived by adding up the intensive variables and then subtracting the number of independent relationships between them. For a system containing c components distributed between p phases separated by curved interfaces, the phase rule is given by

$$f = c + 1 \quad (48.6)$$

Equation (48.6) differs from the phase rule for bulk systems for which $f = c - p + 2$ because the p phases can sustain different pressures, owing to the interfacial curvature. For example, this generalized phase rule implies that a droplet of pure liquid water in equilibrium with its own vapor requires two intensive thermodynamic variables to be specified in order to determine its boiling point. Specifying the liquid and gas phase pressures, which is equivalent to specifying the curvature of the drop, is then sufficient to determine a unique boiling point.

48.2 First Law of Thermodynamics

Consider two contacting multicomponent phases α and β separated by a single interface having area A . The generalized first law of thermodynamics is then given by

$$\begin{aligned} dU &= T dS - P^\alpha dV^\alpha - P^\beta dV^\beta + \gamma dA + \sum_i \mu_i dN_i \\ &= dQ - dW + \sum_i \mu_i dN_i \end{aligned} \quad (48.7)$$

where U , S , and N_i are the total system internal energy, entropy, and moles of species i , respectively; T is the absolute temperature; μ_i is the chemical potential of i ; P^p and V^p are the pressure and total volume of phase p ($p = \alpha$ or β); γ is the surface tension, an intensive thermodynamic property having units of energy per unit area (J/m^2) or force per unit length (N/m); $dQ = T dS$ is the heat transferred to the system; and $dW = P^\alpha dV^\alpha + P^\beta dV^\beta - \gamma dA$ is the work done by the system. Hence, changing the interfacial area can result in work being done on or by the system.

48.3 Effects of Curved Interfaces

Young and Laplace Equation

Consider the simplification of Equation (48.7) for an isolated system at equilibrium (that is, $dU = dS = dN_i = 0$). For an arbitrary displacement of the interface between α and β , $dA = (C_1 + C_2) dV^\alpha$ and $dV^\alpha = -dV^\beta$; hence,

$$\Delta P \equiv P^\alpha - P^\beta = \gamma(C_1 + C_2) \quad (48.8)$$

Equation (48.8), the Young and Laplace equation, predicts a pressure drop across a curved interface, which is referred to as a *capillary pressure effect*. For planar interfaces, $\Delta P = 0$, whereas for spherical liquid drops having a radius r , $\Delta P = 2\gamma/r$. Note the pressure is higher on the concave (positive curvature) side of the interface.

As an example of the use of Equation (48.8) consider the force required to separate two glass plates between which $V = 1$ ml of water is spread to a thickness of $H = 10 \mu\text{m}$, as shown in [Figure 48.1](#). Since $C_2 \ll C_1$, we have

$$F = \Delta P A = \gamma C_1 \frac{V}{H} = \frac{2(72.94 \cdot 10^{-3} \text{ N/m})(1 \cdot 10^{-6} \text{ m}^3)}{(10 \cdot 10^{-6} \text{ m})^2} = 1459 \text{ N (328 lbf)} \quad (48.9)$$

Capillary pressure effects can be quite large and account for phenomena such as the cohesiveness of wet soils.

FIGURE 48.1 A wetting liquid between two parallel glass plates: $C = r^{-1} = H/2$.

FIGURE 48.2 Capillary rise of a wetting liquid β in an ambient gas phase α : $C_1 = C_2 = r^{-1}$.

As a second example, consider the placing of a capillary tube vertically into a wetting liquid (one having a convex interface when viewed through the liquid) as shown in Figure 48.2; the liquid will rise until the pressure drop across the curved interface is equal to the hydrostatic pressure exerted by the liquid column of height h ; that is,

$$\Delta P = \frac{2\gamma}{r} = \Delta\rho gh \quad (48.10)$$

where $\Delta\rho$ is the density difference between the liquid (phase β) and the ambient fluid (phase α), and g is the gravitational acceleration. For example, a $1\ \mu\text{m}$ capillary can draw water to a height of 30 m (98 ft) in air. Capillary rise is involved in absorbent wicking and also is used as a method for measuring L/G and L/L surface tensions.

As a third example, consider the insertion of a capillary tube containing an insoluble gas vertically into a wetting liquid. If the volume of the gas is slowly increased, the curvature of the L/G interface will adjust to satisfy Equation (48.8). The gas-phase pressure will pass through a maximum when the bubble radius is equal to the tube radius. This is the basis of the maximum bubble pressure method for determining surface tensions.

The Kelvin Equation

The Young and Laplace equation also implies that liquids bounded by an interface having positive curvature will exert a higher vapor pressure P^v than that exerted by liquids bounded by a planar interface P_o^v ; these two vapor pressures are related by the Kelvin equation:

$$P^v = P_o^v \exp\left(\frac{2\gamma\bar{V}_l}{RT r}\right) \quad (48.11)$$

where \bar{V}_l is the molar volume of the liquid and R is the gas constant. A water droplet having a radius of $0.01\ \mu\text{m}$ will have a $P^v = 1.11P_o^v$. The Kelvin equation can also be applied to S/L systems to predict the increased solubility of small crystals in solution. Equation (48.11) explains the formation of supersaturated vapors and Ostwald ripening whereby large crystals grow at the expense of small crystals. It also explains the falling rate period in drying during which water must be removed from progressively smaller pores, causing reduced vapor pressures.

The Gibbs–Thompson Equation

The Young and Laplace equation also implies that wetting liquids in small capillaries will have a lower freezing temperature T than the normal freezing temperature T_o ; these two freezing temperatures are related by the Gibbs–Thompson equation:

$$T = T_o - \frac{\gamma T_o \bar{V}_s}{\Delta H^f} (C_1 + C_2) \quad (48.12)$$

where \bar{V}_s is the molar volume of the solid phase and ΔH^f is the latent heat of fusion. Water in a capillary having a radius $0.01 \mu\text{m}$ will freeze at -5.4°C . Equation (48.12) explains why freezing in wet soils occurs over a zone rather than at a discrete plane.

48.4 Adsorption at Interfaces

The Gibbs Adsorption Equation

The interfacial concentration $\Gamma_i \equiv N_i^s / A$ — where N_i^s denotes the moles of i in the interface — depends on the location of the interface. It can be determined from the concentration dependence of the surface tension using the Gibbs adsorption equation, which is the interfacial analogue of the Gibbs–Duhem equation derived from the generalized first law and given by

$$d\gamma = - \sum_i \Gamma_i d\mu_i \quad (48.13)$$

Consider determining the interfacial concentration for the special case of a binary ideal solution for which the surface tension is a linear function of the bulk concentration of solute, c_2 , given by $\gamma = \gamma_o - bc_2$. We will locate the interface to ensure no net adsorption of solvent 1; that is, $\Gamma_1 = 0$. This is the commonly used Gibbs convention for locating the dividing surface. Hence, Equation (48.13) implies that the interfacial concentration of solute in this convention, Γ_2^1 (where the superscript 1 denotes the Gibbs convention), is given by

$$\Gamma_2^1 = - \frac{\partial \gamma}{\partial \mu_2} = - \frac{N_2}{RT} \frac{\partial \gamma}{\partial N_2} = \frac{bc_2}{RT} = \frac{\gamma_o - \gamma}{RT} = \frac{\pi}{RT} \quad (48.14)$$

where $\pi \equiv \gamma_o - \gamma$ is referred to as the *surface pressure*, having units of force per unit length. Equation (48.14) implies that $\pi \sigma_i = RT$, where $\sigma_i \equiv 1/\Gamma_2^1$ is the area per mole of solute in the interface. This is a two-dimensional analogue to the familiar ideal gas law. Hence, by analogy one would expect a linear dependence of surface tension on bulk concentration at low surface pressures where intermolecular forces and the size of the molecules can be ignored. The two-dimensional equations of state are used to describe the $\pi - \sigma_i - T$ behavior of interfaces just as the three-dimensional analogues are used to describe the $P - V - T$ behavior of bulk phases.

Note that $b > 0 \Rightarrow \pi > 0 \Rightarrow \Gamma_2^1 > 0$; that is, surface tension decreasing with increasing solute concentration implies positive adsorption of the solute at the interface. Solutes displaying positive adsorption are said to be *surface-active* and are referred to as *surfactants*. Surfactants are used to alter the wettability of surfaces in applications such as the manufacture of cleaning detergents and tertiary oil recovery. If $b < 0 \Rightarrow \pi < 0 \Rightarrow \Gamma_2^1 < 0$, negative adsorption occurs; this is characteristic of ionizing salts in aqueous solution, which avoid the air/water interface, which has a lower dielectric constant.

If the surface pressure is eliminated from the equation of state using the prescribed equation for the surface tension dependence on bulk concentration, one obtains a relationship between the surface and bulk concentrations referred to as the *adsorption isotherm*. The Gibbs adsorption equation provides the

FIGURE 48.3 Spreading of liquid 1 on liquid 2 in the presence of gas or liquid 3.

link between the interfacial equation of state, the adsorption isotherm, and the surface tension dependence on bulk concentration.

48.5 Wettability and Adhesion

Wetting and Spreading

Wetting relates to the propensity of a liquid to spread over another liquid or a solid. Consider the spreading of liquid 1 on liquid 2 in the presence of gas or liquid 3, as shown in Figure 48.3, to create dA of interface between 1 and 2 and between 1 and 3 while destroying dA of interface between 2 and 3. Equation (48.7) implies that the reversible work of spreading dW_s/dA at constant T and P is given by

$$\frac{dW}{dA} = -\gamma_{12} - \gamma_{13} + \gamma_{23} \equiv S_{12} \quad (48.15)$$

where γ_{ij} denotes the surface tension between phases i and j and S_{12} is defined as the *spreading coefficient* of phase 1 on phase 2. Note that if $dW/dA = S_{12} > 0$, spreading will occur spontaneously since work can be done by the system to increase the contact area between phases 1 and 2. Consider the spreading of heptane (1) on water (2) in air (3) at 20°C, for which $\gamma_{12} = 50.2$ mN/m, $\gamma_{13} = 20.14$ mN/m, and $\gamma_{23} = 72.94$ mN/m. Hence, $dW/dA = S_{12} = 2.6$ mN/m, and we conclude that spreading will occur spontaneously. Wetting is an important consideration in developing coatings of various types, solders and welding fluxes, water-repellent fabrics, and so on.

Adhesion and Cohesion

Adhesion relates to the cohesiveness of the “bond” between two contacting phases. A measure of this property is the work of adhesion W_{ad} , the work that must be done on the system to separate the two phases in contact. Consider the separation of phase 1 from phase 2 in the presence of phase 3, as shown in Figure 48.4, to create dA of interface between 1 and 3 and between 2 and 3 while destroying dA of interface between 1 and 2. Equation (48.7) implies that the reversible work of adhesion W_{ad} at constant T and P is given by

$$W_{ad} = -\frac{dW}{dA} = \gamma_{13} + \gamma_{23} - \gamma_{12} \quad (48.16)$$

A special case of the above is the work of cohesion W_{co} , which is the work required to separate a single phase 1 in the presence of phase 3, thereby creating two interfaces between phases 1 and 3. Equation (48.16) implies that

$$W_{co} = -\frac{dW}{dA} = \gamma_{13} + \gamma_{13} = 2\gamma_{13} \quad (48.17)$$

FIGURE 48.4 Work of adhesion necessary to separate phase 1 from phase 2 in the presence of phase 3.

FIGURE 48.5 A drop of phase 1 resting on phase 2 in the presence of phase 3, showing the contact angle θ .

Comparison of Equation (48.15), Equation (48.16), and Equation (48.17) indicates that $S_{12} = W_{ad} - W_{co}$; that is, the spreading coefficient is equal to the difference between the work of adhesion and cohesion. Adhesion is involved in developing bonding materials, laminates, paints, printing inks, and so on.

Contact Angles

If phase 1 completely “wets” phase 2 in the presence of phase 3, it will spread over phase 2. If phase 1 does not wet phase 2, it will form a drop having a contact angle θ , where θ is measured from the interface between phases 1 and 2 through phase 1 to the tangent line at the contact line between phases 1, 2, and 3, as shown in Figure 48.5. The contact angle is an intensive thermodynamic property of the system uniquely determined by the surface tensions via Young’s equation, given by

$$\gamma_{12} - \gamma_{23} + \gamma_{33} \cos\theta = 0 \quad (48.18)$$

If $\theta = 0$, phase 1 is said to *wet* phase 2; if $\theta > 90^\circ$, phase 1 is said to be *nonwetting* to phase 2 in the presence of phase 3. Equation (48.16) can be combined with Equation (48.18) to obtain

$$W_{ad} = \gamma_{13}(1 + \cos\theta) \quad (48.19)$$

Equation (48.19) implies that the work of adhesion of phase 1 to phase 2 can be obtained by merely measuring the interfacial tension γ_{13} and the contact angle of phase 1 on phase 2 in the presence of phase 3. This provides a simple means for determining the strength of adhesion between two materials.

Defining Terms

Capillary pressure effects — A pressure difference sustained across curved interfaces owing to surface tension.

Contact angle — The angle measured through a liquid phase to the tangent at the contact line where three phases meet.

Interface — A dividing surface between two phases to which intensive thermodynamic properties are assigned that satisfy the conservation of extensive thermodynamic properties of the overall system consisting of the interface and the two bulk phases whose intensive properties are assumed to persist up to the dividing plane.

Surface tension — An intensive property of an interface that characterizes the distinct energy state whereby it sustains a tensile stress at equilibrium.

Surfactants — Solutes that have a propensity to positively adsorb at the interface.

Benjamin G. Kyle
Kansas State University

The best way to understand the rationale underlying the application of thermodynamics to phase equilibrium is to regard thermodynamics as a method or framework for processing experimentally gained information. From known properties for the system under study (information), other properties may be determined through the network of thermodynamic relationships. Thus, information about a system can be extended. The thermodynamic framework is also useful for conceptualizing and analyzing phase equilibrium. This allows extrapolation and interpolation of data and the establishment of correlations as well as evaluation and application of theories based on molecular considerations.

For the most part, the variables of interest in phase equilibrium are intensive: temperature, pressure, composition, and specific or molar properties. The phase rule determines the number of intensive variables, F , required to define a system containing π phases and C components.

$$F = C + 2 - \pi \quad (49.1)$$

The thermodynamic network also contains other intensive variables such as **fugacity** and the activity coefficient, which are necessary for computational purposes but possess no intrinsic value; they are simply useful thermodynamic artifacts. Specifically, the basis for the thermodynamic treatment of phase equilibrium is the equality of the fugacity of each component in each phase in which it exists.

49.1 Pure-Component Phase Equilibrium

Equilibrium between phases of a pure component can be visualized with the aid of [Figure 49.1](#), which shows areas in the pressure–temperature (PT) plane labeled S, L, and V and representing conditions where, respectively, solid, liquid, and vapor exist. In accordance with the phase rule, specification of two intensive variables (here, T and P) is required to define the state of the system. Conditions where two phases are in equilibrium are represented on this diagram by lines (such as ab , bc , and bd) and therefore only one variable need be specified. The intersection of three lines results in a triple point, where three phases are in equilibrium and no variables may be specified. Some systems exhibit more than one triple point.

FIGURE 49.1 Pressure-temperature graph of pure-component phase equilibrium.

The Clapeyron Equation

For two phases in equilibrium, say the α and β phases, the equating of fugacities leads to the Clapeyron equation:

$$\frac{dP}{dT} = \frac{h^\alpha - h^\beta}{(v^\alpha - v^\beta)T} \quad (49.2)$$

This equation relates the slope of a coexistence line on Figure 49.1 (e.g., ab) to differences in molar enthalpy and molar volume and can be used to determine the value of one variable when all the others are known.

The Clausius-Clapeyron Equation

When one of the phases is a vapor, the number of variables in the Clapeyron equation can be reduced; the result is the Clausius-Clapeyron equation:

$$\frac{d \ln P^0}{d(1/T)} = -\frac{\Delta h}{R} \quad (49.3)$$

If Equation (49.3) is integrated under the assumption of constant Δh , the result is

$$\ln P^0 = c - \frac{\Delta h}{RT} \quad (49.4)$$

where c is a constant of integration. Equation (49.3) and Equation (49.4) relate the vapor pressure, P^0 , to temperature and the heat of vaporization or heat of sublimation, Δh , and predict that a plot of $\ln P^0$ versus reciprocal of absolute temperature should be linear with a slope of $-\Delta h/R$. Equation (49.3) and Equation (49.4) find use in correlating, interpolating, and extrapolating vapor pressure data and in determining the heat of vaporization or sublimation from vapor pressure data.

Despite some questionable assumptions made in arriving at Equation (49.3) and Equation (49.4), the linear relationship has been found to hold over a wide range of temperature. In fact, the Antoine equation,

$$\log P^0 = A - \frac{B}{C+t} \quad (49.5)$$

which has been found to give excellent representation of vapor pressure data, can be seen to be an empiricized version of Equation (49.4). Extensive compilations of Antoine parameters (A , B , and C) are available [Boublik et al., 1973; Reid et al., 1987].

49.2 Phase Equilibrium in Mixtures

There are two approaches to the treatment of phase equilibrium in mixtures — the use of an equation of state and the use of activity coefficients. The latter is developed here; the former is delineated by Kyle [1999] and also in [Chapter 47](#) of this text.

Vapor–Liquid Equilibrium (VLE)

Although the activity coefficient approach can be used for systems at any pressure, it is predominantly applied at low to moderate pressure. Here, consideration will be restricted to low pressure. This method is based on the ideal solution model for representing the fugacity of a component in a solution. Unlike the pure-component fugacity, which can be easily calculated or estimated, it is usually not possible to directly calculate the fugacity of a component in a solution, and a model — the ideal solution model — is therefore employed. This model is applied to both the vapor and liquid phases. It has been found to represent the vapor phase reasonably well and will be used here without correction. On the other hand, the model fits very few liquid-phase systems and needs to be corrected. The activity coefficient, γ_i , is the correction factor and is expected to depend upon temperature, pressure, and the liquid-phase composition. The effect of pressure is usually neglected and activity-coefficient equations of demonstrated efficacy are used to represent the temperature and composition dependence [Reid et al., 1987].

Employment of the equal fugacity criterion along with these models yields the basic equation for treating vapor–liquid equilibrium,

$$Py_i = P_i^0 x_i \gamma_i \quad (49.6)$$

where P is the system pressure, P_i^0 is the vapor pressure of component i , x_i is its liquid mole fraction, and y_i is its vapor mole fraction.

Determination of Activity Coefficients

Although methods for estimating activity coefficients are available (see [Chapter 47](#)), it is preferable to use experimental phase equilibrium data for their evaluation. The exception to this rule is when it is known that a system forms an ideal liquid solution and γ values are therefore unity. These systems, however, are rare and occur only when all the constituents belong to the same chemical family (e.g., paraffin hydrocarbons). Equation (49.6) is used to calculate γ_i from experimental values of x_i , y_i , and P at a given temperature where P_i^0 is known. Thus, for a binary system, γ for each component can be evaluated from a single VLE data point.

Once a set of γ_1 , γ_2 , and x_1 data has been determined from binary VLE data, it is customary to fit these data to an activity-coefficient equation. The Wilson equation, shown below for a binary system, is outstanding among equations of proven efficacy:

$$\ln \gamma_1 = -\ln(x_1 + x_2 G_{12}) + x_2 \left(\frac{G_{12}}{x_1 + x_2 G_{12}} - \frac{G_{21}}{x_2 + x_1 G_{21}} \right) \quad (49.7)$$

$$\ln \gamma_2 = -\ln(x_2 + x_1 G_{21}) - x_1 \left(\frac{G_{12}}{x_1 + x_2 G_{12}} - \frac{G_{21}}{x_2 + x_1 G_{21}} \right) \quad (49.8)$$

The G values are empirically determined parameters that are expected to show the following exponential dependence on temperature:

$$G_{12} = \frac{v_2}{v_1} \exp\left(-\frac{a_{12}}{RT}\right); \quad G_{21} = \frac{v_1}{v_2} \exp\left(-\frac{a_{21}}{RT}\right) \quad (49.9)$$

where v_1 and v_2 are the liquid molar volumes of components 1 and 2, and a_{12} and a_{21} are empirically determined parameters. Some type of parameter estimation technique is used to determine the best values of G . This can easily be done on a spreadsheet using the optimization feature to find the parameters that minimize the following objective function:

$$\sum_{i=1}^n (Q^{\text{exp}} - Q^{\text{cal}})_i^2 \quad (49.10)$$

where Q is defined as

$$Q = x_1 \ln \gamma_1 + x_2 \ln \gamma_2 \quad (49.11)$$

In Equation (49.10), Q^{exp} is determined from Equation (49.11) and values of γ_1 and γ_2 from experimental VLE data, while Q^{cal} is determined at the same composition from Equation (49.11) using Equation (49.7) and Equation (49.8). The difference in these Q values and, consequently, the objective function [Equation (49.10)] is a function only of the G values. Executable programs for optimizing Equation (49.10) are available [Kyle, 1999].

Sensing a certain amount of circularity, one may well question the value of this procedure that uses experimental VLE data to determine parameters in the Wilson equation that will then be used to calculate VLE by means of Equation (49.6). However, the procedure becomes more attractive when one recognizes that VLE data at one condition can be used to evaluate Wilson parameters that can then be used to calculate VLE at another condition. Or one might use the minimum amount of VLE data (one data point) to evaluate Wilson parameters and then proceed to calculate, via Equation (49.6), sufficient data to represent the system. When no experimental information is available, activity coefficients may be estimated by the UNIFAC method, which is based on the behavior of functional groups within the molecules composing the solution rather than on the molecules themselves [Reid et al., 1987]. An executable program using the UNIFAC method is available [Kyle, 1999].

Azeotropes

An azeotrope is the condition in which the vapor and liquid compositions in a system are identical. As the knowledge of the existence of azeotropes is crucial to the design of distillation columns, much effort has been expended in determining and compiling this information [Horsely, 1952, 1962]. These compilations represent a source of VLE data: values of T , P , and x_1 , where $x_i = y_i$. At a specified T (or P) a value of γ can be calculated for each component via Equation (49.6), the minimum data required to determine Wilson parameters.

For an azeotrope in the 1–2 system, Equation (49.6) can be employed to obtain

$$\frac{P_1^0}{P_2^0} = \frac{\gamma_2}{\gamma_1} \quad (49.12)$$

This equation is useful in estimating the effect of temperature (which is manifested as a corresponding change in pressure) on the composition of the azeotrope. The vapor pressure ratio depends only on temperature, whereas the γ values depend on temperature and composition. If one assumes that the ratio γ_2/γ_1 is independent of temperature and uses the azeotropic data point to evaluate Wilson parameters,

the right-hand side becomes a known function of x_i , and, thus, a value of x_i can be determined from the vapor pressure ratio evaluated at any temperature.

Computational Procedures

The computations for VLE involving Equation (49.6) cannot be directly executed because all of the necessary variables cannot be specified prior to the calculation. According to the phase rule, a system of two phases possesses C degrees of freedom. If the composition of a phase is specified at the expense of $C - 1$ variables, there remains only one additional variable to be specified — T or P . Because the quantities in Equation (49.6) depend on T and P , it is necessary to adopt a trial-and-error computational procedure. If, for example, T and the x_i values are specified, a value of P would be assumed and Equation (49.6) used to calculate the y_i values. If these calculated y_i values all sum to unity, the assumed value of P would be correct; if not, other values of P would be assumed until this condition is met. A similar procedure would be used for a system described in different terms.

Multicomponent Vapor–Liquid Equilibrium

In order to effectively treat multicomponent systems, it is necessary to be able to represent activity coefficients as a function of temperature and composition for use in Equation (49.6). The Wilson equation can be extended to any number of components and requires only two parameters (G_{ij} and G_{ji}) for each binary pair that can be formed from the components of the system [Kyle, 1999]. A comprehensive study [Holmes and Van Winkle, 1970] has established the ability of the Wilson equation to calculate ternary VLE with acceptable accuracy from parameters obtained from the three constituent binary systems.

Liquid–Liquid Equilibrium (LLE)

When two liquid phases are in equilibrium, the equating of fugacities results in the following expression for each component:

$$\gamma'_i x'_i = \gamma''_i x''_i \quad (49.13)$$

where ' and '' distinguish the liquid phases. Because activity coefficients are required for each phase, calculations involving LLE are computationally intensive. These calculations entail either the computation of LLE from available information concerning activity coefficients or the use of LLE to obtain information concerning activity coefficients [Kyle, 1999].

Solid–Liquid Equilibrium (SLE)

For pure solid component i in equilibrium with a liquid solution containing component i , the equating of fugacities results in

$$RT \ln x_i \gamma_i = \frac{L_{mi}(T - T_{mi})}{T_{mi}} + \Delta c_{pi}(T_{mi} - T) + T \Delta c_{pi} \ln \frac{T}{T_{mi}} \quad (49.14)$$

where T_{mi} is the freezing point and L_{mi} is the heat of fusion of component i . Usually, the data for the evaluation of Δc_{pi} are unavailable and only the first right-hand term is used. Figure 49.2 shows a phase diagram for a simple binary system where the curves AE and BE are represented by Equation (49.14) with i equal to 2 and 1, respectively. The **eutectic point** E is merely the intersection of these two curves.

To apply Equation (49.14) where liquid solutions are not ideal, it will be necessary to have access to enough experimental phase equilibrium data to evaluate parameters in the Wilson, or equivalent, activity-coefficient equation. When reliable parameters are available, it has been demonstrated [Gmehling et al., 1978] that good estimates of SLE can be obtained for systems of nonelectrolytes. Alternatively, SLE data

FIGURE 49.2 Phase diagram for a simple binary system.

can be used as a source of activity coefficient information for use in other types of phase equilibrium calculations involving a liquid phase.

The solid phase can be either pure or a solid solution. For a given system, solid solutions will exhibit larger deviations from the ideal solution model than will liquid solutions, and, therefore, an activity coefficient will also be required for the solid phase. Thus, calculations for this type of system will require some experimental data for the evaluation of liquid- and solid-phase activity coefficients [Kyle, 1999].

49.3 Perspective

In this work the emphasis has been placed on delineating the rationale for the application of thermodynamics to phase equilibrium rather than on amassing a set of “working equations.” Such a set would be useful in dealing with routine or standard problems; however, with the exception of pure components, few such problems exist in phase equilibrium. Each problem is defined by the nature of the system, what information is desired, and what information is available; judgments concerning the suitability of data and the fitting of data may also be involved. This endeavor can be regarded as information processing in which the activity coefficient provides the means by which information (experimental phase equilibrium data) at one condition is processed in order to generate information at other conditions.

Defining Terms

Eutectic point — The existence of two solid phases and a liquid phase in equilibrium at a temperature below the melting points of the pure solid components.

Fugacity — A thermodynamic function that requires for its evaluation PVT data for a pure substance and PVT-composition data for a component in a mixture. It is often regarded as a thermodynamic pressure because it has the units of pressure and is equal to pressure for an ideal gas and equal to partial pressure for a component in an ideal gas mixture.

Thermodynamic Cycles

William J. Cook
Iowa State University

50.1 Power Cycles
50.2 Refrigeration Cycles

A thermodynamic cycle is a continuous series of thermodynamic processes that periodically returns the **working fluid** of the cycle to a given state. Although cycles can be executed in closed systems, the focus here is on the cycles most frequently encountered in practice: **steady-flow** cycles, cycles in which each process occurs in a steady-flow manner. Practical cycles can be classified into two groups: power-producing cycles (power cycles) and power-consuming cycles (refrigeration cycles). The working fluid typically undergoes phase changes during either a power cycle or a refrigeration cycle. Devices that operate on thermodynamic cycles are widely used in energy conversion and utilization processes since such devices operate continuously as the working fluid undergoes repeated thermodynamic cycles.

The fundamentals of cycle analysis begin with the **first law of thermodynamics**. Since each process is a steady-flow process, only the first law as it applies to steady-flow processes will be considered. For a steady-flow process occurring in a **control volume** with multiple inflows and outflows, the first law is written on a time rate basis as

$$\dot{Q} + \sum [\dot{m}(h + V^2/2 + gz)]_{\text{in}} = \dot{W} + \sum [\dot{m}(h + V^2/2 + gz)]_{\text{out}} \quad (50.1)$$

For a single-stream process between states i and j , Equation (50.1) on a unit mass basis becomes

$${}_i q_j + h_i + V_i^2/2 + gz_i = {}_i w_j + h_j + V_j^2/2 + gz_j \quad (50.2)$$

where ${}_i q_j = \dot{Q}_j/\dot{m}$, ${}_i w_j = \dot{W}_j/\dot{m}$, and \dot{m} is the mass rate of flow. See Sonntag et al. [2002]. In processes involved with the cycles considered here, changes in kinetic and potential energies ($V^2/2$ and gz terms, respectively) are small and are neglected. Power \dot{W} is considered positive when it is transferred out of the control volume, and heat transfer rate \dot{Q} is considered positive when heat transfer is to the control volume. In the figures herein that describe the transfer of power and heat energy to and from cycles, arrows indicate direction and take the place of signs. The accompanying \dot{W} or \dot{Q} is then an absolute quantity. Where confusion might arise, absolute value signs are used. Only power transfer and heat transfer occur across a closed boundary that encloses the complete cycle. For such a boundary,

$$\left[\sum \dot{Q} = \sum \dot{W} \right]_{\text{cycle}} \quad (50.3)$$

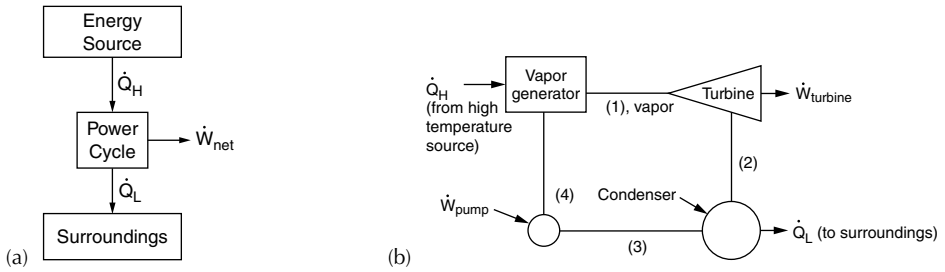

FIGURE 50.1 Descriptions of power cycles: (a) Power cycle operation. (b) The simple vapor power cycle.

50.1 Power Cycles

The purpose of a power cycle is to produce a net power output on a continuous basis from **heat energy** supplied to it from a high-temperature energy source. The device in which the power cycle is executed is sometimes referred to as a *heat engine*. Gas-turbine engines and reciprocating internal combustion engines are used widely to produce power. Strictly speaking, these engines are not classified as power cycles because their working fluids do not undergo thermodynamic cycles. Figure 50.1(a) shows a heat engine that receives heat energy at the rate \dot{Q}_H from a high-temperature energy source and produces net power \dot{W}_{net} . As a consequence of its operation, it rejects heat energy to the lower-temperature surroundings at the rate \dot{Q}_L . A widely used performance parameter for a power cycle is η , the cycle thermal efficiency, defined as

$$\eta = \dot{W}_{\text{net}} / \dot{Q}_H \quad (50.4)$$

Second law considerations for thermodynamic power cycles restrict η to a value less than unity. Thus, \dot{W}_{net} in Figure 50.1(a) is less than \dot{Q}_H . By Equation (50.3), the rate at which heat energy is rejected to the surroundings is

$$|\dot{Q}_L| = \dot{Q}_H - \dot{W}_{\text{net}} \quad (50.5)$$

It is useful to consider cycles for which the energy source and the surrounding temperatures — denoted, respectively, as T_H and T_L — are uniform. The maximum thermal efficiency any power cycle can have while operating between a source and its surroundings, each at a uniform temperature, is that for a totally reversible thermodynamic cycle (a Carnot cycle, for example) and is given by the expression

$$\eta_{\text{max}} = (T_H - T_L) / T_H \quad (50.6)$$

where the temperatures are on an absolute scale [Sonntag et al., 2002].

Figure 50.1(b) illustrates a simple vapor power cycle. Each component operates in a steady-flow manner. The vapor generator delivers high-pressure high-temperature vapor at state 1 to the turbine. The vapor flows through the turbine to the turbine exit state, state 2, and produces power \dot{W}_{turbine} at the turbine output shaft. The vapor is condensed to liquid, state 3, as it passes through the condenser, which is typically cooled by a water supply at a temperature near that of the surroundings. The pump, which consumes power \dot{W}_{pump} compresses the liquid from state 3 to state 4, the state at which it enters the vapor generator. Heat energy at the rate \dot{Q}_H is supplied to the vapor generator from the energy source to produce vapor at state 1. Thus, the working fluid executes a cycle, in that an element of the working fluid initially at state 1 is periodically returned to that state through the series of thermodynamic processes as it flows through the various hardware components. The net power produced, \dot{W}_{net} , is the algebraic sum of the positive turbine power \dot{W}_{turbine} and the negative pump power \dot{W}_{pump} .

TABLE 50.1 Properties at Cycle States for Example 50.1

| State | Pressure, kPa | Temperature, °C | Quality, kg/kg | Entropy, kJ/kg K | Enthalpy, kJ/kg | Condition |
|-------|---------------|-----------------|----------------|------------------|-----------------|----------------------|
| 1 | 1000 | 480 | ^a | 7.7055 | 3435.2 | Superheated vapor |
| 2 | 7 | 39 | 0.9261 | 7.7055 | 2394.4 | Liquid–vapor mixture |
| 3 | 7 | 39 | 0 | — | 163.4 | Saturated liquid |
| 4 | 1000 | — | ^a | — | 164.4 | Subcooled liquid |

^a Not applicable

Example 50.1

Consider the power cycle shown in Figure 50.1(b) and let water be the working fluid. The mass flow rate \dot{m} through each component is 100 kg/h, the turbine inlet pressure P_1 is 1000 kPa, and turbine inlet temperature T_1 is 480°C. The condenser pressure is 7 kPa and saturated liquid leaves the condenser. The processes through the turbine and the pump are assumed to be isentropic (adiabatic and reversible, hence constant entropy). The pressure drop in the flow direction is assumed to be negligible in both the steam generator and the condenser as well as in the connecting lines. Compute \dot{W}_{net} , \dot{Q}_H , η , and \dot{Q}_L .

Solution

Table 50.1 lists the properties at each state and Figure 50.2 shows the temperature (T) versus entropy (s) diagram for the cycle. Property values were obtained from *Steam Tables* by Keenan et al. [1978]. Evaluation of properties using such tables is covered in basic textbooks on engineering thermodynamics, for example, Sonntag et al. [2002]. Properties at the various states were established as follows. State 1 is in the superheat region and the values of entropy and enthalpy were obtained from the superheat table of *Steam Tables* at the noted values of P_1 and T_1 . Also, since s_2 is equal to s_1 ,

$$s_2 = s_f + x_2(s_g - s_f) = 7.7055 = 0.5592 + x_2(8.2758 - 0.5592)$$

This yields the value for the quality x_2 as 0.9224 and allows h_2 to be calculated as

$$h_2 = h_f + x_2(h_g - h_f) = 163.4 + 0.9261(2572.5 - 163.4) = 2394.4 \text{ kJ/kg}$$

In these equations, quantities with f and g subscripts were obtained from the saturation table of *Steam Tables* at P_2 . The value of enthalpy at state 4 was determined by first computing ${}_3w_4$, the work per unit mass for the process through the pump, using the expression for the reversible steady-flow work with negligible kinetic and potential energy changes [Sonntag et al., 2002]:

FIGURE 50.2 Temperature–entropy diagram for the steam power cycle in Example 50.1.

$${}_3w_4 = -\int_3^4 v \, dP = -v_3(P_4 - P_3)$$

where the specific volume v is assumed constant at v_3 since a liquid is pumped. With v_3 obtained from *Steam Tables* as v_f at P_3 ,

$${}_3w_4 = -0.001007(1000 - 7) = -1.00 \text{ kJ/kg}$$

Writing Equation (50.2) for the adiabatic process from state 3 to state 4,

$$h_4 = h_3 - {}_3w_4 = 163.39 - (-1.00) = 164.4 \text{ kJ/kg}$$

Proceeding with the solution for \dot{W}_{net} ,

$$\begin{aligned}\dot{W}_{\text{net}} &= \dot{W}_{\text{turbine}} + \dot{W}_{\text{pump}} = \dot{m}_1 w_2 + \dot{m}_3 w_4 = \dot{m}(h_1 - h_2) + \dot{m}_3 w_4 \\ &= 100.0(3435.2 - 2394.4) + 100.0(-1.00) = 103980 \text{ kW}\end{aligned}$$

where ${}_1w_2$ was obtained by writing Equation (50.2) between states 1 and 2. Next, \dot{Q}_H is determined by writing Equation (50.1) for a control volume enclosing the steam generator and noting that there is no power transmitted across its surface. Equation (50.1) reduces to

$$\dot{Q}_H = \dot{m}h_1 - \dot{m}h_4 = 100.0(3435.2 - 164.4) = 327080 \text{ kW}$$

To find η , substitution into Equation (50.4) yields

$$\eta = 103980 / 327080 = 0.318 \text{ or } 31.8\%$$

The solution for \dot{Q}_L can be obtained by either of two approaches. First, by Equation (50.5),

$$|\dot{Q}_L| = \dot{Q}_H - \dot{W}_{\text{net}} = 327080 - 103980 = 223 \, 100 \text{ kW}$$

The solution is also obtained by writing the first law for the process between state 2 and state 3. The result is

$$|\dot{Q}_L| = |\dot{m}(h_2 - h_3)| = |100(163.4 - 2394.4)| = 223 \, 100 \text{ kW}$$

The cycle in this example is known as the *Rankine cycle with superheat*. Modified forms of this cycle are widely used to provide shaft power to drive electric generators in steam-electric power plants and other power applications.

Example 50.2

Let \dot{Q}_H in Example 50.1 be supplied from a high-temperature source at a fixed temperature of 500°C and let the surrounding temperature be 20°C . Find the maximum thermal efficiency a cycle could have while operating between these regions and compare this value with η calculated in Example 50.1.

Solution

Equation (50.6) gives the expression for maximum thermal efficiency:

$$\eta_{\max} = (T_H - T_L) / T_H = [(500 + 273) - (20 + 273)] / [500 + 273] = 0.621 \text{ or } 62.1\%$$

compared to 31.8% for Example 50.1. The maximum value of cycle thermal efficiency was not realized because of the inherent **irreversibilities** associated with heat transfer across finite temperature differences in the heat reception and heat rejection processes for the cycle.

50.2 Refrigeration Cycles

The function of a refrigeration cycle is to cause heat energy to continuously flow from a low-temperature region to a region at a higher temperature. The operation of a refrigeration cycle is illustrated in Figure 50.3(a), in which heat energy flows at the rate \dot{Q}_L from the low-temperature refrigerated region, heat is rejected at the rate \dot{Q}_H to the higher-temperature surroundings, and power \dot{W}_{net} is required. From Equation (50.3) these are related as

$$|\dot{Q}_H| = \dot{Q}_L + |\dot{W}_{\text{net}}| \quad (50.7)$$

The performance parameter for conventional refrigeration cycles is termed *coefficient of performance* and is defined as

$$\beta = \dot{Q}_L / |\dot{W}_{\text{net}}| \quad (50.8)$$

The maximum value β can have when regions at uniform temperature T_H and T_L are considered is again derived from consideration of totally reversible cycles [Moran and Shapiro, 2000]. The expression, in terms of absolute temperatures, is

$$\beta_{\max} = T_L / (T_H - T_L) \quad (50.9)$$

Figure 50.3(b) illustrates a simple vapor-compression refrigeration cycle. The compressor receives the refrigerant (working fluid) in the vapor phase at low pressure, state 1, and compresses it to state 2, where $P_2 > P_1$. Cooling at the condenser by means of a liquid or air coolant causes the vapor to condense to a liquid, state 3, after which it passes through a throttling device to the evaporator pressure. The refrigerant is a mixture of saturated liquid and saturated vapor at state 4. The liquid in the evaporator undergoes a phase change to vapor that is caused by the transfer of heat energy from the refrigerated region. The refrigerant leaves the evaporator as vapor at state 1, completing its thermodynamic cycle. The cycle illustrated in Figure 50.3(b) is the basis for practical refrigeration cycles.

FIGURE 50.3 Descriptions of refrigeration cycles: (a) Refrigeration cycle operation. (b) The simple vapor compression refrigeration cycle.

FIGURE 50.4 Temperature–entropy diagram for the refrigeration cycle in Example 50.3.

TABLE 50.2 Properties at Cycle States for Example 50.3

| State | Pressure, psia | Temperature, °F | Quality, lbm/lbm | Entropy, Btu/lbm R | Enthalpy, Btu/lbm | Condition |
|-------|----------------|-----------------|------------------|--------------------|-------------------|----------------------|
| 1 | 23.767 | 5 | 1.00 | 0.22470 | 103.745 | Saturated vapor |
| 2 | 150 | 118.7 | ^a | 0.22470 | 120.3 | Superheated vapor |
| 3 | 150 | 105.17 | 0.0 | 0.09464 | 46.78 | Saturated liquid |
| 4 | 23.767 | 5 | 0.368 | 0.10210 | 46.78 | Liquid–vapor mixture |

^a Not applicable

Example 50.3

A simple vapor compression refrigeration cycle, Figure 50.3(b), has a refrigerating capacity of three tons (36,000 Btu/h) and operates with R134a as the refrigerant. The temperature of the refrigerated region is 15°F and the surroundings are at 90°F. Saturated vapor leaves the evaporator at 5°F and is compressed isentropically by the compressor to 150 psia. The refrigerant leaves the condenser as saturated liquid at 150 psia and flows through the throttling device to the condenser, in which the temperature is uniform at 5°F. Determine \dot{W}_{net} , β , and the maximum coefficient of performance a refrigerator could have while operating between the refrigerated region and the surroundings.

Solution

Figure 50.4 shows the T - s diagram for the cycle and the temperatures of the two regions. Table 50.2 lists values for the various properties obtained for R134a from the *ASHRAE Handbook* [2002] at the four states. The mass rate of flow is determined by applying Equation (50.1) to the evaporator. The result is

$$\begin{aligned}\dot{Q} + \dot{m}h_1 &= \dot{m}h_2 = 36000 + \dot{m}(46.78) = \dot{m}(103.745) \\ \dot{m} &= 632.0 \text{ lbm/h}\end{aligned}$$

To find \dot{W}_{net} , application of Equation (50.1) to the compressor yields

$$\dot{W}_{\text{net}} = \dot{W}_2 = \dot{m}(h_1 - h_2) = 632.0(103.745 - 120.3) = -10460 \text{ Btu/h}$$

To find β , Equation (50.8) yields

$$\beta = 36000/10460 = 3.44$$

The solution for maximum coefficient of performance is obtained by applying Equation (50.9) as follows:

$$\beta_{\max} = [15 + 460] / [(90 + 460) - (15 + 460)] = 6.33$$

Irreversibilities present due to finite temperature differences associated with the heat transfer processes and the irreversibility related to the throttling process cause β to be less than β_{\max} .

Defining Terms

Control volume — A region specified by a control surface through which mass flows.

First law of thermodynamics — An empirical law that in its simplest form states that energy in its various forms must be conserved.

Heat energy — Energy that is transferred across a control surface solely because of a temperature difference between the control volume and its surroundings. This form of energy transfer is frequently referred to simply as heat transfer.

Irreversibilities — Undesirable phenomena that reduce the work potential of heat energy. Such phenomena include friction, unrestrained expansions, and heat transfer across a finite temperature difference.

Steady flow — A condition that prevails in a flow process after all time transients related to the process have died out.

Working fluid — The substance that is contained within the apparatus in which the cycle is executed. The substance undergoes the series of processes that constitute the cycle.

There are two modes of **heat transfer** — diffusion and radiation. A *diffusion* process occurs due to the presence of a gradient (say, of temperature, density, pressure, concentration, electric potential, etc.) and *requires* a material medium. Both conduction and convection are diffusion processes. A radiative process, on the other hand, does *not* require a material medium.

This chapter will cover the basic ideas of conduction, convection, radiation, and phase change. The mode of heat transfer in solids and fluids at rest due to the exchange of the kinetic energy of the molecules or the drift of free electrons due to the application of a temperature gradient is known as *conduction*. The heat transfer that takes place due to mixing of one portion of a fluid with another via bulk movement is known as *convection*. All bodies that are at a temperature above absolute zero are thermally excited and emit electromagnetic waves. The heat transfer that occurs between two bodies by the propagation of these waves is known as *radiation*. *Phase change* takes place when a body changes its state (i.e., solid, liquid, or gas) either by absorption or release of thermal energy.

51.1 Conduction

Heat conduction in solids can be attributed to two basic phenomena — lattice vibrations and transport of free electrons due to a thermal gradient.

The mechanism of heat conduction in a solid can be qualitatively described as follows. The geometrical structure in which the atoms in a solid are arranged is known as a *crystal lattice*. The positions of the

atoms in the lattice are determined by the interatomic forces between them. When one part of a solid body is at a higher temperature than the rest of it, there is an increased amplitude of the lattice vibrations of the atoms in that region. These vibrations are eventually transmitted to the neighboring cooler parts of the solid, thus ensuring that conduction is in the direction of the temperature gradient. The mechanical oscillations of these atoms are known as *vibration modes*. In classical physics, each of these vibrations can have an *arbitrary* amount of energy. However, according to quantum mechanics, this energy is *quantized*. These quanta (in analogy with the theory of light) are called **phonons** and are the primary carriers of heat in dielectrics. The mathematical theory that studies heat conduction due to such lattice vibrations is known as the *phonon theory of conduction* (see Ziman [1960]).

On the other hand, in a metal an abundance of free electrons is present, and they are the primary carriers of heat. There is a certain amount of conduction due to phonons, but it is usually negligible. A metal can be modeled as a lattice of positively charged nuclei surrounded by closed shells of electrons and immersed in a sea of free valence electrons. The free valence electrons are the carriers of energy, and their motion in the absence of a thermal gradient is determined by the combined electric fields of the ions in the lattice. At thermal equilibrium (no net temperature gradient) there are as many electrons moving in one direction as in the opposite, and there is no net energy transport. However, when a temperature gradient is imposed, electrons that cross a given cross-section of the solid have different temperatures (different velocities) at different points because the electrons collide with the ions in the lattice and reach local thermal equilibrium. This directed migration of the electrons eventually ceases when the thermal gradient disappears and the temperature becomes uniform throughout. This model can be used to determine the heat flux in terms of the applied temperature gradient and a material property known as the *thermal conductivity*.

Fourier's Law of Heat Conduction

The important quantities in the study of heat conduction are the temperature, the heat flux, and the thermal conductivity of the material. The total amount of energy per unit time that crosses a given surface is known as the *heat flow* across the surface, Q . The energy per unit time per unit area across the surface is called the *heat flux*, \mathbf{q} . Heat flux (unlike heat flow) is a vector quantity and is directed along the normal to the surface at which it is measured.

The fundamental relation between the heat flux and the temperature gradient is **Fourier's law**, which states that heat flow due to conduction in a given direction is proportional (see [Figure 51.1](#)) to the temperature gradient in that direction and the area normal to the direction of heat flow. Mathematically,

$$Q_x(x, t) = -\kappa A \frac{dT(x, t)}{dx} \quad (51.1)$$

where $Q_x(x, t)$ is the heat flow in the positive x direction through the area A , $dT(x, t)/dx$ is the temperature gradient at point x at time t , and κ is the **thermal conductivity** of the material. The minus sign on the

FIGURE 51.1 Flow of heat in a slab.

right-hand side of Equation (51.1) is in accordance with the second law of thermodynamics and implies that heat flow due to conduction must occur from a point at higher temperature to a point at lower temperature. Equation (51.1) can be generalized for a solid to yield

$$\mathbf{q}(\mathbf{r}, t) = -\kappa \nabla T(\mathbf{r}, t) \quad (51.2)$$

where $\mathbf{q}(\mathbf{r}, t)$ is the heat flux vector (i.e., heat flow per unit area, Q_x/A) and $T(\mathbf{r}, t)$ is the temperature at a point in the body whose position vector is \mathbf{r} at time t . In SI units, heat flux is measured in W/m^2 , temperature gradient in $^\circ C/m$, and thermal conductivity in $W/m^\circ C$.

When the domain thickness is on the order of the electron/phonon mean free path, the Fourier law of conduction cannot be applied.

Thermal Conductivity of Materials

Materials display a wide range of thermal conductivities. Between gases (e.g., air) and highly conducting metals (e.g., copper, silver), κ varies by a factor of 10^4 . Metals have the highest thermal conductivity ($\sim 10^4 W/m^\circ C$) and gases such as hydrogen and helium are at the lower end of the range ($\sim 10^{-2} W/m^\circ C$). Materials such as oils and nonmetallic oxides have conductivities that range between $10^{-1} W/m^\circ C$ and $10^2 W/m^\circ C$ and are known as *thermal insulators*. Thermal conductivity is also known to vary with temperature. For some materials the variation over certain temperatures is small enough to be neglected. Generally, the thermal conductivity of metals decreases with increase in temperature. For gases (air, CO_2 , H_2 , etc.) and most insulators (asbestos, amorphous carbon, etc.) it increases with increase in temperature.

Generally speaking, good thermal conductors are also good electrical conductors and vice versa. The free electron theory of metals accounts for their high conductivities and shows that the thermal and electrical conductivities of metals are related by the *Weidemann–Franz law*, which states that at absolute temperature T ,

$$\frac{\kappa}{\sigma_e T} = 2.23 \cdot 10^{-8} W\Omega/K^2$$

where σ_e is the electrical conductivity of the metal.

The Energy Equation

The study of heat conduction is primarily concerned with knowing the temperature distribution in a given body as a function of position and time. Consider an arbitrary body of volume V and area A , bounded by a surface S . Let the body have an internal heat source that generates heat at the rate of $g(\mathbf{r}, t)$ per unit volume (in SI units, the units for this quantity are W/m^3). Then, *conservation of energy* requires that the sum of heat fluxes that enter the body through its surface and the internal rate of heat generation in the body should equal the net rate of accumulation of energy in it. Mathematically,

$$\begin{aligned} -\oint_S \mathbf{q}(\mathbf{r}, t) \cdot \hat{\mathbf{n}} dA|_{\text{conduction}} &= \oint_S \mathbf{q}(\mathbf{r}, t) \cdot \hat{\mathbf{n}} dA|_{\text{other modes}} - \oint_V g(\mathbf{r}, t) dV \\ &+ \oint_V \rho C_p \frac{\partial T(\mathbf{r}, t)}{\partial T} dV \end{aligned} \quad (51.3)$$

where the left-hand side represents the net heat flux that enters the body by conduction, the first term on the right-hand side represents the corresponding term for other modes of heat transfer (i.e., convection or radiation), the second term on the right-hand side represents the total heat generated in the body, and the last term represents the accumulation of thermal energy in it. Here $\hat{\mathbf{n}}$ is the outward drawn unit normal to the surface of the body, ρ is the density of the body, and C_p its specific heat. Equation (51.3)

is known as the *integral form* of the **energy equation**. In Equation (51.3), the internal heat generation can be due to electromagnetic heating, a chemical or nuclear reaction, etc.

Using Gauss's divergence theorem, the surface integrals of the heat flux can be converted into volume integrals, and this leads to

$$-\nabla \cdot \mathbf{q}(\mathbf{r}, t)|_{\text{conduction}} = \nabla \cdot \mathbf{q}(\mathbf{r}, t)|_{\text{other modes}} - g(\mathbf{r}, t) + \rho C_p \frac{\partial T(\mathbf{r}, t)}{\partial t} \quad (51.4)$$

The above equation is known as the *distributed form* of the energy equation. When conduction is the only mode of heat transfer, Fourier's law [Equation (51.2)] can be used for a *homogeneous isotropic* medium (i.e., a medium whose thermal conductivity does not vary with position or direction) in Equation (51.4) to give

$$\nabla^2 T(\mathbf{r}, t) + \frac{1}{\kappa} g(\mathbf{r}, t) = \frac{1}{\alpha} \frac{\partial T(\mathbf{r}, t)}{\partial t} \quad (51.5)$$

where α is the **thermal diffusivity** of the medium and is defined as

$$\alpha = \kappa / (\rho C_p) \quad (51.6)$$

The thermal diffusivity of a material governs the rate of propagation of heat during transient processes. In SI units it is measured in m²/sec. When there is no internal heat generation in the body, Equation (51.5) is known as the *diffusion equation*.

In many instances the temperature in the body may be assumed to be constant over its volume and is treated only as a function of time. Then Equation (51.3) may be integrated to give

$$-Q|_{\text{conduction}} = Q|_{\text{other modes}} - G + \rho C_p V \frac{dT}{dt} \quad (51.7)$$

where T is the temperature of the body and G is the net heat generated in it. This is known as the *lumped form* of the energy equation.

One of the main problems of heat conduction is to obtain the solution of Equation (51.5) subject to appropriate boundary conditions and an initial condition. The boundary conditions for the solution of Equation (51.5) are of three kinds. The *constant temperature boundary condition* is obtained by prescribing the temperature at all points on the surface S . The *constant heat flux boundary condition* is invoked when the body is losing a known amount of heat to (or receiving heat from) the external ambient, for example, by conduction, convection, or radiation. The *mixed boundary condition* is used when a linear combination of the surface temperature and the heat flux leaving the surface is known. This situation typically occurs when a body is losing heat by convection from its surface to an ambient at a lower temperature. These boundary conditions are also known as *Dirichlet*, *Neumann*, and *Cauchy* boundary conditions, respectively. Once the boundary conditions and the initial condition for a given heat conduction situation are formulated, the problem reduces to a boundary value problem. The solutions to these problems are well documented in standard texts on heat conduction such as Carslaw and Jaeger [1959] and Ozisik [1993].

Limits of Fourier's Law

In certain applications that deal with transient heat flow in very small periods of time, temperatures approaching absolute zero, heat flow due to large thermal gradients, and heat flow on a nano- or microscale (such as in thin films), Fourier's law of heat conduction [Equation (51.1)] is known to be unreliable. This is because the diffusion equation predicts that the effect of a temperature gradient at a point \mathbf{r} that is established at time t should be instantly felt everywhere in the medium, implying that

temperature disturbances travel at an *infinite* speed. In order to account for the *finite* speed of propagation of heat, Equation (51.1) has been modified as

$$\tau \frac{\partial \mathbf{q}(\mathbf{r}, t)}{\partial t} + \mathbf{q}(\mathbf{r}, t) = -\kappa \nabla T(\mathbf{r}, t) \quad (51.8)$$

where τ is a *relaxation time*. When this equation is used in the differential form of the energy equation, Equation (51.5), it results in a hyperbolic differential equation known as the *telegrapher's equation*:

$$\nabla^2 T(\mathbf{r}, t) + \frac{1}{\kappa} \left[g(\mathbf{r}, t) + \frac{\alpha}{c^2} \frac{\partial g(\mathbf{r}, t)}{\partial T} \right] = \frac{1}{c^2} \frac{\partial^2 g(\mathbf{r}, t)}{\partial T} \quad (51.9)$$

where c is the wave propagation speed and is given by $c = (\alpha / \tau)^{-1/2}$. The solution for Equation (51.9) indicates that heat propagates as a wave at a finite speed and is the basis of the theory of *heat waves*. For $\tau \rightarrow 0$, Equation (51.8) reduces to Fourier's law [Equation (51.2)], and when $c \rightarrow \infty$, Equation (51.9) becomes the diffusion equation, Equation (51.5).

Dimensionless Variables in Heat Conduction

If a body is subject to a mixed boundary condition given by

$$-\kappa \hat{\mathbf{n}} \cdot \nabla T(\mathbf{r}, t) = h(T(\mathbf{r}, t) - T_\infty)$$

on the surface S , where h is the heat transfer coefficient from the surface of the body, then Equation (51.5) can be nondimensionalized with the following variables: the *Fourier number*, $Fo = \alpha t / L^2$ (i.e., the dimensionless time variable), the dimensionless heat generation variable $[g(\mathbf{r}, t)L^2] / [\kappa (T_o - T_\infty)]$, and the *Biot number*, $Bi = hL / \kappa$, where L and T_o are suitable length and temperature scales, respectively. The Fourier number denotes the ratio of the heat transferred by conduction to the heat stored in the body and is useful in solving transient problems. When the Fourier number is very large, transient terms in the solution of the diffusion equation may be neglected. The Biot number is a measure of the relative magnitudes of the heat transfer due to conduction and convection (or radiation) in the body. When the Biot number is very small (< 0.1), the temperature in the body may be assumed to be a constant, and the lumped form of the energy equation may be used.

51.2 Convection

Convection takes place when a fluid moves over a solid and their temperatures are unequal. Heat transfer occurs due to actual material transport, unlike in the case of conduction. In many engineering applications the heat transfer due to convection may be calculated by using **Newton's law of cooling**. It states that if the heat transfer coefficient is h , the heat flux q due to convection from a surface at temperature T_w into a fluid at temperature T_f is given by

$$q = h(T_w - T_f) \quad (51.10)$$

There are three kinds of convection: forced, natural, and mixed. *Forced convection* takes place when the motion of the fluid that causes convection is sustained by an externally imposed pressure gradient. Forced convection typically occurs in systems such as blowers and air conditioners. Sometimes, even in the absence of external forces, pressure gradients are created due to differences in density that are caused by local heating in the fluid. This heat transfer is known as *free* or *natural* convection. *Mixed* convection, as the name implies, is the situation in which both forced and free convection are present.

FIGURE 51.2 The thermal boundary layer.

Thermal Boundary Layer

In analogy with the momentum (or the velocity) boundary layer, a thermal boundary layer can be defined. Imagine a fluid of uniform temperature T_∞ flowing with a uniform velocity U_∞ (the free stream values) along a flat plate maintained at temperature $T_w (< T_\infty)$ (see Figure 51.2). When the fluid comes into contact with the flat plate, the layers of fluid immediately adjacent to the plate attain the temperature T_w . Deeper into the fluid (away from the plate) the temperature of the fluid increases slowly. Finally, the temperature of the fluid becomes uniform at T_∞ . This suggests that there is a “temperature profile” and hence a “temperature gradient” in the layers of the fluid close to the flat plate. It is now convenient to define a dimensionless temperature $\theta(x, y)$ at each point (x, y) of the fluid as

$$\theta(x, y) = \frac{T(x, y) - T_w}{T_\infty - T_w}$$

For a point very close to the wall, for example, $y = 0$, the temperature of the fluid is the same as that of the wall and, hence, $\theta(x, y) = 0$. At points sufficiently far away from the wall, the temperature of the fluid is T_∞ and, hence, $\theta(x, y) \rightarrow 1$. For each location x along the flat plate, there is a distance y from the plate at which $\theta(x, y) = 0.99$. The locus of all such points is called the *thermal boundary layer*. For practical purposes, locations *outside* the boundary layer are thermally not affected by the plate.

Heat Transfer Coefficient

The **heat transfer coefficient** h [Equation (51.10)] is a very useful concept in the determination of the heat transfer due to convection. Consider the case shown in Figure 51.2. Very close to the wall, the fluid particles are stationary (due to the no-slip boundary condition) and the heat transfer is due to conduction in the fluid. Then the heat flux due to conduction at the wall is

$$q|_{\text{wall}} = -\kappa_f \left. \frac{\partial T(x, y)}{\partial y} \right|_{y=0} \quad (51.11)$$

where κ_f is the thermal conductivity of the fluid. In engineering applications the heat transfer between the fluid and the wall is related to the heat transfer coefficient using Newton’s law of cooling by

$$h_x = -\kappa_f \frac{[\partial T(x, y) / \partial y]_{y=0}}{(T_\infty - T_w)} \quad (51.12)$$

The heat transfer coefficient h_x in Equation (51.12) may vary along the length of the surface shown in Figure 51.2, that is, it may be a function of x . It is therefore useful to define a *mean* or *bulk* value of the heat transfer coefficient over a finite length L as

$$h_m = \frac{1}{L} \int_0^L h_x dx \quad (51.13)$$

In SI units h_x is measured in $\text{W}/\text{m}^2\text{C}$. The heat transfer coefficient is often expressed via an important dimensionless quantity known as the *Nusselt number*. The Nusselt number is defined as

$$\text{Nu}_x = \frac{h_x x}{\kappa_f} \quad (51.14)$$

and denotes the ratio of the actual convection heat flux to the conduction heat flux that would occur through a fluid slab of thickness x . Note the similarity of the Nusselt number with the Biot number (defined earlier). As in the case of h , it is useful to define a mean or bulk Nusselt number as follows:

$$\text{Nu}_m = \frac{h_m L}{\kappa_f} \quad (51.15)$$

Similarity Parameters of Convection

Heat transfer by convection depends on the characteristics of the flow pattern of the fluid, its thermophysical properties, the geometry of the flow passage, and surface conditions. The flow patterns may be characterized as *laminar*, *transitional*, or *turbulent*. The thermophysical properties that determine heat transfer are the fluid density ρ , thermal conductivity κ_f , kinematic viscosity ν , and specific heat C_p . The flow may be *external* or *internal* and the flow geometry may take such forms as flow over a flat plate, a cylinder, or a sphere, flow in a channel or an enclosed space, etc. Consider the laminar flow along a flat plate in which the local heat transfer coefficient at a location x is h_x . The local heat transfer coefficient h_x is a function of x , κ_f , the local velocity U_x , ρ , ν , the volume expansion coefficient of the fluid β , a characteristic temperature difference $\Delta T (\sim [T_\infty - T_w])$, and C_p . It has been found that these variables can be grouped into a set of five nondimensional numbers in a functional relationship of the form

$$\text{Nu}_x = f(\text{Re}_x, \text{Pr}, \text{Gr}_x, \text{Ec}) \quad (51.16)$$

where the arguments of f are the nondimensional numbers discussed as follows. The importance of Equation (51.16) is that it suggests that instead of determining h_x as a function of nine variables, it may be sought as a function of four nondimensional numbers. Further, Equation (51.16) is obtained by a method known as *similarity analysis*. Similarity analyses usually indicate the actual functional form of Equation (51.16) in advance.

Reynolds Number

The local *Reynolds number* is defined by

$$\text{Re}_x = \frac{U_\infty x}{\nu} = \frac{\rho U_\infty x}{\mu} \quad (51.17)$$

where μ is the dynamic viscosity of the fluid and is related to ν by $\nu = \mu/\rho$. It denotes the relative magnitudes of the inertial to viscous forces that govern the flow. For large values of the Reynolds number, the inertial forces dominate (low-viscosity flows), whereas the viscous forces dominate in small Reynolds number flow (creeping flows, viscous fluids).

Prandtl Number

The *Prandtl number* is defined as

$$\text{Pr} = \frac{\nu}{\alpha_f} \quad (51.18)$$

and is the ratio of the kinematic viscosity and the thermal diffusivity $\alpha_f (= \kappa_f / \rho C_p)$ of the fluid. It represents the relative rates of the diffusion of the momentum and thermal boundary layers. In liquid metals, $\text{Pr} \ll 1$ and therefore the rate diffusion of thermal energy greatly exceeds that of momentum. In oils, $\text{Pr} \gg 1$ and the converse holds.

Grashof Number

The *Grashof number* is significant in the analysis of free convection, which is discussed later. It is defined as

$$\text{Gr}_x = \frac{g\beta x^3 (T_w - T_\infty)}{\nu^2} \quad (51.19)$$

where g is the acceleration due to gravity, β is the coefficient of volume expansion of the fluid, and $T_w - T_\infty$ is a characteristic temperature difference that generates free convection. This number signifies the relative importance of the buoyant and the viscous forces in the flow. When there is no natural convection (for example, in microgravity situations $g \approx 0$, or when there is not enough thermal gradient to cause appreciable convection, i.e., ΔT is very small) and there is only forced convection, $\text{Gr} = 0$.

Eckert Number

The *Eckert number* appears due to the inclusion of the *viscous dissipation* term in the equation for the conservation of the energy in boundary layer. The viscous dissipation term denotes the rate at which mechanical energy is being dissipated into thermal energy due to the presence of viscous forces in the fluid. The viscous dissipation is proportional to the square of the velocity gradient and the dynamic viscosity of the fluid. The Eckert number is defined as

$$\text{Ec} = \frac{U_\infty^2}{C_p \Delta T} \quad (51.20)$$

and measures the kinetic energy of the flow with respect to the enthalpy difference across the thermal boundary layer.

The principal aim of convection can be said to be the determination of the Nusselt number as a function of the problem parameters that are expressed in terms of the above nondimensional numbers.

Forced Convection over Bodies (External Flows)

When there is only forced convection and the viscous dissipation is small enough ($\text{Ec} \approx 0$), Equation (51.16) becomes

$$\text{Nu}_x = f(\text{Re}_x, \text{Pr}) \quad (51.21a)$$

A more specific functional form for the above relation may be chosen as

$$\text{Nu}_x = K(\text{Re}_x)^a (\text{Pr})^b \quad (51.21b)$$

where K , a , and b must be chosen by fitting curves to the experimental data or by analysis of the governing equations of convection. It is convenient to combine the Reynolds and Prandtl numbers to define a new nondimensional number, the *Peclet number*, as

$$\text{Pe}_x = \text{Re}_x \text{Pr} = \frac{U_\infty x}{\alpha_f} \quad (51.22)$$

Actual correlations in terms of these nondimensional numbers for different flow situations are given in standard textbooks of heat transfer [Bayazitoglu and Ozisik, 1988; Kreith and Bohn, 1986].

For laminar flow, correlations of the form given by Equation (51.21) may be obtained by analytical methods. However, when the flow is turbulent, it is not easy to determine such correlations analytically and experimental methods must be used. In experiments it is often simpler to measure the drag coefficient c_x rather than the heat transfer coefficient. Furthermore, there are correlations between the heat transfer and drag coefficients. One such relation is the *Reynolds–Colburn* analogy given by

$$\text{St}_x \text{Pr}^{2/3} = \frac{1}{2} c_x \quad (51.23a)$$

where

$$\text{St}_x = \frac{\text{Nu}_x}{\text{Re}_x \text{Pr}} = \frac{h_x}{\rho U_\infty C_p} \quad (51.23b)$$

is the local *Stanton number* and is the nondimensional local heat transfer coefficient. The Reynolds–Colburn analogy may be used to develop expressions for local heat transfer coefficients. The relevant physical fluid properties that appear in these correlations are functions of the temperature and are usually evaluated at the **film temperature** T_f which is defined as the mean boundary layer temperature:

$$T_f = \frac{T_w + T_\infty}{2} \quad (51.24)$$

Forced Convection in Ducts (Internal Flows)

The following concepts (in addition to the ones discussed in the previous section) are needed to understand convection due to fluid flow in ducts. When the fluid (see [Figure 51.3](#)) enters a tube whose wall is maintained at a temperature different from that of the fluid, there is heat transfer and the temperature distribution is such that, starting at the tube inlet, a thermal boundary layer develops and grows along the length of the tube until the thermal boundary layer occupies the entire width of the duct. The region from the entrance of the duct to the point where the thermal boundary layer reaches the axis of the duct is known as the *thermal entrance region*. The length of this region is called the *thermal entry length*, L_t . In this region the temperature distribution varies along the radius and the length of the duct. Beyond this region the temperature is only a function of the radial coordinate. This region is known as the *thermally developed region*. In the thermal entrance region the average temperature of the fluid at any cross-section (averaged along the radial direction) is known as the *mean fluid temperature*. If the axial velocity of the fluid inside the duct is $U(r)$, the mean temperature is given by

$$T_m(z) = \frac{\int_0^R \rho C_p U(r) T(r, z) (2\pi r) dr}{\int_0^R \rho C_p U(r) (2\pi r) dr} \quad (51.25)$$

FIGURE 51.3 Thermal entrance and thermally developed regions for flow in a duct.

Based on this equation, the local heat transfer coefficient h_z is defined as

$$h_z = -\frac{\kappa_f}{T_m(z) - T_w(z)} \frac{\partial T(r, z)}{\partial r} \Big|_{r=R, \text{ wall}} \quad (51.26)$$

where $T_w(z)$ is the tube wall temperature at z . A quantity known as the *logarithmic mean temperature difference (LMTD)*, ΔT_{in} , which is useful in the determination of the total heat transfer between the fluid and wall of the duct (for example, in heat exchangers), is defined as

$$\Delta T_{\text{in}} = \frac{\Delta T_1 - \Delta T_2}{\ln(\Delta T_1 / \Delta T_2)} \quad (51.27)$$

where ΔT_1 and ΔT_2 are temperature differences between the fluid and the wall at the inlet and the outlet, respectively. Finally, in internal flows, the characteristic length parameter that is used to define the Nusselt number is known as the *hydraulic diameter* and is defined as $D_h = 4 A_c / P$, where A_c is the cross-sectional area of the duct and P is its perimeter.

When the flow is turbulent, the heat transfer analysis is more complicated. There are several empirical correlations to calculate the heat transfer in ducts that carry turbulent flows. For flow in a smooth pipe of length L and diameter D , the *Dittus-Boelter* and the *Petukhov* equations are most commonly used. (See Bayazitoglu and Ozisik [1988] for the actual relations.)

Although they are incomplete, recently several analytical and experimental works have been performed to have a better understanding of heat transfer at microscale. Since the ratio of the surface area to channel cross-section is large for microchannels and steep velocity gradients exist in laminar flow, the effects of viscous heating can be significant.

Free Convection

Consider a vertical flat plate at a temperature T_w immersed in a fluid at temperature T_∞ . If $T_w > T_\infty$, there is heat transfer from the plate to the fluid. The velocity and temperature profiles for this case of free convection are shown in [Figure 51.4](#).

The Grashof number [defined in Equation (51.19)] plays an important role in free convection. In the absence of forced convection and viscous dissipation, Equation (51.16) becomes

$$\text{Nu}_x = f(\text{Gr}_x, \text{Pr}) \quad (51.28a)$$

For gases, $\text{Pr} \cong 1$ and Equation (51.28) suggests that $\text{Nu}_x = f(\text{Gr}_x)$.

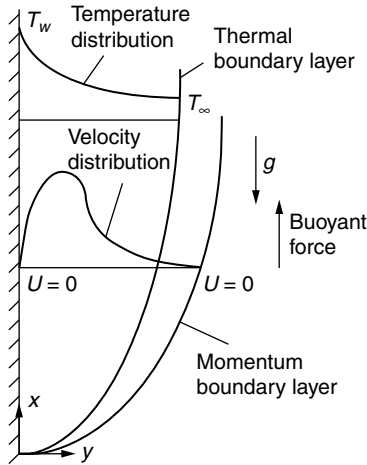

FIGURE 51.4 Free convection over a heated vertical plate.

The role of the Grashof number in free convection is similar to that of the Reynolds number in forced convection. However, free convection may take place even in situations where forced convection dominates. In such cases the relative importance of these two modes of convection is determined by the parameter Gr/Re^2 . If $Gr/Re^2 \ll 1$, forced convection dominates and free convection may be neglected. When $Gr/Re^2 \gg 1$, free convection dominates and the heat transfer correlations are of the form given by Equation (51.28a). And when $Gr/Re^2 \sim 1$, both free and forced convection must be considered. The heat transfer correlations are sometimes defined in terms of the *Rayleigh number*, Ra , given by

$$Ra_x = Gr_x Pr = \frac{g\beta(T_w - T_\infty)x^3}{\nu\alpha} \quad (51.28b)$$

In some of the free convection correlations, the physical properties are evaluated at a mean temperature given by

$$T_m = T_w - 0.25(T_w - T_\infty) \quad (51.28c)$$

Free convection inside closed volumes involves an interesting but complicated flow phenomenon. Consider a fluid between two large horizontal plates maintained at temperatures T_h and T_c and separated by a distance d . If the bottom plate is at temperature T_h ($>T_c$), heat flows upward through the fluid, thus establishing a temperature profile that decreases upward. The hotter layers of fluid are at the bottom, whereas the colder (and less dense) layers are at the top. This arrangement of the fluid layers remains stationary and heat transfer is by conduction alone. This unstable state of affairs lasts as long as the buoyancy force does not exceed the viscous force. If the temperature difference (gradient) between the top and bottom plates is strong enough to overcome the viscous forces, fluid convection takes place. Theoretical and experimental investigations have shown that the fluid convection in such an enclosure occurs when the Rayleigh number reaches a critical value Ra_c , which is given in terms of the (characteristic) spacing d between the plates. The convective flow patterns that arise in such situations are known as *Bernard cells*.

51.3 Radiation

All bodies that are above absolute zero temperature are said to be thermally excited. When bodies are thermally excited, they emit *electromagnetic waves*, which travel at the speed of light ($c = 3 \cdot 10^8$ m/sec in

FIGURE 51.5 The range of the electromagnetic spectrum.

free space or vacuum). This radiation takes place at different wavelengths. Figure 51.5 shows the typical electromagnetic spectrum. The radiation that occurs at wavelengths between $\lambda = 0.1$ and $100 \mu\text{m}$ is called *thermal radiation*, and the ensuing heat transfer is known as *radiative heat transfer*. The wave nature of radiation implies that the wavelength λ should be associated with a frequency ν , which is given by $\nu = c/\lambda$. Bodies emit radiation at different wavelengths, and the intensity of the radiation varies with the wavelength. This is referred to as the *spectral distribution* of the radiation. Since electromagnetic waves can travel in vacuum, radiative transfer as opposed to conductive and convective transfer does *not* require a material medium.

Basic Quantities of Radiation

The radiation that is incident on the surface of a body may be absorbed, reflected, transmitted, or scattered. When all the incident radiation is absorbed by the body, the body is said to be *opaque*. If the material thickness required to absorb the radiation is very large compared to the characteristic thickness of the body, the radiation may be transmitted entirely. For example, glass is a very poor absorber of electromagnetic waves in the visible spectrum and is *transparent* to radiation in the visible spectrum. If the surface of the body is shiny and smooth, a good part of the radiation may be reflected (as with metallic surfaces). A material property can be associated with each of these phenomena: *absorptivity*, α ; *reflectivity*, ρ ; and *transmissivity*, τ . When these properties depend on the frequency of the incident radiation, they are said to exhibit *spectral dependence*, and when they depend on the direction of the incident radiation, they are said to exhibit *directional dependence*. When radiation travels through a relatively transparent medium that contains inhomogeneities such as very small particles of dust, it gets *scattered*. Scattering is defined as the process in which a photon collides with one or more material particles and does not lose all its energy.

When radiative properties (or quantities) depend upon the wavelength and direction of the incident radiation, they are known as *monochromatic directional* properties. When these properties are summed over all directions *above* the surface in question, they are called *hemispherical properties*. When they are summed over the entire spectrum of radiation, they are referred to as *total properties*. When summed over all the directions above the surface in question as well as the entire spectrum of radiation, they are called *total hemispherical properties*.

The *hemispherical monochromatic emissive power*, $E_\lambda(\lambda, T)$, of a body is defined as the emitted energy leaving its surface per unit time per unit area at a given wavelength λ and temperature T . It is worth emphasizing that “emitted” refers to the *original* emission from the body — that is, the radiation due to thermal excitation of the atoms in the body. The *hemispherical monochromatic radiosity*, $J_\lambda(\lambda, T)$, refers to all the radiant energy (emitted and reflected) per unit area per unit time that leaves the surface. Radiant energy that is incident on a surface from all directions is known as *hemispherical monochromatic irradi-*

ation, $G_\lambda(\lambda)$. In each of these cases the total quantity is obtained by integrating the monochromatic quantity over the entire spectrum, that is, from $\lambda = 0$ to ∞ .

Radiation from a Blackbody

In the study of radiation it is useful to define an ideal surface in order to compare the properties of real surfaces. A body that absorbs *all* incident radiation regardless of its spectral distribution and directional character is known as a **blackbody**. Therefore, a blackbody is a perfect absorber. The radiation emitted by a blackbody at a given temperature is the maximum radiation that can be emitted by any body.

The emissive power $E_{b,\lambda}(\lambda, T)$ of a blackbody at a given wavelength λ and absolute temperature T is given by **Planck's law** as

$$E_{b,\lambda}(\lambda, T) = \frac{c_1}{\lambda^5 \{e^{c_2/\lambda T} - 1\}} \quad (51.29)$$

where $c_1 = 3.743 \cdot 10^8 \text{ W} \cdot \mu\text{m}^4/\text{m}^2$ and $c_2 = 1.4387 \cdot 10^4 \mu\text{m K}$. The units for c_1 and c_2 indicate that λ is measured in μm and $E_{b,\lambda}(\lambda, T)$ in W/m^2 . The *total emissive power* $E_b(T)$ of the blackbody is the radiation emitted by it at all wavelengths. Mathematically,

$$E_b(T) = \int_{\lambda=0}^{\infty} E_{b,\lambda}(\lambda, T) d\lambda = \sigma T^4 \quad (51.30)$$

where σ is the *Stefan–Boltzmann constant*, given by

$$\sigma = \left(\frac{\pi}{c_2} \right)^4 \frac{c_1}{15} = 5.67 \cdot 10^{-8} \text{ W} / \text{m}^2 \text{K}^4$$

Equation (51.30) is known as the **Stefan–Boltzmann law** of radiation. Experiments have shown that the peak values of the emission increase with T and occur at shorter wavelengths. This fact is formally given by *Wien's displacement law*, which states that

$$(\lambda T)_{\text{max}} = 2897.6 \mu\text{m K} \quad (51.31)$$

[This relation can also be obtained by differentiating Planck's law, Equation (51.29).] Often, in practice, it is required to know what fraction of the total emission occurs between two given wavelengths. The *blackbody radiation function*, $f_{0,\lambda}(T)$, is defined by

$$f_{0,\lambda}(T) = (\sigma T^4)^{-1} \int_{\lambda=0}^{\lambda} E_{b,\lambda}(\lambda', T) d\lambda' \quad (51.32)$$

and tabulated in standard textbooks. It may be used to find the emission of a blackbody between any two given wavelengths λ_1 and λ_2 by

$$f_{\lambda_1,\lambda_2}(T) = f_{0,\lambda_2}(T) - f_{0,\lambda_1}(T) \quad (51.33)$$

Intensity of Radiation

The fundamental quantity that is used to represent the amount of radiant energy transmitted in a given direction is the *intensity of radiation*. The *spectral intensity of radiation* is defined as the radiative energy

FIGURE 51.6 The definition of intensity of radiation.

per unit time per unit area normal to the direction of propagation per unit solid angle per unit wavelength. The total intensity refers to the intensity summed over all wavelengths. With reference to Figure 51.6, let ΔQ represent the energy radiated per unit time and confined to a solid angle $d\Omega$ around the solid angle $\hat{\Omega}$. The *total intensity of radiation* due to the radiating surface at Q is then defined mathematically as

$$I(\mathbf{r}, \hat{\mathbf{s}}) = \frac{dq}{d\Omega} \frac{1}{\cos\theta} = \frac{dq}{da} \frac{r^2}{\cos\theta} \quad (51.34)$$

where $q = \lim_{\Delta A \rightarrow 0} (\Delta Q / \Delta A)$ is the heat flux that is measured at the radiation source Q , and $d\Omega$ is the solid angle subtended by the area da at Q (which is equal to da/r^2). If the intensity at a point P is constant, Equation (51.34) shows that the flux intercepted by an area varies inversely with the square of its distance from the source and directly as the cosine of the angle between the normals of the radiating and the intercepting surfaces. This is known as *Lambert's cosine law*. Since energy conservation implies that all the flux (emitted as well as reflected) that leaves Q must cross the hemisphere above Q ,

$$q = \int_{\text{hemisphere}} I(\mathbf{r}, \hat{\mathbf{s}}) \hat{\mathbf{n}} \cdot \hat{\mathbf{s}} \, d\Omega \quad (51.35)$$

where q is the total flux radiated by the surface (i.e., at all wavelengths). If only the intensity due to the emission from the surface is considered, the flux that leaves the hemisphere above the surface is known as the *total hemispherical emissive power* and is given by

$$E = \int_{\text{hemisphere}} I(\mathbf{r}, \hat{\mathbf{s}}) \hat{\mathbf{n}} \cdot \hat{\mathbf{s}} \, d\Omega \quad (51.36)$$

If $I(\mathbf{r}, \hat{\mathbf{s}})$ is uniform, then the radiating surface is known as a **diffuse** emitter, and Equation (51.36) becomes

$$q = \pi I \quad (51.37)$$

The radiation emitted by a blackbody is diffuse. Therefore, the total intensity of radiation from a blackbody [due to Equation (51.30) and Equation (51.37)] is

$$I_b = \frac{\sigma T^4}{\pi} \quad (51.38)$$

Radiative Properties of Real (Nonblack) Surfaces

The important radiative properties of a real (nonblack) surface are its emissivity, absorptivity, transmissivity, and reflectivity. In the following sections we consider only the hemispherical monochromatic and total properties. For directional monochromatic quantities see Siegel and Howell [1981] or Modest [1993].

Emissivity

The *hemispherical monochromatic emissivity* of a nonblack surface at a temperature T is defined as the ratio of the hemispherical monochromatic emissive power of the surface $E_\lambda(\lambda, T)$ and the corresponding hemispherical monochromatic emissive power of a blackbody. That is,

$$\varepsilon_\lambda(\lambda, T) = \frac{E_\lambda(\lambda, T)}{E_{b,\lambda}(\lambda, T)} \quad (51.39)$$

The hemispherical total emissivity is the ratio of the corresponding hemispherical total quantities:

$$\varepsilon(T) = \frac{E(T)}{E_b(T)} = (\sigma T^4)^{-1} \int_{\lambda=0}^{\infty} \varepsilon_\lambda(\lambda, T) E_{b,\lambda}(\lambda, T) d\lambda \quad (51.40a)$$

A surface whose monochromatic emissivity does not depend on the wavelength is called an ideal **gray body**. For a gray body,

$$\varepsilon_\lambda(\lambda, T) = \varepsilon(T) \quad (51.40b)$$

Absorptivity

The *hemispherical monochromatic absorptivity* is defined as the fraction of the incident hemispherical monochromatic irradiation that is absorbed by the surface, that is,

$$\alpha_\lambda(\lambda, T) = \frac{G_\lambda(\lambda)|_{\text{absorbed}}}{G_\lambda(\lambda)} \quad (51.41a)$$

From the definitions of intensity and radiosity, the *hemispherical total absorptivity* of a surface may be defined as

$$\alpha(T, \text{source}) = \frac{\int_{\lambda=0}^{\infty} \alpha_\lambda(\lambda, T) \left[\int_{\text{hemisphere}} I_{\lambda,j}(\mathbf{r}, \lambda, \hat{\mathbf{s}}) \cos\theta_i \, d\Omega \right] d\lambda}{\int_{\lambda=0}^{\infty} \int_{\text{hemisphere}} I_{\lambda,j}(\mathbf{r}, \lambda, \hat{\mathbf{s}}) \cos\theta_i \, d\Omega d\lambda} \quad (51.41b)$$

where $I_{\lambda,j}(\mathbf{r}, \lambda, \hat{\mathbf{s}})$ refers to the incident monochromatic intensity of radiation and θ_i is the angle between the incident radiation and the outward drawn normal to the surface. Equations (51.41) indicate that the monochromatic and the total absorptivities depend on $I_{\lambda,j}$ and, hence, on the source of radiation. Consequently, unlike the values of ε , the values of α cannot be easily tabulated.

Reflectivity

Radiation that is incident on a surface gets reflected. If the surface is smooth, the incident and reflected rays are symmetric with respect to the normal at the point of incidence, and this is known as *specular reflection*. If the surface is rough, the incident radiation is scattered in all directions. An idealized reflection law assumes that, in this situation, the intensity of the reflected radiation is constant for all angles of reflection and independent of the direction of radiation. The *hemispherical monochromatic reflectivity*, $\rho_\lambda(\lambda)$, is defined as the fraction of the reflected radiant energy that is incident on a surface. The hemispherical total reflectivity is merely

$$\rho = \int_{\lambda=0}^{\infty} \rho_\lambda(\lambda) d\lambda \quad (51.42)$$

FIGURE 51.7 Determination of the shape factor.

Transmissivity

If a body is semitransparent to radiation (as glass is to solar radiation), part of the incident radiation is reflected by the surface and part of it is absorbed. In this case the sum of the absorptivity and reflectivity is less than unity, and the difference is known as *transmissivity*, τ . Therefore,

$$\alpha_\lambda + \rho_\lambda + \tau_\lambda = 1 \text{ and } \alpha + \rho + \tau = 1 \quad (51.43)$$

For an opaque body $\tau = 0$, implying that $\rho_\lambda = 1 - \alpha_\lambda$ and $\rho = 1 - \alpha$.

Kirchhoff's Law

Kirchhoff's law states that the hemispherical monochromatic emissivity $\epsilon_\lambda(\lambda, T)$ is equal to the hemispherical monochromatic absorptivity $\alpha_\lambda(\lambda, T)$ at a given temperature T . That is,

$$\epsilon_\lambda(\lambda, T) = \alpha_\lambda(\lambda, T) \quad (51.44)$$

However, the hemispherical total values of the emissivity and absorptivity are equal only when one of the two following conditions is met: either (1) the incident radiation of the receiving surface must have a spectral distribution that is the same as that of the emission from a blackbody at the same temperature, or (2) the receiving surface must be an ideal gray surface — that is, $\epsilon_\lambda(\lambda, T)$ is not a function of λ .

Shape Factors

In the exchange of radiant energy between two surfaces, it is important to find the fraction of energy that leaves one surface and strikes the other. The flux of the energy between any two given surfaces can be expressed in terms of the *shape factor* (also known as *view factor*). The shape factor is purely a function of the geometry of the two surfaces and their relative orientation. The shape factors for the two surfaces shown in Figure 51.7 are given by

$$F_{1,2} = \frac{1}{A_1} \int_{A_1} \int_{A_2} \frac{\cos\theta_1 \cos\theta_2}{\pi r^2} dA_2 dA_1 \quad (51.45a)$$

and

$$F_{2,1} = \frac{1}{A_2} \int_{A_2} \int_{A_1} \frac{\cos\theta_2 \cos\theta_1}{\pi r^2} dA_1 dA_2 \quad (51.45b)$$

If the radiation between the two surfaces is diffuse, the fraction $Q_{1,2}$ of the radiant energy that leaves surface A_1 and is intercepted by A_2 is given by

$$Q_{1,2} = A_1 J_1 F_{1,2} \quad (51.46)$$

where J_1 is the radiosity of surface A_1 . In the above relations the order of the subscripts is important since $F_{1,2} \neq F_{2,1}$.

Further, shape factors possess the following properties. Any two given surfaces A_1 and A_2 satisfy the *reciprocal property*:

$$A_1 F_{1,2} = A_2 F_{2,1} \quad (51.47)$$

If a surface A_1 is divided into n parts ($A_{1_1}, A_{1_2}, \dots, A_{1_n}$) and the surface A_2 into m parts, the following *additive property* holds:

$$A_1 F_{1,2} = \sum_n \sum_m A_{1_n} F_{1_n,2_m} \quad (51.48)$$

If the interior of an enclosure is divided into n parts, each with a finite area A_i , $i = 1, 2, \dots, n$, then the *enclosure property* states that

$$\sum_{j=1}^n F_{i-j} = 1, \quad i = 1, 2, \dots, n \quad (51.49)$$

Radiative Transfer Equation

When a medium absorbs, emits, and scatters the radiant energy flowing through it, it is called a **participating medium**. An example of a participating medium is a gas with particles. Experiment shows that the intensity of radiation decays exponentially with the distance traveled in the medium. Further, if it encounters the particles in the gas, it gets scattered. Scattering takes place when one or more of diffraction, reflection, or refraction occur. Taking absorption and scattering into account, the transmissivity of a medium [also see “Radiative Properties of Real (Nonblack) Surfaces”] may be written as

$$\tau_\lambda = e^{-(\delta_\lambda + \zeta_\lambda)s} = e^{\beta_\lambda s} \quad (51.50)$$

where δ_λ is the *monochromatic scattering coefficient*, ζ_λ is the *monochromatic absorption coefficient*, and s is the thickness of the medium. β_λ is known as the *monochromatic extinction coefficient* of the medium.

In the solution of heat transfer problems that involve multiple modes of heat transfer, the energy equation must be solved. In such cases the term $\nabla \cdot q|_{\text{radiation}}$ [also see Equation (51.4)] must be calculated. Consider an absorbing, emitting, scattering medium with a monochromatic scattering coefficient δ_λ and a monochromatic absorption coefficient ζ_λ . Let a beam of monochromatic radiation of intensity $I_\lambda(s, \hat{\Omega}, t)$ travel in this medium along the direction $\hat{\Omega}$. The *radiative transfer equation* (RTE) is obtained by considering the energy balance for radiation due to emission, absorption, and in-and-out scattering in a small volume of this medium. The steady divergence of the heat flux for this case is then given by

$$\nabla \cdot q|_{\text{radiation}} = 4\pi \int_0^\infty \zeta_\lambda I_{b,\lambda}(T) d\lambda - \int_0^\infty \zeta_\lambda \left[\int_{4\pi} I_\lambda(s, \hat{\Omega}) d\hat{\Omega} \right] d\lambda \quad (51.51)$$

where $I_{b,\lambda} = E_{b,\lambda} / \pi$ and $I_\lambda(s, \hat{\Omega})$ is obtained as a solution to the RTE.

51.4 Phase Change

Phase change occurs when a substance (solid, liquid, or gas) changes its state due to the absorption or release of energy. Below we briefly discuss melting/freezing (solid \leftrightarrow liquid) and condensation/boiling (liquid \leftrightarrow vapor).

Melting and Freezing

The analysis of situations in which a solid melts or a liquid freezes involves the *phase change* or *moving boundary problem*. The solutions to such problems are important in the making of ice, the freezing of food, the solidification of metals in casting, the cooling of large masses of igneous rock, the casting and welding of metals and alloys, etc. The solution of such problems is difficult because the *interface* between the solid and the liquid phases is in motion, due to the absorption or release of the latent heat of fusion or solidification. Thus, the location of the moving interface is not known beforehand and is a part of the solution to the problem. The heat transfer problem in these situations can be treated as a problem in heat conduction with moving boundaries, which requires a solution to Equation (51.6) under appropriate boundary conditions. The solution to these problems is beyond the scope of this chapter, and the interested reader is referred to works such as Ozisik [1993].

Condensation

Consider a vapor that comes into contact with a surface that is maintained at a temperature that is lower than the saturation temperature of the vapor. The resulting heat transfer from the vapor to the surface causes immediate *condensation* to occur on the surface. If the surface is cooled continuously so as to maintain it at a constant temperature, and the condensate is removed by motion due to gravity, it is covered with a thin film of condensed liquid. This process is known as *filmwise condensation*. Filmwise condensation usually occurs when the vapor is relatively free of impurities. Sometimes, when oily impurities are present on surfaces or when the surfaces are highly polished, the film of condensate breaks into droplets. This situation is known as *dropwise condensation*. In filmwise condensation the presence of the liquid film acts as a barrier for the heat transfer between the vapor and the surface. In dropwise condensation, less of a barrier exists between the vapor and the surface. As a result, heat transfer coefficients are five to ten times the corresponding values for film condensation. Since fluid motion plays a significant role in condensation and boiling, they are studied along with convective heat transfer processes. However, significant differences exist between convective heat transfer during phase change and single-phase processes. The study of condensation and boiling is useful in the design of condensers and boilers, two widely used types of heat exchangers.

Filmwise Condensation

Consider a cold vertical plate of length L maintained at a constant temperature T_w and exposed to saturated vapor at temperature T_v . Figure 51.8 shows the formation of the film of condensate on the plate. By the analysis of the boundary layer equations for the film of condensate, Nusselt obtained the heat transfer coefficient h_x at location x (with respect to Figure 51.8) for this case. Nusselt's analysis is also valid for condensation outside a long cylinder or tube if its radius is large compared to the thickness of the condensing film. The actual correlation for this case and for filmwise condensation on other surfaces can be found in standard textbooks [see, for instance, Bejan (1984)]. In condensation problems the Reynolds number of the condensate flow is given by

$$\text{Re} = \frac{4\dot{m}}{\mu_f P} = \frac{4A_t h_m (T_v - T_w)}{h_{fg} \mu_f P} \quad (51.52)$$

FIGURE 51.8 Filmwise condensation on a vertical surface.

where \dot{m} is the mass flow rate of the condensate at the lowest part of the condensing surface. The wetted perimeter P is defined as w for a vertical plate of width w and πD for a vertical cylinder/tube with outside diameter D . A_t is the total condensing surface area, h_m is the mean heat transfer coefficient, and h_{fg} is the latent heat of condensation.

Condensers are usually designed with horizontal tubes arranged in vertical tiers. If the drainage from one tube is assumed to flow smoothly onto the tube below, then, for a vertical tier of N tubes each of diameter D ,

$$[\text{Nu}_m]_{\text{for } N \text{ tubes}} = \frac{1}{N^{1/4}} [\text{Nu}_m]_{\text{for one tube}} \quad (51.53)$$

Dropwise Condensation

Experiments have shown that if traces of oil or other selected substances (known as **promoters**) are present either in steam or on the condensing surface, the condensate film breaks into droplets. The droplets grow, coalesce, and run off the surface, leaving a greater portion of the surface exposed to the incoming steam. Therefore, dropwise condensation is a more efficient method of heat transfer. Typical heat transfer coefficients of $5.7 \cdot 10^4$ to $50 \cdot 10^4 \text{ W/m}^2\text{C}$ may be obtained as opposed to heat transfer coefficients in the order of $5 \cdot 10^3 \text{ W/m}^2\text{C}$ for filmwise condensation. If sustained dropwise condensation can be maintained, it will result in considerable reduction in the size of condensers and their cost. Research in this area has thus been aimed at producing long-lasting dropwise condensation via the use of promoters. A satisfactory promoter must repel the condensate, stick tenaciously to the substrate, and prevent oxidation of the surface. Some of the most popular promoters are fatty acids such as oleic, stearic, and linoleic acids. In order to prevent failure of dropwise condensation as a result of oxidation, coatings of noble metals such as gold, silver, and palladium have been used in the laboratory. Such coatings have sustained over 10,000 h of continuous dropwise condensation. However, this method is too expensive for use on an industrial scale.

Another problem in dropwise condensation is the presence of a noncondensable gas. If a noncondensable gas such as air is present in the vapor even in small amounts, the heat transfer coefficient is significantly reduced. When the vapor condenses, the noncondensable gas is left at the surface of the condensate, and the incoming vapor must diffuse through this body of vapor–gas mixture before reaching the condensing surface. This diffusion process reduces the partial pressure of the condensing vapor and in turn its saturation temperature; that is, the temperature of the surface of the layer of condensate is lower than the bulk saturation temperature of the vapor. Therefore, in practical applications, there is a provision to vent the noncondensable gas that accumulates inside the condenser.

FIGURE 51.9 Principal regimes in pool boiling of water at atmospheric pressure and saturation temperature.

Pool Boiling

Boiling occurs when a liquid changes phase and becomes vapor due to the absorption of heat. When the heating surface is submerged in a quiescent pool of liquid, the boiling phenomenon is known as *pool boiling*. The boiling that might occur in a fluid that moves due to an externally imposed pressure gradient is called *forced convection boiling*.

In 1934, Nukiyama performed a systematic study of pool boiling by immersing an electric wire into a body of saturated water and heating it. He determined the heat flux and temperature from current and voltage measurements. Figure 51.9 illustrates the characteristics of pool boiling for water at atmospheric pressure. It shows the heat transfer coefficient (or the heat flux) as a function of the wire and water saturation temperatures. This curve shows that there are three distinct regimes of pool boiling: the *free-convection* regime, nucleate boiling regime, and *film boiling* regime.

Initially, heat transfer is by free convection. The temperature of the heater surface is a few degrees above the saturation temperature, and free convection is sufficient to remove heat from it. The heat transfer correlations, as expected, are of the form given by Equation (51.28).

In the **nucleate boiling** regime, bubbles are formed on the surface of the heater. There are two distinct regions in this regime. In the first, bubbles are formed at certain favored sites but are dissipated in the liquid as soon as they are detached from the surface. In the second region, the bubble generation is high enough to sustain a continuous column. Thus, large heat fluxes may be obtained in this region. In the nucleate boiling regime, the heat flux increases rapidly with increasing temperature difference until the peak heat flux is reached. The location of this peak heat flux is known as the *burnout point*, *departure from nucleate boiling* (DNB), or *critical heat flux*. After the peak heat flux is exceeded, an extremely large temperature difference is needed to realize the resulting heat flux, and such high temperature differences may cause “burnout” of the heating element.

As indicated in Figure 51.9, the peak heat flux occurs in the nucleation boiling regime. This maximum value must be known beforehand because of burnout considerations. That is, if the applied heat flux is greater than the peak heat flux, the transition takes place from the nucleate to the stable film boiling regime, in which (depending on the kind of fluid) boiling may occur at temperature differences well above the melting point of the heating surface.

After the peak heat flux is reached, the *unstable film boiling region* begins. No correlations are available for the heat flux in this region until the minimum point in the boiling curve is reached and the stable film boiling region starts. In the stable film boiling region the heating surface is separated from the liquid by a vapor layer across which heat must be transferred. Since vapors have low thermal conductivities,

large temperature differences are needed for heat transfer in this region. Therefore, heat transfer in this regime is generally avoided when high temperatures are involved.

Defining Terms

Blackbody — A body that absorbs all incident radiation from all directions at all wavelengths without reflecting, transmitting, or scattering it.

Diffuse — The radiation from a body or a radiative property that is independent of direction.

Energy equation — The equation that makes use of the principle of conservation of energy in a given process [see Equation (51.3) through Equation (51.5)].

Film temperature — The mean boundary layer temperature [see Equation (51.24)].

Fourier's law — The law that relates the heat flow to the temperature gradient in a body [see Equation (51.2)].

Gray surface — A surface whose monochromatic emissivity is independent of the wavelength.

Heat transfer coefficient — A quantity that determines the heat flux due to convective heat transfer between a surface and a fluid that is moving over it [see Equation (51.12) and Equation (51.26)].

Newton's law of cooling — The relation that determines the heat flux due to convection between a surface and moving fluid [see Equation (2.10)].

Nucleate boiling — The stage in (pool) boiling of a fluid at which bubbles are formed at favored sites on the heating surface and detached from it.

Participating medium — A medium that absorbs, emits, and scatters the radiation that passes through it.

Phonons — A term that refers to the quantized lattice vibrations in a solid. Phonons are the energy carriers in a dielectric solid and are responsible for conduction of heat and electricity.

Planck's law — The law that relates the emissive power of a blackbody at a given wavelength to its temperature [see Equation (51.29)].

Promoters — Substances that are introduced into a pure vapor or onto a condensing surface to facilitate dropwise condensation on a surface.

Stefan-Boltzmann law — The relation that determines the heat flux due to radiation from a surface [see Equation (51.30)].

Thermal conductivity — A property that determines the ability of a substance to allow the flow of heat through it by conduction [see Equation (51.2)].

Thermal diffusivity — A material property that governs the rate of propagation of heat in transient processes of conduction [see Equation (51.6)].

A **heat exchanger** is a device that is used to transfer heat between two or more fluids that are at different temperatures. Heat exchangers are essential elements in a wide range of systems, including the human body, automobiles, computers, power plants, and comfort heating/cooling equipment. In the chemical and process industries, heat exchangers are used to concentrate, sterilize, distill, pasteurize, fractionate, crystallize, or control the fluid flow and chemical reaction rates. With the recent global promotion of energy efficiency and protection of the environment, the role of heat exchangers in efficient utilization of energy has become increasingly important, particularly for energy-intensive industries, such as electric power generation, petrochemical, air conditioning/refrigeration, cryogenics, food, and manufacturing.

The Carnot efficiency for an ideal heat engine that receives Q_H amount of heat from a high-temperature reservoir at temperature T_H and rejects Q_L amount of heat to a reservoir at temperature T_L is

$$\eta = 1 - \frac{T_L}{T_H} = 1 - \frac{Q_L}{Q_H} \quad (52.1)$$

Equation (52.1) represents the maximum possible efficiency for a heat engine operating between a low- and a high-temperature reservoir. The Carnot efficiency is a good reference against which the performance of an actual heat engine can be compared. From the Carnot efficiency, it is clear that heat exchangers play a direct role in the overall efficiency of thermal machinery and equipment. By employing a more effective heat exchanger in a thermal cycle, one can get a higher T_H and lower T_L , resulting in higher efficiencies for the cycle as a whole.

In this chapter, we will first outline the basic classifications of heat exchangers and the relevant terminology used. Next, essential features and fundamental design aspects of **shell-and-tube** and **compact heat exchangers** will be described. Recent advances in thermal performance of heat exchangers will be discussed in the last section of this chapter.

52.1 Heat Exchanger Types

Heat exchangers can be classified in many different ways. Shah [1981] provides a comprehensive and detailed description of the various categories, the associated terminology, and the practical applications of each type. As indicated there, heat exchangers can be broadly classified according to the six categories described below.

Transfer Processes

In this category, heat exchangers are classified into direct contact and indirect contact types. In the direct type, the heat exchanging streams (hot and cold streams) come into direct contact and exchange heat before they are separated. Such heat exchangers are more common in applications where both heat and mass transfer are present. A familiar example is evaporative cooling towers used in power plants and in comfort cooling for desert environments. In an indirect contact heat exchanger, the hot and cold fluids are separated by a solid, impervious wall representing the heat transfer surface. The conventional shell-and-tube heat exchangers fall in this category.

Number of Fluids

In many applications, the two-fluid heat exchangers are the most common type. However, in certain applications, such as cryogenics and the chemical and process industries, multifluid heat exchangers are also common.

The Degree of Surface Compactness

In this category, heat exchangers are classified according to the amount of heat transfer surface area per unit volume incorporated into the heat exchanger. This is represented by the heat transfer area-to-volume ratio ($\beta = A/V$). For example, for compact heat exchangers $\beta \approx 700 \text{ m}^2/\text{m}^3$ or greater, for **laminar flow heat exchangers** $\beta \approx 3000 \text{ m}^2/\text{m}^3$, and for **micro heat exchangers** $\beta \approx 10,000$ or greater.

Construction Features

In this category, heat exchangers are often divided into four major types: tubular, plate type, extended surface, and regenerative types. There are other types of heat exchangers with unique construction that may not fall in these four categories. However, they are not commonly used and are specific to specialized applications.

Flow Arrangements

Heat exchangers can be classified according to the manner in which the fluid flows through the tube and shell sides. The two broad types are single pass and multipass. When the fluid flows through the full length of the heat exchanger without any turns, it is considered to have made one pass. A heat exchanger is considered single pass when the hot and cold fluids make one pass in the heat exchanger. Within the single pass category, the common flow arrangements for the hot and cold fluids are parallel flow, counterflow, cross-flow, split flow, and divided flow. Multipass heat exchangers are classified according to the type of construction. The common types include extended surface, shell-and-tube, and plate heat exchangers.

Heat Transfer Regimes

Exchange of thermal energy in a heat exchanger from the hot fluid to the exchanging wall to the cold fluid can employ one or more modes of heat transfer. For example, in gas-to-gas heat exchangers, heat

transfer on both the hot and cold fluids is by single phase convection. In water-cooled steam condensers, single phase convection takes place in one side and condensation in the other side. Yet, in certain cryogenic heat exchangers, condensation takes place on one side and evaporation on the other side. Basic components and essential features of the two most commonly used heat exchangers — namely, shell-and-tube and plate-fin heat exchangers — will be discussed in the following sections.

52.2 Shell-and-Tube Heat Exchangers

General Features

Among the various heat exchanger types, shell-and-tube heat exchangers are the most commonly used in a number of industries, including process, chemical, power, and refrigerating/air conditioning. In this type of heat exchanger, one fluid flows inside the tubes while the other fluid is forced through the shell side and over the tubes in a cross-flow arrangement.

The shell-and-tube heat exchangers have several main advantages that, as a whole, have contributed to their nearly universal acceptance for a wide range of applications. They can be custom designed for almost any capacity, working fluid type, operating pressure, and temperature conditions. The type of material used to construct the heat exchanger can be any of the most commonly used materials. Shell-and-tube heat exchangers yield a relatively large surface area density. Methods for cleaning and other maintenance, such as periodic replacement of gaskets and tubes, are well established and easily performed. Their broad worldwide use over the years has resulted in good methods for design and fabrication.

The size of a shell-and-tube heat exchanger can vary over a wide range from compact to supergiant configurations. Common examples of shell-and-tube heat exchangers are steam generators, condensers, evaporators, feed water heaters, oil coolers in the power and refrigeration industries, and process heat exchangers in the petroleum refining and chemical industries. Classification of shell-and-tube heat exchangers is usually according to the number of tube and shell passes. The heat exchangers schematically shown in Figure 52.1(a), Figure 52.1(b), and Figure 52.1(c) represent, respectively, one shell pass and one tube pass, two shell passes and one tube pass, and one shell and four tube passes.

FIGURE 52.1 Examples of shell-and-tube heat exchanger configurations.

FIGURE 52.2 Major components of a shell-and-tube heat exchanger.

Major Components

Major components of a shell-and-tube heat exchanger are shown in Figure 52.2. A variety of different constructions are used in shell-and-tube heat exchangers. Major types are identifiable by a special notation developed by the Tubular Exchanger Manufacturer’s Association (TEMA), in which each heat exchanger is designated by a three-letter combination. The first letter indicates the front-end head type, the second the shell type, and the third letter identifies the rear-end head type. The standard in single shell arrangement type is TEMA E, in which the entry and outlet nozzles are placed at opposite ends. Figure 52.3 shows three sample TEMA configurations.

The baffles in a shell-and-tube heat exchanger serve two tasks. First, they direct the flow in the shell side tube bundle approximately at right angles to the tubes so that higher heat transfer coefficients in the shell side can be obtained while reducing thermal stresses on the tubes due to the cross-flow effect. The second, and more important, function of baffles is to provide additional support for the tubes during assembly and operation and minimize flow-induced vibration of the tubes.

The tubes used in a shell-and-tube heat exchanger can be either bare (plain) or of the enhanced type. The enhanced types utilize a combination of additional surface area (e.g., through use of various fin structures) and various mechanisms to increase the heat transfer coefficients at the tube surface. As described in Ohadi [1991] and Webb [1994], some of the recently developed enhanced heat transfer mechanisms can yield in excess of a tenfold increase in the magnitude of the heat transfer coefficients when compared to conventional plain tubes.

The tube sheet in a shell-and-tube heat exchanger is usually a single, round, metallic plate that has been suitably drilled and grooved to accommodate the tubes, the gasket, and other associated accessories. The main purpose of the tube sheet is to support the tubes at the ends. In addition to its mechanical

FIGURE 52.3 Sample TEMA configurations.

FIGURE 52.4 A basic plate-fin heat exchanger construction.

requirements, the tube sheet must be resistant to corrosion from fluids in both the tube and shell sides and must be electrochemically compatible with the tube side materials. The tube sheets are sometimes made from low-carbon steel with a thin layer of corrosion-resistant alloy.

52.3 Compact Heat Exchangers

Definition

A heat exchanger is referred to as a compact heat exchanger if it incorporates a heat transfer surface having a surface density above approximately $700 \text{ m}^2/\text{m}^3$ on at least one of the fluid sides, usually the gas side. Compact heat exchangers are generally of plate-fin type, tube-fin type, tube bundles with small diameter tubes, and regenerative type. In a plate-fin exchanger, corrugated fins are sandwiched between parallel plates as shown in Figure 52.4. In a tube-fin exchanger, round and rectangular tubes are most commonly used and fins are employed either on the outside, the inside, or on both the outside and the inside of the tubes, depending upon the application. Basic flow arrangements of two fluids are single pass cross-flow, counterflow, and multipass cross-counterflow.

Characteristics

Some of the subtle characteristics and uniqueness of compact heat exchangers are:

1. Usually at least one of the fluids is a gas.
2. The fluid must be clean and relatively noncorrosive.
3. Fluid pumping power is always of prime importance.
4. Operating pressure and temperatures are somewhat limited compared to shell-and-tube exchangers due to construction features.

The shape of a compact heat exchanger is usually distinguished by having a large frontal area and short flow lengths. Thus, the proper design of the header for compact heat exchangers is very important for a uniform flow distribution. A variety of surfaces are available for use in compact heat exchangers having different orders of magnitude of surface area densities. Such surfaces could introduce substantial cost, weight, or volume savings as desired by the design. Figure 52.5 shows some sample surfaces and geometries currently employed in compact heat exchangers.

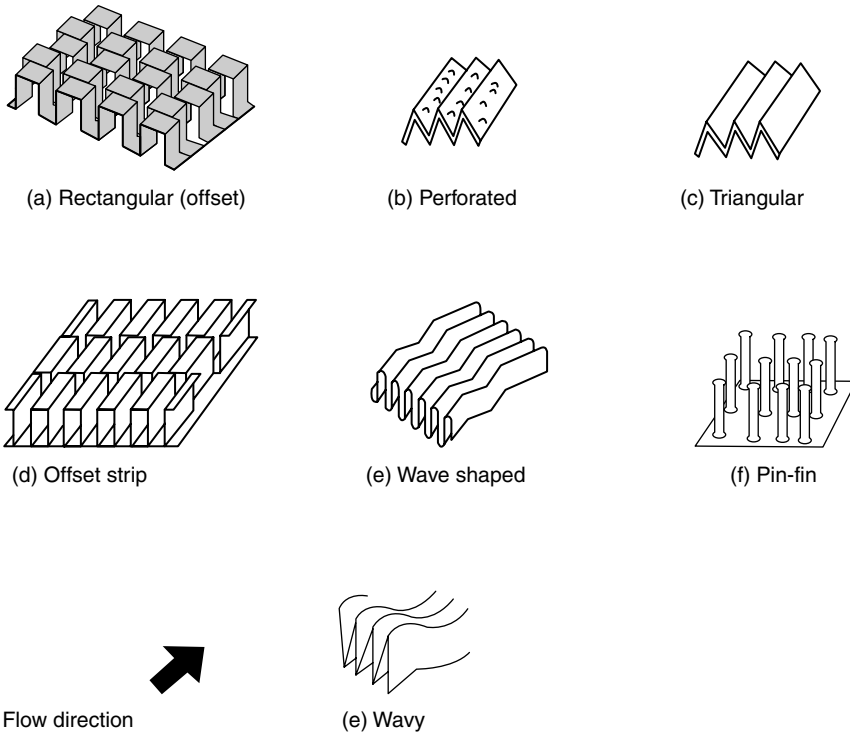

FIGURE 52.5 Examples of plate-fin surface geometries.

Applications

The major heat exchangers in cars and trucks are radiators for engine cooling, heaters for passenger compartment heating, evaporators and condensers for air conditioning, oil coolers for engine oil and transmission oil cooling, and charge air coolers and intercoolers for cooling charge air for increased mass flow rate through the engine.

A variety of compact heat exchangers are needed in space applications where the minimum weight and volume, as well as the absolute reliability and durability, are essential. Very high heat fluxes in low-weight and low-volume heat exchangers can be obtained by employing two-phase flow in offset strip fins. Such heat exchangers will have a significant impact on emerging applications, such as condensers and evaporators for thermal control of space stations, satellite instrumentation, aircraft avionics packages, thermal control of electronics packages, and thermal control of space life support and astronauts.

In commercial aircraft applications, a variety of primarily compact heat exchangers are used for cabin air conditioning and heating, avionics cooling, deicing, and oil cooling applications.

52.4 Design of Heat Exchangers

Basic Design

When designing a heat exchanger, the following requirements must be satisfied for most typical applications:

- Meet the process thermal requirements within the allowable pressure drop penalty
- Withstand the operational environment of the plant, including the mechanical and thermal stress conditions of the process, operational schedule, and resistance to corrosion, erosion, vibration, and fouling

Provide easy access to those components of the heat exchanger that are subject to harsh environments and require periodic repair and replacement
 Should have a reasonable cost (combination of initial and maintenance costs)
 Should be versatile enough to accommodate other applications within the plant, if possible

Broadly speaking, the various design tasks in a new heat exchanger can be classified into two categories: (1) the mechanical design and (2) the thermal-hydraulic design. The mechanical design deals with the proper distribution of thermal and mechanical stresses and the general integrity of the heat exchanger for the conditions specified. The thermal-hydraulic design deals with calculations of heat transfer and pressure drop coefficient and, subsequently, determination of the overall required dimensions of the heat exchanger for specified thermal operating conditions. The mechanical design aspects are beyond the scope of this article and can be found elsewhere [Hewitt et al., 1994]. An introduction to the thermal-hydraulic design criteria will be given in the following.

Thermal-Hydraulic Design

As discussed by Shah [1986], the various steps in the thermal-hydraulic design of heat exchangers can be classified into two distinct problems: the *rating problem* (also referred to as the *performance problem*) and the *sizing problem* (also referred to as the *design problem*).

The rating problem involves the determination of the overall heat transfer coefficients and pressure drop characteristics utilizing the following input data: the heat exchanger configuration, flow rates on each side, inlet temperatures and pressure data, thermophysical properties of the fluid fouling factors, and complete details on the materials and surface geometries of each side. The sizing problem utilizes the data provided in the rating problem and determines the overall (core) dimensions (core length and surface areas) for the heat exchanger. Steps involved in the rating and sizing problems are schematically shown in Figure 52.6.

The LMTD Method

It is a general practice to determine the heat transfer between two fluids in a heat exchanger using the mean quantities and the following defining equation:

$$q = FU_m A \Delta T_m \quad (52.2)$$

in which U_m and ΔT_m represent the mean heat transfer coefficient and effective temperature difference, respectively. The factor F is a function of flow arrangement and is provided graphically for various heat exchanger configurations [Shah, 1983]. The required surface area in the heat exchanger is then determined utilizing the following equation:

$$A = \frac{q}{FU_m \Delta T_m} \quad (52.3)$$

The above equation is based on several assumptions, such as constant specific heats, constant overall heat transfer coefficients in the heat exchanger, constant fluid properties, absence of heat losses to and from the surroundings, and absence of heat sources in the heat exchanger. The probable errors due to the above assumptions are regarded as the penalty for the simplicity of the method. In practice, correction factors are applied to adjust the calculations for the errors involved.

The overall heat transfer coefficient U_m is determined by taking into account the various thermal resistances involved in the heat transfer path between the hot and cold fluids:

$$U_m = \frac{1}{\sum R} = \frac{1}{(1/hA)_h + R_{fh} + R_w + R_{fc} + (1/hA)_c} \quad (52.4)$$

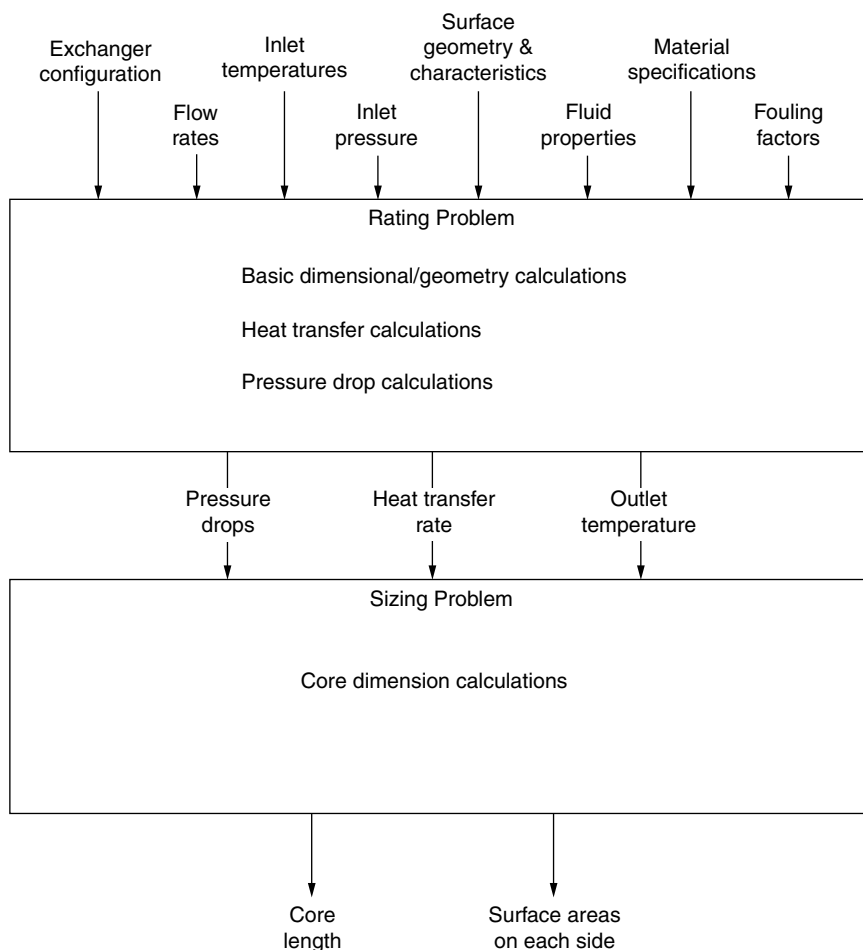

FIGURE 52.6 Schematic presentation of the heat exchanger rating and sizing problems.

in which $(1/hA)_h$ and $(1/hA)_c$, respectively, represent the convective resistance on the hot and cold sides of the heat exchanger, R_{fh} and R_{fc} represent fouling resistance on the hot and cold sides, and R_w is thermal resistance due to wall tubing. Representative values of U for common fluids are listed in [Table 52.1](#).

To determine the mean temperature difference between the hot and cold fluids over the heat exchanger length (ΔT_m), it is a common practice to use the log mean temperature difference (LMTD), defined as

$$\Delta T_m = \frac{\Delta T_i - \Delta T_o}{\ln(\Delta T_i / \Delta T_o)} \quad (52.5)$$

in which ΔT_i and ΔT_o represent the temperature difference between the hot and cold fluids at the inlet and outlet of the heat exchanger, respectively.

Effectiveness and Number of Transfer Units (NTU) Method

The LMTD method for the prediction of heat exchanger performance is useful only when the inlet and exit temperatures for the heat exchanger are known, either because they have been specified by the design or because they have been measured in a test. For situations where calculation of the inlet and outlet temperatures and flow rates are desired, use of the LMTD method requires iterative solution procedures. This can be avoided if the heat exchanger performance is expressed in terms of effectiveness and number

TABLE 52.1 Representative Values of the Overall Heat Transfer Coefficient (U)

| Hot Side Fluid | Cold Side Fluid | U | |
|--|--------------------------------------|------------------------------|----------------------|
| | | Btu/(hr-ft ² -°F) | W/(m ² K) |
| Water | Water | 200 to 500 | 800 to 2500 |
| Water | Gas | 2 to 10 | 10 to 50 |
| Water | Lubricating oil | 20 to 80 | 160 to 400 |
| Ammonia | Water (e.g., water-cooled condenser) | 150 to 500 | 800 to 2588 |
| Water | Brine | 100 to 200 | 500 to 1000 |
| Light organics | Water | 75 to 150 | 350 to 750 |
| Medium organics | Water | 50 to 125 | 240 to 610 |
| Heavy organics | Water | 5 to 75 | 25 to 370 |
| Light organics | Light organics | 40 to 100 | 200 to 500 |
| Heavy organics | Heavy organics | 10 to 40 | 50 to 200 |
| Heavy organics | Light organics | 30 to 60 | 150 to 300 |
| Steam | Water | 200 to 1000 | 10 to 6000 |
| Steam | Ammonia | 200 to 700 | 1000 to 3500 |
| Freon 12 | Water | 50 to 200 | 300 to 1000 |
| Steam | Heavy fuel oil | 10 to 40 | 50 to 200 |
| Steam | Light fuel oil | 30 to 60 | 200 to 400 |
| Steam | Air (air-cooled condenser) | 10 to 40 | 50 to 200 |
| Finned tube heat exchanger, water in tubes | Air over finned tubes | 5 to 10 | 30 to 60 |
| Finned tube heat exchanger, steam in tubes | Air over tubes | 50 to 700 | 300 to 4500 |

of transfer units (NTU), which will be briefly discussed in the following. The heat exchanger effectiveness, ϵ , is defined as the ratio of actual heat transferred to the maximum heat transfer amount which can be transferred in an infinitely long counterflow heat exchanger. In an infinitely long counterflow heat exchanger, with $(mC_p)_c < (mC_p)_h$, in which subscripts c and h refer to the cold and hot streams, we can write

$$\dot{q}_{\max} = (\dot{m}C_p)_c (T_{h,\text{in}} - T_{c,\text{in}}) \quad (52.6)$$

Similarly, if $(mC_p)_h < (mC_p)_c$ then q_{\max} in an infinitely long counterflow exchanger is

$$\dot{q}_{\max} = (\dot{m}C_p)_h (T_{h,\text{in}} - T_{c,\text{in}}) \quad (52.7)$$

Now if we write

$$C_{\min} = \min[(\dot{m}C_p)_h, (\dot{m}C_p)_c] \quad (52.8)$$

then the maximum heat transfer in a heat exchanger of any configuration is

$$\dot{q}_{\max} = C_{\min} (T_{h,\text{in}} - T_{c,\text{in}}) \quad (52.9)$$

From this equation, the effectiveness is expressed as

$$\epsilon = \frac{\dot{q}}{\dot{q}_{\max}} = \frac{(\dot{m}C_p)_h (T_{h,\text{in}} - T_{h,\text{out}})}{C_{\min} (T_{h,\text{in}} - T_{c,\text{in}})} = \frac{(\dot{m}C_p)_c (T_{c,\text{out}} - T_{c,\text{in}})}{C_{\min} (T_{h,\text{in}} - T_{c,\text{in}})} \quad (52.10)$$

The number of transfer units (NTU) is defined for the hot and cold streams as

$$NTU_h = \frac{AU}{(\dot{m}c_p)_h} \quad (52.11)$$

$$NTU_c = \frac{AU}{(\dot{m}c_p)_c} \quad (52.12)$$

where A is the total heat exchanger area and U is the overall heat transfer coefficient. Similarly, NTU_{\min} corresponding to the stream having the minimum $(\dot{m}c_p)$ is defined as

$$NTU_{\min} = \frac{AU}{(\dot{m}c_p)_{\min}} \quad (52.13)$$

From there it follows that

$$\varepsilon = NTU_{\min} \theta \quad (52.14)$$

where θ is the ratio between the mean temperature difference ΔT_{mean} and the maximum temperature difference ΔT_{max} :

$$\theta = \frac{\Delta T_{\text{mean}}}{\Delta T_{\text{max}}} \quad (52.15)$$

The effectiveness and NTU relations for various heat exchanger configurations have been developed and are available in the literature [Mills, 1992].

52.5 Microchannel Heat Exchangers

The early work by Tuckerman and Pease (1981) demonstrated that advanced microfabrication techniques could be used in the fabrication of compact micro heat exchangers. They suggested that heat rate removal rates on the order of 1000 W/cm² could be possible with their original water-cooled heat exchanger. Microchannels' wide practical applications in highly specialized fields, such as bioengineering and micro-fabricated fluidic systems, have long been known. More recently, microchannels' wide application in the automotive air conditioning industry, fuel cells, and microelectronics has been realized. Today, microchannels have almost completely replaced circular tubes in automotive condensers and have recently become the subject of heavy research and development for cost-effective use as automotive evaporators. The advantage of the microchannel lies in its high heat transfer coefficient and significant potential in decreasing the size of heat exchangers.

Microchannels are fabricated by a variety of processes depending on the dimensions and plate material used, e.g., metals, plastics, and silicon. Conventional machining and electrical discharge machining are two typical options, while semiconductor fabrication processes are appropriate for microchannel fabrication in chip cooling applications. Using microfabrication techniques developed by the electronics industry, it is possible to manufacture three-dimensional structures with length scale as small as 0.1 μm . The prominent characters of microchannel heat sinks lie in the enhanced heat transfer expected to be realized from extremely large surface areas per unit volume (on the order of 10⁵ m²/m³) and heat transfer coefficients (in the order of 10² W/cm²-K) [Incropera, 1999]. Compared to conventional compact heat exchangers, the hydraulic diameters of microchannels are quite small, typically 1 to 2000 μm , and the fluid flow regime in microchannels in most cases is laminar.

Compared with channels of normal size, microchannels have many heat transfer advantages. Since microchannels have an increased heat transfer surface area and a large surface-to-volume ratio, they

FIGURE 52.7 Schematic of refrigerant and airside flow passages in a compact automotive microchannel heat exchanger.

provide a much higher heat transfer. This feature allows heat exchangers to become compact and lightweight. In addition, microchannels can support high heat flux with small temperature gradients. However, microchannels also have weaknesses, such as large pressure drop, high cost of manufacture, dirt clogging, and flow maldistribution, especially for two-phase flows.

In recent years, major progress in compact evaporator development has been made by the automotive, aerospace, and cryogenic industries. The thermal duty and the energy efficiency increased during this period, while the space constraints became more vital. The trend was toward greater heat transfer rates per unit volume. The hot side of the evaporators in these applications was generally air, gas, or a condensing vapor. With advances in the airside fin geometry, significant improvements were achieved from increased heat transfer coefficients as well as greater surface area densities. As the airside heat transfer resistance decreased, more aggressive heat transfer designs were sought on the evaporating side, resulting in use of micro channel flow passages on the liquid side (evaporating or condensing or single-phase regimes). The major changes in recent evaporator and condenser designs for automotive and other compact heat exchanger applications involve use of individual, small-hydraulic-diameter flow passages, arranged in a multi-channel configuration on the liquid side. Figure 52.7 shows a plate-fin evaporator geometry commonly known in compact refrigerant evaporators for automotive and heat pump applications. As seen there, fins are placed in between microchannel flow slabs and the arrangement is brazed together in special ovens.

Two types of microchannel geometries are widely used in the compact heat exchanger designs. These are shown in Figure 52.8 and Figure 52.9, with typical geometric dimensions as those listed in the Table 52.2 [Zhao et al., 2001].

Despite the thin walls in microchannels, they can withstand high operating pressures. For example, a microchannel with a hydraulic diameter of 0.8 mm and a wall thickness of 0.3 mm can easily withstand operating pressures of up to 14 MPa. Another advantage of microchannels is their very large contact surface area per unit volume. This large surface area results from the definition of the hydraulic diameter, $D_h = 4A_c/p$, where A_c is the flow cross-sectional area, and p is the wetted perimeter. For a fixed total cross-sectional area, smaller D_h means larger p , which implies a larger heat transfer surface area. The high heat transfer coefficient attainable in microchannels potentially leads to significant decreases in the size of heat exchangers, thereby saving space and material. The high heat transfer coefficients are due, in part, to the increased heat transfer surface area and large surface-to-volume ratio in microchannels. Because of the high heat transfer performance, microchannels are now used routinely in most automotive condensers and have recently become the subject of study for use as automotive evaporators.

Another application area where microchannels are finding wide applicability is their use for cooling of high flux military and commercial electronics. Two widely known options exist. In one case, microchannels may be machined in a substrate or heat sink to which a chip or an array of chips is attached. In the other, they may be machined in the chip itself. A typical packaging architecture of high power laser array using a microchannel heat sink is shown in Figure 52.10 [Puchert et al., 2000].

FIGURE 52.8 Typical dimensions of a rectangular microchannel for compact heat exchanger applications.

FIGURE 52.9 Typical dimensions of a triangular microchannel for compact heat exchanger applications.

TABLE 52.2 Typical Dimensions of the Two Example Microchannels

| | Microchannel I | Microchannel II |
|--------------------------------|----------------|-----------------|
| Channel geometry | Rectangular | Triangular |
| D_h (hydraulic diameter, mm) | 0.7 | 0.86 |
| Number of channels | 28 | 25 |
| L (length, mm) | 300 | 300 |
| Ht (height, mm) | 1.5 | 1.9 |
| W (width, mm) | 28 | 27.12 |
| Wall thickness (mm) | 0.4 | 0.3 |

The interfaces between laser array packaging materials are bonded with solders. Due to relatively low thermal conductivity of solder materials, the integrity of these solder layers is a critical factor in the thermal performance of laser diodes. Solder voids, delaminations, and other inclusions lead to sharply increased localized temperatures (hot spots) that degrade performance and can lead to the failure of laser diodes. One practical way to improve laser diode arrays is to directly etch microchannels into the silicon substrate of the laser diode arrays as shown in Figure 52.11 [Beach, 2002]. The delivery of a 41-kW-peak-power diode array module constructed using LLNL (Lawrence Livermore National Laboratory) Silicon

FIGURE 52.10 A schematic of a microchannel-cooled laser array on a microchannel heat sink.

FIGURE 52.11 Sketch of a SiMMs package.

Monolithic Microchannels (SiMMs) packages was reported. It makes possible the fabrication of thousands of tiny ($\sim 30 \mu\text{m}$ -wide) cooling microchannels in very close proximity to the heat-producing laser diode bar arrays. The aggressive cooling capability of the SiMMs package enables efficient operation of laser diode arrays in a very tightly packed geometry.

Another approach to reducing the thermal resistance is to use a microchannel heat sink made of chemical-vapor-deposited diamond instead of silicon. This eliminates the impact of the thermal boundary resistance at the diamond bottom boundary and uses the high conductivity of diamond to maximize the efficiency of the microchannel-wall fins. This new configuration has the potential to yield a 75% reduction in the thermal resistance from the diode array to the water coolant compared to that for a conventional configuration based on microchannels in silicon (Goodson, 1997).

Microchannel cooling technology exhibits several advantages that provide highly efficient cooling in both earth- and space-based systems, such as higher heat transfer coefficient at the lower wall superheat temperature, eliminating contact resistance associated heat exchangers through directly fabricated-on-chip substrates, and potential application in space confined area (three-dimensional stacks of chips). However, the fluid flow and heat transfer in microchannel heat exchangers is not well understood, especially in two-phase flow regimes where flow maldistributions may be present. For very small channels, on the order of a micron or less, the heat transfer rates may not be predicted using the correlations developed for macrochannels. The design of microchannel cooling devices is still state-of-the-art, strongly depending on fabrication, channel geometry, channel surface, materials, coolant, pump, packaging, and practical system integration.

Defining Terms

Compact heat exchanger — A heat exchanger that incorporates a high surface area-to-volume density (usually $700 \text{ m}^2/\text{m}^3$ or higher).

- Heat exchanger** — A device in which heat transfer takes place between two or more fluids that are at different temperatures.
- Laminar flow heat exchanger** — A heat exchanger whose surface area-to-volume density is in the neighborhood of $3000 \text{ m}^2/\text{m}^3$.
- LMTD method** — Represents the mean logarithmic temperature difference between the hot and cold fluids in the entire heat exchanger.
- Micro heat exchanger** — A heat exchanger whose surface area-to-volume density is much higher than compact and laminar flow heat exchangers ($10,000 \text{ m}^2/\text{m}^3$ or higher).
- NTU method** — Useful in design of heat exchanger when the inlet and outlet fluid temperatures are not known.
- Shell-and-tube heat exchanger** — A heat exchanger in which one fluid flows inside a set of tubes while the other fluid is forced through the shell and over the outside of the tubes in a cross-flow arrangement.

53.1 Introduction

The subject of combustion is very broad and directly or indirectly touches nearly all aspects of our lives. The electronic devices we use are generally powered by fossil-fuel-fired power plants. The cars we drive use internal combustion engines. The planes we fly in use jet-fuel-powered turbine engines. Most of the materials we use have been made through some type of heating or melting combustion process.

Combustion is complicated by many factors. It combines heat transfer, thermodynamics, chemical kinetics, multi-phase turbulent fluid flow, and pollution formation and control, to name a few areas of physics. Therefore, the study of combustion is interdisciplinary by necessity. Space limitations allow only a cursory discussion of some of these important topics. However, many theoretical [Strehlow, 1968; Williams, 1985; Lewis and von Elbe, 1987; Bartok and Sarofim, 1991; Fristom, 1995; Glassman, 1996] and practical [Griswold, 1946; Stambuleanu, 1976; Perthuis, 1983; Keating, 1993] books have been written on the subject of combustion. Some books consider both theory and application at some length [Edwards, 1974; Barnard and Bradley, 1985; Turns, 1996; Borman and Ragland, 1998]. Some handbooks on combustion applications are also available [Segeler, 1965; Reed, 1981; Pritchard et al., 1977; Reed, 1986; IHEA, 1994]. This chapter focuses specifically on industrial combustion.

53.2 Fundamentals

Combustion Chemistry

Combustion is usually considered to be the controlled release of heat and energy from the chemical reaction between a fuel and an oxidizer. Virtually all of the combustion in industrial processes uses a hydrocarbon fuel. A generalized combustion reaction for a typical hydrocarbon fuel can be written as follows:

The “other species” depend on a number of factors considered later, but typically include N_2 , O_2 , NO_x , and CO .

Fuel Properties

The fuel has a significant influence on the combustion process. One of the most important properties is the heating value of the fuel which is used to determine how much fuel must be combusted to process the desired production rate of material that is being heated. The heating value is specified as either the higher heating value (HHV) or the lower heating value (LHV). The LHV excludes the heat of vaporization which is the energy required to convert liquid water to steam. This means that the LHV assumes all of the products of combustion are gaseous, which is generally the case for nearly all industrial combustion applications. If the combustion products were to exit the process at a temperature low enough that all of the water were converted from a gas to a liquid, then the heat of condensation would be released into the process as an additional source of energy. The HHV of a fuel includes that energy.

The fuel composition is important in determining the composition of the combustion products and the amount of oxidizer that will be needed to combust the fuel, both of which are discussed below. It is also important for determining the soot-producing tendency of the fuel.

Oxidizer Composition

The majority of those processes use air as the oxidizer. However, many of the higher-temperature processes use an oxidizer containing a higher concentration of oxygen than found in air (approximately 21% by volume) which is referred to as oxygen-enhanced combustion [Baukal, 1998]. In many cases the production rate in a heating process can be significantly increased even with only relatively small amounts of oxygen enrichment.

A common way of specifying the oxidizer composition is by calculating the O_2 mole fraction in the oxidizer which may be defined as:

$$\Omega = \frac{\text{volume flow rate of } O_2 \text{ in the oxidizer}}{\text{total volume flow rate of oxidizer}} \quad (53.2)$$

If the oxidizer is air, which contains approximately 21% O_2 by volume, $\Omega = 0.21$. If the oxidizer is pure O_2 , $\Omega = 1.0$. The O_2 enrichment level is sometimes used. This refers to the incremental O_2 volume above that found in air. For example, if $\Omega = 0.35$, then the O_2 enrichment would be 14% ($35\% - 21\% = 14\%$).

Mixture Ratio

A global combustion reaction using CH_4 as the fuel may be written as:

The stoichiometry of a reaction indicates the ratio of oxygen to fuel for a given system. One method of quantifying the stoichiometry is to consider only the O_2 in the oxidizer, since the inerts in the oxidizer are generally not needed for the reaction:

$$S_1 = \frac{\text{volume flow rate of } O_2 \text{ in the oxidizer}}{\text{volume flow rate of fuel}} \quad (53.4)$$

If CH_4 is again used as an example, a global simplified stoichiometric reaction with air can be written as:

where air is represented as $2O_2 + 7.52N_2$. In that case, $S_1 = 2/1 = 2.0$.

The most common way of defining the stoichiometry in industry in the U.S. is as follows:

$$S_2 = \frac{\text{volume flow rate of oxidizer}}{\text{volume flow rate of fuel}} \quad (53.6)$$

For Equation (53.5), this stoichiometry would be calculated as $S_2 = (2 + 7.52)/1 = 9.52$.

In the scientific community, it is common to use the equivalence ratio (ϕ) to specify the mixture ratio:

$$\phi = \frac{\text{stoichiometric volumetric ratio of oxidant:fuel}}{\text{actual volumetric ratio of oxidant:fuel}} \quad (53.7)$$

Excess O₂

Many industrial combustion processes run with approximately 2 to 3% more O₂ than is theoretically needed for perfect combustion. That is often the amount of excess O₂ that is required to minimize the emissions of unburned combustibles such as CO. This is usually due to mixing limitations between the fuel and oxidizer, especially in nonpremixed systems. Too much excess O₂ means that energy is being wasted heating excess combustion air, instead of the load. Therefore it is desirable to only use just enough excess O₂ to get low CO emissions. An example of a simplified global reaction for methane with 3% excess O₂ is the reaction below:

The amount of O₂ in the combustion exhaust products is often used to monitor and control the performance of combustion systems. It is usually desirable to operate at the minimum excess O₂ in the exhaust without producing significant quantities of carbon monoxide.

Combustion Properties

Combustion Products

The actual composition of the exhaust products from the combustion reaction depends on several factors including the oxidizer composition, the temperature of the gases, and the equivalence ratio. An adiabatic process means that no heat is lost during the reaction or that the reaction occurs in a perfectly insulated chamber. Note that this is not the case in an actual combustion process, where heat is lost from the flame by radiation and is only used for comparison purposes. [Figure 53.1\(a\)](#) and [Figure 53.1\(b\)](#) show the predicted major and minor species for the adiabatic equilibrium combustion of CH₄ as a function of the oxidizer composition. As N₂ is removed from the oxidant, there is an increase in the concentrations of CO, CO₂, and H₂O. For this adiabatic process, there is a significant amount of CO at higher levels of O₂ in the oxidizer.

The actual flame temperature is lower than the adiabatic equilibrium flame temperature due to imperfect combustion and radiation from the flame. The actual flame temperature is determined by how well the flame radiates its heat and how well the combustion system, including the load and the refractory walls, absorbs that radiation. A highly luminous flame generally has a lower flame temperature than a highly nonluminous flame. The actual flame temperature will also be lower when the load and the walls are more radiatively absorptive. This occurs when the load and walls are at lower temperatures and have higher radiant absorptivities. These effects are discussed in more detail in [Baukal \[2000\]](#).

[Figure 53.2\(a\)](#) and [Figure 53.2\(b\)](#) show the predicted major and minor species, respectively, for the equilibrium combustion of CH₄ with “air” (21% O₂, 79% N₂) as a function of the gas temperature. The highest possible temperature for the air/CH₄ reaction is the adiabatic equilibrium temperature of 3537°F (2220K). For the air/CH₄ reaction, there is very little change in the predicted gas composition as a function of temperature. [Figure 53.3\(a\)](#) and [Figure 53.3\(b\)](#) show the predicted major and minor gas species, respectively, for the adiabatic equilibrium combustion of air/CH₄ as a function of the equivalence ratio.

[Figure 53.4](#) shows the adiabatic flame temperature as a function of the equivalence ratio for three fuels: H₂, CH₄, and C₃H₈. The peak temperature occurs at stoichiometric conditions ($\phi = 1.0$). In most real flames, the peak flame temperature often occurs at slight fuel lean conditions ($\phi < 1.0$). This is due to imperfect mixing where slightly more O₂ is needed to fully combust all of the fuel.

Available Heat

Available heat is defined as the gross heating value of the fuel, less the energy carried out of the combustion process by the hot exhaust gases. The heat lost from a process through openings in the furnace, through the furnace walls, or by air infiltration are not considered in calculating the theoretical available heat as those are dependent on the process. The theoretical available heat is typically proportional to the amount of energy actually absorbed by the load in an actual process, which is directly related to the thermal efficiency of the system. Therefore, the theoretical available heat is used here to show the thermal efficiency trends as functions of exhaust gas temperature and oxidizer and fuel compositions.

Figure 53.5 shows how the available heat decreases rapidly with the exhaust gas temperature and is relatively independent of the fuel composition for the three fuels shown. Then, to maximize the thermal efficiency of a process, it is desirable to minimize the exhaust gas temperature. Figure 53.6 is a graph of the available heat for the combustion of CH₄ as a function of the O₂ concentration in the oxidizer, for three different exhaust gas temperatures. As the exhaust gas temperature increases, the available heat decreases because more energy is carried out the exhaust stack.

Pollution

Air pollution is generally defined as contaminants that have a harmful effect on the environment. For example, if a process is emitting water in the form of steam into the atmosphere, it would usually not be considered a pollutant unless it was having some type of effect on the visibility at or near the discharge point. Table 53.1 lists some of the common gaseous airborne pollutants, common sources, and atmospheric removal reactions and sinks [Liu and Lipták, 1997]. The U.S. Environmental Protection Agency (EPA) quantifies the emissions from a wide range of sources and geographical locations in the U.S. to track how well regulations are controlling pollution [Elkins et al., 2001].

NO is the primary NO_x compound emitted from industrial combustion sources. In the atmosphere, NO turns into NO₂, which can produce acid rain when it reacts with water in the atmosphere to form nitric acid and plays a role in ozone formation in the lower atmosphere.

A principle unburned combustible is carbon monoxide (CO), which is formed by the incomplete combustion of carbon-containing fuels. CO formation is normally easily prevented by proper control of the combustion process and is not typically a problem for the vast majority of industrial combustion

FIGURE 53.6 Available heat vs. oxidant composition, for a stoichiometric CH₄ flame, at exhaust temperatures of 2000, 2500, and 3000°F (1370, 1640, and 1920K). (Source: Baukal, C. E., Ed., 1998. *Oxygen-Enhanced Combustion*. CRC Press LLC, Boca Raton, FL.)

applications. Over three-fourths of the ambient CO in the atmosphere comes from automobile emissions; only a small portion comes from industrial combustion applications.

SO₂ is a pollutant emission formed in industrial combustion applications during the firing of fuels, such as heavy oil, that contain sulfur. Under typical combustion conditions, essentially all of the sulfur in the fuel is converted to SO₂. The primary environmental concern with SOx emissions is the generation of acid rain when SO₂ reacts with water in the atmosphere to form sulfuric acid.

Particulate matter is a general term used for solid and/or liquid particles emitted into the atmosphere. If the concentration of the particulate emissions is dense enough then visibility can be impaired, which

TABLE 53.1 Sources, Concentrations and Scavenging Processes of Atmospheric Pollutants

| Air Pollutant | Effects |
|---|--|
| Particulates | Speeds chemical reactions; obscures vision; corrodes metals; causes grime on belongings and buildings; aggravates lung illness |
| Sulfur oxides | Causes acute and chronic leaf injury; attacks a wide variety of trees; irritates upper respiratory tract; destroys paint pigments; erodes statuary; corrodes metals; ruins hosiery; harms textiles; disintegrates book pages and leather |
| Hydrocarbons (in solid and gaseous states) | May be cancer-producing (carcinogenic); retards plant growth; causes abnormal leaf and bud development |
| Carbon monoxide | Causes headaches, dizziness, and nausea; absorbs into blood; reduces oxygen content; impairs mental processes |
| Nitrogen oxides | Causes visible leaf damage; irritates eyes and nose; stunts plant growth even when not causing visible damage; creates brown haze; corrodes metals |
| Ozone | Discolors the upper surface of leaves of many crops, trees, and shrubs; damages and fades textiles; reduces athletic performance; hastens cracking of rubber; disturbs lung function; irritates eyes, nose, and throat; induces coughing |

FIGURE 53.7 Flare on an offshore oil platform (courtesy of John Zink Co., Tulsa, OK).

is the primary environmental concern for this pollutant. Some possible sources of particulate emissions from industrial combustion include ash or char from the incomplete combustion of carbon-containing compounds and carryover of solid particles in the production process.

There are several possible sources of noise from combustion processes, including high speed flow through piping and piping components, fan noise from the rotation of the blades, and combustion roar from the combustion process, to name a few. In some cases it is relatively easy to reduce the noise by modifying the process or configuration. In other cases, some type of noise suppression, such as a muffler, may be needed.

Carbon dioxide is a product of combustion from the burning of hydrocarbon fuels. It is considered by many to be a greenhouse gas responsible for global warming. However, this is a controversial subject that does not have widespread agreement among scientists. A primary concern is the increased burning of fuels over the past century, which some believe has caused an imbalance in the ability of nature to absorb the additional CO₂ emissions.

There are a number of other pollutants that typically only apply to a limited number of industrial combustion applications. Some special pollutants are related to the use of flares, including smoke, thermal radiation, and noise. [Figure 53.7](#) shows a flare used on an offshore oil platform, which is used to burn undesired flammable gases. Another example of a special pollutant is lead emissions, which are only present in some select applications such as lead production and waste incineration. These are normally easily controlled with the appropriate posttreatment equipment.

53.3 Combustion System Components

Six components may be important in industrial combustion processes (see [Figure 53.8](#)). One component is the burner, which combusts the fuel with an oxidizer to release heat. Another component is the load itself, which can greatly affect how the heat is transferred from the flame. In most cases, the flame and the load are located inside of a combustor, which may be a furnace, heater, or dryer, which is the third component in the system. In some cases, some type of heat recovery device may be used to increase the thermal efficiency of the overall combustion system; this is the fourth component of the system. The fifth component is the air pollution control system used to minimize the pollutants emitted from the

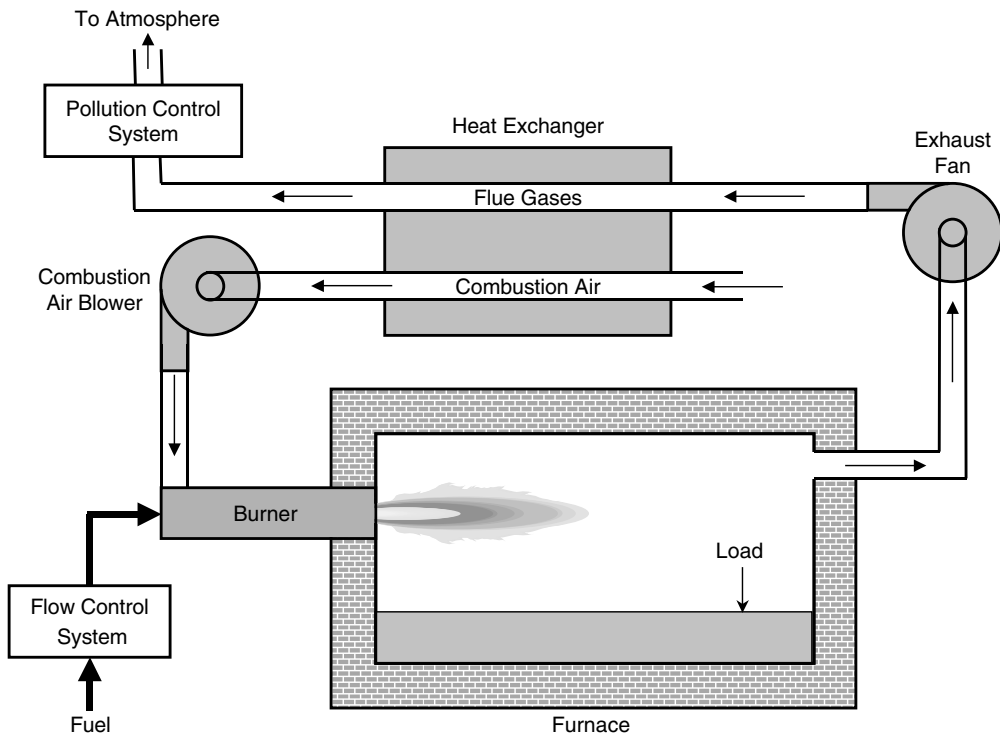

FIGURE 53.8 Schematic of the major components in a combustion system. (Source: Baukal, C. E., Ed., 2003. *The Handbook of Industrial Burners*, CRC Press, Boca Raton, FL.)

exhaust stack into the atmosphere. The sixth and last component is the flow control system used to meter the fuel and the oxidant to the burners. The first five are discussed next. The last component is not discussed here in the interest of space. The interested reader is referred to Gifford and Kodesh [2003] for information on combustion controls.

Burners

General Types

The first component of a typical combustion system is the burner. Burners are classified in numerous ways. One common method for classifying burners is according to how the fuel and the oxidizer are mixed. In premixed burners, shown schematically in Figure 53.9(a), the fuel and the oxidizer are completely mixed before combustion begins. Premixed burners often produce shorter and more intense flames, compared to diffusion flames. In diffusion-mixed burners, shown schematically in Figure 53.9(b), the fuel and the

FIGURE 53.9 Schematic of (a) premixed and (b) diffusion-mixed burners. (Source: Baukal, C. E. 2000. *Heat Transfer in Industrial Combustion*. CRC Press, Boca Raton, FL.)

FIGURE 53.10 Schematic of (a) staged-air and (b) staged-fuel burners. (Source: Baukal, C. E. 2000. *Heat Transfer in Industrial Combustion*. CRC Press, Boca Raton, FL.)

oxidizer are separated and unmixed prior to combustion, which begins where the oxidizer/fuel mixture is within the flammability range (assuming the temperature is high enough for ignition). Oxygen/fuel burners are usually diffusion burners, primarily for safety reasons, to prevent flashback and explosion in a potentially dangerous system. Diffusion gas burners are sometimes referred to as “raw gas” burners, as the fuel gas exits the burner essentially intact with no oxidant mixed with it. Diffusion burners typically have longer flames than premixed burners, do not have as high-temperature a hot spot, and usually have a more uniform temperature and heat flux distribution. It is also possible to have partially premixed burners where a portion of the fuel is mixed with the oxidizer prior to exiting the burner. This is often done for stability and safety reasons where the partial premixing helps anchor the flame, while not fully premixing lessens the chance for flashback. This type of burner often has a flame length and temperature and heat flux distribution that are intermediate between those of the fully premixed and diffusion flames.

Another burner classification based on mixing is known as staging: staged air and staged fuel. Staged air and staged fuel burners are shown schematically in Figure 53.10(a) and Figure 53.10(b), respectively. Secondary and sometimes tertiary injectors in the burner are used to inject a portion of the fuel and/or the oxidizer into the flame, downstream of the root of the flame. Staging is often done to produce longer flames and reduce pollutant emissions such as NO_x. These longer flames typically have a lower peak flame temperature and more uniform heat flux distribution than nonstaged flames. However, an additional challenge is that multiple longer flames may interact with each other and produce unpredictable consequences compared to single flames.

Burners may also be classified according to the fuel type. Gaseous fuel burners are the predominant type used in most of the applications considered here. In general, natural gas is the predominant gaseous fuel used because of its low cost and availability. However, a wide range of gaseous fuels are used in, for example, the chemicals industry [Baukal, 2001]. These fuels contain multiple components such as methane, hydrogen, propane, nitrogen, and carbon dioxide and are sometimes referred to as refinery fuel gases. Gaseous fuels are among the easiest to control because no vaporization is required as in liquid and solid fuels. They are also often simpler to control to minimize pollution emissions because they are more easily staged compared to liquid and solid fuels. Liquid fuel burners are used in some limited applications in the U.S. but are more prevalent in certain areas of the world such as South America. No. 2 and No. 6 oil are the most commonly used liquid fuels. Waste liquid fuels are also used in incineration processes. Fuel atomization and pollutant emissions such as SO_x are particular challenges with liquid fuels. Solid fuels are not commonly used in most industrial combustion applications. The most common solid fuels are coal and coke. Coal is used in power generation, and coke is used in some primary metals production processes. Another type of pseudo solid fuel is sludge that is processed in incinerators. Solid fuels also often contain impurities such as nitrogen and sulfur that can significantly increase pollutant emissions. Some applications require the burner to be able to fire on a gaseous fuel such as natural gas, a liquid fuel such as fuel oil, or both simultaneously.

Burners and flames are sometimes classified according to the type of oxidizer used. The majority of industrial burners use air for combustion. In many of the higher-temperature heating and melting

FIGURE 53.11 Schematic of an (a) oxy/fuel and (b) air-oxy/fuel burner. (Source: Baukal, C. E., Ed., 1998. *Oxygen-Enhanced Combustion*. CRC Press LLC, Boca Raton, FL.)

applications, such as glass production, the oxidizer is pure oxygen. In other applications, the oxidizer is a combination of air and oxygen, often referred to as oxygen-enriched air combustion. Figure 53.11(a) shows a method of using OEC commonly referred to as an oxy/fuel burner. Figure 53.11(b) shows another method of using OEC commonly referred to as an air-oxy/fuel burner.

Burners may also be classified according to how the combustion air is supplied. Most industrial burners are known as forced-draft burners. This means that the combustion air is supplied to the burner under pressure with a fan or blower. In natural-draft burners, the air used for combustion is induced into the burner by the negative draft produced in the combustor and by the motive force of the incoming fuel, which may be at a significant pressure. A schematic is shown in Figure 53.12(a). In this type of burner, the pressure drop and combustor stack height are critical in producing enough suction to induce enough combustion air into the burners. This type of burner [see photo in Figure 53.12(b)] is commonly used in the chemical and petrochemical industries in fluid heaters.

Design Factors

Many factors go into the design of a burner [Baukal, 2003]. There have been many changes in the traditional designs that have been used in burners, primarily because of the recent interest in reducing pollutant emissions. In the past, the burner designer was primarily concerned with efficiently combusting the fuel and transferring the energy to a heat load. New and increasingly stringent environmental regulations have added the requirement to consider the pollutant emissions produced by the burner. In many cases, reducing pollutant emissions and maximizing combustion efficiency are at odds with each other. For example, a well-accepted technique for reducing NO_x emissions is known as staging, where the primary flame zone is deficient of either fuel or oxidizer [Reese et al., 1994]. However, radiant heat transfer from the flame may also be reduced.

In the past, the challenge for the burner designer was often to maximize the mixing between the fuel and the oxidizer to ensure complete combustion, especially if the fuel was difficult to burn, as in the case of low heating value fuels such as waste liquid fuels or process gases from chemical production. Now the burner designer must balance the mixing of the fuel and the oxidizer to maximize combustion efficiency while simultaneously minimizing all types of pollutant emissions. This is no easy task as, for example, NO_x and CO emissions often go in opposite directions as shown in Figure 53.13. When CO is low, NO_x may be high and vice versa.

FIGURE 53.12 (a) Schematic and (b) photo of natural draft burner (courtesy of John Zink Co. LLC, Tulsa, OK).

FIGURE 53.13 NO_x and CO as a function of equivalence ratio. (Source: Baukal, C. E. 2000. *Heat Transfer in Industrial Combustion*. CRC Press, Boca Raton, FL.)

Heat Load

The second component in a combustion system is the heat load. A variety of heat loads are used in industrial applications. In petrochemical production processes, process heaters are used to heat petroleum products up to operating temperatures. The fluids are transported through the process heaters in process tubes. In some applications, heaters and burners are used to heat or dry moving substrates or webs. One common application is the use of gas-fired infrared (IR) burners to remove moisture from paper during the forming process [Longacre, 1997]. Another example of a moving substrate application is using IR burners to remove water during the production of fabrics in textile manufacturing [Smith and Baukal, 1983].

Many loads are considered opaque, which means that they absorb thermal radiation over a broad range of wavelengths. This type of load encompasses a wide range of materials including granular solids

such as limestone and liquids such as molten metal. For this type of load, the heat transfers to the surface of the load and must conduct down into the material. Some loads are highly transparent, as they allow much of any incident radiant energy to penetrate below the surface. The primary example of this load type is glass, which has selective radiant transmission properties. In glass melting, the primary mode of heat transfer is by radiation. Specific radiation characteristics are preferred to enhance the heat transfer from the flame to the glass.

Combustors

The third component in a combustion system is the combustor. There are two predominant categories of combustors used in industry: process heaters and boilers for lower temperature applications (less than about 2000°F) and furnaces for higher temperature applications (greater than about 2000°F). Process heaters include, for example, ovens, heaters, reactors, and dryers. Furnaces include, for example, kilns, incinerators, and thermal crackers. Combustors are used to transform incoming charge materials by, for example, oxidation, reduction, melting, heat treating, curing, baking, and drying.

Design Considerations

A primary consideration for any combustor is the type of material that will be processed including the load handling system, which is dependent on the physical state of the material, whether it is a solid, liquid, or gas. Another factor is the transport properties of the load. For example, the solid may be granular or it might be in the form of a sheet (web). Related to that is how the solid will be fed into the combustor. A granular solid could be fed into a combustor continuously with a screw conveyor or it could be fed in with discrete charges from a front-end loader. The shape of the furnace will vary according to how the material will be transported through it. For example, limestone is fed continuously into a rotating and slightly downwardly inclined cylinder.

Combustor Classifications

Combustors can be classified in several ways, which are briefly discussed in this section. Each type has an impact on the heat transfer mechanisms in the furnace. Furnaces are often classified as to whether they are batch or continuous. In a batch furnace, the load is charged into the furnace at discrete intervals. There may be multiple load charges, depending on the application. Normally, the firing rate of the burners is reduced or turned off during the charging cycle. On some furnaces, a door may also need to be opened during charging. The heating process and heat transfer are dynamic and constantly changing as a result of the cyclical nature of the load charging. In a continuous furnace, the load is fed into and out of the combustor constantly. The feed rate may change sometimes due to conditions upstream or downstream of the combustor or due to the production needs of the plant, but the process is nearly steady state. Some furnaces are semicontinuous, where the load may be charged in a nearly continuous fashion, but the finished product may be removed from the furnace at discrete intervals. An example is an aluminum reverberatory furnace, which is charged using an automatic sidewall feed mechanism. In that process, shredded scrap is continuously added to a circulating bath of molten aluminum. When the correct alloy composition has been reached and the furnace has a full load, some or all of that load is then tapped out of the furnace.

Combustors are often classified as direct [see [Figure 53.14\(a\)](#)] or indirect [see [Figure 53.14\(b\)](#)] heating. In indirect heating, there is some type of intermediate heat transfer medium between the flames and the load that keeps the combustion products separate from the load. One example is a muffle furnace, where there is a high-temperature ceramic muffle between the flames and the load. The flames transfer their heat to the muffle, which then radiates to the load, which is usually some type of metal. The limitation of indirect heating processes is the temperature limit of the intermediate material. Although ceramic materials have fairly high temperature limits, other issues such as structural integrity over long distance spans and thermal cycling can still reduce the recommended operating temperatures. Another example of indirect heating is in process heaters where fluids are transported through metal

FIGURE 53.14 (a) Direct- and (b) indirect-fired process. (Source: Baukal, C. E., Ed., 2003. *The Handbook of Industrial Burners*, CRC Press, Boca Raton, FL.)

tubes heated by flames. Indirect heating processes often have fairly uniform heat flux distributions because the heat exchange medium tends to homogenize the energy distribution from the flames to the load. The heat transfer from the heat exchange surface to the load is often fairly simple and straightforward to compute because of the absence of chemical reactions in between. However, the heat transfer from the flames to the heat exchange surface and the subsequent thermal conduction through that surface are as complicated as if the flame was radiating directly to the load. Indirect heating may also have an advantage for reducing pollutant emissions when contact of the high temperature exhaust gases with the load could generate pollutants.

Another aspect of the geometry that is important in some applications is whether or not the furnace is moving. For example, in a rotary furnace for melting scrap aluminum, the furnace rotates to enhance mixing and heat transfer distribution. This again affects the type of analysis that would be appropriate for that system and can add some complexity to the computations.

Heat Recovery

The fourth component that may be present in a combustion system is a heat recovery unit. Heat recovery devices are often used to improve the efficiency of combustion systems. Some of these devices are incorporated into the burners, but more commonly they are another component in the combustion system, separate from the burners. These heat recovery devices incorporate some type of heat exchanger, depending on the application. The two most common types have been recuperators and regenerators, which are briefly discussed next. Reed [1987] predicts an increasing importance for heat recovery devices in industrial combustion systems for increasing heat transfer and thermal efficiencies.

Gas Recirculation

A common technique used in combustion systems is to design the burner to induce furnace gases to be drawn into the burner to dilute the flame, usually referred to as furnace gas recirculation (FGR). Even though the furnace gases are hot, they are still much cooler than the flame itself. This dilution may accomplish several purposes. One is to minimize NO_x emissions by reducing the peak temperatures in the flame. Another reason to use furnace gas recirculation may be to increase the convective heating from the flame because of the added gas volume and momentum.

Recuperators

A recuperator is a low- to medium-temperature (up to about 1300°F or 700°C) continuous heat exchanger that uses the sensible energy from hot combustion products to preheat the incoming combustion air. These heat exchangers are commonly counterflow, where the highest temperatures for both the combustion products and the combustion air are at one end of the exchanger, with the coldest temperatures at the other end. Lower temperature recuperators are normally made of metal, while higher temperature recuperators may be made of ceramics. Recuperators are typically used in lower-temperature applications because of the limitations of the metals used to construct these heat exchangers.

Regenerators

A regenerator is a higher-temperature, transient heat exchanger that is used to improve the energy efficiency of high-temperature heating and melting processes, particularly in high-temperature processing industries such as glass production. In a regenerator, energy from the hot combustion products is temporarily stored in a unit constructed of firebricks. This energy is then used to heat the incoming combustion air during a given part of the firing cycle up to temperatures in excess of 2000°F (1000°C).

Regenerators are normally operated in pairs. During one part of the cycle, the hot combustion gases are flowing through one of the regenerators and heating up the refractory bricks, while the combustion air is flowing through and cooling down the refractory bricks in the second regenerator. Both the exhaust gases and the combustion air directly contact the bricks in the regenerators, although not both at the same time since each is in a different regenerator at any given time. After a sufficient amount of time (usually from 5 to 30 min), the cycle is reversed so that the cooler bricks in the second regenerator are then reheated while the hotter bricks in the first regenerator exchange their heat with the incoming combustion air. A reversing valve is used to change the flow from one gas to another in each regenerator. The burners used in these systems must be capable of not only handling the high-temperature preheated air, but also the constant thermal cycling.

Pollution Control Strategies

The fifth component of most combustion processes is the pollution control system. There are a number of issues to consider when designing a pollution control system, which may include multiple technologies to handle multiple possible pollutants or even for handling the same pollutant in some cases. Some of these issues include flammability of the gases being treated and removed, applicable construction codes, economics, corrosion, vent sizing, material handling, and chemical storage, to name a few. One of the inherent difficulties in controlling pollutant emissions is that they are sometimes inextricably linked together. For example, some of the techniques for reducing NO_x emissions may increase CO emissions.

There are many factors that go into the selection of the appropriate control technologies to minimize pollution emissions from a process. Some broadly categorize these factors into: environmental, engineering, and economic [Mycock et al., 1995]. Environmental includes such things as equipment location, available space, ambient conditions, availability of utilities, and regulations. Engineering includes contaminant characteristics (physical and chemical properties, concentration, etc.), gas stream characteristics (flow rate, temperature, pressure, humidity, properties, etc.), and performance of the particular control system (power requirements, removal efficiency, temperature limitations, etc.). Economic considerations include the capital cost, ongoing operating costs, and the expected lifetime of the equipment. Spaite and

Burckle [1977] believe the two primary factors used to determine the choice of control techniques are technical feasibility and lowest cost. General pollution control strategies are discussed next with particular emphasis on those relating to the combustion process.

Pretreatment

Pretreatment basically refers to modifying the incoming feed materials to either the process or the combustion system. This would include adding or removing elements from the fuel, oxidizer, or raw materials. The fuel could be modified by cleaning out some impurities, such as removing sulfur in a pretreatment process at the plant. The fuel could also be modified by putting in an additive designed to reduce pollutant emissions. The oxidizer could be pretreated by adding high-purity oxygen to increase the overall oxygen concentration to something above the approximately 21% O₂ by volume contained in normal air. The incoming raw materials could be cleaned to remove some potential pollutant-emitting chemicals.

Process Modification

Process modification refers to either replacing the incoming feed materials to the process or the combustion system with some other alternative, or to modifying the end product in some way. Ramachandran [1997] refers to the former as raw material substitution. An example of a fuel change would be to change from a high-sulfur coal to a low-sulfur coal to reduce SO_x emissions. A more radical example would be to change from fossil fuel heating to electrical heating where the emissions are moved from the plant location to the power generation facility.

Combustion Modification

This strategy involves modifying the combustion process so that fewer pollutants are generated in the first place. This is generally much less costly than removing the pollutants from the exhaust gases after they have been formed. Many combustion modification techniques have been used to reduce emissions from conventional burners, depending on the pollutant. Using NO_x as an example pollutant, air staging, fuel staging, flue gas recirculation, water or steam injection, reducing air preheat temperatures, ultra-lean premix, and pulsed combustion are some of the many ways that have been used to reduce emissions. In some cases, the performance of the overall system may be reduced by these techniques. For example, injecting water into the burner or combustor does reduce NO_x but it also usually reduces thermal efficiency as well.

Posttreatment

Posttreatment refers to removing pollutants from the exhaust gas stream before they are emitted into the atmosphere. This strategy may be chosen for many reasons. In some cases it may not be possible to sufficiently reduce or eliminate the formation of one or more pollutants in the combustion process. It may be more economical to remove the pollutants rather than prevent them from forming in the first place. This may occur when pollutants can be easily recycled back into the process, for example, in the case of particles carried out of the combustor. This could also occur if the changes that would need to be made to minimize pollutant formation have a negative impact on the processing of the product in the combustor. In some plants, it is more economical to duct multiple exhaust gas stacks together going to a single large posttreatment system, rather than modifying each of the individual combustion processes. It may also be necessary to use a posttreatment technique to supplement minimization strategies to economically be below regulated emission levels. Schiffner [2002] has written a good general purpose book on air pollution control equipment primarily focused on posttreatment.

Many of the posttreatment systems for removing pollutants from exhaust streams involve catalysts. There are often difficulties in using catalysts because of the high gas temperatures and dirty exhaust streams from industrial combustion processes that can foul or damage catalytic removal systems. They can be thermally deactivated by sintering, for example. However, they have been successfully used to remove a wide range of pollutants including NO_x, SO_x, CO, and VOCs. Heck and Farrauto [1995] have written a good general-purpose book on the use of catalysts for air pollution control.

Process Control

An important part of minimizing pollution emissions is to control all aspects of the process. This includes accurately metering the fuel and oxidizer flows and compositions to the burners, controlling the combustor itself (e.g., minimizing air infiltration into the process), and monitoring the incoming raw material feed rates into the combustor. If any of the system parameters are out of specification, then pollution emissions may be adversely affected. For example, if the fuel flow increases while the oxidizer flow rate remains the same, then carbon monoxide emissions will likely increase. If there are large air leaks into the furnace, then NO_x emissions are likely to increase. If one of the incoming raw materials contains more fine particles than normal, then particulate emissions may increase.

Other

Another technique that is often important in minimizing pollutant emissions is equipment maintenance. This includes the combustor, the burners, and the control equipment. If combustors are not properly maintained, then emissions can be adversely affected. For example, if the combustor develops cracks that permit air infiltration, NO_x emissions will typically increase. If broken sight ports are not replaced, then large quantities of tramp air can infiltrate into the furnace. If the refractory becomes damaged and is not replaced, hot spots on the outer shell will develop and can injure personnel who may inadvertently come in contact with these hot surfaces.

It is very important to keep burners in good operating conditions to minimize pollutant emissions. If fuel injection nozzles become plugged, the mixing patterns that produce the flame will be adversely affected, which normally would increase NO_x emissions, for example. This commonly occurs in the petrochemical industry when heavy hydrocarbons are improperly fired causing the injection nozzles to clog from carbon buildup due to coking. If the oil injectors become clogged, then oil atomization can be adversely affected, which could increase particulate emissions and opacity. It is not uncommon for broken pieces of refractory to fall onto or into burners, significantly disturbing the designed burner performance. An important part of the burner that is sometimes overlooked is the burner block (also referred to as the burner tile or quarl). A cracked burner block can adversely affect the performance of the burner.

53.4 Industrial Combustion Applications

Metals Production

Metals can be classified as ferrous (iron-bearing) and nonferrous (e.g., aluminum, copper, and lead). Ferrous metal production is often high temperature because of higher metal melting points compared to nonferrous metals. Many metals production processes are done in batch, compared to most other industrial combustion processes considered here, which are typically continuous. Another unusual aspect of metal production is the very high use of recycled materials. This often lends itself to batch production because of the somewhat unknown composition of the incoming scrap materials, which may contain trace impurities that could be very detrimental to the final product if not removed. The metals are typically melted in some type of vessel and then sampled to determine the chemistry so that the appropriate chemicals can be either added or removed to achieve the desired grade of material. Another unique aspect of the metals industry is that transfer vessels are preheated prior to the introduction of molten metals into the vessel to minimize the thermal shock to the refractory. [Figure 53.15](#) shows an example of preheating a transfer ladle.

Since metals melt at higher temperatures, higher-intensity burners are often used in these applications. This includes, for example, oxygen-enhanced combustion [Kistler and Becker, 1998; Saha and Baukal, 1998] and air preheating to increase the flame temperatures and metal melting capability. These higher-intensity burners have the potential to produce high pollutant emissions, so burner design is important to minimize these emissions.

FIGURE 53.15 (a) Schematic and (b) photo of a ladle preheating process. (Source: Baukal, C. E., Ed., 2003. *The Handbook of Industrial Burners*, CRC Press, Boca Raton, FL.)

Another unusual aspect of metals production is that supplemental heating may be required to reheat the metals for further processing. For example, ingots may be produced in one location and then transported to another location to be made into the desired shape (e.g., wheel castings are often made by remelting aluminum ingots or sows). While this process may be economically efficient, it is energy and pollutant inefficient due to the additional heating. Burners are used in the original melting process as well as in the reheating process. This is something that has begun to attract more attention in recent years, where the entire life cycle of a product is considered rather than just its unit cost and initial energy requirements. For example, aluminum has a low life cycle cost compared to many other metals because of its high recycle ratio. While the energy consumption to make aluminum from raw ore is fairly high, remelting scrap aluminum takes only a fraction of that energy, which also means less overall pollution as well.

Minerals Production

Some common minerals processes include the production of glass, cement, bricks, refractories, and ceramics. These are typically high-temperature heating and melting applications that require a significant

FIGURE 53.16 Schematic of a counter-rotating cement kiln. (Source: Baukal, C. E., Ed., 2003. *The Handbook of Industrial Burners*, CRC Press, Boca Raton, FL.)

amount of energy per unit of production. They also tend to have fairly high pollutant emissions as a result of the high temperatures and unit energy requirements. Most of the minerals applications are continuous processes, but a wide range of combustors can be used. Large glass furnaces are typically rectangularly shaped and have multiple burners. On the other hand, cement kilns are long refractory-lined rotating cylinders that are slightly inclined so that the materials flow gradually downhill (see Figure 53.16).

Chemicals Production

This is a very broad classification that encompasses many different types of production processes that have been loosely subcategorized into chemicals (organic and inorganic) and petrochemicals (organic) applications. There is some overlap in terms of the types of heating equipment used, where many of the incoming feed materials are in liquid form (e.g., crude oil) and are processed in heaters with tubes running inside them. These are generally lower-temperature applications (<2300°F or <1300°C) that incorporate heat recovery to preheat the incoming feed materials. Nearly all of the chemicals heating applications employ multiple burners but in a much more diverse configuration compared to many other industries. Burners may be fired horizontally, vertically up, vertically down, or at some angles in between depending on the specific process. Numerous configurations exist for fired process heaters (see Figure 53.17).

FIGURE 53.17 Schematic of a fired process heater (courtesy of John Zink Co. LLC).

Some aspects make this industry unique. The first and one of the most important is the wide range of fuel compositions used to fire the heaters. These are mostly gaseous fuels that are byproducts of the production process. These gaseous fuels often contain significant quantities of hydrogen, methane, and propane and may include large quantities of inert gases such as nitrogen and carbon dioxide. A given heater may need to be able to fire on multiple fuels that may be present during various times in the production process. Another unique aspect of this industry is that many of the heaters are fired with natural draft burners where no blower is used to supply the combustion air. These burners are designed differently than conventional forced draft burners and are more susceptible to variations in ambient conditions such as air temperature, humidity, and wind speed.

Waste Incineration

The objective of waste incineration processes is to reduce or eliminate waste products, which involves combusting those materials. Not only is the incinerator (see [Figure 53.18](#)) fired with burners, but the waste material itself is often part of the fuel that generates heat in the process. However, the waste usually has a very low heating value, hence the need for supplemental fuel. Incineration is a more complicated and dynamic process compared to most other industrial combustion processes by nature of the variability of the feed material. The waste may be very wet after a rainstorm, which may put a huge extra heat load on the incinerator. In some locations where waste materials are separated for recycling, the waste actually fed into the incinerator may have a much higher heating value compared to other incinerators where there is no separation of the waste.

A complicating factor with incinerators is that the end product, for example, the noncombustible waste, must also be disposed of, which means that one of the goals of most incineration processes is to produce minimal waste output. Because of the waste material variability, other pollutants may be generated that are not normally associated with industrial combustion processes. An example is the burning of plastics, which can produce dioxins and furans. The types of incinerators can vary greatly depending upon a variety of factors. In some cases, waste materials to be destroyed may be fed through the burners. This is particularly true of waste hydrocarbon liquids.

Industrial Boilers and Power Generation

Boilers are used for a variety of purposes in an assortment of applications. Common uses include producing hot water or steam for heating, producing steam for use within a plant such as atomizing oil for oil-fired burners, and producing steam to generate power in large power plants. Applications range from small single-burner uses in hospitals, schools, and small businesses up to large multi-burner boilers in power plants. The burners used in boilers are typically regulated because of their proliferation and widespread use in applications involving the general public. The burners are normally required to have a full complement of safety controls to ensure safe operation. These burners are often highly regulated to minimize pollutant emissions, particularly in large power plants because of the size of the source.

Defining Terms

Burners — Devices used to control combustion to generate heat, usually in a combustion chamber of some type.

Combustion — Rapid oxidation of a fuel to produce energy primarily in the form of heat.

Furnaces — Higher-temperature combustion chambers commonly used in the minerals, metals, and incineration industries.

Heaters — Lower-temperature combustion chambers often used in the processing industries.

Pollution — Unwanted products of combustion such as nitrogen oxides (NO_x), sulfur oxides (SO_x), and particulates.

Vapor Compression Cycle • Evaporative Cooling • Absorption
Cooling • Refrigerants

The objective of this chapter is to introduce the reader to basic concepts in air conditioning, as well as some of its history. Details on equipment types, design, selection, installation, operation, and maintenance are not addressed. *The CRC Heating, Ventilating and Air Conditioning Handbook* [Kreider, 2001] and ASHRAE (American Society of Heating, Refrigerating and Air-Conditioning Engineers) handbooks are suggested as sources for further study and reference.

54.1 Historical Sketch

It is likely that the first air conditioning system was the result of concerns that a physician had for the comfort of ailing sailors suffering with critical fever. In the mid-1800s, Dr. John Gorrie constructed an open air-cycle refrigeration machine in order to cool two rooms in a hospital in Apalachicola, Florida, and provide his patients with some relief. Although Gorrie died frustrated, broke, and subject to criticism, he did become the first of a line of air conditioning pioneers, which also includes A. Muhl (who held the first patent for cooling residences — in this case with ether compression and expansion), Alfred R. Wolf (1859–1909; who provided comfort conditioning to more than 100 buildings, including the Waldorf Astoria, Carnegie Hall, and St. Patrick’s Cathedral), and Willis Carrier (1876–1950; who not only provided the first psychrometric chart, but also set new trends in product development and marketing). Equally as fascinating as the history of air conditioning are its thermodynamics, product development, and utilization. Some of these will be addressed in the sections that follow.

54.2 Comfort

The main goal of air conditioning is to ensure human comfort in the built environment. The human body is continuously generating heat and moisture, which in turn must be removed from the environment in order to maintain constant body temperature and comfort. The transfer of heat from the body to the environment depends on the surface conditions of the body (i.e., clothing), as well as the temperature, velocity, and humidity of the surrounding air and the temperature of surrounding surfaces (affecting radiative heat transport to or from the body). Conditions for comfort are obviously influenced by an individual’s age, level of activity, and clothing. In general, nominal ranges for comfort include temperature

FIGURE 54.1 Typical air conditioning process.

FIGURE 54.2 Psychrometric chart schematic.

from 20 to 26°C and **dew-point temperature** from 4 to 17°C, with air velocities under 0.25 m/sec. For details see Kreider [2001], Kreider et al. [2002], or ASHRAE [2001].

54.3 The Air Conditioning Process

The typical processes of air conditioning, one of which is exhibited in Figure 54.1, can best be described on a psychrometric chart. These charts present data for **relative humidity**, **specific volume**, **wet-bulb temperature**, and **enthalpy** for atmospheric air in terms of **dry-bulb temperature** and **humidity ratio**, as shown schematically in Figure 54.2. [For details see Kreider et al. (2002).]

The cooling and dehumidifying coil of Figure 54.1 brings the moist air down to its dew point, then removes moisture in the form of condensate. Air leaves the coil in conditions close to saturated and at a lower temperature than the room return air (see Figure 54.3). Latent cooling is the amount of heat removal necessary to hold the humidity ratio of room air at the comfort level. In turn, the heating section warms the building supply air stream to the dry-bulb temperature needed for comfort conditions. This common kind of system (sometimes called *reheat*) can closely control comfort conditions required. Reduced energy consumption (no need really to first cool the air and then heat it again) is achieved if the saturated cold air can be mixed with warmer return air from a conditioned space; this avoids the need for reheat (a form of energy loss).

FIGURE 54.3 Cooling and dehumidification with reheat.

FIGURE 54.4 Vapor compression cycle components.

54.4 Typical Cycles

Vapor Compression Cycle

Figure 54.4 shows the basic components for a vapor compression cycle used as an air conditioner. Room air flows over the evaporator, thereby being cooled (sensible and latent cooling), while the two-phase refrigerant mixture within the coil boils; it is then heated slightly beyond the saturated condition into the **superheated** region (see Figure 54.5). The compressor increases the pressure of the superheated refrigerant, which is then cooled slightly below saturation temperature in the condenser where cooler outside air is blown over the coil surfaces. Through this process, the air conditioner working fluid, the refrigerant, gains thermal energy, Q_L , from the cooled indoor ambient and rejects thermal energy, Q_H , to the outdoor environment while work, W , is done on the fluid by the compressor. The line losses are generally small; hence a first-order energy balance would require that

$$W + Q_L = Q_H$$

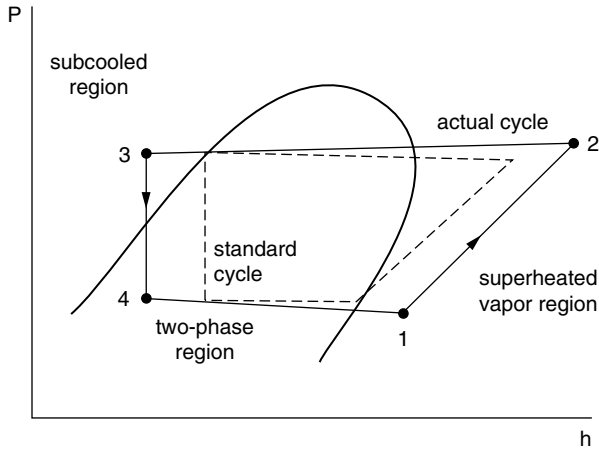

FIGURE 54.5 Ph diagram: vapor compression cycle.

The coefficient of performance (COP), a type of efficiency, is defined as

$$COP = Q_L / W$$

The U.S. industry also uses a similar, dimensional ratio called the energy efficiency ratio (EER), given in units of Btu/h of cooling (numerator) per watt of work (denominator).

The compressor is generally driven by an electric motor; however, in large systems gas-driven engines or steam turbines are also used. The evaporator might also function as a chiller, cooling a separate fluid in a secondary loop for terminal units that provide cooling in different zones of the building. In a similar manner, the condenser might reject its heat through cooling towers, ponds, or ground-coupled sources/sinks. The selection of these other alternatives is dependent on energy sources, building type, cost, and even local building codes and customs.

The corresponding refrigerant Ph (pressure, enthalpy) and Ts (temperature, entropy) diagrams for simple vapor compression systems are shown in Figure 54.5 and Figure 54.6, respectively. The slight superheat at the outlet of the evaporator (point 2) is to ensure that no liquid droplets enter the compressor. The **subcooled** conditions downstream of the condenser (point 3) are desirable to ensure proper response and control by the expansion valve (normally a thermostatic expansion valve or an electrostatic expansion

FIGURE 54.6 Ts diagram: vapor compression cycle.

FIGURE 54.7 Evaporative cooling.

valve). These valves control superheat by adjusting the mass flow rate of refrigerant. In some cases fixed-area throttling devices might be used (such as capillary tubes or fixed-area orifices) for small systems.

Evaporative Cooling

Evaporative cooling is a cost-effective alternative for dry climates. Water, when sprayed and evaporated, will lead to a lowering of dry-bulb temperature of air supplied to a building. The cooling may be *direct* (the water is added to the air being conditioned) or *indirect*. In the case of indirect cooling, a secondary air stream (cooled by evaporation of a spray) flows through a heat exchanger, removing thermal energy from the conditioned ambient return air. The corresponding processes are shown in Figure 54.7. (For details see ASHRAE [2001] or Kreider et al. [2002].)

Absorption Cooling

Ferdinand Carre invented the adsorption system in the mid-1800s. In lieu of a compressor, as used in vapor compression systems, an absorption system uses a small pump and two chemical processes as diagrammed in Figure 54.8. First, the refrigerant leaving the evaporator (in a vapor state) is absorbed in a liquid. This operation takes place in an *absorber*. Heat is removed during this step. Second, the pressure of the solution is increased through a liquid pump. Third, the high-pressure solution is heated in order to release the high-pressure refrigerant in a vapor state and transfer it to the condenser. This third step takes place in a *generator*. The remaining solution (now with a very low concentration of refrigerant) flows through a throttling valve to the absorber. Three features of the absorption system make it sometimes preferable to a vapor-compression system. First, the compressor is exchanged for a liquid pump consuming much less power. Second, absorption cooling lends itself to the use of on site waste heat, solar energy, or similar thermal sources. Third, the working fluids in common use are not “greenhouse gases” described in the next section. Typical fluids are water–lithium bromide and water–lithium chloride, in which water is used as the refrigerant. (See Kreider et al. [2002] or Stoecker and Jones [1982].)

Refrigerants

Refrigerants were originally selected for their safety, low cost, high stability, good compatibility with materials, and excellent thermal performance (examples are R12 for refrigerators and automobile air conditioners and R22 for residential air conditioners). Data from the past two decades or more regarding ozone depletion and theoretical models explaining it placed part of the blame on chlorofluorocarbon (CFC) refrigerants such as R11 and R12. The upshot of this work is the Montreal Protocol, which required

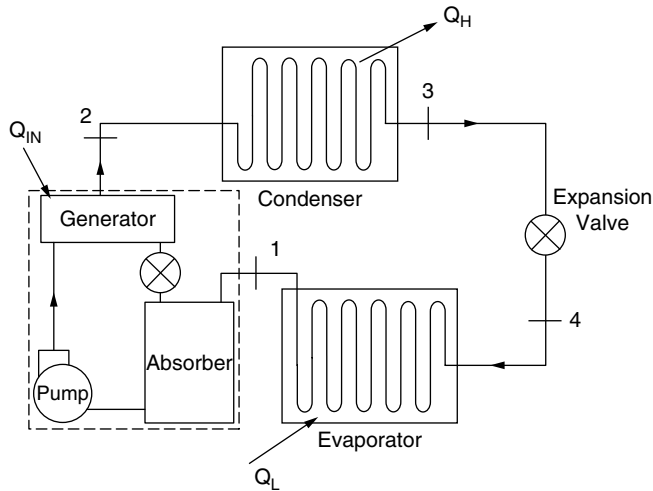

FIGURE 54.8 Absorption cooling cycle components.

an orderly phaseout of refrigerants that were thought to be involved in climate change; gases so implicated are called “greenhouse gases.” Today nearly all such refrigerants are no longer in use except in well-sealed, older systems that rely on them for efficient operation. In the 1980s and 1990s, new and efficient fluids were deployed that have minimal global warming potential while achieving efficiencies very similar to those using older CFC working fluids.

Defining Terms

Dew-point temperature — Temperature at which water vapor begins to condense out of a mixture of dry air and water vapor (becomes saturated) while cooled at constant pressure from an unsaturated state.

Dry-bulb temperature — Conventional thermometer temperature.

Enthalpy — Intrinsic property of a substance determined by the summation of its internal energy and the product of its pressure and volume (denoted $h = u + Pv$).

Humidification — Process of adding moisture to an air stream (dehumidification: removal of moisture).

Humidity ratio — Mass ratio of water vapor to dry air in a mixture.

Refrigeration — Act of maintaining a low-temperature region of finite size at a selected temperature by removing heat from it.

Relative humidity — Ratio of partial pressure of water vapor in a mixture to the saturation pressure of the vapor at the same dry-bulb temperature.

Specific volume — Volume per unit mass of a substance (generally denoted v).

Subcooled — Conditions where a liquid is cooled below its saturation temperature at a given pressure.

Superheated — Conditions where a vapor is heated above its saturation temperature at a given pressure.

Wet-bulb temperature — Temperature from a conventional thermometer where the bulb is covered with a wetted wick.

Refrigeration and Cryogenics

55.1 Desiccant Cooling

55.2 Heat Pumps

55.3 Cryogenics

Physical Properties of Cryogenic Liquids • Cryogenic Refrigeration Systems • Joule–Thomson Refrigerator (Cryocooler) • Stirling Refrigerator (Cryocooler) • Vuilleumier Refrigerator (Cryocooler) • Gifford–McMahon Refrigerator (Cryocooler) • Pulse Tube Refrigerator (Cryocooler) • Magnetic Refrigerators • Dilution Refrigerator (Cryocooler)

Randall F. Barron

Louisiana Tech University

Refrigeration involves the production and utilization of temperatures below normal ambient temperature. The general goal of conventional refrigeration is not only to achieve low temperatures but also to maintain a space or material at subambient temperatures for an extended time. Some examples of the utilization of refrigeration include:

1. Cooling of residences (air conditioning)
2. Ice making
3. Cold storage of foods
4. Condensation of volatile vapors in the petroleum and chemical industries

Cryogenics is a special field of refrigeration that involves the production and utilization of temperatures below -150°C (-240°F) or 123 K. This dividing line was chosen between conventional refrigeration and cryogenics because the refrigerants used in air conditioning, ice making, food cold storage, etc., all condense at temperatures much higher than -150°C . Typical cryogenic fluids (listed in [Table 55.1](#)) include methane, nitrogen, oxygen, argon, neon, hydrogen, and helium. All of these fluids condense at temperatures below -150°C . Some examples of the utilization of cryogenic temperatures are:

1. Production of liquefied gases for industrial and space technology uses
2. Maintaining low temperatures required for superconducting systems
3. Treatment of metals to improve the physical properties of the material
4. Destruction of defective tissue (cryosurgery)

55.1 Desiccant Cooling

Desiccant cooling has been used in connection with solar cooling systems because desiccant systems can achieve both cooling and dehumidification [Duffie and Beckman, 1991]. Lof [1955] described a closed-

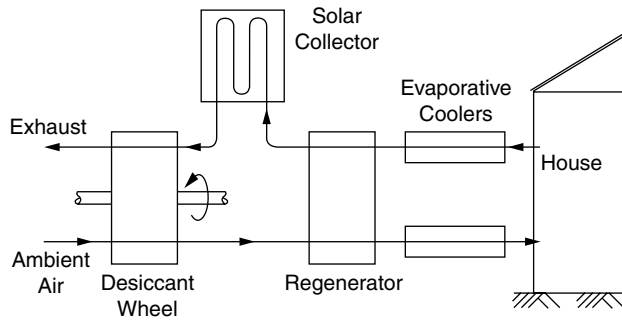

FIGURE 55.1 Solar desiccant cooler. The desiccant wheel acts to remove moisture from the ambient air entering the system.

cycle desiccant cooling system using liquid triethylene glycol as the drying agent. In this system, glycol was sprayed into an absorber to absorb moisture from the air from the building. The stream then flowed through a heat exchanger to a stripping column, where the glycol was mixed with a stream of solar-heated air. The high-temperature air removed water from the glycol, which then returned to the absorber. This system, using steam as the heating medium, has been used in hospitals and similar large installations.

An open cycle desiccant cooling system is shown in Figure 55.1 [Nelson et al., 1978]. The supply air stream is dehumidified in a desiccant regenerative heat exchanger (wheel), then cooled in a heat exchanger and an evaporative cooler before being introduced into the space to be cooled. The return-air stream from the space is evaporatively cooled before returning through the heat exchanger to a solar collector, where the air is heated. The hot air flows back through the desiccant “wheel,” where moisture is removed from the desiccant before the air stream is exhausted to the atmosphere.

55.2 Heat Pumps

Heat pumps are systems that can provide either cooling or heating for a building [McQuiston and Parker, 1994]. The schematic of a typical heat pump is shown in Figure 55.2. The heat pump cycle is shown on the pressure–enthalpy plane in Figure 55.3.

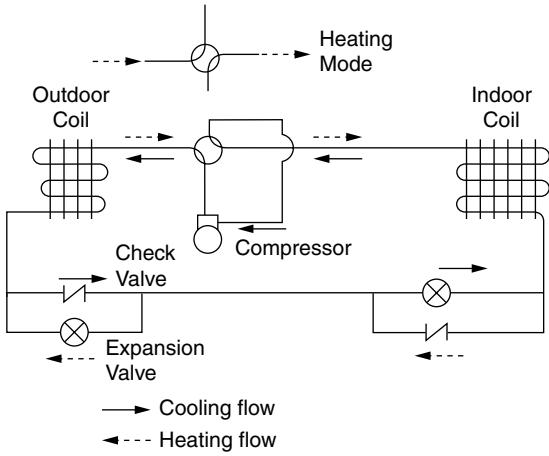

FIGURE 55.2 Heat pump. The flow directions for the cooling mode are shown as solid arrows; the flow directions for the heating mode are shown as dashed arrows.

FIGURE 55.3 Pressure-enthalpy diagram for a heat pump: (1) compressor inlet; (2) compressor outlet; (3) outlet of the outdoor coil (*cooling mode*) or outlet of the indoor coil (*heating mode*); and (4) outlet of the expansion valve.

The dimensionless coefficient of performance (COP) for a heat pump operating in the cooling mode is given by:

$$COP(C) = \frac{Q_A}{-W} = \frac{h_1 - h_3}{h_2 - h_1} \quad (55.1)$$

where Q_A is the energy absorbed from the region to be cooled, W is the net work input (negative work, by convention) to the heat pump, and h is the enthalpy of the working fluid at the corresponding points in the cycle. For an ideal refrigerator (Carnot refrigerator), the COP is

$$COP(C)_{Car} = \frac{T_L}{T_H - T_L} \quad (55.2)$$

where T_H is the high temperature (absolute) in the cycle and T_L is the low temperature (absolute) in the cycle. The COP for an actual heat pump is on the order of one-third to one-half of the ideal COP [Kreider and Rabl, 1994].

For a heat pump operating in the heating mode, the COP is defined by

$$COP(H) = \frac{Q_H}{-W} = \frac{h_2 - h_3}{h_2 - h_1} \quad (55.3)$$

where Q_H is the heat added to the region being heated. For a Carnot heat pump the ideal COP is

$$COP(H)_{Car} = \frac{T_H}{T_H - T_L} \quad (55.4)$$

In the U.S., the COP for a heat pump is often expressed in units of Btu/W-h, and this ratio is called the *energy efficiency ratio* (EER), where $EER = 3.412 COP$

The capacity of a heat pump is strongly dependent on the outside air temperature. When the outdoor temperature falls much below 0°C (32°F) for a heat pump operating in the heating mode, it is often necessary to provide supplemental energy in the form of electrical resistance heating.

Example

A heat pump operating in the heating mode accepts energy from ambient air at 5°C (41°F or 278.2 K) and transfers 8 kW (27,300 Btu/h) to the inside of a residence at 22°C (71.6°F or 295.2 K). The actual COP is 40% of the ideal or Carnot COP. Determine the required power input to the heat pump and the EER.

Solution

The Carnot COP for the heating mode is calculated from Equation (55.4):

$$COP(H)_{Car} = \frac{T_H}{T_H - T_L} = \frac{295.2}{295.2 - 278.2} = 17.36$$

The actual COP is 40% of the ideal COP, or

$$COP(H) = (0.40)(17.36) = 6.95 = Q_H / (-W)$$

The power input to the heat pump is

$$-W = \frac{Q_H}{COP(H)} = \frac{8.00}{6.95} = 1.152 \text{ kW}$$

The energy efficiency rating is found as follows:

$$EER = 3.412 COP(H) = (3.412)(6.95) = 23.7 \text{ Btu} / W - h$$

55.3 Cryogenics

The field of cryogenic refrigeration generally involves temperatures below -150°C (-240°F) or 123 K [Scott, 1959]. This dividing line between conventional refrigeration and cryogenics was selected because the normal boiling points of ammonia, hydrogen sulfide, and other conventional refrigerants lie above -150°C, whereas the normal boiling points of cryogenics, such as liquid helium, hydrogen, oxygen, and nitrogen, all lie below -150°C.

Physical Properties of Cryogenic Liquids

The physical properties of several cryogenic liquids at the normal boiling point (NBP) are listed in [Table 55.1](#). All of the liquids are clear, colorless, and odorless, with the exception of liquid oxygen (pale blue color) and liquid fluorine (straw-yellow color). Liquid nitrogen, liquid oxygen, liquid argon, and liquid neon are generally obtained by separating air into its constituent components in an air distillation system [Barron, 1985].

Hydrogen can exist in two distinct molecular forms: ortho-hydrogen and para-hydrogen. The equilibrium mixture at high temperatures (above room temperature) is 75% o-H₂ and 25% p-H₂, which is called *normal hydrogen*. At its NBP (20.27 K), equilibrium hydrogen is 99.8% p-H₂ and 0.2% o-H₂.

Neither isotope of helium (helium-4 or helium-3) exhibits a triple point (coexistence of the solid, liquid, and vapor phases); however, helium-4 has two liquid phases: liquid helium-I, which is a normal liquid, and helium-II, which exhibits superfluidity. Liquid helium-II exists below the lambda point (2.171 K).

FIGURE 55.4 Joule–Thomson cryocooler.

Cryogenic Refrigeration Systems

The coefficient of performance (COP) of the thermodynamically ideal refrigerator (Carnot refrigerator) is given by

$$COP_{Car} = \frac{T_L}{T_H - T_L} \quad (55.5)$$

where T_L is the low temperature in the cycle and T_H is the high temperature in the cycle. The figure of merit (FOM) for any refrigerator or cryocooler is given by

$$FOM = \frac{COP_{act}}{COP_{Car}} \quad (55.6)$$

Joule–Thomson Refrigerator (Cryocooler)

A schematic of the Joule–Thomson cryocooler is shown in Figure 55.4. The refrigeration effect for this refrigerator is given by

$$Q_A / m = (h_1 - h_2) - (1 - \epsilon)(h_1 - h_g) \quad (55.7)$$

where ϵ is the heat exchanger effectiveness, h_1 is the fluid enthalpy at temperature T_2 and pressure p_1 , and h_g is the saturated vapor enthalpy at pressure p_1 . Nitrogen is typically used as the working fluid for the temperature range between 65 and 115 K. Microminiature J–T cryocoolers using nitrogen–methane gas mixtures have been manufactured for operation at 65 K (–343°F) to cool electronic components [Little, 1990].

Stirling Refrigerator (Cryocooler)

The Stirling cryocooler consists of a cylinder enclosing a power piston and a displacer piston, as shown in Figure 55.5. The two chambers are connected through a regenerator (heat exchanger) that is one of the more critical components of the refrigerator [Barron, 1999]. Walker [1983] gives a detailed description of the Stirling refrigerator and its thermodynamic and mechanical performance. Ideally, the Stirling refrigerator has a FOM of unity; however, actual Stirling cryocoolers have FOM values of approximately 0.36.

FIGURE 55.5 Stirling cryocooler. The power piston compresses the working fluid (typically, helium gas), while the displacer piston (operating 90° out of phase with the power piston) moves the working fluid from the warm space through the regenerator to the cold space and back again. Heat is absorbed from the cryogenic region at the cold end, and cooling water in the cooling coils removes the heat at the warm end.

Vuilleumier Refrigerator (Cryocooler)

The Vuilleumier (VM) cryocooler, first patented by Rudolph Vuilleumier in 1918 in the U.S., is similar to the Stirling cryocooler, except that the VM cryocooler uses a thermal compression process (Stirling engine) instead of the mechanical-drive compression process used in the Stirling system [Timmerhaus and Flynn, 1989]. A schematic of the VM refrigerator is shown in Figure 55.6. The COP for an ideal VM refrigerator is given by:

$$COP = \frac{Q_A}{Q_H} = \frac{T_L(T_H - T_o)}{T_H(T_o - T_L)} \quad (55.8)$$

where T_o is the intermediate temperature (absolute) in the cycle.

Gifford–McMahon Refrigerator (Cryocooler)

A schematic of the Gifford–McMahon (GM) cryocooler, developed by W. E. Gifford and H. O. McMahon [1960], is shown in Figure 55.7. This system has valves and seals that operate at ambient temperature, so low-temperature valve and seal problems are eliminated. The GM refrigerator is well suited for multistaging, where refrigeration is provided at more than one temperature level [Gifford and Hoffman, 1961]. For example, in systems in which thermal shields are placed around a region to be maintained at cryogenic temperatures, refrigeration may be provided for both the thermal shields (at 77 K, for example) and the low-temperature region (at 20 K, for example) by a single refrigerator.

FIGURE 55.6 Vuilleumier refrigerator.

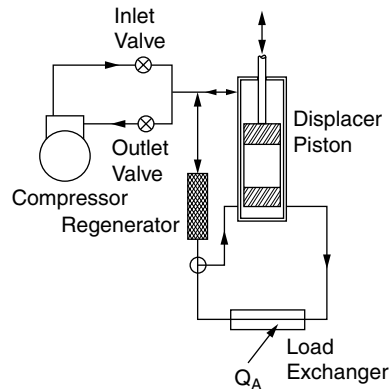

FIGURE 55.7 Gifford–McMahon refrigerator.

FIGURE 55.8 Pulse-tube cryocooler. The rotary valve is the source of pressure oscillation for the pulse tube. Typical switching frequencies range between 10 and 50 Hz. The orifice–reservoir volume combination is needed to control the phase angle between the mass flow and pressure in the system.

Pulse Tube Refrigerator (Cryocooler)

A schematic of the pulse tube refrigerator utilizing orifice restrictions is shown in Figure 55.8. The basic system was originally proposed by Gifford and Longworth [1965] in 1963. The addition of the orifice impedance and buffer volume, suggested by Mikulin et al. [1984], allowed higher-frequency operation and resulted in an improvement in the refrigeration effect. Other than the compressor and reversing rotary valve, the pulse tube refrigerator has no moving parts; therefore, the reliability of the system is high. The pulse tube refrigerator has been used primarily in systems requiring cooling effects of 500 W or smaller [Weisend, 1998].

The pulse tube refrigerator consists of a compressor with a rotating valve distributor (or a source of pressure oscillation), a regenerator for heat exchange, and the pulse tube. The pulse tube is connected at the ambient temperature end to a buffer volume through an orifice, needle valve, or other suitable flow resistance element. High-pressure gas enters the regenerator, in which the gas is cooled. The cold gas leaving the regenerator enters the pulse tube at the cold end and acts as a gas piston to compress the gas already within the pulse tube. The compressed gas flows through the pulse tube to the warm end, where the gas is cooled by exchanging energy in an ambient-temperature heat exchanger. The rotary valve is turned such that the gas inlet is closed, the exhaust is opened, and the cooled gas in the pulse tube expands and experiences a decrease in temperature. The expanding gas flows back through the pulse tube, absorbs energy from the region to be refrigerated, and leaves the system through the regenerator.

The total refrigeration effect for the pulse tube refrigerator is given by [Radebaugh, 1990]:

$$Q_A = \frac{\gamma u_o A_t \Delta P \cos \phi}{2(\gamma - 1)} \quad (55.9)$$

where γ = specific heat ratio ($\gamma = 1.67$ for helium gas), u_o = maximum gas velocity in the pulse tube, A_t = cross sectional area of the pulse tube, ΔP = maximum pressure change of the gas in the pulse tube,

FIGURE 55.9 Magnetic refrigerator. The main magnet controls the magnetic field within the working paramagnetic salt, while the valve magnets switch the thermal valves (strips of lead) from the “off” state (superconducting) to the “on” state (normal).

and ϕ = phase angle between the gas velocity and pressure peak in the gas. The phase angle is controlled by the size of the buffer volume and the orifice impedance.

Magnetic Refrigerators

Cooling through the application of the adiabatic demagnetization process with a paramagnetic salt is one technique used to maintain temperatures below 1 K. The refrigerator consists of a paramagnetic salt such as iron ammonium alum, which is the cooling medium for the refrigerator, along with a solenoid to control the magnetic field around the working salt, as shown in Figure 55.9. Thermal valves are used to control the heat transfer to and from the working salt. Ideally, the FOM for the magnetic refrigerator would be unity; however, real magnetic refrigerators have a FOM in the range from 0.40 to 0.80.

The magnetic refrigerator has also been constructed in a “wheel” configuration, in which the magnetic field remains stationary and the paramagnetic material is moved through regions of high and low (near zero) magnetic field strength to accomplish cooling of a gas flowing through the wheel [Barclay et al., 1985].

Dilution Refrigerator (Cryocooler)

The He-3/He-4 dilution refrigerator is widely used to maintain temperatures in the range between 0.005 and 0.85 K. The basis for the operation of this refrigerator is the phase separation of mixtures of normal He-3 and superfluid He-4, discovered by K. G. Walters and W. M. Fairbank [1956], that occurs at temperatures below 0.86 K. The refrigeration effect of the dilution refrigerator is determined from

$$Q_A = n_3(h_m - h_i) \quad (55.10)$$

where n_3 is the molar flow rate of He-3, and h_m and h_i are the enthalpies of the streams leaving and entering the mixing chamber of the refrigerator, respectively. These enthalpies can be calculated from the following, for temperatures below about 0.04 K [Radebaugh, 1967].

$$h_m = (94 \text{ J/mol} - K^2)T_m^2 \quad (55.11)$$

$$h_i = (12 \text{ J/mol} - \text{K}^2) T_i^2 \quad (55.12)$$

where T_m is the temperature of the fluid leaving the mixing chamber and T_i is the temperature of the fluid entering the mixing chamber.

Defining Terms

Adiabatic demagnetization — The process of reduction of the magnetic field strength around a material while allowing negligible transfer of heat. This process results in a decrease in temperature of the material.

Closed cycle — A system in which the working fluid is recirculated.

Coefficient of performance (COP) — The ratio of the useful heat load to the required work input for a heat pump or refrigerator. The COP gives a measure of the effectiveness of the system.

Cryocooler — A refrigerator operating at cryogenic temperatures.

Cryogenics — The science and technology involving very low temperatures.

Desiccant — A material that has a high affinity for water.

Energy efficiency ratio (EER) — The coefficient of performance of a heat pump or refrigerator expressed in units of Btu/W-h.

Lambda point — The temperature at which liquid helium-4 changes from a normal fluid to a superfluid.

Normal boiling point (NBP) — The boiling point of a liquid at standard atmospheric pressure (101.325 kPa or 14.696 psia).

Open cycle — A system in which the working fluid is exhausted to the atmosphere and not recirculated.

Superconducting — The state for certain materials for which the electrical resistivity is zero and the magnetic field surrounding the material is expelled from the bulk of the material.

Superfluidity — The physical phenomenon for liquid helium-4 in which the liquid can flow with zero pressure drop through a tube heated at one end and cooled at the other end.

Triple point — The state at which all three phases (solid, liquid, and vapor) coexist in thermodynamic equilibrium.

Heat Transfer to Non-Newtonian Fluids

E.F. Matthys
*University of California, Santa
Barbara*

- 56.1 Introduction
- 56.2 The Fluids
- 56.3 Friction
- 56.4 Heat Transfer
- 56.5 Instrumentation and Equipment

56.1 Introduction

Many, if not most, fluids used in industrial applications are **non-Newtonian**. Of course, the very name tells us that we lump in this category all the fluids except one type, the *Newtonian* fluids. Newtonian fluids are those that obey Newton's law relating shear stress and shear rate through a simple material property (the viscosity) dependent on basic thermodynamics variables such as temperature and pressure, but independent of flow parameters such as shear rate or time. These Newtonian fluids constitute therefore only one category of fluids: essentially the "simplest" ones. (These may, of course, nevertheless be very important. Consider water, for instance.) Conversely, non-Newtonian fluids are then defined as being all the other ones. One might therefore reasonably assume that the state of knowledge about non-Newtonian fluid heat transfer is much more extensive and sophisticated than that about Newtonian fluid heat transfer because of the size and importance of the field, but that is not the case. A major reason why this is so is that it is usually much more difficult to study non-Newtonian fluids because of their complex nature and their complex interactions with the flow field. As a result, much of the information on friction and heat transfer for non-Newtonian fluids is very empirical and consists primarily of simple correlations where the constants are determined by best-fit of experimental data.

Many engineers — when dealing with fluid mechanics or heat transfer — generally think automatically in terms of Newtonian fluids and their behavior because these are usually the main — or even the only — fluids covered in a typical undergraduate engineering education. The average engineer may therefore never had much — or any — exposure to non-Newtonian fluids before his or her first encounter with them on the job. This has important consequences as far as engineering practice, because serious mistakes can be readily made if one is not aware of the bizarre behavior of some of these fluids. Practically speaking, when the fluid is not a very simple or one-component liquid or gas such as water, oil, or air, there is a very good chance that it may indeed exhibit some non-Newtonian properties. Fluids of great importance in engineering practice, such as suspensions of particles and fibers, slurries, **polymer** solutions and melts, **surfactant** solutions, paints, foodstuffs, biofluids, soaps, inks, organic materials, adhesives, etc., may all exhibit strongly non-Newtonian behavior. The engineer should therefore be aware of the potential problems and be able to decide — on an informed basis — whether to use simpler (but perhaps leading

to large errors) Newtonian fluid correlations or to use the more complex information (perhaps) available on non-Newtonian fluids.

Given the breadth and complexity of the field, and space limitations, the nonspecialist reader will be best served in this author's opinion by a short chapter that focuses on giving a general idea of the basic issues and difficulties involved and on providing some useful references for deeper study. Mentioning only a few equations here may do disservice to the reader interested in this complicated field, as it is more likely to lead to inadvertent inappropriate usage than to be a timesaver. For some basic information, the reader is instead referred to some readily available handbook articles that provide numerous correlations: for example those by Irvine et al. [1987] on **purely viscous non-Newtonian fluids** and by Hartnett et al. [1998] dealing with **viscoelastic non-Newtonian fluids**. Some other references and recent work will also be mentioned hereafter. A focus of this chapter will be drag-reducing fluids because these are among the most challenging and interesting non-Newtonian fluids.

56.2 The Fluids

It should be noted first that one needs only to address the issue of *moving* fluids here, because the very concept of a non-Newtonian substance implies that the related fluid characteristics manifest themselves under flow. Accordingly, only convective heat transfer needs to be discussed here, because both conduction and radiation are normally unaffected, and require only that appropriate material properties such as thermal conductivity and emissivity be known, as in the case of Newtonian fluids. Another point to consider is that the definition of a non-Newtonian fluid covers only the *shear* viscosity of the fluid, but many non-Newtonian fluids will also show a complex *extensional* flow behavior. Some non-Newtonian fluids, perhaps the most difficult to deal with, are also viscoelastic.

The first step in trying to predict the heat transfer behavior of a non-Newtonian fluid is therefore to determine its nature and type. For simplicity, one often classifies these fluids as purely viscous vs. viscoelastic, the former lacking the elastic component of the latter. All of these may exhibit a viscosity that can either increase or decrease both with shear rate and with time, and some fluids may also exhibit a yield stress. In addition, viscoelastic fluids in general exhibit memory effects, but some may also show particularly large time-dependent effects in addition to shear rate-related variations (e.g., some surfactant solutions).

In general, the heat transfer to purely viscous fluids can be quantified by relatively simple modified Newtonian fluid correlations, and with some information on the viscosity one can then predict reasonably well the heat transfer and friction. These fluids have been studied early on, and many flow configurations have been investigated. Reviews and handbooks, even somewhat older ones, may provide most of the state-of-the-art information. For viscoelastic fluids, on the other hand, and especially in turbulent flow, much less information is available; they are still an area of active current research. Some of these fluids exhibit a fascinating property: that of reducing greatly the friction or heat transfer under turbulent flow conditions. This phenomenon is called **drag or heat transfer reduction**. For these fluids, using a Newtonian-like approach to predict heat transfer may well result in very large errors. This field is evolving rapidly; much of the current information may need to be sought in technical journals.

It is relatively easy to determine whether a fluid might be viscoelastic, even with some simple qualitative experiments such as recoil, finger-dip and fiber-pull, rod-climbing, die swell, and tubeless siphon. One could also pretty much guess that most fluids that are not viscoelastic but are nevertheless mixtures, solutions, or suspensions may likely be purely viscous non-Newtonian fluids. Beyond such simple classification, however, some data on the viscous or viscoelastic nature of the fluid may be necessary to help correlate or predict heat transfer or friction quantitatively. This information has to be acquired from some **rheology** experiments, although rough estimates can at times be found in the literature. One should be especially cautioned, however, against using viscosity models beyond their proven range of applicability, as is often done for the ubiquitous power-law model, for example. Much information, including books on rheological measurements, is readily available, and several companies produce instrumentation dedicated to such measurements.

It cannot be emphasized enough for the engineer who is not yet familiar with non-Newtonian fluids that one should be particularly wary of relying on one's experience with Newtonian fluids or one's intuition when tackling the more complex non-Newtonian fluids. The latter's behavior may indeed be very surprising. For example, a few parts per million of a polymer or surfactant in solution in water could well reduce the heat transfer by a factor of more than 10. Accordingly, the reader is strongly advised to consult some of the additional material referred to here to develop enough of an understanding of the issues to avoid such problems.

56.3 Friction

The reader is referred to another chapter in this handbook and to many articles in the literature where one can find fluid mechanics information on these fluids. An approach similar — although simpler — to that discussed here for heat transfer can usually be followed for friction. It is important to note, however, that the strong coupling between friction and heat transfer for Newtonian fluids, which enables one to predict heat transfer if one knows friction (and vice versa) for these fluids, was long believed not to hold for some non-Newtonian fluids such as drag-reducing solutions, and may be discussed as such in earlier literature. Conversely, recent studies have suggested that for these latter fluids at least, this coupling appears indeed to remain applicable. If this is indeed more generally true, a powerful new tool for the prediction of heat transfer for these fluids will have been added to the arsenal of the engineer because simpler friction experiments may then be all that is needed to predict or estimate heat transfer.

56.4 Heat Transfer

As mentioned above, one is usually reduced to using simple empirical correlations to predict the heat transfer for these fluids. In addition to the handbooks listed above, the reader is also referred to a number of reviews for additional information [Metzner, 1965; Skelland, 1967; Dimant et al., 1976; Shenoy et al., 1982; Hartnett et al., 1989; Matthys, 1991].

As in the case of Newtonian fluids, one may use the **Nusselt number** to quantify the convective heat transfer coefficient. In the case of a purely viscous non-Newtonian fluid, the Nusselt number will usually be a function of modified **Reynolds** and **Prandtl** numbers. For viscoelastic non-Newtonian fluids, it may be in addition a function of other non-dimensional numbers that may be related to the elasticity of the fluid through a relaxation time (e.g., a **Weissenberg** number) or to the extensional viscosity of the fluid or some other parameter. It is also crucial to distinguish between the several types of Reynolds numbers (and corresponding Prandtl numbers) that are used for the prediction of friction and heat transfer for these fluids. (Note that such a distinction is not always made clearly in the literature, and one should proceed cautiously.) Often, *generalized* Reynolds and Prandtl numbers are used for laminar flow, whereas *apparent* Reynolds and Prandtl numbers may be more suitable for turbulent flow. These various definitions involve the actual viscosity of the fluids in different ways. For applied engineering work, researchers often use *solvent-based* numbers, a potentially dangerous practice that leads to large errors for some fluids and should be used with great care. Indeed, even with dilute solutions, it is generally essential to measure the viscosity of the actual fluid if it is not in actuality very close to that of the solvent. This viscosity has to be measured in the laboratory and should be done as a matter of routine when dealing with non-Newtonian fluids. Indeed, if information is not available on the viscosity of the fluid, and the latter is not properly taken into account in the nondimensionalizations, significant errors may occur. Conversely, the use of proper parameters and viscosity values may, for example, reveal that a fluid at first believed to be exhibiting non-asymptotic behavior is in actuality indeed fully asymptotic [Aguilar et al., 2001]. Good discussions and definitions of these parameters can be found in some of the reviews listed above.

Since the main effects of the non-Newtonian character of the fluid on the heat transfer result from interactions between fluid and flow field through large variations in viscosity or elasticity (sometimes over several orders of magnitude), the variations in other thermophysical parameters (e.g., thermal conductivity and specific heat capacity) are often of much lesser importance. One may then often

satisfactorily assume that these properties vary only with temperature in a given manner for a specific non-Newtonian fluid, or even that they remain those of the Newtonian solvent (e.g., for low-concentration solutions). Naturally, for highly concentrated suspensions of fibers or particles, for example, one has to use appropriate properties for the actual fluid, and procedures are available to predict such properties based on the concentration of the suspended material. For more complex or lesser-known fluids, one may well be forced to measure these properties directly. It is useful to note that for viscoelastic fluids, in particular, the large reductions in heat transfer seen in turbulent flow are not related to modifications of the “static” thermophysical properties, but rather to fluid/turbulence interactions, i.e., a dynamic process. This is why these fluids do not normally show such large effects on the heat transfer in the laminar regime. The distinction between laminar and turbulent flows is therefore even more crucial to make here than for Newtonian fluids. Note that the transition between the two regimes takes place under relatively similar conditions for both Newtonian and non-Newtonian fluids, and that the usual Newtonian fluid criteria for transition are often used. (In addition, some viscoelastic effects such as drag reduction may only appear after some minimum value of a flow parameter — such as the shear stress, for example — is exceeded.)

Laminar Regime — Heat transfer in the laminar regime can be fairly readily predicted for non-Newtonian fluids because of the simple nature of the flow and the absence of significant elastic effects. A good discussion on this issue for some fluids is provided in Skelland [1967]. Generally, one simply modifies the Nusselt number calculated for a Newtonian fluid with a coefficient that involves a parameter reflecting the change in velocity profile (e.g., a power-law exponent n) and possibly the aspect ratio if it is internal flow in a noncircular duct [Irvine et al., 1987; Hartnett et al., 1989]. For heat transfer in the entrance region, one has to introduce another parameter such as a Graetz number to account for the temperature profile development (as in the case of Newtonian fluids). Also as in the case of Newtonian fluids, the laminar thermal entrance region can be fairly long for high Reynolds numbers. Overall, the change in Nusselt number introduced by the non-Newtonian nature of the fluid is often moderate in the laminar regime, and if nothing else is available, the use of a Newtonian value may not be too far off in first approximation for fluids with a moderate power-law exponent, for example. For external flow, simple empirical corrections to Newtonian expressions can also be used [e.g., Irvine et al., 1987]. For free and mixed convection, relatively little information is available, and the reader is referred in particular to the review by Shenoy et al. [1982]. Specific information for polymer melts can be easily found in the processing literature. The viscosity of the latter fluids is generally very large, however, and most applications will likely involve only laminar or viscosity-dominated conditions, which simplifies the analysis considerably, in contrast to the situation for dilute solutions.

Turbulent Regime — For this regime, it becomes necessary to pay particular attention to the distinction between purely-viscous and viscoelastic fluids. Heat transfer to many purely-viscous fluids can be adequately predicted by the use of simple relations involving the Nusselt number and apparent Reynolds and Prandtl numbers or by taking advantage of the analogy between friction and heat transfer for these fluids [Metzner, 1965; Cho et al., 1985; Matthys et al., 1987]. The thermal entrance region for these fluids is generally similar to that of Newtonian fluids and very short (e.g., about 20 to 50 diameters for flow in a tube).

For viscoelastic fluids, on the other hand, the situation is very different. Some suspensions of very long fibers may exhibit such a nature, as will polymer melts or solutions and many complex fluids. Dilute solutions of a polymer or surfactant in tube flow, in particular, are of great interest in this regard. These fluids may indeed exhibit dramatic drag and heat transfer reductions with respect to the solvent alone at the same Reynolds number. (Some good reviews for information on drag-reducing fluids can be found in Gyr and Bewersdorff [1995] and in Zakin et al. [1998].) This effect is very large, even with very small (e.g., subpercent level) traces of polymer or surfactant additives. The level of drag and heat transfer reductions at a given Reynolds number will generally increase with concentration of drag-reducing additive in the solvent. Interestingly, there is a minimum below which the drag and heat transfer can no longer be reduced, the so-called drag and heat transfer reduction asymptotes [e.g., Matthys, 1991; Aguilar et al., 2001]. One advantageous feature of this **asymptotic regime** is that the concentration no longer

plays a role there in determining the friction and heat transfer, which also means that the Nusselt number is no longer a function of an additional parameter besides the Reynolds and Prandtl number. Good correlations exist for this regime, in fact surprisingly robust ones. The asymptotes were long thought to be the same for all drag-reducing fluids, but some recent work has suggested that there may well be differences between polymer and surfactant solutions, for example [Aguilar et al., 2001]. There may also be some more fundamental differences between distinct types of drag-reducing fluids [Gasljevic et al., 2001]. In the asymptotic regime, there also appears to be a strong coupling between friction and heat transfer, seen most readily if more physically meaningful nondimensional numbers are used, rather than the numbers based on simpler calculations of drag and heat transfer reductions that are commonly used [Aguilar et al., 1999]. Indeed, when working with drag-reducing fluids, one should pay particular attention to the nondimensional numbers used for the quantification of the drag and heat transfer reduction levels. For instance, the most widely used definitions of the drag and heat transfer reduction factors are based on a comparison between the solvent friction and a hypothetical fluid of zero friction. This is a convenient representation, but it has been shown instead that more physically meaningful definitions can be generated based on comparison between turbulent and laminar flows [Gasljevic and Matthys, 1999]. The use of these better parameters allows for more accurate correlations and may help explain apparently surprising results and unexpected behaviors.

In the region between the Newtonian and asymptotic limits, the friction and heat transfer are a function of the concentration (i.e., viscoelasticity) of the fluid as well as of the diameter of the pipe. At this time, there appears to be no universal technique that allows us to predict directly the heat transfer in this region based on simple material properties measurements or basic principles. The non-Newtonian (nonlinear) diameter effects, in particular, mandate that some special scaling methods be used for adequate predictions [e.g., Gasljevic et al., 1999]. Note also that for a given concentration and diameter, the level of friction and heat transfer reduction in this regime will still depend on the Reynolds number (i.e., shear stress or shear rate), and a fluid may exhibit Newtonian behavior at low Reynolds number but then progressively phase in its asymptotic behavior at high Reynolds number. In some cases there may be an onset shear stress that has to be exceeded before any drag or heat transfer reduction behavior is observed. In the nonasymptotic regime, there still appears to be coupling between friction and heat transfer, but of a more complicated nature, perhaps quantifiable by a constant nonunity turbulent Prandtl number [Aguilar et al., 1999].

Interestingly, the heat transfer is usually reduced proportionally more than the friction for drag-reducing fluids (e.g., by 95 vs. 90% for a typical asymptotic solution), but the ratio between the two remains essentially constant if proper nondimensional parameters are used [Aguilar et al., 1999]. For polymer solutions, the heat transfer and drag reductions decrease simultaneously and at the same rate as the polymer is degraded mechanically. Departures from asymptotic conditions due to dilution also take place simultaneously for friction and heat transfer. It should also be noted that the entrance lengths for these fluids are much longer than for Newtonian fluids. For polymer and surfactant solutions in tubes, for example, the thermal entrance length may easily be several hundred diameters long (compared to 20 or so for Newtonian or purely viscous fluids). Here again, more recent work suggests a good coupling between friction and heat transfer in the development region, and a substantial independence of these development effects on the velocity [Gasljevic et al., 1997]. The very long thermal entrance lengths, in particular, should be kept in mind when designing or analyzing heat exchangers for these fluids, as it is likely that the heat transfer may never reach fully developed conditions in many exchangers. Correlations exist that give the heat transfer in the entrance region as a function of distance [e.g., Matthys, 1991; Gasljevic et al., 1997]. It should also be noted that the recent evidence of strong coupling between friction and heat transfer for drag-reducing fluids suggests that it may well be possible to predict heat transfer from friction measurements, which are generally much easier to conduct. This may well save the engineer much work or aggravation when it comes to predicting heat transfer or to designing heat exchangers.

Another issue is very important when one is studying or using viscoelastic fluids: that of **degradation**. Indeed, the polymeric fluids, for example, being macromolecular in nature, may be very susceptible to mechanical degradation. This means that — when subjected to flow in tubes and especially through

pumps and filters — some macromolecules will be permanently broken and that the drag and heat transfer reductions will then be lost partially — or perhaps even completely — depending on the level and duration of exposure. This can be often seen as an increase in friction or heat transfer at high Reynolds number. Degradation can also be caused by thermal or chemical processes. A consequence is that polymer solutions are not well suited for recirculating flows. Surfactant solutions, on the other hand, are much less susceptible to permanent degradation, although the drag and heat transfer reductions can be eliminated completely (but reversibly) under high shear stress (e.g., at high Reynolds number or in hydraulic components). They also possess the remarkable ability to reconstitute rapidly (depending on the temperature) after being subjected to high shear (e.g., in a centrifugal pump). In that respect they are very attractive, and even though relatively little known at this time, will undoubtedly become used more in the future. Many applications of such fluids are possible that would capitalize on their remarkable drag-reducing properties. We are studying presently, for example, their use as energy conservation agents in hydronic heating and cooling systems, a very promising application indeed. For applications involving heat exchangers, the large reductions in heat transfers exhibited by some of these fluids may introduce serious practical difficulties, however, and we have therefore developed approaches allowing us to regain and control heat transfer as needed in the heat exchangers through intentional temporary degradation of the surfactant solution in the heat exchangers. This technology has enabled us to conduct successful field tests of surfactant solutions as energy-saving thermal transport fluids for hydronic HVAC systems.

56.5 Instrumentation and Equipment

Much of the equipment encountered or needed when dealing with non-Newtonian fluids is similar to that used with Newtonian ones, although, of course, some additional equipment may be needed for the quantification of the non-Newtonian nature of the fluid. Typically, this rheological work will require the use of rheometers, perhaps over a wide range of temperature and flow conditions. Numerous such devices exist and are discussed in books on rheometry.

As far as basic instrumentation, a few words of caution are — again — in order. Pressure measurements, for instance, can be complicated by errors due to viscoelastic pressure effects in the taps. These can be minimized by paying particular attention to the shape and uniformity of the tap holes or by using differential pressure measurements whenever possible. Flow measurements may be particularly troublesome, and one should not rely automatically on flowmeters designed for water such as orifice meters or turbine meters, which can give large errors for non-Newtonian fluids unless a careful calibration has been conducted for the specific fluid and relevant flow conditions. Positive displacement devices are generally less troublesome. Ultrasonic flow meters may also be used depending on their built-in velocity profile calibration. Velocity measurements with typical LDV systems should be readily possible, but the use of hot wire anemometry would probably lead to large errors in many cases if appropriate corrections are not introduced.

For temperature measurements, thermocouples, RTDs, thermistors, and thermometers are all generally suitable under steady-state conditions. Note that the flow field may be affected, however, and also that the heat transfer may also be reduced, which may mean, for example, that a longer time might be needed before a steady-state measurement is achieved. Indeed, unsteady measurements may be more difficult. When drag-reducing flows are involved, the temperature gradients in a tube, say, may also be much larger than for Newtonian fluids at a given heat flux, because of the reduced convective heat transfer coefficients. More extensive mixing may then be necessary for bulk temperature measurements. Note also that — as discussed above — the thermal entrance length may be very long for these fluids, and that fully developed conditions may never be reached in practical situations. Some buoyancy effects appear also to be very significant for some non-Newtonian fluids and may introduce large errors in heat transfer measurements if not taken into account [Gasljevic et al., 2000].

The performance of some heat exchangers may be significantly impacted by the fluids, especially drag-reducing solutions [e.g., Gasljevic et al., 1993], and caution should be exercised there as well. The magnitude of the heat transfer reductions will of course depend greatly on the particulars of the fluids

and heat exchangers. Generally speaking, tube heat exchangers will exhibit greater reductions in heat transfer than comparable plate heat exchangers, for example. Mixing devices may also perform differently with non-Newtonian fluids. Centrifugal pumps in most cases will work appropriately, even with improved efficiency at times but may also affect the fluid if excessive shear stress is applied. Pump and valve flow curves do not appear to be changed dramatically in most cases. Naturally, issues of erosion, corrosion, fouling, disposal, etc. should also be investigated for the fluid of interest.

Defining Terms

Asymptotic regime — The regime of maximum drag and heat transfer reduction that can be achieved by drag-reducing fluids. This is the point where increasing the concentration will no longer result in further decreases in drag or heat transfer, if everything else is equal.

Degradation — A modification imparted to the fluid by mechanical, thermal, or chemical effects that changes its properties (e.g., a reduction in viscosity or drag-reducing capability). Typically, mechanical degradation will be permanent in polymeric fluids but only temporary in surfactant solutions.

Heat transfer (and drag) reduction — A sometimes dramatic decrease in heat transfer (and friction) in turbulent flow due to interactions between the viscoelastic nature of the fluid and the flow field.

Non-Newtonian fluid — A fluid that does not obey Newton's law of simple proportionality between shear stress and shear rate. Its viscosity is then also a function of shear rate, time etc.

Nusselt number — A nondimensional number involving the convective heat transfer coefficient. It is a measure of the fluid capability to transfer heat to a surface.

Reynolds number — A nondimensional number involving the flow velocity and the fluid viscosity. It is a measure of the flow rate and level of turbulence in the flow.

Polymer — A material constituted of molecules made of repeating units (monomers).

Prandtl number — A nondimensional number comparing the diffusivity of momentum and heat. It reflects the relative ease of transport of momentum (friction) vs. energy at the molecular level.

Purely viscous non-Newtonian fluid — A non-Newtonian fluid that does not exhibit elasticity.

Rheology — The study of flow and deformation of matter. (Rheology is generally associated with measurements of viscosity and other material properties for *non-Newtonian* fluids.)

Surfactant — A material leading to reduced surface tension effects when added to a solvent. When in solutions, surfactants may also under some conditions form large micellar structures that may result in large viscoelastic drag and heat transfer reductions. (These are not caused by surface tension effects but rather by bulk viscoelastic effects similar to those exhibited by polymer solutions.)

Viscoelastic non-Newtonian fluid — A fluid which — in addition to variations of viscosity with shear rate — exhibits also an elastic character (i.e., has a memory, shows recoil, etc.).

Weissenberg number — A nondimensional number reflecting the viscoelasticity of a fluid through its relaxation time.

Heat Pipes

- 57.1 Heat Pipe Container, Working Fluid, and Wick Structures
- 57.2 Heat Transfer Limitations
- 57.3 Effective Thermal Conductivity
- 57.4 Application of Heat Pipes

Jay M. Ochterbeck
Clemson University

The heat pipe is a capillary-driven two-phase (liquid–vapor) heat transfer device that transfers heat from a heat source to a heat sink. Gaugler originally conceived the basic concept of the heat pipe in 1944, but the operational characteristics of heat pipes were not widely publicized until independent developments by Trefethen in 1962 and by Grover and colleagues at the Los Alamos National Laboratory in 1964. Many types of heat pipes since have been developed and are widely used in a variety of industries. The main attractive feature is that a heat pipe is a passive heat transfer device that transfers heat over relatively long distances via the latent heat of vaporization of a working fluid. The fluid is circulated by **capillary pressure** developed in a **wick**, or porous material.

Figure 57.1 shows a schematic of a heat pipe, which may be inclined at an angle ψ relative to gravity. A heat pipe generally has three sections: an evaporator section for heat addition, an adiabatic (or transport) section, and a condenser section for heat rejection. The major components of a heat pipe are a sealed container, a wick structure, and a working fluid. The wick structure is placed on the inner surface of the heat pipe wall, is saturated with liquid working fluid, and provides the structure to develop the capillary action for liquid returning from the condenser to the evaporator section. With evaporator heat addition, the working fluid is evaporated as it absorbs an amount of heat equivalent to the latent heat of vaporization, while in the condenser section, the working fluid vapor is condensed. The mass addition to the vapor core in the evaporator and the mass rejection in the condenser result in a pressure gradient along the vapor channel that drives the vapor flow. Liquid return through the wick to the evaporator from the condenser is provided by the liquid pressure difference, which is due to the net difference in capillary pressures in the evaporator and condenser sections. Classification of heat pipes may be in terms of geometry, intended applications, or the type of working fluid utilized. Proper selection and design of the heat pipe container, working fluid, and wick structure are essential to the successful operation of a heat pipe. The **heat transfer limitations** and **effective thermal conductivity** define the operational characteristics of the heat pipe.

57.1 Heat Pipe Container, Working Fluid, and Wick Structures

The combination of the container, working fluid, and wick structure of a heat pipe determines its operational characteristics. The container and wick must be chosen to take into account chemical compatibility with the working fluid. Chemical reactions between the working fluid and the container/

FIGURE 57.1 Schematic of a typical heat pipe.

wick (or with contamination not removed during processing) can seriously impair heat pipe performance. Noncondensable gases created during a chemical reaction will accumulate near the end of the condenser, thus decreasing the condensation surface area. This reduces the ability of the heat pipe to transfer heat to the external heat sink. The heat pipe container also must have high burst strength, low weight, and high thermal conductivity.

Using the proper working fluid for a given application is a critical element of proper heat pipe operation. The working fluid must have good thermophysical properties for the specified operational temperatures. The operational temperature range of the working fluid lies between the fluid triple point and critical point, as a two-phase saturated liquid–vapor condition must exist. Working fluids used in heat pipes range from cryogenic (e.g., nitrogen) to room temperature (e.g., water) to liquid metals (e.g., sodium). The **wettability** of the working fluid contributes to its capillary pumping and priming (filling of the wick) capability. High-surface-tension fluids are desired for heat pipe use as the surface tension relates to the necessary capillary pumping. However, the maximum heat transport of a heat pipe depends on a combination of thermophysical properties, which include the latent heat of vaporization, viscosities of the liquid and vapor, densities, and surface tension. Selections of fluids are typically based on groupings of the fluid properties referred to as a Figure of Merit found in Chi [1976] or Peterson [1994], which allow direct comparison of one fluid to another over given temperature ranges.

The wick structure provides the path for liquid return to the evaporator and provides the structure for the necessary capillary forces to be developed. Heat pipe wicks can be made from numerous porous

FIGURE 57.2 Heat transfer limitations in heat pipes.

materials, where some examples are wrapped screens, sintered particles, axial grooves, annular passages, and arterial. To optimize performance, more than one type of porous material can be used to balance the need for small pore sizes (high capillary pressures) with the need for high permeability (minimal flow resistance). These composite wicks can be made from variable screen mesh, screen-covered grooves, and screen tunnels with grooves. The selected pairing of the wick structure and working fluid determines the heat transfer limitations of heat pipes.

57.2 Heat Transfer Limitations

The heat transported by a heat pipe (i.e., heat transfer limitation) depends on the working fluid, the wick structure, the geometry of the heat pipe, and the heat pipe operational temperature. Figure 57.2 gives a qualitative description of the various heat transfer limitations, which include vapor pressure, sonic, entrainment, capillary, and boiling limitations. Each results from a specific, operational phenomenon within the heat pipe. The composite curve enclosing the shaded region in Figure 57.2 gives the maximum heat transfer rate transported by the heat pipe as a function of the operational temperature. The figure shows that, as the operational temperature increases, the maximum heat transfer rate of the heat pipe is limited by different physical phenomena. As long as the operational heat transfer rate falls within the shaded region, the heat pipe can function properly. It is important to note that within the heat transfer limitations, the vapor pressure and sonic limits do not represent “failure” cases — only that the heat pipe must increase the operation temperature if the heat input exceeds these values. For the capillary, boiling, and entrainment limitations, these represent failure cases as sufficient liquid flow to the evaporator is not possible and the heat pipe will cease to operate properly above these values.

The vapor pressure limitation (or viscous limitation) is reached when the required pressure drop in the vapor core reaches the same order of magnitude as the available vapor (saturation) pressure in the evaporator region. In this case, the total vapor pressure will be balanced by opposing viscous forces in the vapor channel. Thus, the total vapor pressure within the vapor region may be insufficient to sustain an increased flow. A general expression for the vapor pressure limitation is given by Dunn and Reay [1982]:

$$Q_{vp,max} = \frac{\pi r_v^4 h_{fg} \rho_{v,e} P_{v,e}}{12 \mu_{v,e} l_{eff}} \quad (57.1)$$

where r_v is the cross-sectional radius of the vapor core (m), h_{fg} is the latent heat of vaporization (J/kg), $\rho_{v,e}$ is the vapor density in the evaporator (kg/m^3), $P_{v,e}$ is the vapor pressure in the evaporator (Pa), and $\mu_{v,e}$ is the vapor viscosity in the evaporator (Nsec/m^2). The value l_{eff} is the effective length of the heat pipe (m), equal to $l_{eff} = 0.5(l_e + 2l_a + l_c)$. The vapor pressure limitation can occur during the startup of heat pipes at the lower end of the working fluid temperature range.

The sonic limitation also can occur in heat pipes at the low operating temperatures and is seen mostly in liquid metal heat pipes during startup. The low temperature produces a low vapor density. Thus, a sufficiently high mass flow rate in the vapor core can cause sonic flow conditions and choke the flow, which restricts the pipe's ability to transfer heat to the condenser. Dunn and Reay [1982] give an expression that was developed by Busse in 1973 for the sonic limitation:

$$Q_{s,max} = 0.474 A_v h_{fg} (\rho_v P_v)^{1/2} \quad (57.2)$$

where A_v is the cross-sectional area of the vapor core (m^2). Operation near the sonic limit is also not desirable as the compressible vapor flow effects result in large temperature gradients along the heat pipe, thus resulting in large deviation from the ideal, near isothermal case.

The entrainment limitation in heat pipes develops when the vapor velocity is sufficient to shear droplets of liquid from the wick surface, thus depleting the necessary liquid mass flow rate. A conservative estimate of the maximum heat transfer rate due to entrainment of liquid droplets has been given by Dunn and Reay [1976] and Faghri [1995] as

$$Q_{e,max} = A_v h_{fg} \left[\frac{\rho_v \sigma_l}{2 r_{c,ave}} \right]^{1/2} \quad (57.3)$$

where σ_l is the surface tension (N/m) and $r_{c,ave}$ is the average capillary radius of the wick (m).

As the driving potential for the circulation of the working fluid is the capillary pressure difference, the maximum capillary pressure must be greater than the sum of all pressure losses inside the heat pipe. The pressure losses in heat pipes can be separated into the frictional pressure drops along the vapor and liquid paths and the pressure drop in the liquid as a result of body forces (e.g., gravity, centrifugal, electromagnetic). It is important to note that the inclination of the heat pipe can either be an adverse tilt (evaporator above condenser) or a favorable tilt (condenser above evaporator) such that the hydrostatic pressure either subtracts from, or adds to, the capillary pumping pressure. For many heat pipes, the frictional pressure losses in the liquid are much greater than the frictional losses in the vapor. In this case, the maximum heat transfer rate due to the capillary limitation can be expressed as [Chi, 1976]

$$Q_{c,max} = \left[\frac{\rho_l \sigma_l h_{fg}}{\mu_l} \right] \left[\frac{A_w K}{l_{eff}} \right] \left(\frac{2}{r_{c,e}} - \left[\frac{\rho_l}{\sigma_l} \right] g L_t \cos \psi \right) \quad (57.4)$$

where K is the wick permeability (m^2), A_w is the wick cross-sectional area (m^2), ρ_l is the liquid density (m^3), μ_l is the liquid viscosity (Nsec/m^2), $r_{c,e}$ is the wick capillary radius in the evaporator (m), g is the acceleration due to gravity (9.8 m/sec^2), and L_t is the total length of the pipe (m). For most practical operating conditions, this limitation is the primary limitation encountered and can be used to determine the maximum heat transfer rate in heat pipes. Chi [1976], Peterson [1994], and Faghri [1995] provide details on the full evaluation of the capillary limit when frictional vapor losses are significant.

The boiling limitation in heat pipes occurs when the degree of liquid superheat in the evaporator is large enough to cause the nucleation of vapor bubbles within the wick structure. Boiling is undesirable in heat pipes because vapor bubbles within the wick obstruct the liquid flow in the evaporator. An expression for the boiling limitation is [Chi, 1976]

$$Q_{b,\max} = \frac{2\pi L_{\text{eff}} k_{\text{eff}} T_v}{h_{fg} \rho_l \ln(r_i / r_v)} \left(\frac{2\sigma_l}{r_n} - \frac{2\sigma_l}{r_{c,e}} \right) \quad (57.5)$$

where k_{eff} is the effective thermal conductivity of the composite wick and working fluid (W/m K), T_v is the vapor saturation temperature (K), r_i is the inner container radius (m), and r_n is the nucleation radius (conservative estimate is $2.00 \cdot 10^{-6}$ m in the absence of noncondensable gas). The boiling limit differs from the other limits as it is a radial limit in the evaporator as opposed to axial transport in the case of the other limitations.

57.3 Effective Thermal Conductivity

One key attribute of the heat pipe is that it can transfer a large amount of heat while maintaining nearly isothermal conditions. The temperature difference between the external surfaces of the evaporator and the condenser can be determined from the following expression:

$$\Delta T = R_t Q \quad (57.6)$$

where R_t is the total thermal resistance ($^{\circ}\text{C}/\text{W}$) and Q is the heat transfer rate (W). Figure 57.3 shows the thermal resistance network for a typical heat pipe and the associated thermal resistances. In most cases the total thermal resistance can be approximated by

$$R_t = R_1 + R_2 + R_3 + R_5 + R_7 + R_8 + R_9 \quad (57.7)$$

as the resistances R_{10} and R_{11} are typically several orders of magnitude greater than the other resistances, thus negating the parallel path through these resistances. The effective thermal conductivity of the heat pipe is defined as the heat transfer rate divided by the temperature difference between the heat source and heat sink,

$$k_{\text{eff}} = \frac{L_t}{R_t A_t} \quad (57.8)$$

where A_t is the overall cross-sectional area of the pipe (m^2). Under normal operating conditions, the total thermal resistance is relatively small, making the temperature in the evaporator nearly equal to that in the condenser. Thus, the effective thermal conductivity of a heat pipe is very high (several orders of magnitude greater than aluminum or copper).

57.4 Application of Heat Pipes

Heat pipes have been applied to a wide variety of thermal processes and technologies. One of the first areas where heat pipes were widely used was in the aerospace industry, where heat pipes are used successfully in controlling the temperature of satellites, instruments, and space suits. Heat pipes also are applied in:

1. The electronics industry for cooling various devices (e.g., infrared sensors, parametric amplifiers)

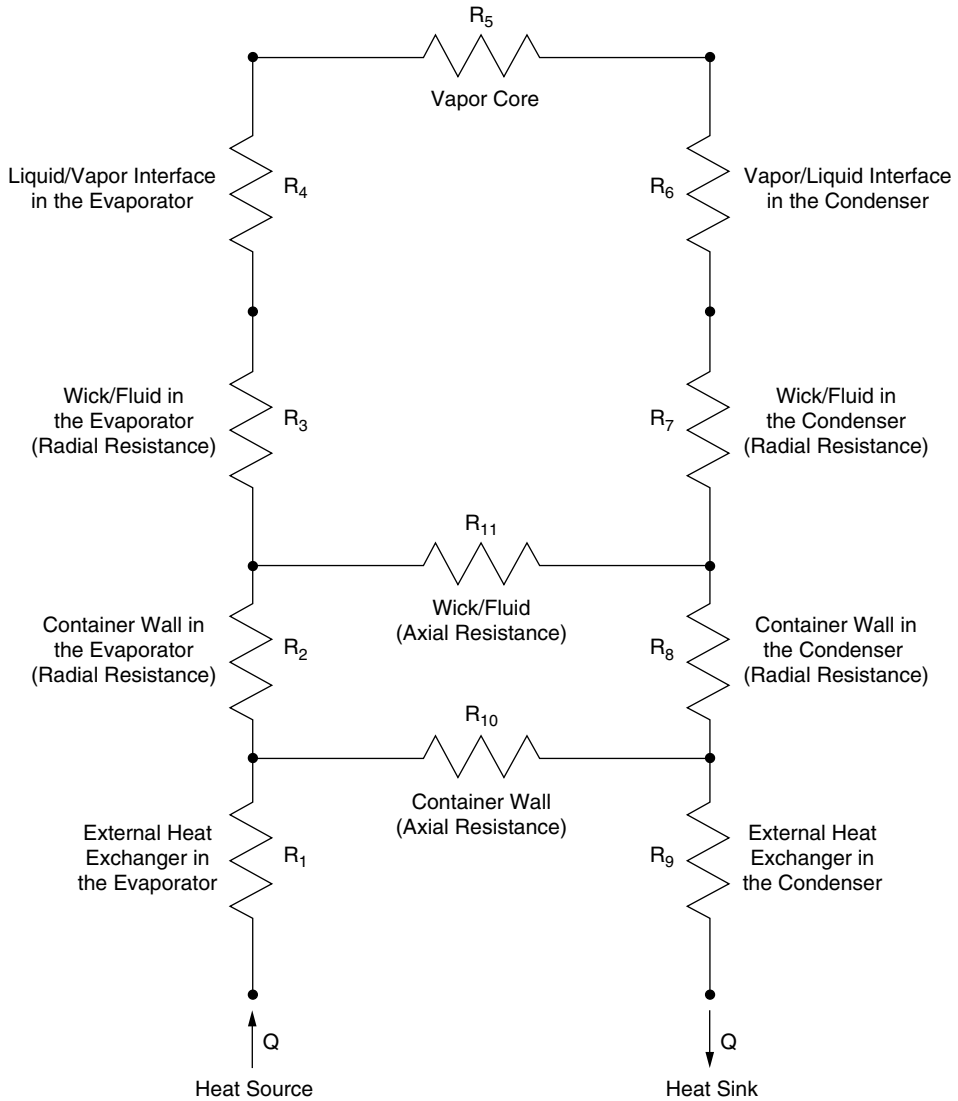

FIGURE 57.3 Thermal resistance network in a heat pipe.

2. Computers for cooling of processors
3. The medical field for surgery

Other cooling applications include:

1. Turbine blades, generators, and motors
2. Nuclear and isotope reactors
3. Heat collection from exhaust gases, and solar and geothermal energy
4. The Alaskan pipeline

In general, heat pipes have advantages over many traditional heat-exchange devices when:

1. Heat needs to be transferred nearly isothermally over relatively long distances.
2. Low weight and passive operation are essential.
3. Fast thermal-response times are required.
4. Low maintenance is mandatory.

Further advances in the heat pipe field include the development of the loop heat pipe by Maydanik and colleagues at the Russian Academy of Sciences. The loop heat pipe can transport even greater amounts of heat than standard heat pipes do as it separates the vapor passage from the liquid passage and reduces the overall size of the wick in the heat pipes. This optimizes the balance of small pores for capillary pumping and low frictional losses. Ochterbeck [2003] has further information on loop heat pipes.

Defining Terms

Capillary pressure — The pressure developed across a curved liquid–vapor interface, which is a function of the surface tension, the contact angle between the liquid and wick structure, and the pore size of the porous media.

Effective thermal conductivity — The heat transfer rate divided by the temperature difference between the evaporator and condenser outer surfaces. This relates the heat pipe to a conductivity which can be compared to conduction in a solid.

Heat transfer limitations — Limitations on the heat transfer capacity of a heat pipe which are imposed by different physical phenomena (e.g., vapor pressure, sonic, entrainment, capillary, and boiling).

Wettability — The ability of a liquid to spread over a surface. A wetting liquid spreads over a surface, whereas a nonwetting liquid forms droplets on a surface.

Wick — A porous material used to generate the capillary pressure that circulates the working fluid in a heat pipe.

James R. Fair

University of Texas, Austin

Distillation is a method of separation that is based on the difference in composition between a boiling liquid mixture and the vapor formed from it. The composition difference is due to differing effective vapor pressures, or volatilities, of the components of the liquid mixture. When such a difference does not exist, as at an azeotropic point, separation by normal distillation is not possible. Distillation as normally practiced involves condensation of the vaporized material, usually in multiple vaporization/condensation operations. It thus differs from evaporation, which normally is applied to separate a liquid from a solid, but which can be applied to simple liquid concentration operations. In the chemical and petroleum industries, distillation represents a large fraction of plant investment, yet also is one of the largest consumers of energy among the several processing operations employed.

Distillation is the most widely used industrial method of separating liquid mixtures and is at the heart of the separation processes in many chemical and petroleum plants. The most elementary form of the method is simple **batch distillation**, in which the liquid is brought to boiling and the vapor formed is separated and condensed to form a product. In some cases, a normally gaseous mixture is condensed by using refrigeration and the resulting liquid is then amenable to distillation separation, as in the case of distillation of air. If the process is continuous with respect to feed and product flows, it is called *flash distillation*. If the feed mixture is available as an isolated batch of material, the process is a form of **batch distillation** and the compositions of the collected vapor and residual liquid are thus time dependent. The term *fractional distillation* (which may be contracted to **fractionation**) was originally applied to the collection of separate fractions of condensed vapor, each being segregated. Currently, the term is applied to distillation processes in general, where an effort is made to separate an original mixture into several components by means of distillation. When the vapors are enriched by contact with counterflowing liquid reflux, the process is called *rectification*. When fractional distillation is accomplished with a continuous feed of material and continuous removal of product fractions, the process is called **continuous distillation**. When steam is added to the vapors to reduce the partial pressures of the components to be separated, the term *steam distillation* is used.

Most distillations conducted commercially operate continuously, with a more volatile fraction recovered as **distillate** and a less volatile fraction recovered as **bottoms** (or residue). If a portion of the distillate

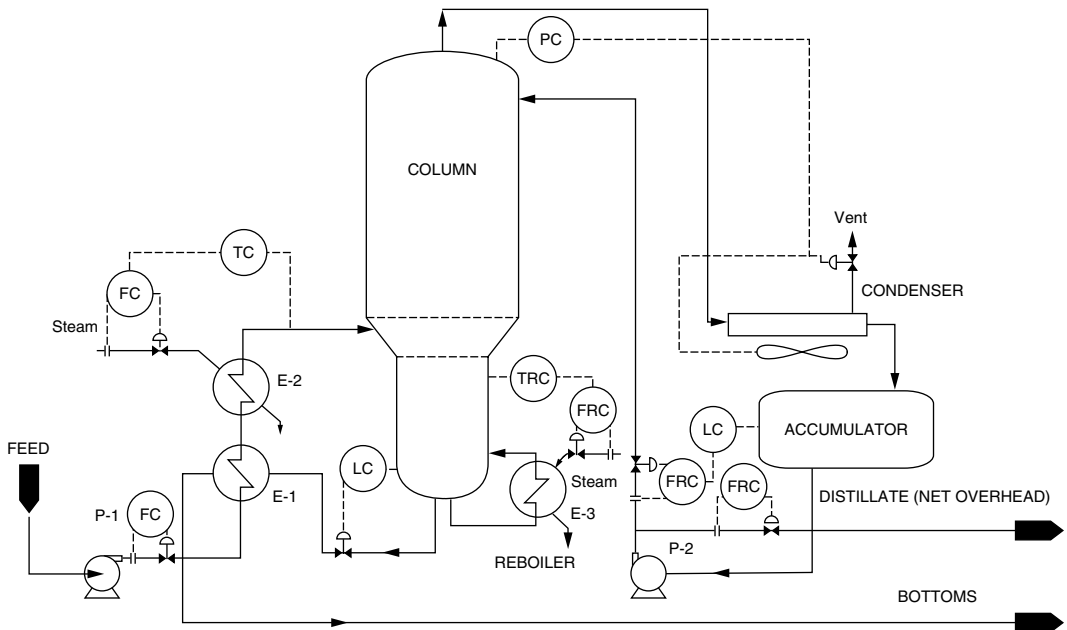

FIGURE 58.1 Flow diagram of a representative distillation system. For the case shown, the column has two diameters, commensurate with the changing flows of liquid and vapor in the column. Many columns have a single diameter. The condenser is air cooled, but water is also often used as a coolant.

is condensed and returned to the process to enrich the vapors, the liquid is called **reflux**. The apparatus in which the enrichment occurs is usually a vertical, cylindrical vessel called a still or *distillation column*. This apparatus normally contains internal devices for effecting intimate contact between rising vapor and descending liquid. The devices may be categorized as *plates* or *packings*. In some cases a batch distillation is preferred, where the **feed** mixture is placed in a stillpot and heat is added. The vaporized mixture is condensed and analyzed. Clearly, this method of operation is in a time-variant domain, unlike continuous distillation.

Distillation has been practiced in one form or another for centuries. It was of fundamental importance to the alchemists and has been in use for more than 2000 years. Because it is a process involving vaporization of a liquid, energy must be supplied if it is to function.

A representative continuous distillation system is shown in Figure 58.1. The design of such a system, or the analysis of an existing system, follows a fixed procedure. The steps in this procedure are described in the following sections, with primary emphasis on the distillation column. Such a procedure also provides an overall summary of the technology associated with distillation column design and operation.

58.1 Separation Specification

If a mixture is to be separated by distillation, it is crucial that the mixture composition be defined carefully. Serious problems can arise when some components of the mixture are disregarded or not known to be present. Next, the extent of required separation must be defined. Often there are two key **components** of the feed between which the separation specification can be related. The specification may deal with composition, recovery, or both. For example, for a benzene/toluene feed mixture, the specification may be a minimum of 95% of the benzene in the feed to be taken overhead with the distillate (the percent recovery), and the minimum purity of benzene in the distillate to be 99.5%. Simply stated, one must determine in advance the degree of separation desired.

58.2 Required Basic Data

A key parameter that is related to the ease (or difficulty) of making the separation is known as the **relative volatility**. This is a ratio of the effective vapor pressures of the components to be separated. It might be thought of as an index of the difficulty of making the separation. It is determined from the following relationship:

$$\alpha_{ij} = \frac{\gamma_i^L P_i^o}{\gamma_j^L P_j^o} \quad (58.1)$$

where components i and j are those between which the specification of separation is written (key components), γ^L is a thermodynamic parameter called the liquid phase activity coefficient, and P^o is the vapor pressure. In Equation (58.1), component i is more volatile than component j (i.e., i is more likely to be distilled overhead than is j). When liquid mixtures behave ideally (no excess energy effects when the mixture is formed), the activity coefficients have a value of 1.0. The vapor pressures of compounds are readily available from various handbooks. When the key components have a relative volatility of 1.10 or less, separation by distillation is difficult and quite expensive. For cases where α_{ij} is 1.50 or greater, the separation is relatively easy.

The determination of relative volatility involves the discipline of *solution thermodynamics*, and for distillation a sub-area is called vapor–liquid equilibrium (VLE). There are many approaches to determining VLE: direct measurement, correlation of the data of others, extrapolation of correlations beyond the area of measurement, and prediction of equilibrium data when no measurements have been made.

58.3 Index of Separation Difficulty

After the needed equilibrium data have been obtained, the next step is to determine the difficulty (or ease) of separation, using some index that is reliable and generally understood. The most used index is based on the required number of **theoretical stages**. For rigorous calculations, the stage count results from a detailed analysis of flow and composition changes throughout the column. For a simplified analysis, a basic parameter is the minimum number of theoretical stages:

$$N_{\min} = \frac{\ln \left[\left(y_i / y_j \right)^D \left(x_j / x_i \right)^B \right]}{\ln \alpha_{ij, \text{avg}}} \quad (58.2)$$

where i and j are the components between which the specified separation is to be made, y and x are mole fractions, D and B refer to distillate and bottoms. The value of N_{\min} can serve as a general criterion of separation difficulty. An example material balance for a ternary separation is

| Component | Feed (moles) | Distillate | | Bottoms | |
|-----------|-----------------|------------|-----------------|---------|-----------------|
| | | (moles) | (mole fraction) | (moles) | (mole fraction) |
| i | 45.0 | 44.6 | 0.9911 | 0.4 | 0.0073 |
| j | 45.0 | 0.4 | 0.0089 | 44.6 | 0.8109 |
| k | 10.0 | nil | nil | 10.0 | 0.1818 |
| | 100.0 | 45.0 | 1.0000 | 55.0 | 1.0000 |

The key components i and j have a relative volatility of 1.40, and i is to have a minimum 99% recovery to the distillate, and a minimum purity of 99.0% in the distillate. Component k is relatively nonvolatile. The minimum theoretical stages are calculated from Equation 58.2:

$$N_{\min} = \frac{\ln \left[\frac{0.9911}{0.0089} \times \frac{0.8109}{0.0073} \right]}{\ln 1.40} = 28.0 \text{ stages} \quad (58.3)$$

As a very rough rule of thumb, the number of theoretical stages at an optimum reflux rate will be about twice the minimum number of stages. In the example, about 60 total theoretical stages will be required. Equation (58.2) is suitable for making quick comparisons between the design conditions of overhead and bottoms compositions, and of relative volatility.

58.4 Required Actual Stages

The distillation column is a vertical, cylindrical vessel into which are placed contacting devices that cause the rising vapor and descending liquid to come into intimate contact. Such contact is necessary if the column is to make an efficient separation. As indicated in Figure 58.1, a return of some of the distillate product is necessary for the column to work efficiently. This flow stream is called the reflux. The ratio of this reflux flow to the flow of distillate is called the *reflux ratio*. The designer has the option of varying this ratio, and in so doing can influence the required number of theoretical stages, as shown in Figure 58.2. The asymptote for stages is N_{\min} as described above. The asymptote for reflux ratio is the minimum reflux ratio R_{\min} , a parameter related to the design compositions and the relative volatility. There is some optimum reflux ratio that relates to the economic conditions that exist for the design. Often the optimum reflux ratio is taken as about 1.3 times the minimum reflux ratio.

The actual number of stages required for the column is based on stage efficiency:

$$N_{act} = N_t / E_{oc} \quad (58.4)$$

where N_p , the number of theoretical stages, can be computed from

$$\frac{N_t - N_{\min}}{N_t + 1} = 0.75 - 0.75 \left(\frac{R - R_{\min}}{R + 1} \right)^{0.567} \quad (58.5)$$

In Equation 58.5, N_{\min} and R_{\min} are taken from a plot such as Figure 58.2 or, more likely, from rigorous calculations using modern computer programs. The reflux ratio R is a design variable, as mentioned

FIGURE 58.2 General relationship between stages and reflux. A given curve represents a specific separation requirement.

earlier. The value of the overall efficiency E_{oc} for use in Equation (58.4) must be obtained from experience or from predictive mathematical models. It is often in the range of 0.60 to 0.85 (60 to 85%). In the earlier example requiring about 60 theoretical stages, and for 85% efficiency, about 70 actual stages (plates) would be used in the column.

58.5 Column Dimensions

The height of the column is a function of N_{act} , the number of actual stages required for the separation. The height of each stage is a function of the geometry of the contacting device that is used. If the device is represented by a flat, horizontal sheet metal “plate” containing perforations, then the vertical spacing of these plates will determine the required height of the column. For example, if 40 theoretical stages are needed, and the efficiency of such a plate is 80%, then 50 actual stages (plates) are required. If these plates must be spaced at 0.61 m (24 in.) intervals, then the column must be at least 30 m (98 ft) high to accommodate the vapor and liquid flows. Considering other needs for internal devices, the column might have an actual height of perhaps 35 m.

If, instead of plates, a type of internal device called *packing* is used, some equivalent dimension must be used. The required height is obtained from

$$Z = (N_t)(HETP) \quad (58.6)$$

where *HETP* is the height equivalent to a theoretical plate (stage), and its value usually is obtained from the manufacturer or vendor of the packing device. There are many different sizes and shapes of packing used commercially, and some of them allow prediction of HETP by rigorous models.

If the height of the column is determined from the needed stages, the diameter must be determined from the required flow rates of vapor and liquid in the column. These rates are based on the total amount of feed mixture to be processed, as well as the amount of reflux that is returned to the column. In turn, the device (plate or packing) selected for contacting must have the capacity to handle the required flow rates. A schematic diagram of the factors that influence column diameter is shown as Figure 58.3. The device must be able to handle the vapor flow without tending to carry the liquid upward. Likewise, the device must be able to handle the liquid flows without choking the column because of a buildup of liquid. Correlations are available for assigning numbers to the scales of Figure 58.3, and an optimum design will place the design condition well within the shaded area.

FIGURE 58.3 Generalized operating diagram for a distillation column, showing ranges of operation as a function of relative vapor and liquid flows. (a) Plate column. (b) Packed column.

58.6 Column Auxiliaries

Figure 58.1 shows that a distillation system contains more than just the column. Of the several auxiliary components, two heat exchangers are of particular importance — the reboiler and the condenser. The reboiler at the base receives the net heat input to the column (often in the form of condensing low-pressure steam) and establishes the amount of vapor to be handled by the column. Much of the heat added at the reboiler is removed in the overhead condenser, rejecting the heat directly to the atmosphere (as shown in Figure 58.1) or to a stream of cooling water. While the heat duties of the condenser and reboiler are often about the same, the overall heat balance depends also on the heat contents of the streams entering and leaving the column and on the amount of heat losses to the surroundings.

58.7 Batch Distillation

Although most commercial distillations are run continuously, batch distillation is the method of choice for certain applications. For this method, a charge, or batch, of the initial mixture is placed in a vessel, where it can be heated and distilled over a period of time. Compositions of the charge and product thus vary with time, which is not the case for continuous distillation. Particular cases where batch distillation may be preferred are:

1. Semiworks operations producing interim amounts of product in equipment that is used for multiple purposes
2. Distillations of specialty chemicals where contamination can be a problem (Batch equipment can be cleaned or sterilized between batch runs.)
3. Operations involving wide swings in feed compositions and product specifications, where batch operating conditions can be adjusted to meet the varying needs
4. Laboratory distillations where separability is being investigated without concern over the scale-up to commercial continuous operations

Batch distillations are generally more expensive than their continuous counterparts in terms of cost per unit of product. Close supervision and computer control are required, the equipment is more complex if several products are to be recovered, and total throughput is limited by the needs for changing operating modes and for recharging the system with feed material.

Defining Terms

Batch distillation — A distillation operation in which the feed mixture is charged to a vessel, heated to boiling, and the vapor condensed into different fractions over a period of time (the batch cycle).

Bottoms — The product of the distillation that is relatively nonvolatile and that flows from the bottom of the column (also called *residue*).

Continuous distillation — A distillation operation in which the feed mixture is charged continuously to the distillation column, with the products withdrawn continuously with invariant compositions.

Distillate — The product of the distillation that is relatively volatile and that flows from the top of the column (also called *net overhead*).

Feed — The mixture to be distilled.

Fractionation — A contraction of *fractional distillation*, a term used loosely to denote a distillation operation that provides two or more products (fractions), normally by means of reflux and a plurality of theoretical stages.

Reflux — Liquid that is derived from the distillate product and fed back to the top of the column for the purpose of enhancing the separability.

Relative volatility — A ratio of effective vapor pressures of the components of a mixture to be distilled. An important index of ease of separation.

Theoretical stage — A conceptual term which refers to the “ideal” situation in which the vapor leaving a defined section of a column is in thermodynamic equilibrium with the liquid leaving the same section.

Absorption and Stripping

James R. Fair

University of Texas, Austin

- 59.1 Basic Property Data
- 59.2 Design Methodology — Absorption
- 59.3 Design Methodology — Stripping
- 59.4 Stage Efficiency
- 59.5 Packed Columns

Absorption and stripping are two chemical process operations that normally are coupled in order to remove a minor component, the **solute**, from an incoming process gas stream and then recover that same component in a more concentrated form (see [Figure 59.1](#)). A carefully selected **solvent**, in which the solute is selectively soluble, is fed to the **absorber** (or “scrubber”), and the rich solvent is then fed to the **stripper**, where the solute is recovered. In some cases, absorbers are used separately when the **rich solvent** does not need further processing. Likewise, strippers can be used alone for separating a minor component from a liquid mixture. An example of the coupled system, other than the one shown in [Figure 59.1](#), is the removal of carbon dioxide from natural gas by absorption in an aqueous amine solution, with subsequent recovery of high purity carbon dioxide by stripping at a lower pressure and a higher temperature. The gas is purified and a useful product results.

Examples of the separate systems include the absorption of ammonia in water to form ammonium hydroxide and the stripping of dissolved volatile organic compounds (VOCs) from contaminated groundwater using air as the stripping gas. A representative flow diagram of a separate stripping system is shown in [Figure 59.2](#).

59.1 Basic Property Data

If an absorber is to be designed for efficient and economical service, it is critical to select the proper solvent. Attributes of a good solvent for coupled systems include availability, cost, stability, and volatility. Further, the solvent should be nonhazardous. But by far the most critical property is the solubility of the solute in the solvent. This is usually the first consideration. The equilibrium solubility of component i may be expressed in terms of a *Henry's Law coefficient* H_i :

$$H_i = \frac{\text{partial pressure of } i \text{ in gas}}{\text{mole fraction of } i \text{ in liquid}} = \frac{p_i}{x_i} \quad (59.1)$$

A related term, used both in absorption and stripping and in distillation, is the *equilibrium ratio* K_i :

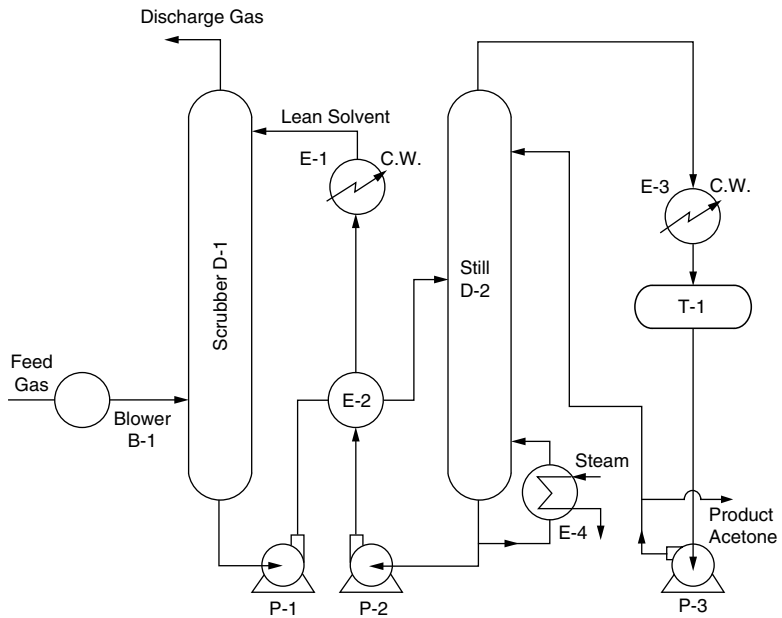

FIGURE 59.1 Coupled absorption-stripping system. Acetone is recovered from air using a water solvent. The acetone–water solution is then stripped to provide high purity acetone.

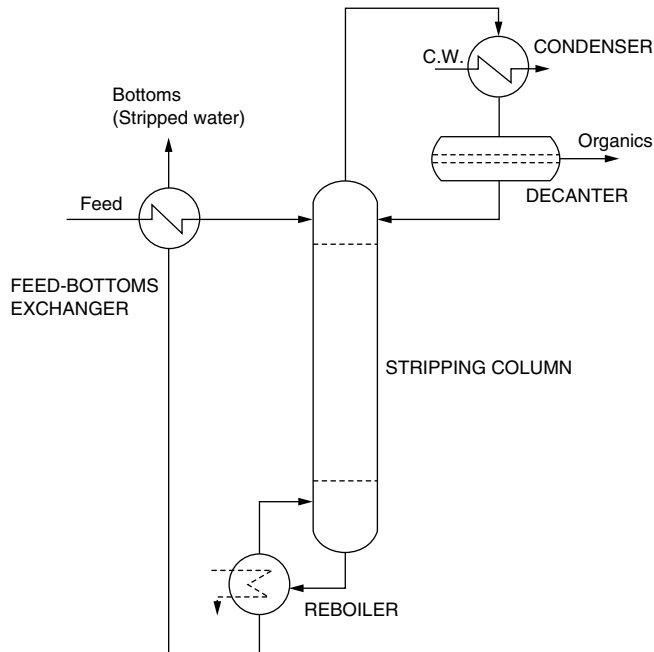

FIGURE 59.2 Flow diagram for the steam stripping of contaminants from process water. Since water is the stripped product, it can be produced *in situ* with a reboiler. Alternately, external steam can be used.

$$K_i = \frac{y_i}{x_i} \quad (59.2)$$

It is important to recognize that these terms are based on thermodynamic equilibrium. Usually, Dalton's Law is applicable, so that

$$H_i = K_i P \quad (59.3)$$

where P is the total pressure of the system. For the nonideal systems usually encountered in absorption and stripping, the K_i value can be expressed as follows:

$$K_i = \frac{\gamma_i P_i^{sat}}{P} \quad (59.4)$$

where γ_i is the liquid phase activity coefficient for i in the solvent, P_i^{sat} is the vapor pressure of i , and P is the total pressure.

Handbooks usually report solubilities as Henry's Law coefficients. However, design procedures usually employ the K value, easily obtained from H by Equation (59.3). When solubility data are not available for the conditions at hand, there is methodology for estimating values of the activity coefficient, one summary being in the book by Reid et al. Vapor pressure data are widely available.

Equation (59.1) through Equation (59.4) apply to a single solute. For dilute mixtures, equations for other solutes, if present, are considered to be independent of each other. For more concentrated mixtures, thermodynamic interactions must be determined, and effective values of K and H obtained.

59.2 Design Methodology — Absorption

The first step in design is to establish separation specifications. For example, a vent gas containing 2000 parts per million by volume (ppmv) of a pollutant must be scrubbed to a level of 200 ppmv in the exit gas. Or for a gaseous mixture which is a nonpollutant, the specification may deal with the fractional recovery (proportion absorbed) of that constituent in the rich solvent. For stripping, an example is the removal of dissolved contaminants in water to a level compatible with environmental regulations. *Fractional removal* and *limiting composition* are interchangeable in a given process, and the former will be used in the design equations given here.

In designing an absorber or stripper, one must ascertain some index of "difficulty of separation." The index to be used here is the number of required *theoretical stages*. An alternate criterion, often used for absorbers containing packing, is the required number of *transfer units*. Easy separations require few theoretical stages or transfer units. Very difficult separations may require many stages, perhaps 20 or more.

Absorption stages may be calculated from the so-called Kremser–Brown equation:

$$E_{Ai} = \frac{Y_{N+1} - Y_1}{Y_{N+1} - Y_o^*} = \frac{A_i^{N+1} - A_i}{A_i^{N+1} - 1} \quad (59.5)$$

where E_{ai} = fraction of i absorbed; Y_{N+1} = moles i per mole of solute-free gas entering; Y_1 = moles i per mole solute-free gas leaving the top of the absorber; Y_o^* = moles i per mole solute-free gas, determined as in equilibrium with the entering solvent composition; N = number of required theoretical stages; A_i = absorption factor for component $i = L/(V K_i)$; L = total moles of liquid (solvent + solute) flowing down the column; and V = total moles of vapor flowing up the column.

Note that in Equation (59.5), superscripts are exponents. If the amount absorbed is relatively low, as in most environmental applications, heat effects are minimal and the operation may be assumed to be isothermal. For this case, L and V are essentially constant.

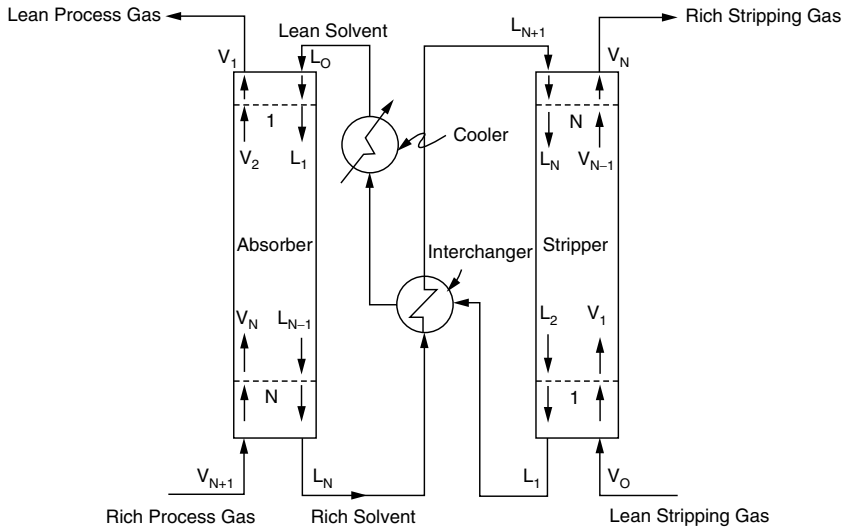

FIGURE 59.3 Nomenclature for use of the equations for absorbers or strippers. In order to maintain similarity of the design equations, for absorption the stages are numbered down from the top and for stripping the stages are numbered up from the bottom.

Equation (59.5) is a rating equation; it tells how much recovery can be obtained with a given number of stages N . A more useful equation is a rearrangement explicit in N :

$$N = \frac{\ln\left(\frac{E_{A_i} - A_i}{E_{A_i} - 1}\right)}{\ln A_i} - 1 \quad (59.6)$$

The solubility effect is contained in the absorption factor A_i . If the entering solvent contains none of the solute (e.g., completely stripped out), then the term Y_o^* drops out of Equation (59.5). Note that the compositions are in terms of *mole ratios*; for very dilute mixtures, mole fractions γ can be used. In Equation (59.5) and Equation (59.6), the stages are numbered down from the top. Figure 59.3 includes a guide to the nomenclature for both absorption and stripping.

59.3 Design Methodology — Stripping

For stripping, a liquid mixture is fed to the column and a stripping gas is used to remove one or more “key components” of the mixture. If the feed stream comes from a coupled absorber, then the composition is known, and the key components are likely to be those that were selectively absorbed. The stripping gas may be an external stream such as steam or air, or it may be generated by a reboiler as shown in Figure 59.1. In some respects, a reboiled stripper resembles a conventional distillation column and may even have a reflux stream.

If the stripper stages are numbered up from the bottom, Equation (59.5) and Equation (59.6) have exact counterparts:

$$E_{S_i} = \frac{X_{N+1} - X_1}{X_{N+1} - X_o^*} = \frac{S_i^{N+1} - S_i}{S_i^{N+1} - 1} \quad (59.7)$$

$$N = \frac{\ln\left(\frac{E_{S_i} - S_i}{E_{S_i} - 1}\right)}{\ln S_i} - 1 \quad (59.8)$$

where E_{S_i} = fraction of i stripped; X_{N+1} = moles i per mole of solute-free liquid entering; X_i = moles i per mole solute-free liquid leaving the bottom of the stripper; X_o^* = moles i per mole solute-free liquid, determined as in equilibrium with the entering stripping gas composition; N = number of required theoretical stages; S_i = absorption factor for component $i = (V K_i)/L$; L = total moles of liquid (solvent + solute) flowing down the column; V = total moles of gas (stripping gas + solute) flowing up the column.

Superscripts in Equation (59.7) are exponents. If the amount stripped is relatively low, V and L are essentially constant. If the stripping gas contains no solute, X_o^* drops out of the equation.

For the methodology given here, absorption and stripping are direct counterparts. The absorption factor A is the reciprocal of the stripping factor S . A short example shows the use of Equation (59.8) [and Equation (59.6)]:

Example

A plant effluent liquid flows at 295,800 lb/h and contains 15 lb/h benzene. The benzene removal is to be 99.95%. Steam is to be the stripping gas. The stripping factor is 100. Using Equation (59.8),

$$N = \frac{\ln\left(\frac{0.9995 - 100}{0.9995 - 1}\right)}{\ln 100} - 1 = 1.65 \text{ theoretical stages}$$

Few theoretical stages are required because of the low solubility of benzene in water (high stripping factor). However, because contacting operations in stripping towers are inefficient, 20 or more actual stages may be required. This is discussed in the next subsection.

59.4 Stage Efficiency

Since gas-liquid contacting efficiency in absorbers and strippers is relatively inefficient, the required number of theoretical stages must be corrected to actual, or real, stages (plates, trays) by a stage efficiency:

$$\text{No. actual plates (trays)} = \frac{\text{No. theoretical stages}}{\text{Stage efficiency}} = \frac{N}{E_{oc}} \quad (59.9)$$

where E_{oc} is an overall column efficiency, dependent on the mass transfer characteristics of the system and the fluid mechanics of the counterflowing phases. A great deal of theory and practice is available for the estimation of E_{oc} , as described in Perry's *Chemical Engineers' Handbook*. A low solubility invariably leads to a low efficiency. For approximate work, typical values may be used:

Absorbers $E_{oc} = 0.30 = 30\%$

Strippers $E_{oc} = 0.20 = 20\%$.

The required height of the contacting zone is

$$Z = \frac{N \times TS}{E_{oc}} \quad (59.10)$$

where TS is the height spacing between actual trays.

59.5 Packed Columns

One may infer that the preceding material applies only to absorbers or strippers with trays (valve, sieve, etc.) but this is not the case. Packed columns do not contain such devices and operate in a continuum of gas and liquid flows. A more fundamental approach to estimating the required height is through the use of transfer units. There is a mathematical connection between theoretical stages and transfer units, expressed approximately as:

$$N_{og} = N \left(\frac{\ln S}{S-1} \right) \quad (59.11)$$

where N_{og} = number of overall transfer units required (gas phase basis); N = number of theoretical stages required; S = stripping factor ($V K/L$), which applies to absorbers as well as strippers.

The objective is to determine the height of packing required for a given separation. This height is calculated by:

$$Z = (\text{HETP})(N) \quad (59.12)$$

or

$$Z = (H_{og})(N_{og}) \quad (59.12a)$$

where the height Z is expressed in the same units (ft, m) as HETP and H_{og} .

Values of HETP and H_{og} differ with the type and size of packing used. Approximate values can be obtained from vendors, but for more rigor, special mass transfer equations must be used. A discussion of the values together with the fundamental methods for calculating them may be found in Chapter 14 of Perry's *Chemical Engineers' Handbook*, as well as from many other sources.

Defining Terms

Absorption — Process for removing a minor component (or solute) from a gas stream using a liquid solvent.

Absorber (or absorption tower) — Usually a metal column containing packing materials or plates and designed to enhance gas–liquid contacting efficiency.

Rich solvent — Solvent + solute flowing from the absorber.

Solute — Component to be removed from the gas entering the absorber or from the liquid entering the stripper.

Solvent — Liquid employed for removing solute from the incoming solute-rich gas stream.

Stripper (or stripping tower) — Usually, a metal column containing packing materials or plates and designed to enhance gas–liquid contacting efficiency.

Stripping — Process for removing relatively insoluble solutes from a liquid mixture.

Extraction

Vincent Van Brunt
University of South Carolina

- 60.1 Representative Extraction Processes
- 60.2 Solvent Characteristics and Solvent Screening
- 60.3 Extraction Equilibria
- 60.4 Extraction Staging and Equipment

If a mixture cannot be easily separated using a direct separation such as evaporation or distillation, alternative indirect separation processes are considered. Extraction is an indirect separation that relies on the ease of separating a chemical from a solvent compared to that from its original feed.

As an example, consider the separation of acetic acid from water. Although the acid boils 18 degrees higher than water does, secondary bonding effects in the liquid phase and nonideal chemical effects in the vapor phase reduce the relative volatility of the water to acetic acid to approximately 1.1. Recovery of the acid from water requires that all the water be vaporized and be in the distillate. The low relative volatility implies that a distillation column will have a high reflux ratio and a large diameter. The combined effect is to increase both the operating and capital costs for distillation.

However, acetic acid can be recovered from dilute aqueous solutions using extraction. Several solvents are selective for acetic acid over water. A simplified extraction operation is shown in [Figure 60.1](#). The denser aqueous *feed* flows down the extractor and countercurrently contacts the less dense *solvent* flowing up. The solvent-rich *extract* leaves the top. It contains more acid than water. The water-rich *raffinate* stream leaves the bottom with reduced acid content. The extractor is followed by a distillation column that simultaneously purifies the solvent and recovers the solute from it. [Figure 60.1\(a\)](#) shows a process with an ideal separation from a more volatile solvent such as ethyl or isopropyl acetate, whereas [Figure 60.1\(b\)](#) shows a configuration with a less volatile solvent such as diisobutyl ketone. Finally, [Figure 60.1\(c\)](#) shows a process configuration for acetic acid recovery with the additional column and separators needed for using a more volatile solvent. The stripping column is needed to reduce solvent loss in the raffinate.

Both the capital and the operating costs for recovering acetic acid by the extraction route are less than those for distillation. Choosing between a solvent that is more or less volatile than acetic acid depends on several factors, including relative **selectivity** for acetic acid versus water, relative capacity for acetic acid called **loading**, and relative volatility versus that of acetic acid. The purity of acid required in the product and the initial composition of acid fed to the process greatly influence solvent selection. In general, as the composition of the acid in the aqueous feed diminishes, the quantity of solvent needed for extraction will increase. This, in turn, will necessitate more solvent vaporization in the recovery step. A way around this increase in recovery cost for a more volatile solvent is to switch to a less volatile one. The acid will then become the distillate product in the recovery step, reducing the energy and operating costs for its recovery. Comparative costs are related to the entire process and not dominated by the extraction step. In fact, it usually represents only a small fraction of the overall expenses.

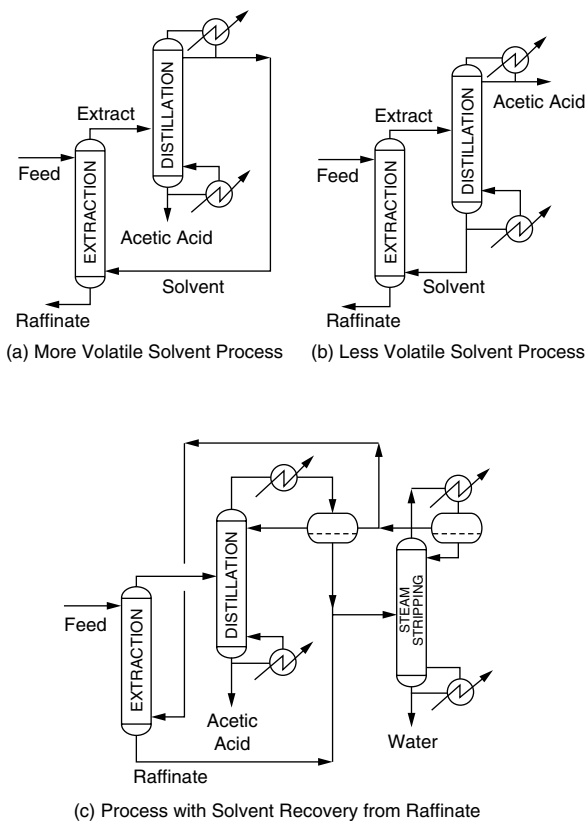

FIGURE 60.1 Acetic acid extraction processes.

The example shows that extraction needs to be considered in the context of an entire separation process. It is justified only when three factors are met. First, the solute must be easier to separate from the new solvent than the original. Second, the solvent must be able to be regenerated and recycled. And third, the solvent losses must be insignificant to the overall process. Thus, extraction is an indirect separation process that requires its evaluation and consideration with a second process step to regenerate the solvent and a third process step to recover the solute from it. In the example already given, even though the solute recovery and solvent regeneration steps were combined, still another process step is needed to reduce solvent loss in the raffinate.

60.1 Representative Extraction Processes

Extraction is used for purifying both inorganic and organic chemicals; see [Rydberg et al., 1992] and [Blumberg, 1988]. Examples of industrial uses are shown in Table 60.1 through Table 60.4. The inorganic applications are represented by purification of phosphoric acid and recovery of metals from ore leach solutions. In the latter case the metal salts are nonvolatile and usually in the presence of impurities that prevent direct recovery via, for example, electro-winning. Extraction permits the desired metal to be isolated and then recovered. The solvent for hydrometallurgical applications often relies on a specific chemistry. The examples chosen represent a sampling of the chemistries available [Sekine and Hasegawa, 1977].

The organic applications include recovering heat-sensitive chemicals such as penicillin, antibiotics, and vitamins, as well as separating close boiling mixtures. Of particular note is the separation of aromatics from aliphatics, for which there are several competing processes.

TABLE 60.1 Representative Inorganic Extraction Systems^a

| Separation | Solvent/Extractant Type | Extractant |
|-------------------------------|--|---|
| Cobalt/nickel | Phosphoric acid | Di-2-ethyl hexyl phosphoric acid (D2EHPA) |
| Copper | Acid chelating — hydroxyime | 2-hydroxyl 5-nonyl benzo phenone oxime (LIX65N) |
| Uranium | Anion exchanger — tertiary amine | n-trioctyl amine (Alamine 336) |
| Vanadium | Anion exchanger — quaternary ammonium salt | n-trioctylethylammonium chloride (Aliquat 336) |
| Zirconium/hafnium | Solvating — phosphoric acid ester | n-tributyl phosphate (TBP) |
| Actinides — fuel reprocessing | Solvating — phosphoric acid ester | TBP in dodecane |
| Phosphoric acid | Solvating — alcohols | Mixtures of butanol and pentanol |
| Actinides | Aqueous biphasic, polyethylene glycol (PEG) rich | Crown ethers |

^a All feeds are aqueous acid solutions; all diluents are kerosene, except as noted.

|--------------------|---------------------------------|---------------------|
| Zinc/iron | Inorganic | |
| | Triisooctyl amine (TIOA) | D2EHPA |
| | Water strip | Sulfuric acid strip |
| Lube oil | Organic | |
| | Mix of phenol + cresol | Propane |
| Aromatic/aliphatic | Dimethyl sulfoxide (DMSO)–water | Paraffin |

Source: Lo, T. C., Baird, M. H. I., and Hanson, C. 1983. *Handbook of Solvent Extraction*, Wiley-Interscience, New York.

Supercritical carbon dioxide is used for the recovery of essential oils, flavors, and aromas and for decaffeination [McHugh and Krukoni, 1986].

Aqueous biphasic systems have a second, stable, less dense, aqueous phase formed by adding polyethylene glycol (PEG) and an inorganic salt such as ammonium sulfate. Both inorganic and organic processes are being developed that use water-soluble complexants to provide selectivity.

Figure 60.2 shows the key steps in a hydrometallurgical fractional **extraction cycle**. In this example zirconium is recovered and separated from hafnium. As in a distillation column, the feed enters between a rectifying and stripping cascade. The **extraction cascade** below the feed recovers zirconium from it.

TABLE 60.4 Representative Extraction–Reaction Systems

| Reaction | |
|------------------------|---|
| Inorganic | |
| Uranium/plutonium | Plutonium reduction/partitioning with hydroxylamine nitrate (HAN) |
| Potassium nitrate | Potassium chloride + nitric acid → potassium nitrate + hydrochloric acid |
| Organic | |
| p-cresol/m-cresol | m-cresol partitioning using NaOH to form an aqueous soluble salt |
| m-xylene/xylenes | Preferential extraction and isomerization of m-xylene with HF-BF ₃ |
| Irreversible Reactions | |
| Aromatic nitration | Use of aqueous nitric and sulfuric acids to nitrate toluene |

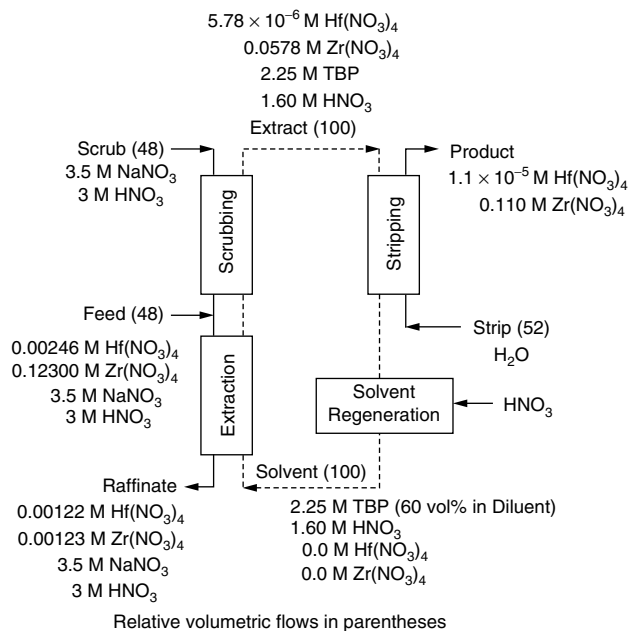

FIGURE 60.2 Zirconium–hafnium extraction cycle. (Adapted from Benedict, M. et al. 1981. *Nuclear Chemical Engineering*, 2nd ed. McGraw-Hill, New York.)

Each additional extraction stage improves the zirconium fractional recovery from the feed. Leaving the extraction cascade, the loaded solvent also contains coextracted impurities, including hafnium. As in distillation, the upper **scrubbing cascade** enhances the purity of the zirconium product by back-extracting hafnium (and other contaminants) from the solvent. Each additional scrubbing stage further decontaminates the zirconium by reducing the solvent’s hafnium content.

In distillation only the reflux flow rate and its temperature can be adjusted to modify the overhead purity. In the extraction analog the *scrub* flow rate, pH, chemistry, and even temperature can all be independently adjusted to purify the zirconium. Note the presence of the nonextracted sodium nitrate in both the scrub and the feed. This **salting agent** permits an independent adjustment of the common anion, nitrate, in addition to a pH adjustment by changing the nitric acid content. The zirconium is

recovered from the solvent by contacting it with an aqueous *strip* solution. Not shown are zirconium recovery from the strip solution by precipitation and the fate of the acid that is recovered and recycled.

Multiple extraction steps are used in several processes to enhance loading and to partition species extracted into the first solvent. Representative inorganic and organic mixtures are shown in [Table 60.3](#). The zinc purification from spent electrolyte acid solution first separates zinc chloride using triisooctyl amine (TIOA). The first solvent is stripped with water before contact with the di-2-ethylhexylphosphoric acid (D2EHPA), which further purifies the zinc. Extraction of rare earths from a leach liquor is a sequential use of extraction cycles. In organic systems the second solvent may be used for solvent regeneration to lower process energy costs or to aid in solute and solvent recovery.

Both reversible and irreversible reactions are performed in the presence of two liquid phases. Extraction and reaction are used for fine separations such as isomer purification and for actinide partitioning. Isomer purification processes exploit a reversible reaction in an aqueous phase to enhance the selectivity between the isomers. Likewise, the plutonium reduction uses an irreversible reaction to effect a similar result by significantly reducing its organic phase solubility. Some representative systems are shown in [Table 60.4](#) and several other irreversible reaction systems are tabulated in Van Brunt and Kanel.

Highly exothermic irreversible reactions such as nitrations, oxidations, and sulfonations are readily performed in liquid–liquid two-phase reactors; the second liquid phase provides a heat sink enabling reaction control. Reactive extraction needs to be considered: when reactants are immiscible, when the product undergoes an undesirable further reaction in the original reaction phase but is itself soluble in a second phase, when the products are immiscible with the reactants or catalyst, and when the product equilibrium can be enhanced by the presence of a second liquid-phase product sink. Many industrial products are produced using extraction–reaction systems; see Van Brunt and Kanel.

60.2 Solvent Characteristics and Solvent Screening

Since the solvent is present in the entire process, each of its characteristics and properties must be weighed to consider the net effect. The most significant considerations are shown in [Table 60.5](#). The first grouping examines the solvent's relative process compatibility. A solvent or class of solvents that, even in minute quantities, reduces the value or marketability of the solute can be eliminated from consideration. Solute selectivity and loading ability must be balanced against ease of reversing and unloading it, recovering the solvent, and reducing the solvent losses.

TABLE 60.5 Desirable Solvent Characteristics

| | |
|--------------------------|---|
| Process compatibility | High solute selectivity Regeneration capability High solute distribution coefficient High solute loading Low raffinate solubility Solute compatibility |
| Processing and equipment | Low viscosity Density different from the feed (>2%, preferably >5%) Moderate interfacial tension Reduced tendency to form a third phase Low corrosivity |
| Safety and environmental | Low flammability, flash point Low toxicity Low environmental impact, both low volatility and low effect or raffinate disposal costs |
| Overall | Low cost and availability |

Adapted from Robbins, L. 1983. In *Perry's Chemical Engineers' Handbook*, 6th ed., ed. R. H. Perry and D. Green. McGraw-Hill, New York; Cusack, R. W., Fremeaux, P., and Glatz, D. 1991. A fresh look at liquid-liquid extraction. *Chem. Eng.* February.

Once a solvent has met these tests, it must pass those in the second grouping that affect processing equipment design and specification. Since extraction relies on intermittent dispersion and coalescence, desirable processing characteristics are those that enhance settling and coalescence, such as density difference with the feed and moderate interfacial tension. In general, a solvent with a lower viscosity is preferred. Likewise, the preferred solvent is less corrosive than the feed solution. Solvent chemistry can be altered to improve processing behavior.

The last grouping covers safety and environmental concerns. Safety issues such as toxicity and flammability may dominate over all others. If the raffinate or any other process stream is sent to waste treatment facilities, the solvent must be compatible with them or have low disposal costs. Finally, the preferred solvent is a readily available and low-cost commercial product.

60.3 Extraction Equilibria

Extraction equilibria affect the initial solvent screening. However, since many solvents contain more than one component, conclusions drawn from three component systems may not readily translate into the selection of a practical one. Almost always, experimental testing with the actual feed solution is needed. It is common practice to consider a solvent as having three parts, each piece contributing to desirable solvent properties. The **diluent** provides the bulk properties, such as viscosity and density. The **extractant** provides the active reversible solvent–solute interactions. Its efficiency affects both selectivity and loading. The **modifier** improves the interfacial tension and affects third-phase formation. An effective modifier will either increase the interfacial tension, thereby preventing or reducing emulsion stability or, conversely, it may be chosen to reduce the interfacial tension to enhance dispersion and interfacial area.

Organic diluents are usually petroleum fractions of varying naphthenic, aromatic, and aliphatic composition. Water may be added to aqueous soluble solvents as a diluent. Common modifiers are 2-ethylhexanol, isodecanol, tributyl phosphate and n-nonyl phenol. Ritcey and Ashbrook [1984] discusses their behavior. Extractant chemistry is discussed in Sekine and Hasegawa [1977], Alegret [1988], and Marcus and Kertes [1969].

For organic systems the thermodynamics of extraction equilibria can be used to screen potential solvents. The **distribution coefficient** is the ratio of a solute's mole fraction in the two phases. Here y refers to the organic, or less dense phase, mole fraction and x refers to the aqueous, or more dense phase, mole fraction.

$$K_i = y_i/x_i \quad (60.1)$$

For two chemical constituents the selectivity, β , can be expressed as

$$\beta_{ij} = K_i/K_j = (y_i/x_i)/(y_j/x_j) \quad (60.2)$$

Here the selectivity is written to evaluate the relative concentrations of i and j in the solvent phase, designated S , versus that in the feed phase, designated F . At equilibrium the chemical potential for each species is the same in each phase. In terms of activities this becomes

$$\gamma_i^F x_i = \gamma_i^S y_i \quad (60.3)$$

where γ is the activity coefficient. Using Equation (60.3), the distribution coefficient can be expressed as

$$K_i = \gamma_i^F/\gamma_i^S \approx \gamma_i^{\infty F}/\gamma_i^{\infty S} \quad (60.4)$$

where the ∞ indicates infinite dilution. Likewise, the selectivity becomes

TABLE 60.6 Qualitative Solvent Screening

| Group | Solute | Solvent | | | | | | | | |
|-------|---|---------|---|---|---|---|---|---|---|---|
| | | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 |
| 1 | Acid, aromatic OH, for example, phenol | 0 | - | - | - | - | 0 | + | + | + |
| 2 | Paraffinic OH (alcohol), water, amide or imide with active H | - | 0 | + | + | + | + | + | + | + |
| 3 | Ketone, aromatic nitrate, tertiary amine, pyridine, sulfone, phosphine oxide, or trialkyl phosphate | - | + | 0 | + | + | - | 0 | + | + |
| 4 | Ester, aldehyde, carbonate, nitrite or nitrate, phosphate, amide without active H; intermolecular bonding, for example, o-nitrophenol | - | + | + | 0 | + | - | + | + | + |
| 5 | Ether, oxide, sulfide, sulfoxide, primary, or secondary amine or imine | - | + | + | + | 0 | - | 0 | + | + |
| 6 | Multihalo-paraffin with active H | 0 | + | - | - | - | 0 | 0 | + | 0 |
| 7 | Aromatic, halogenated aromatic, olefin | + | + | 0 | + | 0 | 0 | 0 | 0 | 0 |
| 8 | Paraffin | + | + | + | + | + | + | 0 | 0 | 0 |
| 9 | Mono-halogenated paraffin or olefin | + | + | + | + | + | 0 | 0 | + | 0 |

Notes: The + sign means that the solvent tends to raise the activity coefficient of the solute in a row group; the - sign means that the solvent tends to lower the activity coefficient of the solute in a row group. A 0 indicates no appreciable effect. Solvation is expected for negative group interactions. Potential solvents are those that lower the activity, that is, have minus signs.

Source: Cusack, R. W., Fremeaux, P., and Glatz, D. 1991. A fresh look at liquid-liquid extraction. *Chem. Eng.* February.

$$\beta_{ij} = \frac{\gamma_i^F / \gamma_i^S}{\gamma_j^F / \gamma_j^S} = \left(\frac{\gamma_i}{\gamma_j} \right)^F \left(\frac{\gamma_j}{\gamma_i} \right)^S \quad (60.5)$$

Since the composition of the species in the feed is known, the ratio of activity coefficients at the feed composition can be determined using one of the nonideal models, such as Van Laar, NRTL, UNIQUAC, or UNIFAC. The reader is referred to Sorensen and Arlt [1980] for more details. Examining Equation (60.5), one sees that the solvent selectivity for species i and j increases if the solvent phase activity coefficient for i is less than that for j . A preferred solvent would create solvent-solute interactions for species i , which reduces its activity coefficient below 1.0 — that is, to have negative deviations from ideality. Furthermore, the ideal solvent would preferentially reject species j and have its activity coefficient greater than 1.0 — that is, have positive deviations from ideality.

These effects can be used to identify potential solvent classes. Table 60.6 shows the expected deviations from ideality for solute-solvent pairs. For the acetic acid-water mixture the solute-solvent pairs that have negative deviations from ideality for the acid and no deviation or positive deviation for water are groups 2 through 5. Suitable solvents will probably come from those classes. In fact, solvents from those classes have all been used in practice or research. See C. J. King's chapter in Lo et al. [1983] for more details.

For the separation of benzene from n-hexane, Table 60.6 still provides some guidance. Although no negative deviations from ideality are shown, groups 3, 5, and 6 show positive deviations for the aliphatics (n-hexane) and 0 deviations for aromatics (benzene). This implies that solvents from those classes will probably be selective for benzene. The table also indicates that a solvent that is preferential for the aliphatics (n-hexane) over the aromatics (benzene) cannot be identified readily.

Another refinement for solvent screening is to use infinite dilution activity coefficients. Equation 60.5 can be approximated as

$$\beta_{ij}^\infty \cong \left(\frac{\gamma_i}{\gamma_j} \right)^F \left(\frac{\gamma_j^\infty}{\gamma_i^\infty} \right)^S \approx \left(\frac{\gamma_j^\infty}{\gamma_i^\infty} \right)^S \quad (60.6)$$

TABLE 60.7 Infinite Dilution Selectivity of Benzene–n-Hexane

| Solvent | Table 60.6 Group | $\beta_{\text{BH}}^{\infty} \frac{\gamma_{\text{n-hexane}}^{\infty}}{\gamma_{\text{benzene}}^{\infty}}$ |
|---------------------|------------------|---|
| Sulfolane | 5,5 | 30.5 |
| Dimethylsulfoxide | 5 | 22.7 |
| Diethylene glycol | 1,5 | 15.4 |
| Triethylene glycol | 1,5 | 18.3 |
| Propylene carbonate | 4 | 13.7 |
| Dimethylformamide | 2 | 12.5 |
| n-methylpyrrolidone | 3 | 12.5 |
| Acetonitrile | 3 | 9.4 |
| Succinonitrile | 3 | 46.8 |
| g-butyrolactone | 3 | 19.5 |
| Aniline | 5 | 11.2 |
| Dichloroacetic acid | 1 | 6.1 |

Source: Modified from Tiegs, D. et al. 1986. *Activity Coefficients at Infinite Dilution. C1-C9*, DECHEMA Chemistry Data Series, vol. IX, part 1. DECHEMA, Frankfurt.

Here one neglects the activity coefficient ratio in the feed solvent as a given quantity and focuses attention on the ratio for the solutes to be separated in potential solvents. Further, the ratio is approximated by the ratio at infinite dilution — that is, for each of the solutes at infinite dilution in the solvent. Again, one sees that the selectivity of the solvent for i over j is *inversely* proportional to the ratio of their activity coefficients. If one uses infinite dilution activity coefficient data for common solvents from those groups suggested from Table 60.6, one obtains Table 60.7. The high values obtained for the industrial solvents are striking. Also, the difference between the two nitriles indicates an effect of carbon number. There are generally lower values for solvents having groups not identified using the qualitative screening table. Prediction of infinite dilution activity coefficients for solvent screening may also be performed using the MOSCED model and refinements to it; see Park and Carr [1987] and Hait et al. [1993].

60.4 Extraction Staging and Equipment

Procedures for extraction equilibrium-stage calculations are given in standard references, for example, Treybal [1963] and Lo et al. [1983]. For dilute systems, staging can be calculated by assuming a constant selectivity and constant solvent-to-feed ratio. An extraction factor — equivalent to a stripping factor and equal to the ratio of equilibrium to operating lines — can be used to calculate the number of equilibrium stages using the Kremser equation. For concentrated systems, neither the operating nor the equilibrium lines are of constant slope, and calculation procedures must account for the change in the solvent-to-feed ratio.

Although equilibrium-stage calculations are suitable for costing and comparing processes, detailed design *requires* an experimental evaluation of extractor performance. Because extraction uses phases that are the same order of magnitude in density, column performance is reduced by dispersion (also called *axial mixing* or *backmixing*). Dispersion will reduce extraction efficiency and can be approximated; see Lo et al. [1983] and Godfrey and Slater [1994]. However, it is extremely equipment- and chemistry-dependent.

Actual equipment sizing is tied to the physical properties of the specific extraction system being evaluated. Unlike with distillation, many different types of equipment are used. Logic diagrams for specifying extractors are given in standard texts such as Ladda and Degaleesan [1978], Lo et al. [1983], and Godfrey and Slater [1994]. Figure 60.3 presents a simplified version of the equipment decision tree [Ladda and Degaleesan, 1973]. It is strongly recommended that pilot testing be performed to determine both sizing needs and operating limits for new processes. Pilot campaigns with actual process chemicals

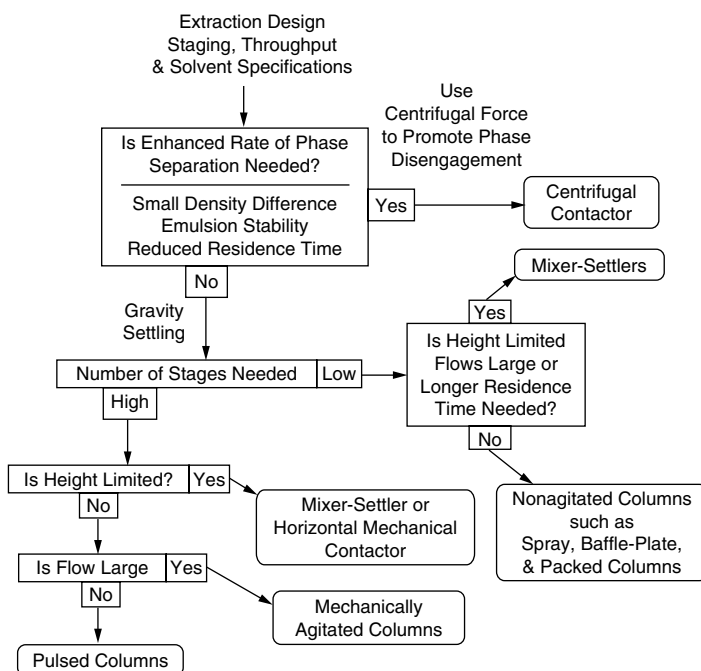

FIGURE 60.3 Equipment type selection decision tree. (Adapted from Ladda, G. S. and Degaleesan, T. E. 1978. *Transport Phenomena in Liquid Extraction*, McGraw-Hill, New York.)

will enable understanding of real processing behavior — for example, observation of interfacial solids buildup or changes in emulsion stability with degree of agitation.

Defining Terms

Diluent — The bulk constituent of a solvent, primarily used to improve solvent properties that affect processing and equipment choice.

Distribution coefficient (K) — The ratio of the mole fraction of a chemical species in the solvent phase divided by the mole fraction of the same chemical in the feed phase.

Extractant — The active part of a solvent that has solvating characteristics with the solute or specific solute–solvent chemistry such as chelation or ion-pair formation.

Extraction cascade — A series of stages to recover the solute from a feed solution by contacting it with a relatively immiscible solvent.

Extraction cycle — A sequence of extraction, scrubbing, and stripping cascades to recover and purify a particular solute. Cycles may themselves be staged to enhance solute purity.

Loading — The capacity of the solvent for the solute. Usually, this is expressed on a per mole solvent basis. Higher values indicate reduced solvent needs.

Modifier — A chemical added to a solvent to retard third-phase formation.

Salting agent — A nonextracted chemical, usually a salt, used to change the process chemistry. For inorganic systems the salting agent may have an anion in common with the solute but have the wrong cation valence or size to be extracted.

Scrubbing — The operation of decontaminating a loaded solvent of chemicals coextracted with the solute. Scrubbing purifies the solute-loaded solvent. A *scrubbing cascade* is a series of stages to perform scrubbing.

Selectivity (β) — The separation factor for extraction is the ratio of distribution coefficients for two solutes. The higher the value is, the greater the ability of the solvent to separate the two species.

Stripping — The operation of unloading the solute from the solvent by extracting it back into a feed-like phase, from which it can be easily removed. Stripping also recovers the solvent for recycle back to the extraction cascade. A *stripping cascade* is a series of stages to perform stripping.

Further Information

The first general reference for extraction chemistry, equipment, and its operation is the *Handbook of Solvent Extraction*. Equipment is further described in *Transport Phenomena in Liquid Extraction* and in *Liquid–Liquid Extraction Equipment*.

The European Federation of Chemical Engineering has established three systems for evaluation of extraction operations. These guidelines are available in Misek, T. 1984. *Recommended Systems for Liquid-Liquid Extraction*, Institute of Chemical Engineers. Rugby, UK.

Sources of reliable extraction data include all the volumes of Sorenson and Arlt [1979, 1980, 1980, 1987] as well as all the volumes of Wisniak and Tamir [1980, 1980, 1987]. The text by Francis, A. W., 1963, *Liquid-Liquid Equilibriums*, Wiley-Interscience, New York also contains references to reliable data.

The International Solvent Extraction Conference (ISEC) is held every three years with bound proceedings available. The conference presents the latest information about extraction chemistry and equipment. See listings under *Proceedings of ISEC*. Each set of proceedings has been published by a different professional organization. The latest advances in extraction chemistry and processing may be found in the proceedings from ISEC '99 in Barcelona, Spain, *Solvent Extraction for the 21st Century*, M. Cox, M. Hidalgo, and M. Valiente, Eds., SCI, London 2001 and ISEC 2002 in Capetown. South Africa, *Proceedings of ISEC 2002*, Chris van Rensburg Publications Ltd, Melville, South Africa 2002. Each of these proceedings is published in two volumes.

Many extraction processes and refinements of them are discussed in the journals *Solvent Extraction and Ion Exchange* and *Separation Science and Technology*. The series *Ion Exchange and Solvent Extraction* contains tutorial articles about specific topics.

The science of extraction has been greatly influenced by nuclear applications, including nuclear reprocessing. Many references are available, including chapters in Long, J. T. 1978. *Engineering for Nuclear Fuel Reprocessing*. American Nuclear Society, La Grange Park, La Grange, IL; Benedict, M., Pigford, T. H., and Levi, H. L. 1981. *Nuclear Chemical Engineering*, 2nd ed. McGraw-Hill, New York; and all four volumes of Schultz and Navratil [1984, 1987, 1990, 1991].

Shivaji Sircar

Air Products and Chemicals, Inc.

Adsorption is a surface phenomenon. When a pure fluid (gas or liquid) is contacted with a solid surface (adsorbent), fluid–solid intermolecular forces of attraction cause some of the fluid molecules (adsorbates) to be concentrated at the surface. This creates a denser region of fluid molecules, which extends several molecular diameters near the surface (adsorbed phase). For a multicomponent fluid mixture, certain components of the mixture are preferentially concentrated (selectively adsorbed) at the surface due to differences in the fluid–solid forces of attraction between the components. This creation of an adsorbed phase having a composition different from that of the bulk fluid phase forms the basis of separation by adsorption technology.

Adsorption is a thermodynamically spontaneous process. Energy is released (exothermic) during the process. The reverse process by which the adsorbed molecules are removed from the surface to the bulk fluid phase is called **desorption**. Energy must be supplied to the adsorbed phase (endothermic) for the desorption process. Both adsorption and desorption form vital steps in a practical separation process in which the adsorbent is repeatedly used. This concept of regenerative ad(de)sorption is key to the practical use of this technology. It has found numerous commercial applications in chemical, petrochemical, biochemical, and environmental industries for separation and purification of fluid mixtures, as listed in [Table 61.1](#).

61.1 Adsorbent Materials

A key element in the development of adsorption technology has been the availability of a large spectrum of micro- and mesoporous adsorbents. They have large specific surface areas (500 to 1500 m²/g), varying pore structures, and surface properties (polar and nonpolar) that are responsible for selective adsorption of specific components of a fluid mixture. These include activated carbons, zeolites, aluminas, silica gels, polymeric adsorbents, and ion-exchange resins. Adsorbents may be energetically homogeneous, containing adsorption sites of identical adsorption energy, or heterogeneous, containing a distribution of sites of varying adsorption energies.

TABLE 61.1 Key Commercial Applications of Adsorption Technology

| Gas Separation | Liquid Separation | Environmental Separation | Bioseparation |
|---|--|--|--------------------------------------|
| Gas drying | Liquid drying | Municipal and industrial waste treatment | Recovery of antibiotics |
| Trace impurity removal | Trace impurity removal | Ground and surface water treatment | Purification and recovery of enzymes |
| Air separation | Olefin-paraffin separation | VOC removal | Purification of proteins |
| Carbon dioxide-methane separation | Xylene, cresol, cymene isomer separation | | Removal of microorganisms |
| Carbon monoxide-hydrogen separation | Fructose and glucose separation | | Recovery of vitamins |
| Hydrogen and carbon dioxide recovery from SMR off gas | Breaking azeotropes | | |
| Production of ammonia-synthesis gas | | | |
| Normal-iso paraffin separation | | | |
| Ozone enrichment | | | |
| Solvent vapor recovery | | | |

61.2 Adsorption Equilibria

Adsorption equilibria determine the thermodynamic limits of specific amounts of adsorption (moles/g) of a pure fluid or the components of a mixture under a given set of conditions [pressure (P), temperature (T), and mole fraction (y)] of the bulk fluid phase. A convenient way to represent adsorption equilibria is in terms of adsorption isotherms in which the specific amount adsorbed of a pure gas (n_i^o) or that of component i (n_i) from a multicomponent gas mixture is expressed as a function of P (pure gas) or as functions of P and y_i (fluid mixtures) at constant T . The values n_i^o and n_i decrease with increasing T for a given P and y_i . Adsorption isotherms can have many different shapes, but most microporous adsorbents exhibit the shape (type I) shown in Figure 61.1 (pure gas) and Figure 61.2 (binary gas).

The simplest thermodynamic system for adsorption from liquids consists of a binary liquid mixture. The adsorption isotherm in this case is measured in terms of Gibbs surface excess (moles/g) of component i (n_i^e):

$$n_i^e = n_i - y_i \sum_i n_i; \quad \sum_i n_i^e = 0, \quad i = 1, 2; \quad n_i^e = 0 \text{ for pure liquid} \quad (61.1)$$

FIGURE 61.1 Langmuirian pure gas adsorption isotherms on Na-mordenite. (Source: Kumar, R. and Sircar, S. 1986. *Chem. Eng. Sci.* 41:2215–2223.)

FIGURE 61.2 Langmuirian binary gas adsorption isotherms on Na-mordenite. (Source: Kumar, R. and Sircar, S. 1986. *Chem. Eng. Sci.* 41:2215–2223.)

FIGURE 61.3 Benzene-cyclohexane liquid phase surface excess isotherms on silica gel. (Source: Sircar, S., Novosad, J., and Myers, A. L. 1972. *Ind. Eng. Chem. Fundam.* 11:249–254.)

The liquid phase surface excess is a function of y_i and T . Figure 61.3 shows an example of bulk binary liquid phase isotherm. For adsorption of a very selective trace component ($y_i \ll 1$), n_i^e is approximately equal to n_i . The isotherm in that case (Figure 61.4) is type I in shape.

The simplest model to describe pure and multicomponent gas adsorption isotherms on a homogeneous adsorbent is the Langmuir equation,

FIGURE 61.4 Surface excess isotherms for a trace component from liquids. (Source: Rahman, M. A. and Ghosh, A. K. 1980. *J. Colloid Interface Sci.* 77:50–52.)

$$\text{Pure gas } n_i^o = \frac{mb_i P}{1 + b_i P}; \quad \text{Mixed gas } n_i = \frac{mb_i P y_i}{1 + \sum_i b_i P y_i} \quad (61.2)$$

where b_i is the gas–solid interaction parameter for component i . The term b_i is a function of temperature [Equation (61.7)] only. The term m is the saturation-specific adsorption capacity (moles/g) for the components.

The Toth equation is often satisfactory for describing gas adsorption isotherms on heterogeneous adsorbents:

$$\text{Pure gas } n_i^o = \frac{mb_i P}{[1 + (b_i P)^k]^{1/k}}; \quad \text{Mixed gas } n_i = \frac{mb_i P y_i}{[1 + (\sum_i b_i P y_i)^k]^{1/k}} \quad (61.3)$$

The term k (≤ 1) is the heterogeneity parameter. The lower the value of k is, the larger is the degree of adsorbent heterogeneity. The adsorbent is homogeneous when k is unity (Langmuir model).

Statistical mechanics of adsorption dictates that the gas adsorption isotherms become linear functions of pressure (pure gas) and component partial pressures (mixed gas) when the total gas pressure approaches zero ($P \rightarrow 0$):

$$\text{Pure gas } n_i^o = K_i P; \quad \text{Mixed gas } n_i = K_i P y_i \quad (61.4)$$

K_i is called the Henry's law constant for pure gas i . It is a function of temperature only [Equation (61.7)].

The simplest model isotherm for adsorption of an ideal binary liquid mixture of equal adsorbate sizes on a homogeneous adsorbent is given by

$$n_1^e = \frac{m y_1 y_2 (S - 1)}{S y_1 + y_2} = -n_2^e \quad (61.5)$$

where S is the selectivity of adsorption of component 1 over component 2.

61.3 Heat of Adsorption

The thermodynamic variable of practical use that describes the differential heat evolved (consumed) during the ad(de)sorption process due to a differential change in the adsorbate loading (n_i^o or n_i) of a pure gas (q_i^o) or the components of a gas mixture (q_i) is called the isosteric heat of adsorption (kcal/mole). It is given by

$$\text{Pure gas } q_i^o = RT^2 \left[\frac{\partial \ln P}{\partial T} \right]_{n_i^o}; \quad \text{Mixed gas } q_i = RT^2 \left[\frac{\partial \ln Py_i}{\partial T} \right]_{n_i}, \quad i = 1, 2, \dots \quad (61.6)$$

It follows from Equation (61.2), Equation (61.3), Equation (61.4), and Equation (61.6) that

$$K_i = K_i^* \exp[q_i^* / RT]; \quad b_i = b_i^* \exp[q_i^* / RT] \quad (61.7)$$

where q_i^* is the isosteric heat of adsorption of pure gas i at the limit $P \rightarrow 0$ (Henry's law region), and K_i^* and b_i^* are constants.

The terms q_i^o and q_i are constants and equal to q_i^* for any adsorbate loading for a homogeneous adsorbent. They are functions of loadings for a heterogeneous adsorbent. Thus, for the Toth model,

$$q_i^o = q_i^* + \left(\frac{RT^2}{k} \right) \left(\frac{d \ln k}{dT} \right) F_i(\theta_i^o); \quad q_i = q_i^* + \left(\frac{RT^2}{k} \right) \left(\frac{d \ln k}{dT} \right) F(\theta) \quad (61.8)$$

$$F(\theta_i^o) = \frac{[1 - (\theta_i^o)^k] \ln[1 - (\theta_i^o)^k] + (\theta_i^o)^k \ln(\theta_i^o)^k}{[1 - (\theta_i^o)^k]} \quad (61.9)$$

where (θ_i^o) is fractional coverage ($= n_i^o / m$) by pure gas i . The term $\theta (= \Sigma \theta_i)$ is the total fractional coverage ($= \Sigma n_i / m$) by all adsorbates for the mixture. $F(\theta)$ has the same mathematical form as Equation (61.9) except that θ_i^o is replaced by θ .

Equation (61.8) shows that q_i^o or q_i decreases with increasing θ_i^o or θ_i for a heterogeneous adsorbent. The higher energy sites of the adsorbent are predominantly filled at lower adsorbate loadings, and the lower energy sites are progressively filled at higher coverages.

Figure 61.5 shows examples of isosteric heats of adsorption of pure gases on heterogeneous adsorbents. Figure 61.6 shows the variation of isosteric heats of the components of a binary gas mixture with coverage (or gas composition) at a constant total gas pressure according to the Toth model.

An integral heat of adsorption called *heat of immersion* (kcal/mole) can be measured by contacting a clean adsorbent with a pure liquid (ΔH_i^o) or a liquid mixture (ΔH). The typical variation of (ΔH) as a function of bulk liquid phase concentration is shown in Figure 61.7. For an ideal binary liquid system [Equation (61.5)], ΔH is given by

$$\Delta H = \frac{S y_1 \Delta H_1^o + y_2 \Delta H_2^o}{S y_1 + y_2} \quad (61.10)$$

61.4 Thermodynamic Selectivity of Adsorption

Most practical adsorptive separations are based on thermodynamic selectivity. The selectivity S_{ij} ($= n_j / n_{y_j}$) of adsorption of component i over component j from a mixture determines the maximum achievable separation between the components under equilibrium conditions. Component i is selectively adsorbed

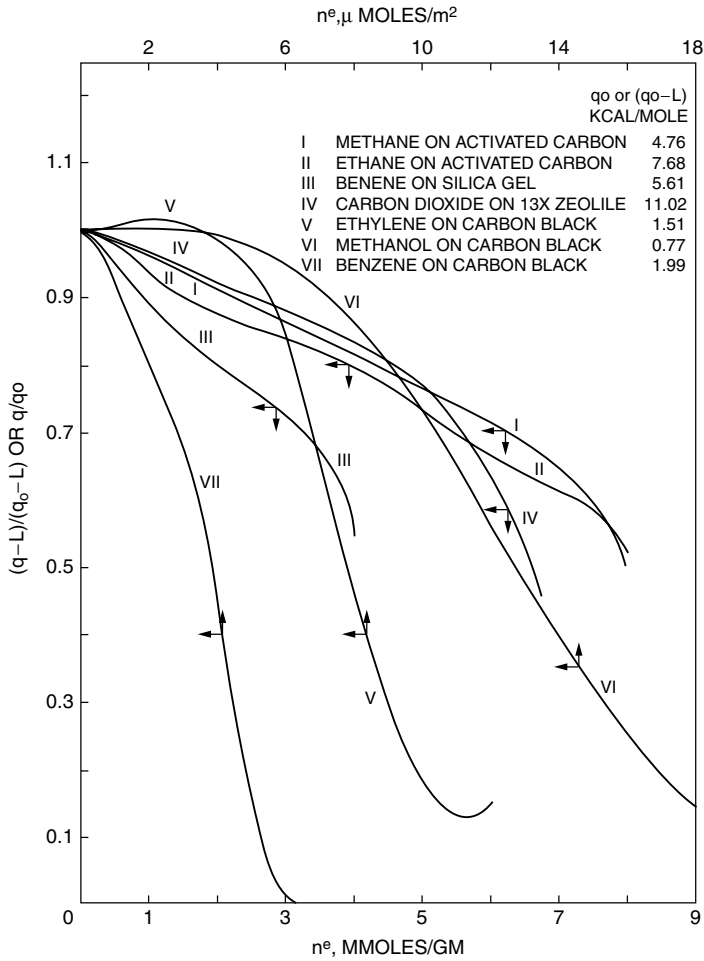

FIGURE 61.5 Isosteric heats of adsorption of pure gases on heterogeneous adsorbents. (Source: Sircar, S. and Gupta, R. 1981. *Am. Inst. Chem. Eng. J.* 27:806–812.)

over component j when $S_{ij} > 1$. S_{ij} can approach infinity if component j is excluded from entering the pores of the adsorbent (molecular sieving).

The selectivity of adsorption (S_{ij}^*) in the Henry's law region ($P \rightarrow 0$) is given by

$$S_{ij}^* = \frac{K_i}{K_j} = \left(\frac{K_i^*}{K_j^*} \right) \exp \left[\frac{q_i^* - q_j^*}{RT} \right] \quad (61.11)$$

S_{ij} values can be strong functions of adsorbate loadings of the components when the adsorbates have different molecular sizes and when the adsorbent is heterogeneous, as shown in [Figure 61.8](#).

For adsorption of an ideal binary liquid system [Equation (61.5)],

$$S = \exp[\phi_2^o - \phi_1^o]/m RT \quad (61.12)$$

where ϕ_i^o is the surface potential for adsorption of pure liquid i . S for liquid mixtures can be strong functions of bulk phase concentrations when the adsorbates have different sizes or when the adsorbent is heterogeneous.

FIGURE 61.8 Binary selectivity of adsorption on activated carbon. (Source: Sircar, S. and Myers, A. L. 1985. *Adsorp. Sci. Technol.* 2:69–87.)

61.5 Adsorption Kinetics

The actual physisorption process is very fast (milliseconds to reach equilibrium). However, a finite amount of time may be required for an adsorbate molecule to travel from the bulk fluid phase to the adsorption site in a microporous adsorbent. This rate process is generally referred to as *adsorption kinetics*. Adsorbate mass transfer resistance may be caused by:

1. Fluid film outside the adsorbent particle (for mixture adsorption)
2. Anisotropic skin at the particle surface
3. Internal macro- and microporous diffusional resistances (pore and surface diffusion)

FIGURE 61.9 Pure gas adsorption kinetics on carbon molecular sieve. (Source: Sircar, S. 1994. In *Separation Technology: The Next Ten Years*, ed. J. Garside, Institute of Chemical Engineers, Rugby, Warwickshire, U.K. p. 49.)

FIGURE 61.10 Adsorption kinetics of a trace liquid adsorbate on 3A zeolite. (Source: Sircar, S. and Myers, A. L. 1986. *Sep. Sci. Technol.* 21:535–562.)

The transport of an adsorbate can be severely affected by:

1. The presence of other adsorbates in the pores
2. Local temperature changes caused by heat of ad(de)sorption

Gas phase adsorption is generally faster than liquid phase adsorption. The overall mass transfer coefficient for adsorption can be increased by reducing the length of diffusional path (adsorbent particle size).

Figure 61.9 shows examples of uptakes of pure gases by a carbon molecular sieve. Figure 61.10 shows an example of uptake of a trace adsorbate from a bulk liquid mixture by a zeolite. The terms y and y_0 are, respectively, bulk phase mole fractions at time t and at the start of the test.

The simplest model for describing gas phase adsorption kinetics is known as the linear driving force (LDF) model:

$$\begin{aligned}
 \text{Pure gas} \quad \frac{d n_i^o(t)}{dt} &= k_i^o [n_i^{o*}(t) - n_i^o(t)]; \\
 \text{Mixed gas} \quad \frac{d n_i(t)}{dt} &= k_{ii} [n_i^*(t) - n_i(t)] + \sum_j k_{ij} [n_j^*(t) - n_j(t)]
 \end{aligned}
 \tag{61.13}$$

The terms $n_i^o(t)$ and n_i are, respectively, the transient adsorbate loading of pure component i , and that for component i from a mixture at time t . The terms $n_i^*(t)$ and $n_i^o(t)$ are, respectively, the corresponding equilibrium adsorbate loadings of component i at the instantaneous bulk phase conditions. The term k_i^o (sec^{-1}) is the overall mass transfer coefficient for pure component i . The terms k_{ii} and k_{ij} are the overall straight and cross (between component i and j) mass transfer coefficients for component i in the mixture. The temperature and adsorbate loading dependence of the mass transfer coefficients is determined by the governing transport mechanism. The LDF model can also describe the kinetics of adsorption of liquid mixtures by rewriting Equation (61.13) in terms of transient surface excess $n_i^e(t)$ and equilibrium surface excess n_i^{e*} of component i .

An experimental gas adsorption kinetics process is generally nonisothermal, whereas liquid phase adsorption kinetics can be measured isothermally due to high heat capacity of the liquid.

Separation of the components of a fluid mixture can also be achieved by a kinetic selectivity when certain components of the mixture are adsorbed at a much faster rate than the others, even though there

FIGURE 61.11 Type I column dynamics. (Source: Sircar, S. and Myers, A. L. 1985. *Adsorp. Sci. Technol.* 2:69–87.)

is no thermodynamic selectivity of adsorption between the components. Figure 61.9 is an example of such a case.

61.6 Adsorption Column Dynamics

Practical separation and purification of fluid mixtures are carried out in packed columns of adsorbent materials. The dynamics of the ad(de)sorption process in columns is determined by the adsorption equilibria, heats, and kinetics and by the modes of operation of the process. The simplest case of the adsorption dynamics is to flow a binary gas mixture consisting of a single adsorbate (mole fraction y^o) and an inert carrier gas through a packed column that has previously been saturated with the pure inert gas at the pressure (P^o) and temperature (T^o) of the feed gas. Two types of behavior may be observed:

Type I. Two pairs of mass and heat transfer zones are formed in the column, as shown in Figure 61.11.

The column ahead (section I) of the front zones (section II) remains saturated with the carrier gas at initial conditions. The column (section III) between the front and rear zones (section IV) is equilibrated with a gas mixture of mole fraction y^* ($< y^o$) at temperature T^* ($> T^o$). The column (section V) behind the rear zones is equilibrated with feed gas mixture at feed conditions.

Type II. A pure heat transfer zone (section II) is formed, followed by a pair of mass and heat transfer zones (section IV), as shown in Figure 61.12. The adsorbate is absent in sections I to III in this case. The column behind (section V) the rear zones remains equilibrated with feed gas at feed conditions.

FIGURE 61.12 Type II column dynamics. (Source: Sircar, S. and Myers, A. L. 1985. *Adsorp. Sci. Technol.* 2:69–87.)

FIGURE 61.13 Rollover effect for binary adsorbate system. (Source: Sircar, S. and Myers, A. L. 1985. *Adsorp. Sci. Technol.* 2:69–87.)

Approximate criteria for formation of these two types of systems are as follows:

$$\text{Type I: } n^o / y^o < C_s / C_g; \quad \text{Type II: } n^o / y^o > C_s / C_g \quad (61.14)$$

The term n^o is adsorbate loading at feed conditions. C_s and C_g are heat capacities of the adsorbent and the feed gas. The zones move through the column as more feed gas is introduced.

Adsorbates with type I adsorption equilibria generally yield constant pattern (unchanging shape and size) front zones (type I dynamics) and rear zones (type II dynamics) in a long column. The zones can be proportionate pattern (expanding in size with time) when the adsorption isotherms are linear. The zones eventually leave the column, and the measured adsorbate concentration–time and temperature–time profiles (breakthrough curves) are mirror images of these profiles within the column. Multiple transfer zones and equilibrium sections are formed in systems with multicomponent adsorbates. They are often characterized by rollover effects in which the more strongly adsorbed species (component 1) displaces the weaker species (component 2) as the zones propagate. This effect is illustrated in Figure 61.13 for isothermal adsorption of a binary adsorbate from inert carrier gas.

Well-defined mass and heat transfer zones and equilibrium sections can also be formed in the column during the desorption process. Figure 61.14 is an example for isobaric desorption of a single adsorbate from a column saturated with the adsorbate at mole fraction y^o and temperature T^b that is being purged with an inert gas at T^b . Again, two pairs of mass and heat transfer zones (sections II and IV) and three equilibrium sections (I, III, V) are formed.

Nonisothermal column dynamics is generally a rule. Near-isothermal dynamics (mass transfer zones only) can be obtained for ad(de)sorption from (a) liquid mixtures and (b) trace gaseous adsorbates. Figure 61.15 shows two examples of isothermal breakthrough curves for adsorption of trace single adsorbate from (a) an inert gas and (b) an inert liquid. For isothermal–isobaric adsorption of a trace Langmuirian adsorbate i from an inert carrier gas in a column, which is initially free of the adsorbate, and where a constant pattern mass transfer zone is formed, the LDF mechanism of mass transfer yields

$$(t_2 - t_1) \cong \frac{b_1 m}{(1 + b_1) k_i^o n_i^o} \ln \left[\frac{\phi_2 (1 - \phi_1)}{\phi_1 (1 - \phi_2)} \right] + \ln \frac{\phi_1}{\phi_2} \quad (61.15)$$

The terms t_1 and t_2 correspond to time difference in the breakthrough curve corresponding to two arbitrary composition levels ϕ_1 and ϕ_2 [$\phi = y_i(t) / y_i^o$].

FIGURE 61.14 Column dynamics for desorption by purge. (Source: Sircar, S. and Myers, A. L. 1985. *Adsorp. Sci. Technol.* 2:69–87.

FIGURE 61.15 Isothermal breakthrough profiles for a single-trace adsorbate. [Sources: (a) Garg, D. R. and Ruthven, D. M. 1974. *Chem. Eng. Sci.* 29:571–581. (b) Mathews, A. P. 1984. 61.7 Adsorptive Separation Processes and Design

Three generic adsorptive process schemes have been developed to serve most of the applications described by Table 61.1. These are (a) **thermal swing adsorption (TSA)**, (b) **pressure swing adsorption (PSA)**, and (c) **concentration swing adsorption (CSA)**.

TSA is by far the most frequently used industrial application of this technology. It is used for removal of trace impurities as well as for drying gases and liquids. The adsorption is carried out at near ambient temperature and the desorption is achieved by directly heating the adsorbent using a part of the cleaned fluid or steam. The adsorbent is then cooled and reused.

PSA is primarily used for bulk gas separations and for gas drying. These processes consist of a series of sequential cyclic steps. The adsorption step is carried out at higher partial pressures of the adsorbates and the desorption is achieved by lowering their partial pressures in the column by (a) decreasing the total pressure of the column and (b) flowing an adsorbate free gas through the column. Many complementary process steps are also used in modern PSA processes in order to:

1. Increase the recovery and purity of desired products from a multicomponent feed gas mixture

FIGURE 61.16 Schematic flowsheet of a PSA process. (Source: Sircar, S. 1989. In *Adsorption Science and Technology*, ed. A. I. Rodrigues et al. NATO ASI Series E158. Kluwer Academic, Dordrecht, The Netherlands. p. 285.)

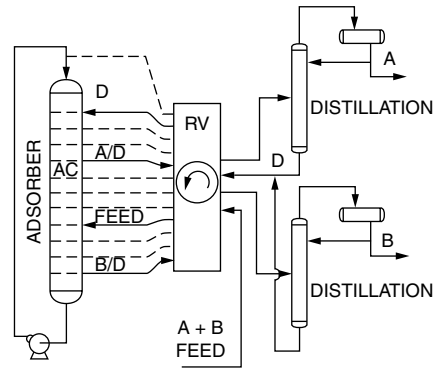

FIGURE 61.17 Schematic flowsheet of an SMB process. (Source: Keller, G. E., Anderson, R. A., and Yon, C. M. 1987. In *Handbook of Separation Process Technology*, ed. R. W. Rousseau, John Wiley & Sons, New York. p. 644.)

2. Produce more than one pure product
3. Decrease adsorbent inventory
4. Reduce energy of separation

Figure 61.16 shows a schematic flowsheet for a PSA process.

The CSA processes are generally designed for separation of bulk liquid mixtures. Certain components of a liquid mixture are adsorbed at ambient conditions, and the desorption is effected by flowing a less strongly adsorbed liquid (eluent) over the adsorbent. Simple distillation may be necessary to separate the eluent from the components of the feed mixture. Simulated moving bed (SMB) adsorbers have been designed for this purpose, as shown schematically in Figure 61.17. The feed and eluent injection points as well as the liquid withdrawal points are changed periodically in a fixed column to simulate continuous countercurrent operation.

The design of adsorptive processes requires simultaneous solutions of differential mass, heat, and momentum balance equations describing the operations of the cyclic process steps in the adsorbent column using the appropriate initial and boundary conditions for each step. The final column conditions at the end of a step become the initial conditions for the next step. Numerical integration of the equations is often necessary in order to reach a cyclic steady state solution. Multicomponent adsorption equilibria, heats, and kinetics from the key input variables for the solution. Bench- and pilot-scale process performance data are generally needed to confirm design calculations.

Defining Terms

Adsorbent — A material used for carrying out the adsorption process.

Adsorption — The surface phenomenon by which the molecules of a bulk fluid phase are attracted by a solid surface in contact with the fluid.

Adsorption equilibria — The thermodynamic property describing the extent of adsorption of a fluid species by a solid surface.

Adsorption kinetics — The measure of travel time of an adsorbate molecule from bulk fluid phase to the adsorption site.

Column dynamics — Defines behavior of mass and heat transfer zone movements within an adsorption column during the ad(de)sorption process.

Concentration swing adsorption — An adsorptive process in which desorption is effected by changing the fluid phase concentration of the adsorbate.

Desorption — The process of removing the adsorbed molecules from the solid surface to the bulk fluid phase.

Heat of adsorption — The measure of thermal energy released during the exothermic adsorption process.

Pressure swing adsorption — An adsorptive process in which desorption is effected by lowering the partial pressure of the adsorbate.

Selectivity of adsorption — The measure of extent of separation of a component of a fluid mixture by adsorption process.

Thermal swing adsorption — An adsorptive process in which desorption is effected by heating the adsorbent.

Swenson Process Equipment, Inc.

A **crystal** is a solid bounded by plane surfaces. Crystallization is important as an industrial process because a large number of commodity chemicals, pharmaceuticals, and specialty chemicals are marketed in the form of crystals. The wide use of crystallization is due to the highly purified and attractive form in which the compounds can be obtained from relatively impure solutions by means of a single processing step. Crystallization can be performed at high or low temperatures, and it generally requires much less energy for separation of pure materials than other commonly used methods of purification do. While crystallization may be carried on from vapor or a melt, the most common industrial method is from a solution.

A solution is made up of a liquid (solvent) — most commonly water — and one or more dissolved species that are solid in their pure form (solute). The amount of solute present in solution may be expressed in several different units of concentration. For engineering calculations, expressing the solubility in mass units is the most useful. The solubility of a material is the maximum amount of solute that can be dissolved in a solvent at a particular temperature. Solubility varies with temperature and, with most substances, the amount of solute dissolved increases with increasing temperature.

For crystallization to occur, a solution must be supersaturated. **Supersaturation** means that, at a given temperature, the actual solute concentration exceeds the concentration under equilibrium or saturated conditions. A supersaturated solution is metastable, and all crystallization occurs in the metastable region. A crystal suspended in saturated solution will not grow. Supersaturation may be expressed as the ratio between the actual concentration and the concentration at saturation [Equation (62.1)] or as the difference in concentration between the solution and the saturated solution at the same temperature [Equation (62.2)].

$$S = C/C_s \quad (62.1)$$

$$\Delta C = C - C_s \quad (62.2)$$

where C is the concentration (g/100 g of solution), and C_s is the concentration (g/100 g of solution) at saturation. This difference in concentration may also be referenced to the solubility diagram and expressed as degrees ($^{\circ}\text{C}$) of supersaturation.

Nucleation is the birth of a new crystal within a supersaturated solution. Crystal growth is the layer-by-layer addition of solute to an existing crystal. Both of these phenomena are caused by supersaturation. Nucleation is a relatively rapid phenomenon that can occur in a matter of seconds. Growth is a layer-by-layer process on the surface of an existing crystal and takes considerably more time. The ratio of nucleation to growth controls the size distribution of the crystal product obtained. Generating a high level of supersaturation spontaneously leads to both nucleation and growth. The competition between these two processes determines the character of the product produced.

62.1 Methods of Creating Supersaturation

Supersaturation may be created by cooling a solution of normal solubility into the metastable zone. Typically, the amount of supersaturation that can be created in this way without causing spontaneous nucleation is in the range of 1 to 2 $^{\circ}\text{C}$. Evaporation of solvent at a constant temperature also produces supersaturation by reducing the amount of solvent available to hold the solute. The reaction of two or more chemical species, which causes the formation of a less soluble species in the solvent, can also produce supersaturation. Finally, the addition of a miscible nonsolvent in which the solute is not soluble to a solvent will cause a decrease in the solubility of the solute in the solution. This technique is most often used in pharmaceutical operations involving the addition of alcohol or similar solvents to the primary solvent (water).

62.2 Reasons for the Use of Crystallization

Crystallization is important as an industrial process because a large number of materials can be marketed in the form of crystals that have good handling properties. Typically, crystalline materials can be separated from relatively impure solutions in a single processing step. In terms of energy requirements, the energy required for crystallization is typically much less than for separation by distillation or other means. In addition, crystallization can often be performed at relatively low temperatures on a scale that involves quantities from a few pounds up to thousands of tons per day.

62.3 Solubility Relations

Equilibrium relations for crystallization systems are expressed in the form of solubility data, which are plotted as phase diagrams or solubility curves. The starting point in designing any crystallization process is knowledge of the solubility curve, which is ordinarily plotted in terms of mass units as a function of temperature. An example is given in [Figure 62.1](#) for the solubility of magnesium sulfate in water as a function of temperature. At any concentration and temperature, the information on the diagram allows one to predict the mixture of solids and solution that exists. Note that, in the case of magnesium sulfate, a number of different hydrates can exist in addition to the solution itself, or ice plus the solution. The line that forms a boundary between the solution area and the various crystal hydrate areas is a solubility curve.

Starting from point (1) at 50 $^{\circ}\text{C}$ and cooling to 30 $^{\circ}\text{C}$ at point (2) is a path that crosses the solubility line. During the cooling process, crossing the line in this manner indicates that the solution has become supersaturated for the concentration in question. If the supersaturation is within the metastable range — which is approximately 1 $^{\circ}\text{C}$ — then growth can occur on existing crystals, but no substantial amount of nucleation will occur. If the cooling proceeds further, the system can become unstably supersaturated, and spontaneous nucleation takes place. If spontaneous nucleation takes place, very small crystals or nuclei form, and they will grow as long as the solution remains supersaturated.

As growth takes place, the concentration drops in the direction of point (3), and, as it approaches the solubility line, growth ceases because the driving force approaches zero. Organic and inorganic materials

FIGURE 62.1 Weight fraction of MgSO₄ versus temperature. (Source: Courtesy of Swenson Process Equipment Inc.)

have similar solubility curves and they vary in concentration and temperature for each compound. Some materials have no hydrates and others exhibit a wide range of hydrates similar to those shown in Figure 62.1. Solubility information on most compounds is available from the literature in publications, such as the *International Critical Tables* [Campbell and Smith, 1951] and *Lang's Solubility of Inorganic and Organic Compounds* [Linke, 1958], and in various software packages that are becoming available.

62.4 Product Characteristics

The shape and size of a crystal are determined by its internal structure as well as external conditions that occur during its growth cycle. These external conditions include growth rate, the solvent system, the level of agitation, and the effect of impurities that may be present. Crystalline material is almost always

separated from its mother liquor before the crystal can be dried or used. The filterability of the crystals, whether separation is done on a centrifuge or filter, is an important characteristic of the product. Generally, larger particles filter more readily, but the average particle size by itself is not an unfailing indication of filterability. The particle size distribution is important because, if it is very broad, small particles may be trapped between the larger particles, making the drainage rates much lower. This could lead to retention of mother liquor, which will degrade the purity of the final product. Broad distributions that increase the amount of mother liquor retained also make the cake less pervious to wash liquids. Products crystallized from continuous crystallizers typically have a coefficient of variation of 45 to 50%. Products made from batch crystallizers, which are fully seeded, often show narrower size distributions with a coefficient of variation of approximately 25 to 30%.

The bulk density of the dried material is affected not only by the crystal density itself, but also by the size distribution. A broader distribution leads to tighter packing and, therefore, a higher bulk density. The flow properties of a crystal product are affected by the crystal shape. Rounded crystals that are formed under conditions of relatively high attrition flow very well, particularly if the particles are in the size range of -8 to +30 U.S. Mesh.

62.5 Impurities Influencing the Product

Since crystallization is generally performed to produce high-purity products, it is important that the crystal be grown in such a way that the impurities that are part of the mother liquor are not carried out with the crystalline particles. Impurities can affect the growth rate and nucleation rate during crystallization and, as a consequence, affect both the mean particle diameter and the habit of the particles being crystallized. Most habit modifiers cause a change in the crystal shape because they are absorbed on one or more of the crystal faces, thereby altering the growth rate of that face and causing that face to either become predominant or largely disappear. Impurities that have this influence can be either ionic, surface-active compounds or polymers.

Under some conditions, the impurities in a product can be increased by lattice incorporation, which occurs when an impurity in the mother liquor substitutes for molecules in the product crystal lattice. Mixed crystals — which are really two separate species crystallizing at the same time — can also be produced. Surface absorption of species that are in the mother liquor not only can add to the impurity level of the product, but can also alter the growth rate and, therefore, the habit of the crystals. Solvent inclusion can occur when rapidly growing crystals form around small volumes of mother liquor that become trapped inside the crystal lattice. The liquor in these inclusions may or may not find its way to the surface during the subsequent drying operations.

Solvent inclusion probably accounts for the largest increase in impurity levels in a crystal, with lattice incorporation generally less, and surface absorption accounting for only very minute amounts of contamination. Normally, recrystallization from a relatively pure solution will eliminate virtually all the impurities, except for a material whose presence is due to lattice incorporation.

62.6 Kinds of Crystallization Processes

Crystallization can be carried on in either a batch or continuous manner, irrespective of whether evaporation, cooling, or solvent change is the method of creating supersaturation. Batch processes are almost always used for small capacities and have useful application for large capacities when a very narrow particle size distribution is required, such as with sugar, or when materials (e.g., pharmaceuticals) that require very accurate inventory control are being handled.

A continuous crystallization process normally must operate around the clock because the retention times typically used in crystallizers range from about 1 to 6 h. As such, it takes at least four to six retention times for the crystallizer to come to equilibrium, which means there may be off-spec product when the system is started up. To minimize this, the unit should be kept running steadily as long as

possible. The cost of at least three operators per day and the instrumentation required to continuously control the process represent a substantially greater investment than what is required for batch processing. This disadvantage can only be overcome by utilizing that labor and investment at relatively high production rates.

62.7 Calculation of Yield in a Crystallization Process

In order to calculate the yield in a crystallization process, it is necessary that the concentration of feed, mother liquor, and any change in solvent inventory (evaporation) be known. In most crystallization processes, the supersaturation in the residual mother liquor is relatively small and can be ignored when calculating the yield. With some materials, such as sugar, a substantial amount of supersaturation can exist, and under such circumstances the exact concentration of the solute in the final mother liquor must be known in order to make a yield calculation. The product crystal may be hydrated, depending on the compound and temperature at which the final crystal is separated from the mother liquor.

Shown below is a formula method for calculating the yield of a hydrated crystal from a feed solution [Myerson, 1993].

$$P = R \frac{100W_o - S(H_o - E)}{100 - S(R - 1)} \quad (62.3)$$

where

P = weight of product

R = $\frac{\text{mole weight of hydrate crystal}}{\text{mole weight of anhydrous crystal}}$

S = solubility at the mother liquor (final) temperature in units/100 units of solvent

W_o = weight of anhydrous solute in feed

H_o = weight of solvent in feed

E = evaporation

62.8 Mathematical Models of Continuous Crystallization

Randolph and Larsen [1988] developed a method of modeling continuous crystallizers in which the growth rate is independent of size and the slurry is uniformly mixed. Such crystallizers are often referred to as the mixed-suspension mixed-product removal (MSMPR) type. For operation under steady conditions, the population density of an MSMPR crystallizer (FC and DTB types shown in [Figure 62.2](#) and [Figure 62.3](#), respectively) is

$$n = n^o e^{-L/GT} \quad (62.4)$$

where

n = population density, number/mm

G = growth rate, mm/h

T = retention time, h

L = characteristic length, mm

n^o = nuclei population density (i.e., intercept at size $L = 0$)

A plot of the $\ln n$ versus L will be a straight line if the system is operating under the conditions assumed above. The nucleation rate and the mean particle size (by weight) are

$$B^o = Gn^o \quad (62.5)$$

FIGURE 62.2 Swenson forced-circulation crystallizer. (Source: Courtesy of Swenson Process Equipment Inc.)

$$L_a = 3.67GT \quad (62.6)$$

where

L_a = average particle by weight
 B^o = nucleation rate, number/cc-sec

It is possible to calculate the particle size distribution by weight if the assumptions above are valid and if the plot of $\ln n$ versus L is a straight line. The weight fraction up to any size L is

$$W_x = 1 - e^{-x} \left(1 + x + \frac{x^2}{2} + \frac{x^3}{6} \right) \quad (62.7)$$

where

$x = L/GT$
 W_x = cumulative weight fraction up to size L

FIGURE 62.3 Swenson draft-tube baffle crystallizer. (Source: Courtesy of Swenson Process Equipment Inc.)

In solving Equation (62.4) and Equation (62.5), it must be remembered that the growth rate and the nucleation rate must be measured under the same conditions. In evaluating performance of crystallization equipment, it is necessary to know the heat balance, material balance, and population balance of the particles being used as seed (when used), as well as the product population balance.

62.9 Equipment Designs

While many solvent systems are possible, most large-scale industrial crystallizers crystallize solutes from water. Organic solvents are sometimes encountered in the petroleum industry, and alcohol solutions or mixtures of alcohol and water are found in pharmaceutical applications. Typically, water solutions have

viscosities in the range of 1 to 25 cp and boiling point elevations from 1 up to 12°C. The viscosity of a solution is very important because it determines the settling rates of particles within the solution and heat transfer rates in heat exchange equipment required for heating or cooling the solution. The boiling point elevation represents a temperature loss in an evaporative system where condensation of the vapor in a multiple-stage evaporative crystallizer or condenser is required.

The evaporation rate is determined from the basic process requirements and the heat balance around the system. The evaporation rate and the temperature at which evaporation occurs determine the minimum body diameter. The specific volume of water vapor is strongly influenced by pressure and temperature. Low temperatures, which represent relatively high vacuum for water at its boiling point, require larger bodies than do systems operating at atmospheric pressure. The other consideration in sizing the body is the minimum volume required to provide the retention time required for crystal growth.

Shown in [Figure 62.2](#) is a forced-circulation evaporator-crystallizer, which is often used for the production of sodium chloride, citric acid, sodium sulfate, sodium carbonate, and many other inorganic compounds produced by evaporative crystallization. The body diameter and straight side are determined by the vapor release rate and retention time required to grow crystals of the desired size. The sizes of the circulating pipe, pump, heat exchanger, and recirculation pipe are based on the heat input required to cause the evaporation to take place. Crystals in the solution circulated throughout the body are kept in suspension by the action of the recirculating liquor. Tube velocities, heat transfer rates, and circulation rates are determined by the particular application and the physical properties of the solution. Slurry leaving the crystallizer is pumped by the product discharge pump into a centrifuge, filter, or other separation equipment. This type of crystallizer is often referred to as an MSMPR type, and the crystal size distribution can be described by the mathematical model described in Equation (62.4) through Equation (62.7). The crystal size typically produced in equipment of this type is in the range of 30 to 100 Mesh, and slurry discharge densities typically handled in such equipment range from about 20 to 40% by weight solids.

Shown in [Figure 62.3](#) is a draft-tube baffle (DTB) crystallizer of the evaporative type, including an elutriation leg. Slurry within the crystallizer body is pumped to the surface by means of a slow propeller and recirculates to the suction of the propeller where it is mixed with heated solution exiting the heating element. Surrounding the body of slurry in the crystallizer is an annular space between the skirt baffle and the settler. Liquid is pumped from this annular space at a controlled rate so that small crystal particles from the body can be removed, but the bulk of the circulated liquor and crystals enters the propeller suction. The flow from the annular area is pumped through a circulating pipe by a circulating pump through the heat exchanger, where the temperature rise destroys small particles that are present. This continuous removal and dissolution of small particles by temperature increase serves two purposes:

1. The heat required for the evaporation is transferred into the liquid so that a constant vaporization rate can be maintained.
2. Small particles are continuously removed so as to limit the seed crystals in the body to values low enough so that the production can be obtained in a coarse crystal size.

When the crystals become too large to be circulated by the propeller, they settle into the elutriation leg, where they are washed by a countercurrent stream of mother liquor pumped from behind the baffle. Crystals leaving the leg are therefore classified generally at a heavier slurry density than would be true if they were pumped from the body itself. This combination of removal of unwanted fines for destruction and classification of the particle size being discharged from the crystallizer encourages the growth of larger particles than would be obtained in a crystallizer such as the forced circulation type in [Figure 62.2](#). Typically, the DTB crystallizer is used for products in the range of 8 to 20 Mesh with materials such as ammonium sulfate and potassium chloride.

Shown in [Figure 62.4](#) is a surface-cooled crystallizer, which is frequently used at temperatures close to ambient or below. Slurry leaving the body is pumped through a heat exchanger and returns to the body through a vertical inlet. Surrounding the circulating slurry is a baffle that permits removal of unwanted fine crystals or provides for the removal of clarified mother liquor to increase the slurry density

FIGURE 62.4 Swenson surface-cooled crystallizer. (Source: Courtesy of Swenson Process Equipment Inc.)

within the crystallizer body. Slurry pumped through the tubes of the cooler is chilled by a coolant that is circulated outside the tubes. The temperature difference between the coolant and the slurry flowing through the tubes must be limited to approximately 3 to 8°C. The temperature drop of the slurry passing through the tubes is normally about 0.5°C. These very low values are required in order to minimize the growth of solids on the tubes. Crystallizers of this type produce a product that ranges between 20 and 150 Mesh in size. Common applications are for the production of copper sulfate pentahydrate, sodium chlorate, sodium carbonate decahydrate, and sodium sulfate decahydrate.

Shown in [Figure 62.5](#) is a reaction-type DTB crystallizer. This unit, while in many respects similar to the DTB crystallizer shown in [Figure 62.3](#), has the important difference that no heat exchanger is required to supply the heat required for evaporation. The heat of reaction of the reactants injected into the crystallizer body supplies this heat. Typically, this type of equipment is used for the production of ammonium sulfate, where sulfuric acid and gaseous ammonia are mixed in the draft tube of the crystallizer so as to produce supersaturation with respect to ammonium sulfate. The heat of reaction is removed by vaporizing water, which can be recirculated to the crystallizer and used for the destruction of fines. Whenever a chemical reaction causes a precipitation of crystalline product, this type of equipment is worth considering because the conditions used in crystallization are compatible with low temperature rises and good heat removal required in reactors. By combining the reactor and crystallizer, there is better control of the particle size with an obvious decrease in equipment costs.

62.10 Evaporation

When a solution is boiled (evaporated) at constant pressure, the total pressure above the solution represents the sum of the partial pressures of the liquids that are boiling. If only water is present, then the pressure above the solution at any temperature corresponds to water at its boiling point at that pressure. If there is more than one component present and that component has a vapor pressure at the temperature of the liquid, then the total pressure represents the vapor pressure of water plus the vapor

FIGURE 62.5 Swenson reaction-type DTB crystallizer. (Source: Courtesy of Swenson Process Equipment Inc.)

pressure of the other component. Vapor leaving such a system, therefore, represents a mixture of solvents in the ratio of their partial pressures. In a sense, an evaporator is a single plate distillation column. In most applications, the vapor pressure of the solute is negligible and only water is removed during boiling, which can be condensed in the form of a pure solution. However, when volatile compounds are present (e.g., H_3BO_3 , HNO_3), some of the volatile material will appear in the overhead vapor.

Since the heat required to vaporize water is approximately 556 cal/kg (1000 Btu/lb), it is important to reduce the amount of energy required as much as possible so as to improve the economics of the process. For this reason, multiple-effect evaporators were developed in the middle of the 19th century and continue today as an important means for achieving good economy during evaporation or crystallization. A multiple-effect falling-film evaporator consisting of three vessels and a condenser is shown in Figure 62.6. In this type of equipment, the vapor boiled from the first effect (the vessel where the steam enters) is conducted to the heat exchanger of the second effect, where it acts as the heating medium. Vapor boiled in the second effect is conducted to the third effect, where it again acts as the heating medium. Vapor leaving the third effect, in this case, is condensed in a condenser utilizing ambient-

FIGURE 62.6 Swenson triple-effect falling-film evaporator. (Source: Courtesy of Swenson Process Equipment Inc.)

temperature water. The flow of feed solution to the evaporator can be either forward, backward, or parallel. In a forward feed evaporator, the feed enters the first effect, then passes to the second effect, and is ultimately removed from the third effect as concentrated liquor. With this type of flowsheet, heat exchange means must be employed to minimize the sensible heat required for the liquid fed to the first effect. In a backward feed evaporator, this is not normally done.

An alternative means for reducing energy consumption during evaporation is shown in the recompression evaporative crystallizer in [Figure 62.7](#). The technique can be employed on both evaporation and crystallization equipment. In this case, a single vessel is employed, and the vapor boiled out of the solvent is compressed by a centrifugal compressor and used as the heating medium in the heat exchanger. The compressed vapor has a higher pressure and a higher condensing temperature so that there is a change in temperature between the vapor being condensed in the heater and the liquid being heated in the heat exchanger. In utilizing this technique, it must be remembered that the boiling point elevation decreases the pressure of the vapor above the liquid at any given temperature and, thereby, represents a pressure barrier that must be overcome by the compressor. The efficiency of this process varies greatly with the boiling point elevation. As a practical matter, such techniques are limited to those liquids which have boiling point elevations of less than about 13°C. Typically, such compressors are driven at constant speed by an electric motor. The turndown ratio on a constant speed compressor is about 40%. A variable-speed drive would give a greater range of evaporative capacity.

During the last 100 years, a wide variety of evaporator types has evolved, each offering advantages for certain specific applications. The forced-circulation crystallizer shown in [Figure 62.2](#) is utilized for many applications where no crystallization occurs, but the liquids being handled are viscous, and use of the circulation system is needed to promote heat transfer. A number of evaporator types have been developed that require no external circulating system. For the most part, these rely upon thermo-syphon effects to promote movement of liquid through the tubes as an aid to heat transfer. The calandria evaporator (or Roberts type) shown in [Figure 62.8](#) is a design that has been widely used since the 19th century for both crystallization and evaporation applications. It relies on natural circulation in relatively short tubes (1 to 2 m) to maintain heat transfer rates; a relatively large amount of recirculation occurs through the tubes. Since there is no recirculation pump or piping, this type of equipment is relatively simple to operate and requires a minimum of instrumentation. The volume of liquid retained in this vessel is much larger than in some of the rising or falling film designs and, therefore, in dealing with heat-sensitive materials where concentration must proceed at relatively short retention times, the calandria would be

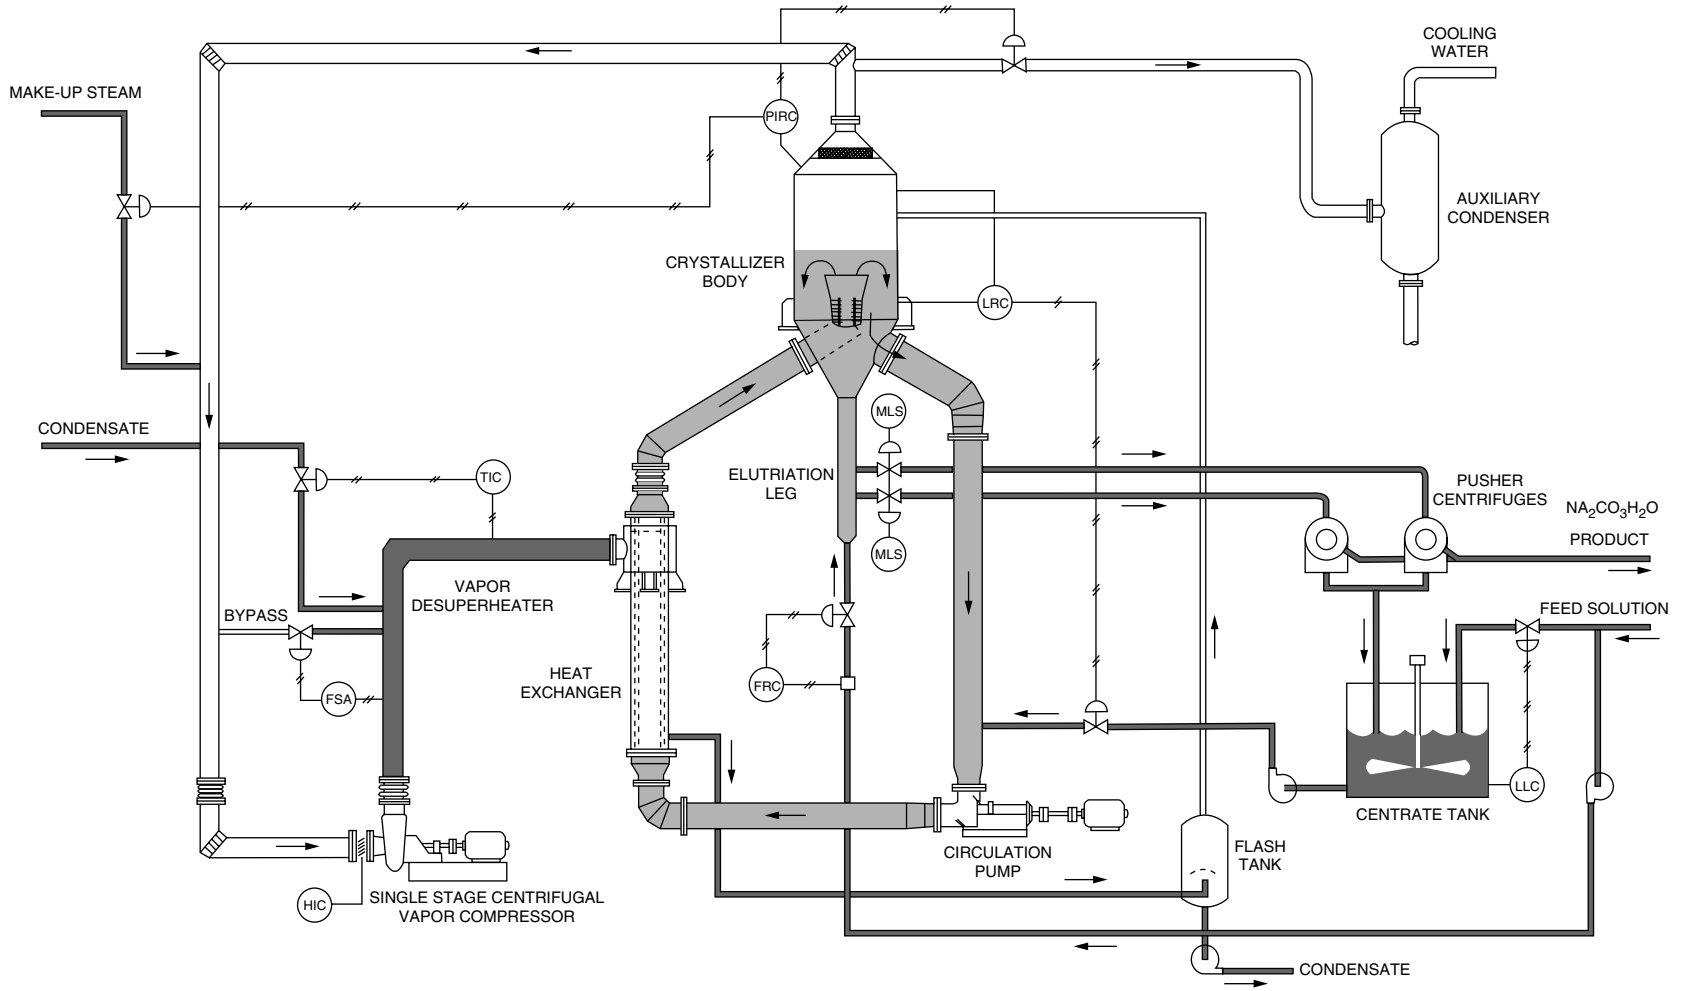

FIGURE 62.7 Swenson recompression evaporator-crystallizer. (Source: Courtesy of Swenson Process Equipment Inc.)

FIGURE 62.8 Swenson calandria evaporator. (Source: Courtesy of Swenson Process Equipment Inc.)

a poor choice. In many situations, however, especially where some crystallization may occur, this evaporator may be operated successfully in a semi-batch or continuous manner.

The falling-film evaporator shown in [Figure 62.9](#) is similar to the rising-film evaporator, except that there must be sufficient liquid at all times entering the heater at the feed inlet to wet the inside surface of the tubes in the heat exchanger bundle. With insufficient circulation, solute material can dry on the tubes and cause a serious reduction in heat transfer. Many falling-film evaporators operate with a recirculating pump between the concentrated liquor outlet and the feed inlet to be certain that the recirculation rate is adequate to maintain a film on the tubes at all times. If this is done, the system can operate stably through a wide range of capacities and achieve very high rates of heat transfer, often 50 to 100% more than are obtained in a rising-film evaporator. The other advantage of the falling film evaporator is that it can operate with very low temperature differences between the steam and the liquid since there is no hydrostatic pressure drop of consequence within the tubes to prevent boiling at the inlet end of the heat exchanger. As a result, this type of design has found wide application as a recompression evaporator.

Even though evaporators are typically used where no precipitation of solids occurs, there is often a trace of precipitation in the form of scaling components that coat the inside of the tubes over a relatively long period of time. This scaling is analogous to that which occurs in boilers and many other types of heat transfer equipment. Typically it is due to either a small amount of precipitation or, because of the composition of the materials being concentrated, some inverted solubility components. Such scaling may often be reduced by a technique known as “sludge recirculation.” This is commonly done in cooling tower blowdown evaporation and in the evaporation of salt brines where scaling components are present.

FIGURE 62.9 Swenson falling-film evaporator. (Source: Courtesy of Swenson Process Equipment Inc.)

In these cases, the evaporator flowsheet is designed in such a way that a thickened slurry of the scaling component can be recirculated from the discharge of the evaporator back to the feed side. By maintaining an artificial slurry density of the scaling component, which is higher than the natural slurry density, it is often possible to reduce the growth of scale which occurs on heat transfer surfaces.

Defining Terms

Crystal — A solid bounded by plane surfaces that has an internal order with atoms or molecules in a fixed lattice arrangement.

Crystallizer — An apparatus for causing the crystallization of solutes from solvents by means of changes in heat or solvent inventory.

Evaporator — An apparatus for causing water or other solvents to be removed from a solution in order to increase the concentration of the solution.

Nucleation — The birth of a new crystal within a supersaturated solution.

Recompression — A process for collecting the vapor boiled from the solution in an evaporator or crystallizer and compressing to a higher pressure, where it can be used as the heating medium for said evaporator or crystallizer.

Supersaturation — A metastable condition in a solution that permits nucleation and growth of crystals to occur.

In its simplest form, a membrane is either a porous or dense (i.e., nonporous) material that is used to separate mixtures of gases or liquids. Membranes used for separations such as microfiltration and ultrafiltration are porous and rely upon hydrodynamic sieving of particles from suspending fluids, and are covered separately in other chapters under their respective headings. Unlike such hydrodynamic sieving devices, the separation methods covered in this chapter — dialysis, reverse osmosis, and gas separation membranes — operate at a molecular scale (3 to 5 Å) to achieve selective passage of one or more components in a feed stream. [Figure 63.1](#) illustrates idealized flow schemes of these processes and the materials that they separate. Penetrant partitioning into the membrane and thermally activated diffusion within the membrane cooperate to yield a *solution–diffusion* process defined as *permeation*. The two primary measures of membrane performance are the membrane *permeability* (i.e., productivity) of the desired penetrant and the membrane *selectivity* (i.e., separation effectiveness) between penetrants. Industrially relevant membranes are generally **asymmetric** and typically “packaged” in one of three basic configurations: flat sheet, tubular, and hollow fiber ([Figure 63.2](#)). Implementation of these materials in actual processing environments introduces challenges that could affect membrane stability and performance if not addressed. These considerations as well as a brief section on the future directions of membrane technology are covered in the present chapter.

63.1 Dialysis

Dialysis is a primarily concentration-driven membrane separation, in contrast to most other membrane processes, which are predominantly pressure driven. Dialysis occurs through a semipermeable membrane to separate components based primarily on their different diffusivities through the membrane. Dialysis processes are most effective for systems having solutes that differ significantly in molecular size from the solvent. Although the concentration-driven nature of dialysis limits the flux, it allows application in systems where the species to be separated are sensitive to high shear rates or high temperatures, particularly bioseparations.

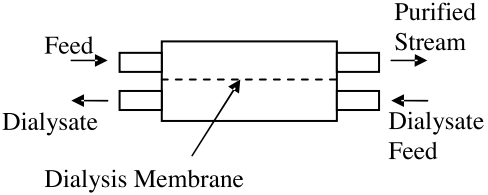

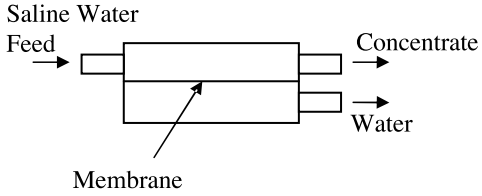

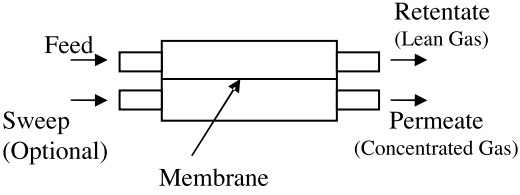

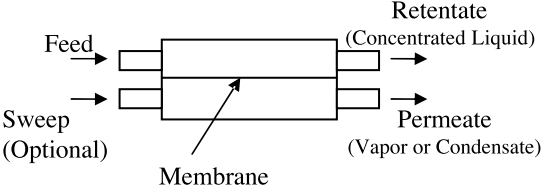

| Process | Concept | Materials Passed | Driving Force | Material Retained |
|---------------------------|--|--|--|---|
| Dialysis |  | Ions and Low-Molecular Weight Organics | Concentration Difference | Dissolved and Suspended Material with Molecular Weight > 1000 |
| Reverse Osmosis |  | Water | Pressure Difference, Typically 100-1500 psi | Virtually All Suspended and Dissolved Material |
| Gas and Vapor Separations |  | Gases and vapors | Pressure Difference, Typically 15-1500 psi | Membrane-Impermeable Gases and Vapors |
| Vapor-Liquid Separations |  | Vapors | Pressure Difference and Vapor-Liquid Equilibrium | Membrane-Impermeable Liquids and Vapors |

The most prominent use of dialysis membranes is in the treatment of end-stage renal disease, or kidney failure. In this process, low- and intermediate-molecular-weight waste products are removed from the blood of a patient. Hemodialysis represents the largest market for membrane materials, although growth in this market is limited compared to other membrane applications. To a much smaller extent, dialysis is applied in microbiology for enzyme recovery from cultures, in the food industry for desalting cheese whey solids, and in juice and beverage processing.

The principal membrane material for dialysis is regenerated cellulose. This water-swollen material is a hydrogel and will undergo irreversible, destructive collapse upon drying in the absence of **plasticizer**. Stability upon air drying can be achieved by using synthetic hydrophobic **glassy polymers** such as methacrylates, polysulfones, and various polyacrylonitrile copolymers, although these materials are intrinsically less biocompatible [Sakai, 1994]. Dialysis modules are most commonly available in hollow fiber morphologies (Figure 63.2) because of their high surface areas. This has decreased the time required for each hemodialysis treatment.

As dialysis of a solute occurs, the solute is removed from the feed side solution as shown in Figure 63.1. Solute is transported across the membrane from an interfacial layer between the membrane and the bulk solution. If the flow is laminar — as is common in small-diameter hollow fibers, spiral-wound, and plate-and-frame modules — convective replenishment from the bulk far away from the membrane does not occur, and diffusion from the bulk must be relied upon to replenish the permeating solute at the membrane surface. A concentration gradient therefore exists between the bulk solution and the membrane–solution interface.

After the solute has crossed the membrane, it must be removed from the interfacial layer on the **dialysate** side to maintain the concentration driving force across the membrane. In this interfacial layer a concentration gradient also exists between the membrane–dialysate interface and the bulk dialysate. Mass transfer from the membrane to the dialysate is dependent on the transmembrane flux and the bulk dialysate concentration.

The overall resistance to mass transfer from the bulk feed solution to the bulk dialysate solution is the sum of three terms: the resistance of the fluid boundary layer on the feed side, the resistance to diffusion through the membrane itself, and the resistance of the fluid boundary layer on the dialysate side. These terms are combined to give a total mass transfer coefficient, k_T (cm/sec), and, since resistances to flow are linearly additive, one finds:

$$\frac{1}{k_T} = \frac{1}{k_F} + \frac{\ell}{P_M} + \frac{1}{k_D} \quad (63.1)$$

where k_F and k_D are the mass transfer coefficients (cm/sec) for the feed and dialysate boundary layers, respectively, and P_M (cm²/sec) is the **permeability** of the membrane. The IUPAC definition of permeability (flux·thickness/driving force) has been used here [Koros et al., 1996], although in the dialysis literature, the permeability is frequently defined as the flux over the driving force. Both k_F and k_D are often considered the ratio of the solute diffusion coefficient in the boundary layer to the boundary layer thickness. As solute size increases, the **diffusivity** of the solute through the membrane decreases more rapidly than in the solution boundary layers; therefore, membrane resistance becomes the dominant term. With small solute molecules, however, membrane-limited dialysis will occur only when k_F and/or k_D are large relative to P_M/ℓ . Under these conditions, transport to and from the membrane can become limiting, and a thinner membrane will not increase the flux under comparable feed and dialysate flow conditions.

The simplest case of dialysis is one of countercurrent flow between feed and dialysate, with negligible transmembrane pressure or convection, and equal inlet and outlet flow rates for both the feed and dialysate streams. The overall mass balance is

$$\dot{m} = Q_F(C_{Fi} - C_{Fo}) = Q_D(C_{Do} - C_{Di}) \quad (63.2)$$

where \dot{m} is the mass flow rate of the solute across the membrane from feed to dialysate streams (g/sec), Q is the volumetric flow rate (cm³/sec), F and D refer to feed and dialysate solutions, respectively, and C_i and C_o are the solute concentrations in and out of the dialyzer, respectively (g/cm³). In terms of an overall mass transfer coefficient, k_T , the mass flow rate of solute is

$$m = k_T A \frac{(C_{Fo} - C_{Di}) - (C_{Fi} - C_{Do})}{\ln[(C_{Fo} - C_{Di}) / (C_{Fi} - C_{Do})]} \quad (63.3)$$

where A is the membrane area (cm²). This is analogous to heat transfer in a shell-and-tube heat exchanger. Performance of the dialyzer can be expressed as a *dialysance*, D^* , which is defined as the ratio of the mass flow rate and the inlet concentration difference as follows (cm³/sec):

$$D^* = \frac{\dot{m}}{C_{Fi} - C_{Di}} \quad (63.4)$$

A more detailed discussion of the preceding theoretical considerations is given in the *Membrane Handbook* [Ho and Sirkar, 1992]. The handbook also discusses expressions for other flow configurations including cases where convective transport and ultrafiltration of the feed occur.

Donnan dialysis and *electrodialysis* use charged membranes to more efficiently separate ions. Donnan dialysis is the separation of ionic components in a feed based on their ability to diffuse through an ion exchange membrane. Anion exchange membranes with fixed positive charges exclude positive ions except for protons because of their small size but allow diffusion of anions. Similarly, in the absence of an applied electrical field, positively charged ions can only diffuse through ion exchange membranes with fixed negative charges. Materials with negative fixed charges (e.g., Nafion[®]; Du Pont, Wilmington, DE) are readily available; however, high-efficiency cationic membranes are still under development [Ho and Sirkar, 1992]. Donnan dialysis has found applications in the recovery of acids from metals-processing waste streams.

Another enhanced dialysis method is **electrodialysis**. In electro dialysis, alternating cation- and anion-exchange membranes are aligned between a cathode and an anode. Feed solution passes between each pair of membranes. Positively charged ions flow toward the cathode but can only traverse cation-exchange membranes. Although most are swept away, they tend to accumulate at anion-exchange membranes. Negatively charged ions flow toward the anode, accumulating at cation-exchange membranes. In this manner, alternating streams become enriched and depleted of ions. The accumulation of ions on oppositely charged membranes makes scale formation a major concern (see Section 63.6). This has been overcome by periodically reversing the electrical field to remove the accumulated ions from their respective membranes and then purging the system before introducing fresh feed. Electro dialysis is most economical with total dissolved salt concentrations of less than 1% [Lee and Koros, 2002], and can be used for desalination or protein desalting.

Once again, a detailed theoretical treatment can be found in Ho and Sirkar [1992], but the principal equations are given here. The maximum ionic flux is determined by the **limiting current density**, which occurs when the ion concentration at either the anion-exchange or cation-exchange membrane becomes zero due to a concentration drop in the boundary layer between the membrane and the bulk feed. The limiting current density, i_{LIM} (A/cm²), is given by:

$$i_{LIM} = \frac{C_B z_+ F k}{t_+ - t_+'} \quad (63.5)$$

where C_B (mol/cm³) is the concentration of the bulk feed, z_+ is the charge of the positively charged ion, F is Faraday's constant, k is the mass transfer coefficient (cm/sec), and t_+ and t_+' are the transport numbers (i.e., fraction of total current carried by the positively charged ions) in the membrane and solution, respectively. The permselectivity, α_+ , is given by:

$$\alpha_+ = \frac{t_+ - t'_+}{1 - t'_+} \quad (63.6)$$

Another important factor governing electro dialysis is the **current utilization**. Clearly, a high current utilization is desired for the most economical operation; however, actual current utilization will be less than 100% due to imperfect membrane selectivity, osmotic and ion-bound water transport, and current passing through the stack manifold [Ho and Sirkar, 1992]. The actual required current, I (A), is then given by the following equation:

$$I = \frac{z_+ F Q_F \Delta C_+}{\xi} \quad (63.7)$$

where Q_F (cm³/sec) is the volumetric flow rate of the feed and ΔC_+ (mol/cm³) is the concentration difference between the feed and purified solution. Equation (63.5) through Equation (63.7) are written in terms of the cation, but they can also be written for the anion.

63.2 Reverse Osmosis

Reverse osmosis (RO) uses a pressure driving force to overcome osmotic pressure and force the solvent, usually water, through the membrane, thereby separating it from the solute. Closely related to reverse osmosis is **nanofiltration**, also called “loose” RO, which often uses an ion exchange membrane to allow for lower pressure drops, while retaining larger solutes with good rejection of polyvalent salts. Ideal reverse osmosis membranes should display high water flux; high salt retention; hydrolytic, chemical, and biological stability; and minimal change in properties with time.

The economics are most favorable for low solute concentrations since high concentrations require large energy input to overcome higher osmotic pressures. By far, the largest application of reverse osmosis and nanofiltration membranes is in water and wastewater purification. Specific applications include desalination of brackish water and seawater, purification of municipal wastewater, removal of organic contaminants from process streams, treatment of coal wash water, concentration of waste from metal processing, and recovery of dyes from textile wash water [Lee and Koros, 2002]. However, the membranes also find applications in the paper industry for the concentration and partial fractionation of lignosulfonates in wood pulping and in the food industry for the concentration of whey, milk, and maple syrup.

Initially, cellulose acetate was the most common RO membrane material, but polyamides and polyaramides have become more popular recently because of their chemical and biological stability [Khedr, 2003]. These membranes are fabricated as flat sheet composites with porous support membranes or as monolithic hollow fibers to provide good stability and extremely high flux.

It is common for RO feeds to be pretreated before being pumped through the membrane module(s) to reduce fouling (see Section 63.6) or eliminate chemically or biologically reactive species. The feed pressure must be balanced so that the exit pressure is greater than the osmotic pressure, but not so high as to cause membrane failure. This requirement sometimes dictates the use of booster pumps in the later stages of the process. The typical required driving pressure (operating pressure – osmotic pressure) of 100 to 1500 psi requires a high-pressure pump, which is the dominant energy consumer. A discussion of the economics of reverse osmosis is given by Malek et al. [1996]. Current work focuses on reducing the operating pressure necessary to accomplish the separation. The development of nanofiltration has aided this goal, but nanofiltration cannot efficiently reject monovalent ions.

Reverse osmosis is a solution–diffusion membrane separation process that relies upon an applied pressure to overcome the osmotic pressure of the feed solution. At low solute concentrations, the osmotic pressure, π (kPa), of the solution at temperature T (K) with a solute molar concentration C_s (mol/cm³) is given by:

$$\pi = C_s RT \quad (63.8)$$

where R is the ideal gas constant. The concentration term must include dissociation effects of the solute since π is a colligative property of the solution (e.g., in NaCl, C_s refers to the concentration of Na^+ and Cl^- ions since they exist as dissociated species in water). Some solute passes through the membrane in response to the concentration gradient that develops. Fixed charges within the membrane, as in nanofiltration, can help suppress uptake of ionic solutes by *Donnan exclusion* (see Donnan dialysis in Section 63.1) and minimize the undesirable solute flux from the feed to the permeate side.

The molar flux, N ($\text{mol}/\text{cm}^2 \cdot \text{sec}$), of desired solvent, typically water, through a reverse osmosis membrane of thickness ℓ (cm) is proportional to the difference between the applied pressure difference, Δp (kPa), and the osmotic pressure difference, $\Delta\pi$ (kPa), across the membrane:

$$N_w = \frac{C_w D_w v_w}{RT} \left(\frac{\Delta p - \Delta\pi}{\ell} \right) \quad (63.9)$$

where C_w is the concentration of the solvent in the membrane (mol/cm^3), D_w is the diffusivity of the solvent in the membrane (cm^2/sec), and v_w is the partial molar volume of the solvent (cm^3/mol). The solute flux is given as:

$$N_s = \frac{D_s S_s \Delta C_s}{\ell} \quad (63.10)$$

where D_s is the diffusivity of the solute in the membrane and S_s is a dimensionless partition coefficient for the solute in the membrane material. From Equation (63.9) and Equation (63.10) it is apparent that the solvent flux increases as the pressure applied to the feed is raised, whereas the solute flux does not increase. Thus, by increasing the pressure, rejection of the solute may be 99% or higher.

63.3 Gas and Vapor Separations

Gas separation membranes are starting to compete well with more mature separation technologies, such as pressure swing adsorption and cryogenic distillation, because they are simple in construction, modular in nature, and economical. Development of membrane materials for separation purposes depends on the targeted application. In the most general sense, a membrane material should be chemically and physically stable under anticipated operating conditions, have the productivity and selectivity dictated by process volume and economics, and be conveniently fabricated into modular membrane form. Specifically, materials may be tailored to carry out separations based on size and shape or chemical properties of the penetrants. Because they offer a broad range of functional and structural conformations and are economical ($\sim \$2.0/\text{ft}^2$), polymers are the most frequently used membrane materials and, therefore, the focus of the following discussion. Polymers cannot, however, easily be used in extreme temperature and harsh chemical conditions. For extreme operating conditions, specialty membranes comprised of ceramics, metals, and carbons are also available.

In an idealized sense, gas separation membranes act as molecular-scale filters separating a feed mixture of A and B into a **permeate** of pure A and nonpermeate (**retentate**) of pure B. Figure 63.3 shows that gas separations by membranes can be performed using four types of transport mechanisms: Knudsen diffusion, solution–diffusion, molecular sieving, and selective surface flow. Transport through dense polymeric membranes is best described using the solution–diffusion mechanism. Transport through these materials occurs due to the thermally activated motion of polymer chain segments that create penetrant-scale transient gaps in the matrix, allowing diffusion from the upstream to the downstream side of the membrane.

The driving force for gas separation is the transmembrane partial pressure typically achieved by pressurization of the feed gas. The permeability of the polymer for component i , P_i , is defined as:

| | | |
|------------------------|--|--|
| Knudsen Flow | | Separation is based on the inverse square root ratio of the molecular weights of A & B. Selectivity is very limited. |
| Solution – Diffusion | | Separation is based on both solubility and diffusive considerations. In polymers, transient gaps allow diffusive “jumps” by the penetrants. Permeability and selectivity are limited. |
| Molecular Sieving | | Separation in rigid ultramicroporous materials is based primarily on the much higher diffusion coefficients of the <i>smaller</i> penetrant, but sorption may be important for similarly sized molecules. Selectivity can be infinite. |
| Selective Surface Flow | | Separation in rigid microporous materials is based on the much higher sorption affinity of the more <i>condensable</i> penetrant, which is usually the larger penetrant. Selectivity can be very high. |

FIGURE 63.3 Transport mechanisms for gas separations.

$$P_i = \frac{N_i}{(\Delta p_i / \ell)} \quad (63.11)$$

where N_i is the gas flux [cm^3 (STP)/($\text{cm}^2 \cdot \text{sec}$)], Δp_i is the partial pressure difference between the upstream and downstream faces of the membrane (cm Hg), and ℓ is the thickness of the selective layer of the membrane (cm). Polymer permeabilities are often expressed in Barrers:

$$1 \text{ Barrer} = \frac{10^{-10} \text{ cm}^3 \text{ (STP)} \cdot \text{cm}}{\text{cm}^2 \cdot \text{cmHg} \cdot \text{s}} \quad (63.12a)$$

Closely related is the measure of productivity, known as *permeance*, through an asymmetric membrane. The permeance, P/ℓ , is simply a pressure normalized flux, and is expressed in Gas Permeation Units, or GPUs:

$$1 \text{ GPU} = \frac{10^{-6} \text{ cm}^3 \text{ (STP)}}{\text{cm}^2 \cdot \text{cmHg} \cdot \text{s}} \quad (63.12b)$$

The permeation of penetrants occurs due to a solution–diffusion mechanism, so the permeability coefficient is expressed as a product of two terms:

$$P_i = D_i S_i \quad (63.13)$$

where D_i is the average diffusion coefficient of the penetrant across the membrane (cm^2/sec) and S_i is the effective solubility coefficient of the penetrant in the membrane [cm^3 (STP)/($\text{cm}^3 \cdot \text{cm Hg}$)]. The solubility coefficient is defined as:

$$S_i = C_i / p_i \quad (63.14)$$

where C_i is the concentration of the penetrant i in the polymer [cm^3 (STP)/ cm^3] at equilibrium when the external partial pressure is p_i (cm Hg).

The ideal separation factor, $\alpha_{A/B}^*$, is based on the individual permeabilities of two gases A and B and is given as:

$$\alpha_{A/B}^* = \frac{P_A}{P_B} \quad (63.15)$$

The ideal separation factor provides a measure of the intrinsic **permselectivity** of a membrane material for mixtures of A and B. In the absence of strong polymer-penetrant interactions, $\alpha_{A/B}^*$ in mixed feed situations can typically be approximated to within 10 to 15% using the more easily measured ratio of permeabilities of pure components A and B. If Equation (63.13) is substituted into Equation (63.15), the ideal separation factor can be separated into two parts;

$$\alpha_{A/B}^* = \left[\frac{D_A}{D_B} \right] \left[\frac{S_A}{S_B} \right] \quad (63.16)$$

where D_A/D_B is the diffusivity selectivity and S_A/S_B is the solubility selectivity. The diffusivity selectivity is determined by the ability of the polymer to discriminate between the penetrants based on their sizes and shapes and is governed by intrasegmental motions and intersegmental packing. The sorption selectivity is thermodynamic in nature and depends on the condensability of the components, polymer/penetrant interactions, and free volume within the polymer.

The actual separation factor between two components A and B is defined in terms of permeate (Y_A and Y_B) and feed (X_A and X_B) mole fractions.

$$SF = \frac{(Y_A / Y_B)}{(X_A / X_B)} \quad (63.17)$$

Equation (63.17) can be written in terms of D and S but also includes partial pressure terms.

$$SF = \left[\frac{D_A}{D_B} \right] \left[\frac{S_A}{S_B} \right] \left[\frac{\Delta p_A / P_{A,feed}}{\Delta p_B / P_{B,feed}} \right] \quad (63.18)$$

From Equation (63.18) it is apparent that the actual separation factor may be less than the ideal selectivity. Also apparent is that when the downstream pressure is nearly zero, Equation (63.18) simplifies to Equation (63.16).

The above equations represent the most common methods of evaluating membrane performance for ideal gas separations. For nonideal gases under high pressures, fugacity driving forces and possible bulk flow phenomena should be addressed [Kamaruddin and Koros, 1997]. In practical membrane applications, the retentate and permeate pressures will be nonzero, and the driving force varies along the surface

of the membrane. Under these realistic conditions, even more complex analysis is needed to account for the variations of driving force terms used in Equation (63.18) [Koros and Fleming, 1993].

Applications of membrane-based gas separation technology tend to fall into four major categories: hydrogen separation from a wide variety of slower-permeating **supercritical** components such as CO, CH₄, and N₂; acid gas (CO₂ and H₂S) separation from natural gas; oxygen or nitrogen enrichment of air; and vapor/gas separations, including gas drying and organic vapor recovery.

The order of the various types of gas–gas applications given in this list provides a qualitative ranking of the relative ease of performing these three types of separations. The fourth application, involving the removal of vapors from fixed gases, is generally carried out with the use of rubbery polymers, whereas the first three applications rely upon glassy materials.

The first large-scale applications of membranes for gas separation were for hydrogen recovery. The most well-known recovery processes include H₂ recovery from ammonia purge gas, the separation of H₂ from CO to optimize the reactant stoichiometry for methanol production, and the separation of H₂ from fuel gas [Lee and Koros, 2002]. The extraordinarily small molecular size of H₂ makes it highly permeable through membranes and easily collected as a permeate product compared to many larger-sized gases such as N₂, CH₄, and CO.

Acid gases such as carbon dioxide and hydrogen sulfide can be found in large quantities in natural gas streams. These components are responsible for the “sour” nature of gases from various sources, and their removal from the fuel improves the heating value of the gas and also helps reduce corrosion of pipelines and transmission equipment [Lee and Koros, 2002]. The relatively high solubilities of CO₂ and H₂S in membranes at low partial pressures, coupled with the low diffusivity and solubility of the bulky supercritical methane molecule, give high membrane productivity for these penetrants with good selectivity over CH₄.

The products of air separation, oxygen and nitrogen of various purities, can be utilized in many applications. Combustion efficiency and biochemical processes benefit from oxygen-enriched air containing 30–40% O₂. Nitrogen at 90–99% purity provides an inert atmosphere useful in many applications, including blanketing fuel storage tanks and pipelines to minimize fire hazards, reducing oxidation during annealing, and retarding the spoilage of foods during transport and storage. This is intrinsically the most difficult of the three types of gas–gas separations because both the diffusivities and solubilities of this gas pair in most membranes are similar. This leads to similar permeabilities for the two components and thus modest selectivities, rendering high-purity separation difficult. Nevertheless, well-engineered commercial systems do exist for producing nitrogen-enriched air above 99% purity.

Gas drying and organic vapor recovery from air or nitrogen are both important separations on which membrane technology has a significant impact. Increasing environmental awareness and the rising costs of energy and chemicals have resulted in efforts aimed at using membrane processes as a means of recovering those resources. The separation of vapors from gases is easily accomplished in rubbery polymers because of the condensable vapor’s high solubility selectivity coupled with the near unity diffusivity selectivity. The resulting overall selectivity is quite high. Silicone rubber is a common choice for such applications since it offers high transport rates. This type of separation requires great care to minimize excessive partial pressure buildup of the vapor in the permeate. In many cases a sweep gas or partial vacuum is utilized to reduce the permeate partial pressure buildup at the downstream face of the membrane.

63.4 Vapor–Liquid Separations

Pervaporation is a membrane-mediated evaporation process for separating liquid mixtures. The rate of evaporation of each liquid is governed by the permeability of the component through the separating material. A closely related process utilizes a saturated vapor feed. By either using a vacuum or providing a sweep stream on the downstream side of the membrane, the permeate is collected and either condensed as a liquid or continuously withdrawn. The final composition of permeate is dictated by the composition of the feed stream, which establishes the inherent driving force for transport, and by the permselectivity

of the membrane. The separation factor for the pervaporation process, β_{pervap} , is the product of the evaporation separation factor, β_{evap} , and the membrane separation factor, β_{mem} , as shown below:

$$\beta_{\text{pervap}} = \beta_{\text{evap}} \cdot \beta_{\text{mem}} \quad (63.19)$$

At low permeate pressures, the membrane separation factor, β_{mem} , is simply equal to the ratio of permeability of the individual components. This is completely analogous to the previous discussion of ideal selectivity in gas separations (Equation 63.15). As with gas separations, material development is highly dependent on both the characteristics of the mixtures to be separated, process temperatures, and process pressures.

Opportunities exist for pervaporation technology where distillation techniques are cumbersome. This is especially true when the mixtures to be separated have close boiling points and their composition cannot be changed by conventional distillation unless the thermodynamic equilibrium is shifted by adding an additional component. The dominant use of pervaporation technology is in the separation of ethanol from water, though production scale separations of isopropanol and water have also been attained [Lee and Koros, 2002; Kujawski, 1999; Staudt-Bickel and Lichtenthaler, 1994].

63.5 Practical Implementation of Membrane Systems

Most current membranes are made with an asymmetric morphology. In order to increase flux without sacrificing mechanical integrity, asymmetric membranes are composed of a thin separating layer supported by a thicker, porous layer (Figure 63.4). Several methods can be employed to achieve this asymmetric morphology. Integrally skinned or “simple” membrane structures are constructed from a variety of polymers, including cellulose, polyimides, polyamides, and other soluble heterochain polymers such that a single membrane polymer is used for both the support and thin selective layers. Polysulfone is easily formed into porous structures but is difficult to prepare with the truly pore-free skin that is necessary for gas separations. This obstacle is generally overcome using a *caulking* procedure developed by Henis and Tripodi of Monsanto [Henis and Tripodi, 1980]. Another approach involves the generation of a *composite* membrane comprising a nominally unskinned porous support with subsequent attachment of a separating layer. Asymmetric and composite structures permit the preparation of membranes with thin separating skin thicknesses of 1000 Å or less. If the resistance to transport across the porous support layer exceeds roughly 10% of the resistance of the dense selective layer, the efficacy of the membrane is severely limited. This effect places a premium on the ability to generate low-resistance open-celled porous supports.

Once the microscopic morphology of the membrane material itself has been defined (asymmetric, composite, caulked, etc...), there are several choices for membrane module design, including plate-and-frame, spiral-wound, and hollow fiber, as shown in Figure 63.2. Each of the three options has its own advantages and shortcomings.

Plate-and-frame modules are the simplest design, comprised of flat membrane sheets set in stackable frames. Additional membrane area is achieved by increasing the size of the individual membrane sheets, adding additional plates, or by using pleated sheets. The chief advantages are simplicity of design, production, and operation (high flow rates and easy cleaning). Plate-and-frame modules are limited in their surface area-to-volume ratio. This makes them the design of choice for separations that foul easily (see Section 63.6) and do not require high surface areas.

Spiral-wound modules consist of flat membrane sheets layered with spacers and then wound around a central tube. The spacers provide channels for the flow of feed and permeate. Spiral-wound modules retain many of the positive attributes of plate-and-frame modules. Although slightly more difficult to manufacture, operation and cleaning are still relatively simple, and surface area per volume is significantly increased.

The highest surface area-to-volume ratio is achieved in hollow fiber membranes. With areas over an order of magnitude greater than spiral-wound modules of the same volume, hollow fibers dominate markets that require large surface areas where particulate fouling is not a major issue. Area/volume ratio

FIGURE 63.4 Asymmetric membrane structure. (Source: Koros, W.J. 1988. In *Encyclopedia of Chemical Processing and Design*, vol. 29, McKenna, J. J. and Cunningham, W. A., Eds., Marcel Dekker, New York, p. 301. With permission.)

is inversely proportional to the diameter of the hollow fibers. Smaller fibers allow for more area in a confined space but are more difficult to clean and are more susceptible to fouling.

Another critical factor in module design and operation is the driving force for permeation. Separations rely on a difference in the activity of a species between the upstream and downstream sides of a membrane to drive permeation. It is important to establish and maintain this driving force for effective separations to occur. Either the upstream or downstream activity can be influenced in a number of ways. One of the simplest options, pressure, is found in several applications, especially gas separations and reverse osmosis. By increasing the upstream pressure and/or pulling partial vacuum on the downstream, permeation rates are increased. Another common technique found in many separations is the use of a downstream sweep. In hemodialysis, for example, clean dialysate flowing on the downstream side of the membrane sweeps toxins away, maintaining a near-zero activity and constant driving force for permeation.

Other design considerations include flow patterns, temperatures, pressures, and integration of the membrane unit into the overall process. Numerous articles have been published on design considerations for a variety of applications, including air separation [Ho and Sirkar, 1992], natural gas purification [Tabe-Mohammadi, 1999], petrochemical gas/vapor separations [Baker et al., 1998], and desalination [Matsura, 2001]. These authors and others [Bhide and Stern, 1991a and b; Prasad et al., 1994] also consider the economics of membrane separations for various applications and compare them to competitive technologies. During the design phase, it is also helpful to have a predictive model to assist in sizing the system. One example is the model published by Kovvali et al. [1994] for gas separation with hollow fibers, and numerous models exist for other flow patterns and module designs.

63.6 Practical Membrane Challenges

Membrane research often leads to materials that are ideal candidates for separations when tested in the lab. If the specific feed conditions (e.g., contaminants and minor components) are not carefully matched to the membrane material and configuration, field use can result in below-optimum performance. Membranes will often perform well initially, but over time their performance will deteriorate, usually in

the form of reduced selectivity. Replacement costs must be factored into operating costs when considering membrane economics. Membrane modules are designed to be easily replaced, but if performance can not be maintained for at least 6 to 12 months, replacement costs may become prohibitive. Several factors can contribute to this performance decline, including physical aging, feed fluctuations, and mechanical instability. However, the two main challenges are fouling and chemical stability.

Fouling (e.g., scale formation, microbial growth) occurs when the surface of a membrane becomes contaminated, limiting the productivity of the membrane. Contaminants in a feed stream that are too large to permeate, but are unable to diffuse away or be swept along with the retentate due to interactions with the membrane or insufficient feed flow, will often collect on the upstream side of a membrane. Over time, a layer can build up that significantly increases the resistance of the membrane, reducing productivity. Because this additional resistive layer is not selective, selectivity frequently decreases as well. In order to deal with these issues, systems that are prone to fouling must be designed to accommodate regular cleaning. Cleaning options include physical scrubbing, back-flushing, and chemical cleaning.

Concentration polarization is another deleterious effect that can precede fouling. In this case, a decline in productivity is not caused by the additional permanent resistance of a physical boundary layer, but is due to a boundary layer that must be crossed before permeation through the membrane can occur. Thus, even if the bulk feed composition remains constant, the lower concentration at the membrane interface results in decreased productivity. This effect can often be reduced by increasing the feed flow rate to more effectively shear and thin the boundary layer. Intelligent initial module design can also minimize concentration polarization.

The chemical stability of membranes must also be considered, particularly for those that involve sensitive solution–diffusion transport mechanisms. For example, carbon dioxide and larger hydrocarbons and aromatics will often interact with polymer membranes to cause *plasticization*. This occurs when the penetrant's effect on the polymer matrix is an increase in polymer chain mobility, causing permeability to rise and selectivity to fall. Many of the more aggressive gas separation applications encounter this challenge, including natural gas sweetening and treatment of streams containing aggressive hydrocarbon components.

Pretreatment is one common method for preventing performance decline due to either fouling or plasticization. A coarse filter placed before a solution–diffusion membrane can be effective in removing the particulates that might cause fouling. One major chemical contaminant is water, which could be removed from a gas stream via a coalescing filter before it adversely affects a membrane. Within the membrane itself, modifications can also be made to improve stability. Biofouling in aqueous feeds, for example, can be reduced by modifying the surface of a membrane to make it inhospitable for the organisms that would otherwise accumulate and cause fouling. Several material options are currently under investigation for the reduction of plasticization effects in polymeric membranes. One of the most promising approaches is the use of *crosslinked* membrane materials. By crosslinking the polymer matrix, penetrant-induced chain mobility is reduced, and polymeric membranes are able to withstand much more aggressive feeds without losing selectivity over time.

63.7 Future Directions of Membrane Technology

Mixed Matrix Approach

Though membrane technology has made great strides in increasing productivity and selectivity in large-scale applications such as O_2/N_2 separations, simply maintaining this performance is not sufficient for capturing new markets. To capture the increased selectivity of inorganic zeolites and carbon molecular sieves, while also maintaining the superior processability of polymers, heterogeneous membrane structures are being considered. In these *mixed matrix* materials, high selectivity inserts, such as zeolites or carbon molecular sieves, are embedded in a polymer matrix producing a material that has selectivities well beyond state of the art polymer matrices [Mahajan and Koros, 2000]. The insert may operate either via a molecular sieving mechanism or a selective surface flow mechanism. Molecular sieves favor smaller molecules, while

selective surface flow inserts tend to favor larger, more condensable molecules. Thus, the mixed matrix approach can ideally be used to separate both large and small molecules from feed streams.

Fuel Cell Technology

Fuel cells are electrochemical devices that directly convert available chemical free energy in a fuel into electrical energy. The fuel cell assembly consists of an ion conducting film sandwiched between two platinum-based electrodes. Hydrogen fuel is supplied to the anode while an oxidant is applied to the cathode. Hydrogen dissociates at the anode to yield electrons and protons. These protons migrate through a proton exchange membrane, such as Nafion, while the electrons travel to the cathode through an external circuit. The protons and electrons react with oxygen at the cathode to produce water and heat. The driving force for the reaction manifests itself in the voltage that drives the electrons through the external circuit [Singh, 1999].

Fuel cells have a large advantage over traditional mobile energy generation because of the inherent efficiency (twice as high as internal combustion engines) and negligible emissions. There are still a number of technical issues to overcome prior to large-scale commercialization, including developing the means of supplying the fuel safely and lowering the cost of the membrane. However, once these hurdles are overcome, fuel cell technology has the potential for a large economic and environmental impact [Lee and Koros, 2002].

Controlled Release Materials

A large concern in the pharmaceutical sector is delivering drugs effectively at a constant dosage over an extended period for the required therapeutic effect. Membrane materials developed for these controlled release applications are an effective approach for safe and timely drug delivery. Delivery can be either passive or active. In passive controlled release, a pharmaceutical agent can be dissolved in excess of its solubility limit in a membrane-surrounded reservoir. The excess agent maintains saturation conditions and provides a constant permeation driving force to supply solute to the external sink at a constant rate until the concentration drops below saturation. The release rate of the agent depends on its solubility and diffusivity in the membrane, and can be tuned by tailoring the properties of the membrane. In active controlled release, the membrane is able to respond and alter its permeability to a pharmaceutical agent as the body environment changes. An example is an active controlled release membrane that responds to changes in glucose levels in the body by changing its permeability to insulin. This approach combines biosensing and control functions in a single membrane device.

63.8 Conclusions

In their simplest form, membranes can separate mixtures based on size exclusion principles, and in their most complex, they can act as sophisticated biosensing agents that alter permeation properties with the changing environment. They have a broad spectrum of potential and established uses, and when optimized, are simple, modular, and economical devices that have successfully been implemented in industrial processing environments [Hagg, 1998]. This chapter has focused on the basic principles that are core to the development, implementation, and stabilization of membranes for use in reverse osmosis, dialysis, gas/vapor, and vapor/liquid separations.

Shiao-Hung Chiang
University of Pittsburgh

Solid–liquid separation plays a key role in nearly all manufacturing industries, including chemical, mineral, paper, electronics, food, beverage, pharmaceutical, and biochemical industries, as well as in energy production, pollution abatement, and environmental control. It also serves to fulfill vital needs of our daily life, since we must have cartridge oil/fuel filters for operating an automobile, a paper filter for the coffee machine, a sand filter bed for the municipal water treatment plant, and so on. In fact, modern society cannot function properly without the benefit of the solid–liquid separation.

Technically, solid–liquid separation involves the removal and collection of a discrete phase of matter (particles) existing in a dispersed or colloidal state in suspension. This separation is most often performed in the presence of a complex medium structure in which physical, physicochemical and/or electrokinetic forces interact. Their analysis requires combined knowledge of fluid mechanics, particle dynamics, solution chemistry, and surface/interface sciences.

Although the industrial equipment classified as solid–liquid separation devices are too numerous to be cited individually, it is generally accepted that these may be grouped into six categories of unit operations: (1) **screening**, (2) **sedimentation**, (3) **centrifugation**, (4) **hydrocycloning**, (5) **flotation**, and (6) **filtration**.

64.1 Unit Operations in Solid–Liquid Separation

A description of each unit operation in solid–liquid separation is presented in this section with the exception of filtration. Liquid filtration, one of the most commonly used industrial operations, is discussed separately in subsequent sections to illustrate the fundamental concept and design considerations for solid–liquid separation.

Screening

Screening is the simplest mechanical operation to separate solid particles based on their sizes. When solids are placed on a screen, particles smaller than the screen opening pass through while the larger particles are retained by the screen. In this manner, feed solids can be separated into two different parts,

namely, the undersized and the oversized portions. Often two or more screens of graded openings are used in series to separate a material into different size fractions. In many instances, screening is used as an analytical tool to determine particle size distribution in a sample of solid material. The particle size distribution can be used as a basis for equipment selection in solid–liquid separation (see Section 64.2 below). In addition to size separation, an important usage of screening is to perform mechanical dewatering (often combined with washing) of solid materials [Svarovsky, 1985]. For industrial applications, screens are made of various metals in the forms of wire mesh and slotted or perforated plates. The openings of standard screens range from 10 cm (4 in.) down to as small as a few micrometers. In screening operations, mechanical vibration and shaking are often applied to the screen surface to enhance the effectiveness of separation [Perry and Green, 1997].

Sedimentation

Sedimentation is a unit operation designed to separate suspended solid from a liquid stream by particle settling under the influence of a body force, most commonly gravity. From an operation standpoint, gravity sedimentation can be divided into two basic types: clarification and thickening. The objective of clarification is to remove small quantities of suspended particulates from the liquid stream to produce a clarified effluent or overflow stream. On the other hand, thickening is to concentrate dilute suspensions for their subsequent treatment in filters or centrifuges.

The settling behavior of suspended particulates in a gravitational field is affected by three factors: the particle size, the solid concentration, and the aggregation status of particles. In a dilute suspension, the settling solid behaves as individual particles and the process is regarded as *particulate or free settling regime*. Most clarifier operations fall into this regime. As the solid concentration increases, the suspended particles have more chances to approach each other closely and to form aggregates. Once the concentration reaches a level at which the suspended particles settle as a mass, the corresponding sedimentation is known as *hindered or zone settling*. In this regime, the settling behavior is related more to the solid concentration than to the particle size. As the solid concentration increases further, a settled bed of sediment mass is compressed by the overburden of sediment on top of it. Liquid is expressed from the lower sediment layers and flows upward through the sediment. This regime is termed *compression regime*. Sedimentation with the addition of chemical flocculant usually falls into this regime. A feed suspension in a thickener (or clarifier) can be operated in any regime. Therefore, the design of sedimentation equipment must consider all three regimes.

Figure 64.1 shows a schematic diagram of a thickener that exhibits three distinct zones: a clean liquid (or clarification) zone at the top, a compression zone at the bottom, and a transition zone in between. The thickener consists of several basic components: a tank to contain the slurry, a feed well for feed supply (with or without flocculant), a rotating rake mechanism, an underflow solids-withdrawal and an overflow launder. In addition, an underflow recirculation system (not shown in the diagram) is often used. The physical size of a conventional thickener can vary from a few meters to more than 100 meters in diameter. For the operation of large vessels, careful consideration must be given to the design of the supporting structure for the rotating rake mechanism and the control scheme for liquid levels and flow rates. Detailed descriptions of major components and instrumentations used for different types of thickeners can be found in the literature [Perry and Green, 1997; Schweitzer, 1997].

Centrifugation

Centrifuges are equipment that employs centrifugal force for the effective separation of solid–liquid suspension. The centrifugal force used in such equipment ranges up to 10,000 times the gravitational acceleration. Liquid–solid separation centrifuges can be broadly divided into two types: **sedimentation centrifuges** and **filtering centrifuges**.

Due to its much stronger force field, **sedimentation centrifuges** can be used to separate very fine particles as well as emulsions, which might normally be stable in a gravitational field. These centrifuges

FIGURE 64.1 Schematic diagram of thickener operation.

are not usually sensitive to feed solid concentration because the liquid does not have to move through the solids or a medium. In order for a particle of a given size to be removed from the liquid, a sufficient time should be allowed for the particle to settle and reach the wall of the separator bowl. For example, in a simple tubular centrifuge, as shown in Figure 64.2, the bowl consists of a vertical tube with a large height to diameter ratio, which rotates at a high speed about its vertical axis [McCabe et al., 2001]. The feed point is at the bottom and the liquid discharge is at the top. The incoming suspension starts to rotate with the bowl, and its angular velocity will soon become identical with that of the bowl. There is therefore no tangential flow in the bowl. The rotating liquid moves upward through the bowl at a constant velocity, carrying solid particles with it. In the meantime, under the influence of high centrifugal forces the solid particles begin to settle toward the wall. The total settling time is limited by the residence time of the liquid in the bowl. At the end of this time if the particle does not reach the wall, it leaves the centrifuge with the liquid. Only those particles that reach the wall within the residence time are removed from the liquid.

Filtering centrifuges separate solid particles and liquid from a solid-liquid suspension by employing pressure resulting from the centrifugal action to force the liquor through the filter medium, leaving the solid particles behind [Zeitsch, 1990]. The density difference between the solids and the liquid, which governs the sepa-

FIGURE 64.3 Schematic diagram of hydrocyclone: (a) principal features and (b) flow pattern.

ration in the **sedimentation centrifuges**, is no longer a prerequisite. The common feature of all filtering centrifuges is a rotating basket having a slotted or perforated wall covered with a filter medium, such as canvas or metal cloth, on which the deposited solid particles form a filter cake. Thus, the centrifugal filtration can be viewed as a cake filtration process under constant pressure (due to centrifugal acceleration). The rate of filtration can be calculated using the two-resistance model for cake filtration (see Section 64.4 below).

Hydrocycloning

The hydrocyclone is another device using centrifugal force to separate solids from liquid based on differences in density and particle size. A typical hydrocyclone consists of a cylindrical section and a conical section (with no internal rotating parts) as shown in Figure 64.3. An external pump is used to transport the liquid suspension to the hydrocyclone through a tangential inlet at high velocity, which in turn generates the liquid rotation and the necessary centrifugal force. The outlet for the bulk of the liquid is connected to a vortex finder located on the axis of upper cylindrical section of the vessel. The underflow, which carries most of the solids, leaves through an adjustable opening (apex) at the bottom of the conical section. It should be noted that the solid–liquid separation in hydrocyclones is never complete because there is always a significant amount of liquid discharging with the solids through the underflow. This feature limits the applications of hydrocyclone to clarification and thickening. In some cases, the hydrocyclone is also used as a classifier to separate suspended particles into different size fractions.

The internal working of a hydrocyclone is best described in terms of a double spiral liquid flow pattern within its body [Kelsall, 1952; Rushton et al., 2000; and Svarovsky, 1985]. A schematic view of the spiral flow inside a hydrocyclone is shown in Figure 64.3(b). Liquid on entry commences downward flow in the outer regions of the hydrocyclone body. This combined with the rotational motion to which it is constrained creates the outer spiral. At the same time, some of the downward-moving liquid begins to feed across towards the center. The amount of inward motion of liquid increases as it approaches the cone apex. Liquid in this inward stream ultimately reverses its direction and flows upwards to the cyclone overflow outlet via the vortex finder. The reversal applies only to the vertical component of velocity, and the inner spiral rotates in the same circular direction as the outer one. Wall friction causing “obstruction” of tangential velocity results in a nontangential motion. Consequently, a strong axially directed current occurs near the wall, which carries solid particles to the apex opening and out of the hydrocyclone. Thus, it achieves the desired solid–liquid separation.

Flotation

The use of bubbles to float fine particles in a liquid is commonly known as *flotation process*. Such a process consists of attaching gas bubbles to the suspended solid particles to alter their apparent density for selective levitation of particles to be separated. The flotation operation involves not only the adhesion of small particles to gas bubbles, but also the collection of the gassy particles in the form of froth. Thus, the bubble flotation is also named as *froth flotation*.

The flotation process is fundamentally different from other mechanical separation techniques in that flotation is a surface property-driven process, which depends upon complex phenomena occurring at the interface of solid particles and gas bubbles [Fuerstenau et al., 1985; Jaycock and Parfitt, 1981; and Zettlemoyer, 1969]. In a bubble-particle attachment process, the tendency of the particle to replace its solid-liquid interface by the solid-vapor interface is termed hydrophobicity or floatability. If a surface is completely wetted by water, it would be denoted as high-energy surface (i.e., hydrophilic). Most metals and minerals exhibit high-energy surfaces. On the other hand, hydrocarbon surfaces are low energetic (i.e., hydrophobic). The particles with a low free energy have a high floatability.

The contact between particles and gas bubbles in a suspension is considered as a two-step process: (1) the collision between the particle and the bubble and (2) the attachment of the particle onto the gas bubble. Each step can be modeled as a stochastic event. Thus, the overall probability of particle collection by gas bubble is defined as the product of the probability of particle-bubble collision and the probability of adhesion after the collision. The collision probability depends mainly on the hydrodynamic characteristics of the flotation cell while the adhesion probability is related to the hydrophobicity of the particle.

Traditionally, flotation is carried out in an open cell equipped with a gas-inducing agitator (turbine or impeller). As shown in Figure 64.4, air is induced through the air passage in the agitator shaft by suction. The rotational motion of the agitator disperses air bubbles into the suspension. These bubbles attach to suspended particles to form *aggregates*. The particle-bubble aggregates float upward to the froth layer, which is mechanically skimmed off or flows over a weir into the discharge launder as a froth product. The nonfloatable particles are withdrawn from the bottom of the cell as tailings. A more recent development in flotation is the use of bubble column as a flotation device [Finch et al., 1995]. In Figure 64.5, it shows that the space in a flotation column can be divided into two parts: the collection zone and the froth zone. The feed enters the column via a feed port at the middle and flows downward to the base of the column. The gas bubbles are generated either by an internal sparger near the bottom of the column or an external gas bubble generator. To minimize the effect of unexpected particle entrainment, a wash water device is added near the top of the column just below the overflow weir for cleaning the froth. The operating performance of a flotation column is generally superior to that of open cell flotation.

FIGURE 64.4 Conventional open-cell flotation.

FIGURE 64.5 Column flotation.

64.2 Equipment

The most important criterion for the selection of equipment for a given application of solid-liquid separation is the particle size of the system. Figure 64.6 shows the general range of applicability of major types of equipment in terms of the particle size and representative materials involved. Of course, this representation is an oversimplification of the selection process, as many other factors are not considered. For example, the solid concentration in the feed mixture (suspension) can influence the choice of equipment type. In general, deep-bed filtration is best for treating dilute slurry with solid concentration less than 1%, whereas cake filtration is the method of choice for slurries having solid concentration much greater than 1%.

FIGURE 64.6 Equipment selection for solid-liquid separation based on particle size.

TABLE 64.1 Filtration Equipment

| Discontinuous Filters | Semicontinuous Filters | Continuous Filters |
|------------------------------|----------------------------|-------------------------------------|
| Plate and frame filter press | Rotary pan filter | Drum filter |
| Leaf filter | Semicontinuous belt filter | Rotary disk filter |
| Tray filter | Automatic filter press | Vacuum belt filter |
| | Electrical precipitator | Rotary disk cross-flow filter |
| | | Rotating cylinder cross-flow filter |

It should also be pointed out that the various filtration processes (deep-bed filtration, cake filtration, microfiltration, and ultrafiltration) cover nearly the entire range of particle size. Therefore, the term *filtration* is often used as a synonym to represent the field of *solid–liquid separation*. The most commonly used filtration equipment is given in Table 64.1.

A detailed procedure for equipment selection for a given requirement in solid–liquid separation can be found in *Perry’s Chemical Engineers’ Handbook* [Perry and Green, 1997].

64.3 Fundamental Concept

There are two general types of operations for separating solid particulate matter from a liquid phase. In the first type, the separation is accomplished by moving the particles through a constrained liquid phase. The particle movement is induced by a body force, such as gravity or centrifugal acceleration. For example, in sedimentation, the solid particles settle due to a difference in density between solid and liquid under the influence of gravity. In centrifugation and hydrocycloning, the separation is effected by centrifugal acceleration.

In the second type of operation, exemplified by the filtration process, the separation is accomplished by contacting the solid–liquid suspension with a porous medium (see Figure 64.7). The porous medium acts as a semipermeable barrier that allows the liquid to flow through its capillary channels and retains the solid particles on its surfaces. Depending on the mechanism for arrest and accumulation of particles, this type of separation can be further divided into two classes [Perry and Green, 1997]: deep-bed filtration and cake filtration.

Deep-bed filtration is also known by terms such as *blocking filtration*, *surface filtration*, and *clarification* [see Figure 64.7(b)]. This type of filtration is preferred when the solid content of the suspension is less than 1%. In such an operation, a deep bed of packing material (e.g., sand, diatomite, or synthetic fibers) is used to capture the fine solid particles from a dilute suspension. The particles to be removed are several orders of magnitude smaller than the size of the packing material, and they will penetrate a considerable depth into the bed before being captured. The particles can be captured by several mechanisms [Tien, 1989]:

1. The direct-sieving action at the constrictions in the pore structure
2. Gravity settling
3. Brownian diffusion
4. Interception at the solid–liquid interfaces
5. Impingement
6. Attachment due to electrokinetic forces

Cake filtration is the most commonly used industrial process for separating fine particles from a solid–liquid suspension. In cake filtration, the filtered particles are stopped by the surface of a filter medium (a porous barrier) and then piled upon one another to form a cake of increasing thickness [see Figure 64.7(a)]. This cake of solid particles forms the “true” filtering medium. In the case of liquid filtration, a filter cake with filtrate (the liquid) trapped in the void spaces among the particles is obtained at the end of the operation. In many instances where the recovery of the solids is the ultimate objective, it is necessary that the liquid content in the cake be as low as possible. In order to reduce the liquid

FIGURE 64.7 Mechanisms of filtration: (a) cake filtration, (b) deep-bed filtration, (c) cross-flow filtration (ultrafiltration). (Source: McCabe, W. L., Smith, J. C., and Harriott, P. 2001. *Unit Operations of Chemical Engineering*, 6th ed., Figure 29.3, p. 992. McGraw-Hill, New York.)

content, the cake is subjected to desaturating forces. These forces can be mechanical, hydrodynamic, electrical, or acoustic in nature [Muralidhara, 1989].

When the mean particle size is less than a few micrometers, the conventional cake filtration operation becomes ineffective, primarily due to the formation of high-resistance filter cake. To overcome this obstacle, cross-flow filtration (often coupled with ultrafiltration) is used to limit the cake growth. In the cross-flow configuration (e.g., in continuous ultrafiltration), the solid-liquid suspension flows tangentially to the filter medium rather than perpendicularly to the medium as in conventional filtration. The shear forces of the flow in the boundary layer adjacent to the surface of the medium continuously remove a part of the cake and thus prevent the accumulation of solid particles on the medium surface. In this manner, the rate of filtration can be maintained at a high level to ensure a cost-effective operation.

64.4 Design Principles

Cake Filtration

In the design of a cake filtration process, the pressure drop, Δp , the surface area of the cake, A , and the filtration time, t , are important parameters to be determined. As the filtration proceeds, particles retained on the filter medium form a filter cake (see Figure 64.8). For an incompressible cake the pressure drop, Δp , across the filter cake and filter medium can be expressed as:

$$\Delta p = p_a - p_b = \left(\frac{\alpha m_c}{A} + R_m \right) \mu u \quad (64.1)$$

where μ is the viscosity of the filtrate, u is the velocity of the filtrate, m_c is the total mass of solids in the cake, R_m is the filter-medium resistance, and α is defined as the specific cake resistance. The specific cake

FIGURE 64.8 Pressure gradient in filter medium and cake.

resistance depends on particle size, shape, and distribution. It is also a function of porosity of filter cake and pressure drop. For incompressible cakes, α is independent of the pressure drop and the position in the filter cake.

For data analysis, Equation (64.1) is usually rewritten as follows: [McCabe et al., 2001]

$$\frac{dt}{dV} = \frac{\mu}{A(-\Delta p)} \left[\frac{\alpha c V}{A} + R_m \right] \quad (64.2)$$

where t is the filtration time, V is the volume of filtrate, and c is the mass of solid per unit filtrate volume.

In order to use this equation for design of a cake filtration operation, the specific cake resistance and filter-medium resistance must first be determined by performing experimental tests. Equation (64.2) can be further integrated under constant pressure to give:

$$\frac{t}{V} = \left(\frac{K_c}{2} \right) V + \frac{1}{q_o} \quad (64.3)$$

where

$$K_c = \frac{\mu c \alpha}{A^2 \Delta p} \quad \text{and} \quad \frac{1}{q_o} = \frac{\mu R_m}{A \Delta p} \quad (64.4)$$

A plot of t/V against V yields a straight line with a slope of $(K_c/2)$ and an intercept of $(1/q_o)$. Using Equation (64.4), the values of α and R_m can be calculated. For slightly compressible cake, α becomes a function of pressure drop and can be represented by the following correlation:

$$\alpha = \alpha_0(\Delta p)^a \quad (64.5)$$

where α_0 and a are empirical constants.

Equation (64.2) through Equation (64.5) can be used for design calculations for a filtration operation with incompressible and slightly compressible filter cakes. For the case of highly compressible cakes the effect of variations in cake porosity on specific cake resistance must be considered [Tiller and Shirato, 1964].

Ultrafiltration

Ultrafiltration is a membrane process (see Chapter 63 on membrane separation) capable of separating or collecting submicrometer-size particles from a suspension or solution. It has been widely used to concentrate or fractionate a solution containing macromolecules, colloids, salts, or sugars. The ultrafiltration membrane can be described as a sieve with pore size ranging from molecular dimension to a few micrometers. It is usually polymeric and asymmetric, designed for high productivity (permeation flux) and resistance to plugging. Ultrafiltration membranes are made commercially in sheet, capillary, and tubular forms.

In the design of the ultrafiltration process, either batch operation or continuous operation (employing a cross-flow configuration) can be used. In the batch operation, the retentate is returned to the feed tank for recycling through the filter unit. It is the fastest method of concentrating a given amount of material and it also requires the minimum membrane area. In order to determine the membrane surface area, A , for the ultrafiltration process, the following three parameters are required: flux, J , which is a measure of the membrane productivity; permeate, V_p , which is the amount of material that has passed through the membrane; and retentate, V_r , which is the amount of material that has been retained by the membrane. During the batch ultrafiltration operation, flux decreases because of an increase in concentration in the recycled stream. Furthermore, the phenomenon of concentration polarization tends to cause a higher concentration at the membrane surface than that in the bulk. Therefore, an average flux should be used in the design. The average flux, J_{av} , can be estimated by the following equation:

$$J_{av} = J_f + 0.33(J_i - J_f) \quad (64.6)$$

where J_f is the final flux at the highest concentration and J_i is the initial flux. The material balance gives

$$V_f = V_r + V_p \quad (64.7)$$

where V_f , V_r , and V_p are volume of feed, retentate, and permeate, respectively.

The membrane area can be expressed as

$$A = (V_f - V_r)/J_{av} \quad (64.8)$$

Equation (64.6) to Equation (64.8) can be used to estimate the membrane surface area required for a given ultrafiltration operation [Cheryan, 1986].

64.5 Economics

The cost for a given solid–liquid separation process varies widely. For example, the cost for purchasing industrial filtration equipment can vary from several hundred dollars to over ten thousand dollars per square meter of filter area. Such a large variation in cost is due to a wide variety of individual features and materials of construction required by specific applications. A good source of information on the cost of common industrial filtration and other solid–liquid separation equipment can be found in *Perry's Handbook* [Perry and Green, 1997].

Defining Terms

- Cake filtration** — The separation of particles is effected by contacting the solid–liquid suspension with a porous filter medium (made of cloth, synthetic fibers, or metals). The filter medium allows the liquid to flow through its pores while it retains the particles on its surface to form a cake. As filtration proceeds, the cake of solid particles grows in thickness and becomes the “true” filtering medium.
- Centrifugation** — Centrifugation is a separation process based on the centrifugal force either to hold the material in it or to let the material pass through it. Separation is achieved due to the difference in density.
- Hydrocycloning** — Hydrocycloning is a centrifugal separation process. The feed is introduced tangentially into the cylindrical portion of a cyclone, causing it to flow in a tight conical vortex. The bulk of the liquid leaves upward through a pipe located at the center of the vortex. Solid particles are thrown to the wall and discharged with a small portion of the liquid through the bottom apex of the cyclone.
- Deep-bed filtration** — In this type of filtration a deep bed of packing materials, such as sand, diatomite, or synthetic fibers, is used as the filter medium. The particles are captured within the packed bed while the liquid passes through it.
- Flotation** — Flotation is a gravity separation process based either on the use of a dense medium in which the desired particles will float or on the attachment of gas bubbles to particles, which are then carried to the liquid surface to be separated.
- Membrane filtration** — In membrane filtration a thin permeable film of inert polymeric material is used as the filter medium. The pore size of the membrane ranges from molecular dimension to a few micrometers. It is widely used to collect or fractionate macromolecules or colloidal suspensions. It is also applied to beverage filtration and preparation of ultrapure water.
- Screening** — Screening is an operation by which particles are introduced onto a screen of a given aperture size to separate particles of different sizes.
- Specific cake resistance** — Specific cake resistance is the resistance of a filter cake having unit weight of dry solids per unit area of filtration surface.
- Thickening/sedimentation** — Thickening/sedimentation is a gravity-settling process that removes the maximum quantity of liquid from a slurry and leaves a sludge for further processing.
- Ultrafiltration** — Ultrafiltration is a special type of membrane filtration. It is used for concentration and purification of macromolecular solutes and colloids in which the solution is caused to flow under pressure parallel to a membrane surface (in a cross-flow configuration). Solute (or submicrometer particles) are rejected at the semipermeable membrane while the solvents and small solute molecules pass through the membrane.

Simon P. Hanson
CONSOL, Inc.

- 65.1 Sublimation
- 65.2 Diffusional Separations
- 65.3 Adsorptive Bubble Separation
- 65.4 Dielectrophoresis
- 65.5 Electrodialysis

For the purposes of this publication, “other separation processes” will be confined to sublimation, diffusional separations, adsorptive bubble separation, dielectrophoresis, and electrodialysis.

Sublimation is the transformation of a substance from the solid into the vapor state without formation of an intermediate liquid phase. Desublimation is the reverse. **Sublimation processes** may be used to separate solids not easily purified by more common techniques.

Diffusional separation processes may be employed when the substances to be separated are quite similar (e.g., the separation of isotopes). Gaseous diffusion, thermal diffusion, pressure diffusion, and mass diffusion fit this category. Gaseous diffusion provides separation by selectively permitting constituents of a gas mixture to flow through extremely small holes in a barrier or membrane. Molecules of species in the mixture for which the mean free path is smaller than the holes will pass through (i.e., separate), whereas the bulk flow of the gas will not. Thermal diffusion depends on a temperature gradient for separation and applies to liquids and gases.

Use of pressure diffusion for separation of gaseous mixtures has been largely confined to the laboratory, although considerable work has been done on the use of the gas centrifuge for separating isotopes of uranium. The separation method depends on the imposition of a pressure gradient. Mass diffusion involves the separation of a gas mixture by diffusion into a third component, or **sweep gas**. The sweep gas establishes a partial pressure gradient by introducing it as a gas through a porous wall and then letting it condense as a liquid at another region of the process. The sweep gas sweeps the less diffusible component along with it, thus separating this component of the mixture.

Adsorptive bubble separation utilizes the selective attachment of materials onto the surfaces of gas bubbles passing through a solution or, commonly, a suspension [Lemlich, 1966]. The bubbles rise to create a foam or froth that is swept away, allowing the collapse of the bubbles and recovery of the adsorbed material. Additives commonly are included in the suspension to depress the adsorption of some species and enhance the attachment of others. Probably the greatest use of adsorptive bubble separation is in the minerals-processing industries.

Dielectrophoresis (DEP), related electrophoresis, and electrodialysis all depend on electric gradients to effect a separation. Electrophoresis involves the motion of charged particles in a uniform electric field, whereas DEP applies to neutral, polarizable matter in a nonuniform electric field. DEP works best with

larger-than-molecular-sized particles. Electrodialysis is the removal of electrolytes from a solution through an ion-selective membrane by means of an applied electric potential gradient. The primary application of electrodialysis has been the desalination of seawater and brackish water. Most commercial membranes were developed for this purpose.

65.1 Sublimation

Sublimation has been used most often for separation of a volatile component from other components that are essentially nonvolatile. There has been some interest in separating mixtures of volatile components by sublimation [Gillot and Goldberger, 1969].

The vapor pressure of the subliming components must be greater than their partial pressures in the gas phase in contact with the solid. Usually, the solid must be heated and the gaseous environment in contact with the solid must be controlled. Vacuum operation and the use of nonreactive gas or **entrainer** are means of controlling the gaseous environment. The use of vacuum operation has been the most common commercial approach. For pure substances or mechanical mixtures containing only one volatile component, no theoretical limit to the purity of the product obtained in a sublimation process exists.

In a sublimation process comprised of a sublimer (to volatilize the sublimable components) and a condenser (to recover them), the loss per pass of entrainer gas through the system for a system consisting of two sublimable components is

$$\text{Percent loss} = \frac{r(P_{AC} + P_{BC}) / (P_{AS} + P_{BS})}{(1+r) - [(P_{AC} + P_{BC} - \Delta P) / (P_{AS} + P_{BS})]} \times 100 \quad (65.1)$$

where r is the ratio of moles of inert gas (either unavoidable, as in a vacuum operation, or intentional, as with an entrainer) to the moles of solids sublimed (i.e., $r = P_1 / (P_{AS} + P_{BS}) = (P - P_{AS} - P_{BS}) / (P_{AS} + P_{BS})$). P_A and P_B are the vapor pressures of components A and B , subscripts S and C refer to the sublimer and condenser, P_1 is the partial pressure of inert gas, ΔP is the total pressure drop between sublimer and condenser, and P is the total pressure in the sublimer.

To calculate the **yield per pass**, a material balance must be made on the sublimer and condenser using the calculated loss per pass. For vacuum sublimation where recycling of gas is not possible, the yield of condensed solids is simply the percent loss calculated by Equation (65.1) subtracted from 100.

65.2 Diffusional Separations

Gaseous diffusion requires many stages to result in a clean separation. It is probably economically feasible only for large-scale separation of heavy isotopes (e.g., uranium). The flow rate of the gases to be separated across the gaseous diffusion barrier is described by the equations for Knudsen and Poiseuille flow, the combination of which provides

$$N_T = \frac{a}{\sqrt{M}}(P_F - P_B) + \frac{b}{\mu}(P_F^2 - P_B^2) \quad (65.2)$$

where N_T is the molar flow rate of gas per unit area of barrier, a and b are functions of temperature and barrier properties, M is the molecular weight of the gas, P_F and P_B are the high and low side pressures on the barrier, and μ is the gas viscosity. A comprehensive treatment of the design equations for gaseous diffusion is provided by Pratt [1967].

As with gaseous diffusion, thermal diffusion requires many stages to provide a clean separation. Thus, its use has been confined to isotope separations. The preferred equipment for thermal diffusion evolved into the thermal diffusion or thermogravitational column. In the column, the fluid mixture has a horizontal temperature gradient imposed on it. Thermal convection currents create a countercurrent

flow effect providing a large number of individual separation stages in a single piece of equipment. The fundamental equations for separation by thermal diffusion are heavily dependent on the physical properties of the mixture, the properties of the separating column, and the temperatures imposed.

Gas centrifuges and separation nozzles are the tools used to achieve separation by pressure diffusion. In both, a high pressure gradient is created to segregate the lighter components from the heavier ones. The gas centrifuge is the more highly developed. High energy requirements for operation have confined the use of the technology to the separation of mixtures that are very hard to separate (e.g., isotopes). The maximum separative work a gas centrifuge can accomplish per unit time [Olander, 1972] is

$$\Delta U = \frac{\pi ZCD}{2} \frac{(\Delta MV^2)^2}{(2RT)} \quad (65.3)$$

where ΔU is the separation in moles/units time, Z is the length of the centrifuge, C is the molar density, D is the diffusivity of the gas, ΔM is the mass difference between the gases to be separated, V is the peripheral velocity of the centrifuge, T is the absolute temperature, and R is the gas constant.

Mass diffusion can be conducted in continuous countercurrent flow columns. The sweep gas moves in a closed cycle between liquid and vapor and (returns to) liquid. The less diffusible component is enriched at the bottom of the column, and the more diffusible one is enriched at the top of the column. A treatment of the theory is provided in Pratt [1967].

65.3 Adsorptive Bubble Separation

Adsorptive bubble separation techniques are most often employed for the removal of small amounts of either liquid or solids from large amounts of liquid. In its most common use (i.e., **flotation**), fine particulates are removed from liquid. Adsorptive bubble separations can be conducted in staged cells or in columns, the former being the more common type of equipment used. The mechanisms influencing the effectiveness of the separation are adsorption, bubble size and formation, foam overflow and drainage, foam coalescence, and foam breaking. Perry [1984] provides equations applicable to each mechanism. The techniques, in addition to recovery of minerals and coal, have industrial applications in the areas of pollution control, papermaking, food processing, and the removal of organic materials from water.

65.4 Dielectrophoresis

Separation by DEP is dependent on the fact that, in a nonuniform electric field, a net force will act on even neutral particles in a fluid. Particles will behave differently depending on their polarizability. The net force will direct different particles to regions of varying field strength. A series of equations describing the technique is presented in Pohl [1978]. Application of DEP is reasonably widespread and includes electrofiltration to remove particles from a fluid medium, orientation and separation of biological materials (e.g., cells), and imaging processes.

65.5 Electrodialysis

The ion-selective membrane used in electrodialysis is key. Ion-selective membranes are identified as anionic or cationic depending on the ion permitted passage through the membrane. Their electrochemical behavior is characterized by a conductivity, a transference number, and a transport number. The conductivity is simply the amount of current that passes through the membrane per unit of imposed electric potential gradient. The transference number is the amount of any substance transported through the membrane per unit of current. The transport number is the fraction of the current carried by a particular ionic species. The conductivity, transference number, and transport number are similarly defined for the solution in contact with the membrane.

If the transport number for an ionic species in solution differs from that inside a membrane, separation will occur when an electric current passes through the membrane. The effectiveness of an ion-selective membrane is quantified by the *permselectivity*, as defined [Winger et al., 1957] for anionic and cationic membranes, respectively, by the equations

$$\Psi_a = \frac{t_a^m - t_a^s}{1 - t_a^s} \quad (65.4)$$

$$\Psi_c = \frac{t_c^m - t_c^s}{1 - t_c^s} \quad (65.5)$$

where Ψ is the permselectivity, t is the transport number, subscripts a and c designate anion or cation, and superscripts m and s designate membrane or solution. At low solute concentrations, the transport number for anions in an anionic membrane, or cations in a cationic membrane, approaches unity. As the concentration of solute increases, membrane conductivity increases, but the transport number decreases. This is due to compression of the diffuse charge double layer within the membrane's pores such that passage of excluded electrolyte species cannot be prevented.

Electrodialysis is a selective transport process that directly uses electrical energy to effect separation of charged species from a solvent. The theoretical thermodynamic minimum energy to effect a separation [Spiegler, 1958] is given by

$$U = 2RT(C_i - C_{od}) \left[\frac{\log\left(\frac{C_i}{C_{oc}}\right) \log\left(\frac{C_i}{C_{od}}\right)}{\left(\frac{C_i}{C_{oc}} - 1\right) \left(\frac{C_i}{C_{od}} - 1\right)} \right] \quad (65.6)$$

where R is the ideal gas constant, T is the absolute temperature, C is the concentration in equivalents, and the subscripts i , oc , and od indicate the inlet, concentrate outlet, and dilute outlet streams. The direct use of electric energy is most effective at low concentrations since energy is expended only on removing the contaminant. The actual energy consumed is usually 10 to 20 times the theoretical.

Electrodialysis is competitive with other separation processes for low concentration feeds or for situations in which the specificity of electrodialysis makes it uniquely suitable.

Defining Terms

Entrainer — Nonreactive, gaseous diluent used to assist in the sublimation process.

Flotation — The process of removing fine particulate matter from aqueous solution by attachment of the particulate to air bubbles.

Sublimation process — Either one or both of a combination of sublimation and desublimation steps in equipment designed for that purpose.

Sweep gas — The vapor introduced in mass diffusion separations which moves through the process and assists in the separation.

Yield per pass — The amount of the desirable constituent recovered per pass of the entrainer gas through the sublimation process, usually expressed as a percent of the total.

Materials that possess chemical energy are known as *fuels*. The general categories of fuels are fossil fuels, nuclear fuels, and renewable energy sources. Fossil fuels release their chemical energy during combustion. Nuclear fuels are those that release their chemical energy by nuclear reaction.

There are three general classes of fossil fuels — coal, oil, and natural gas. Other fuels, such as shale oil, tar-sand, and fossil-fuel derivatives, are commonly lumped under one of the three main fossil fuel categories.

Fossil fuels were produced from fossilized carbohydrate compounds with the chemical formula $C_x(H_2O)_y$. These compounds were produced by living plants in the photosynthesis process. After the plants died, the carbohydrates were converted by pressure and heat, in the absence of oxygen, into hydrocarbon compounds with a general chemical formula of C_xH_x . Although hydrocarbon compounds are composed of only carbon and hydrogen, in some molecules the same number of hydrogen atoms can be arranged in various structures to produce compounds that are strikingly different in chemical and physical properties.

66.1 Coal

Coal is the most abundant fossil fuel. It is thought to be fossilized vegetation. At least 20 ft of compacted vegetation is necessary to produce a 1-ft seam of coal. The compacted vegetation — in the absence of air and in the presence of high pressure and temperature — is converted into peat (a very low-grade fuel), then brown coal, then lignite, then subbituminous coal, then **bituminous coal**, and finally anthracite coal. As the aging process progresses, the coal becomes harder, the hydrogen and oxygen content decrease, the moisture content usually decreases, and the carbon content increases. Coal is normally found in the earth's crust. The average seam thickness in the U.S. is approximately 1.65 m.

The American Society for Testing Materials (ASTM) has classified coal into four major classes ([Table 66.1](#)) according to the length of its aging process — the oldest being anthracitic coal, followed by bituminous coal, subbituminous coal, and lignitic coal.

TABLE 66.1 ASTM Classification of Coals (ASTM D388)

| Class | Group | Fixed Carbon Limit% (dry mineral matter-free) | | Volatile Matter Limit% (dry mineral matter-free) | | Calorific Value Limit, Btu/lb (moist mineral matter-free) | | Agglomerating Character |
|------------------|------------------------------------|---|--------|--|-------------|---|--------|----------------------------|
| | | = or > than | < than | > than | = or < than | = or > than | < than | |

Selection of a coal for a particular application involves consideration of its specific chemical and physical properties, as well as general factors involving storage, handling, or pulverizing. Factors related to furnace design include volume, grate area, and the amount of radiant heating surface.

Coal Class

The higher-rank coals are classified according to fixed carbon on a dry basis, whereas the lower-rank coals are classified according to heating value (Btu) on a moist basis.

Coal Analysis

The two basic coal analyses are the proximate analysis and the ultimate analysis. In any coal seam there are two components that can show significant variation throughout the seam — the moisture and the ash. The ash fraction varies because ash is essentially the inorganic matter deposited with the organic material during the compaction process. The moisture content of coal varies significantly, depending on the exposure to groundwater before mining and during transportation and the storage before the coal is burned.

The proximate analysis gives the mass fraction of fixed carbon (FC), volatile matter (VM), and ash of the coal. The analysis can be made by weighing, heating, and burning small samples of coal. A powdered coal sample is carefully weighed and then heated to 110°C (230°F) for 20 min. The sample is then weighed again; the mass loss divided by the original mass gives the mass fraction of moisture (M) in the sample. The remaining sample is then heated to 954°C (1750°F) in a closed container for 7 min, after which the sample is weighed. The resulting mass divided by the original mass is equal to the mass fraction of volatile matter in the sample.

The sample is then heated to 732°C (1350°F) in an open crucible until it is completely burned. The residue is then weighed; the final weight divided by the original weight is the ash fraction (A). The mass fraction of fixed carbon is obtained by subtracting the moisture, volatile matter, and ash fraction from unity. In addition to the FC, the VM, the M, and the A, most proximate analyses list separately the sulfur mass fraction (S) and the higher heating value (HHV) of the coal.

The ultimate coal analysis is a laboratory analysis that lists the mass fraction of carbon (C), hydrogen (H₂), oxygen (O₂), sulfur (S) and nitrogen (N₂) in the coal along with the higher heating value (HHV). It also lists the moisture, M, and ash, A. This analysis is required to determine the combustion-air requirements for a given combustion system and the size of the draft system for the furnace.

The Heating Value (Btu)

The heating value represents the amount of chemical energy in a pound mass of coal (Btu/lbm) on a moist basis. There are two heating values — a higher or gross heating value (HHV) and a lower or net heating value (LHV). The difference between these two values is essentially the latent heat of vaporization of the water vapor present in the exhaust products when the fuel is burned in dry air. In actual combustion systems, this includes the water present in the fuel as burned (the moisture) and the water produced from the combustion of hydrogen, but it does not include any moisture that is introduced by the combustion of air.

Agglomerating Character

Coals are considered agglomerating if, in a test to determine the amount of volatile matter, they produce either a coherent button that will support a 500 g weight without pulverizing or a button that shows swelling or cell structure.

Fixed Carbon (FC) Limit

Two formulas used for calculating the fixed carbon limit, on a mineral matter-free (mm-free) basis, are the Parr formula,

$$\text{Dry, mm-free FC} = \frac{\text{FC} - 0.15\text{S}}{100 - (1.08\text{A} + 0.55\text{S})} \times 100 \quad (66.1)$$

and the approximate formula,

$$\text{Dry, mm-free FC} = \frac{\text{FC}}{10 - (M + 1.1\text{A} + 0.1\text{S})} \times 100 \quad (66.2)$$

Coal Heating Value

Two formulas are used for calculating the coal heating value: the Parr formula,

$$\text{Moist, mm-free Btu} = \frac{\text{Btu} - 50\text{S}}{100 - (1.08\text{A} + 0.55\text{S})} \times 100 \quad (66.3)$$

and the approximate formula,

$$\text{Moist, mm-free Btu} = \frac{\text{Btu}}{100 - (1.1\text{A} + 0.1\text{S})} \times 100 \quad (66.4)$$

Percent Volatile Matter (VM)

The formula used for calculating coal VM value is as follows:

$$\text{Dry, mm-free VM} = 100 - \text{dry, mm-free FC} \quad (66.5)$$

66.2 Oil

Oil Formation

Petroleum or crude oil is thought to be partially decomposed marine life. It is normally found in large domes of porous rock. Crude oils are normally ranked in three categories, depending on the type of residue left after the lighter fractions have been distilled from the crude. Under this system the petroleum is classified as paraffin-based crude, asphalt-based crude, or mixed-based crude.

Oil Composition

Crude oil is composed of many organic compounds, yet the ultimate analysis of all crude oils is fairly constant. The carbon mass fraction ranges from 84 to 87%, and the hydrogen mass fraction from 11 to 16%. The sum of the oxygen and nitrogen mass fractions ranges from 0 to 7%, and the sulfur mass fraction ranges from 0 to 4%.

Crude Oil Refining

Crude oils are more valuable when defined as petroleum products. Distillation separates the crude oil into fractions equivalent in the boiling range to **gasoline**, **kerosene**, gas oil, lubricating oil, and a residual. Thermal or **catalytic cracking** is used to convert kerosene, gas oil, or residual to gasoline, lower-boiling

FIGURE 66.1 Properties of petroleum derivatives. (Source: Babcock & Wilcox Company, 1972. *Steam — Its Generation and Use*, 38th ed. Babcock & Wilcox Company, New York. With permission.)

fractions, and a residual coke. The major finished products are usually blends of a number of stocks, plus additives.

Properties of Petroleum Derivatives

The main variables of petroleum derivatives are the heating value, the specific gravity (*s*), the flash point, and the pour point. The heating value (usually the higher heating value) is reported in units of either kilojoules per kilogram (or Btu per pound mass) or kilojoules per liter (or Btu per gallon).

The heating value of crude oil and petroleum products is shown as a function of the specific gravity in Figure 66.1. The heating value (on unit mass basis) of petroleum derivatives increases as the specific gravity of the product decreases.

The specific gravity of any liquid is the density of the liquid divided by the density of water at 60°F (15.6°C). The specific gravity of crude oil is usually between 0.80 and 0.97. The corresponding °API (American Petroleum Institute) gravity is 45 to 15 degrees. The relationship between the specific gravity and the °API is as follows:

$$\text{°API} = \frac{141.5}{\text{Specific gravity at } 60/60\text{°F}} - 131.5 \quad (66.6)$$

Flash Point

The flash point of a liquid fuel is the minimum fluid temperature at which the vapor coming from the fluid surface will just ignite. At a slightly higher temperature, called the *fire point*, the vapors will support

combustion. When storing the oil, care should be taken to ensure that its temperature does not exceed its flash point.

Pour Point

The pour point of a petroleum product is the lowest temperature at which an oil or oil product will flow under standard conditions. It is determined by finding the maximum temperature at which the surface of an oil sample in a standard test tube does not move for 5 sec when the test tube is rotated to the horizontal position. The pour point is equal to this temperature plus 5 degrees Fahrenheit.

66.3 Natural Gas

Natural gas is the only true fossil fuel gas. It is usually trapped in limestone casing on the top of petroleum reservoirs. Reservoir pressures may reach as high as 350 to 700 bar (5000–10,000 lb/in.²). Natural gas is primarily composed of methane, with small fractions of other gases.

Natural gas has the highest heating value of all fossil fuels — about 55,800 kJ/kg (24,000 Btu/lbm), or 37,000 kJ/m³ (1000 Btu/ft³) at 1 atm and 20°C (68°F). Natural gas is commonly sold in units of “therms” (1 therm = 100,000 Btu).

There are a number of manufactured fossil fuel gases, including liquified petroleum gas (LPG), synthetic or substitute natural gas (SNG), and primary flash distillate (PFD).

66.4 Important Products of Crude Oil Refining

Important products of crude oil refining include:

1. *Natural gas.* Natural gas is composed mainly of CH₄ and some N₂, depending on the source. It is separated from crude oil by natural sources. Its principal use is as a fuel gas.
2. *Liquified petroleum gas (LPG).* LPG is composed of propane and butane. It is usually stripped from “wet” natural gas or from a crude oil cracking operation. LPG is widely used for industrial and domestic applications where natural gas is not available.
3. *Primary flash distillate (PFD).* PFD is composed of propane and butane dissolved in the gasoline–kerosene range of liquids. It is produced by preliminary distillation of crude oil.
4. *Gasoline.* Gasoline has a boiling range of 300 to 450 K (80 to 350°F). It is produced by primary distillation and reforming processes to improve its performance. Its principal use is spark-ignition internal combustion engines.
5. *Kerosene.* Kerosene is a paraffinic hydrocarbon with a boiling range of 410 to 575 K (280 to 575°F). It is produced by distillation and cracking of crude oil. Its principal uses are in agricultural tractors, lighting, heating, and aviation gas turbines.
6. *Gas oil.* Gas oil is a saturated hydrocarbon with a boiling range of 450 to 620 K (350 to 660°F). It is composed of saturated hydrocarbons produced by distillation and hydrodesulfurization of crude oil. Its principal uses are in diesel fuel, heating, and furnaces and as a feed to cracking units.
7. *Diesel fuel. Diesel fuel* is a saturated hydrocarbon with a boiling range of 450 to 650 K (350 to 680°F). It is composed of saturated hydrocarbons produced by distillation cracking of crude oil. Its principal uses are in diesel engines and furnace heating. The ASTM grades for diesel fuel are as follows:
Grade 1-D. A volatile distillate fuel. Suitable for engines in service requiring frequent speed and load changes.
Grade 2-D. A distillate fuel oil of lower volatility. Suitable for engines in industrial and heavy mobile service.
Grade 4-D. A fuel oil for low- and medium-speed engines.
8. *Fuel oil.* Fuel oil has a boiling range of 500 to 700 K (440 to 800°F). It is composed of residue of primary distillation, blended with distillates. Its primary use is in large-scale industrial heating.

9. *Lubricating oil.* There are three types of lubricating oils — mainly aromatic, mainly aliphatic, and mixed — which are manufactured by vacuum distillation of primary distillation residue-solvent extraction.
10. *Wax.* Wax is composed of paraffins produced by chilling residue of vacuum distillation. It is used primarily in food, candles, and petroleum jelly.
11. *Bitumen.* Bitumen is produced from residue of vacuum distillation or by oxidation of residue from primary distillation. It is used for road surfacing and waterproofing.

Nomenclature

| | |
|----------------|--|
| A | Percentage of ash |
| API | American Petroleum Institute |
| Btu | Coal heating value, Btu per pound on moist basis |
| C | Mass fraction of carbon |
| FC | Percentage of fixed carbon |
| H ₂ | Hydrogen |
| HHV | Higher heating value |
| M | Percentage of moisture |
| N ₂ | Nitrogen |
| O ₂ | Oxygen |
| S | Percentage of sulfur |
| s | Specific gravity |
| VM | Percentage of volatile matter |

Defining Terms

Bituminous coal — Soft coal containing large amounts of carbon. It has a luminous flame and a great deal of smoke.

Catalytic cracking — A refinery process that converts a high-boiling fraction of petroleum (gas oil) to gasoline, olefin feed for alkylation, distillate, fuel oil, and fuel gas by use of a catalyst and heat.

Diesel fuel — Fuel for diesel engines obtained from the distillation of crude oil. Its quality is measured by cetane number.

Gasoline — Light petroleum product obtained by refining crude oil with or without additives, blended to form a fuel suitable for use in spark-ignition engines. Its quality is measured by octane rating. The four classes are leaded regular (87–90 octane), unleaded regular (85–88 octane), mid-grade unleaded (88–90 octane), and premium (greater than 90 octane).

Kerosene — Colorless low-sulfur oil products used in space heaters, cook stoves, and water heaters.

Octane — A rating scale used to grade gasoline according to its antiknock properties. Also, any of several isometric liquid paraffin hydrocarbons, C₈H₁₈. Normal octane is a colorless liquid found in petroleum boiling at 124.6°C.

67.1 Solar Thermal Electric Systems

Thomas R. Mancini

Solar thermal power systems, which are also referred to as concentrating solar power systems, use the heat generated from the concentration and absorption of solar energy to drive heat engine/generators and, thereby, produce electrical power. Three generic solar thermal systems, trough, power tower, and dish-engine systems, are used in this capacity. Trough systems use linear parabolic concentrators to focus sunlight along the focal lines of the collectors. In a power tower system, a field of two-axis tracking mirrors, called heliostats, reflects the solar energy onto a receiver that is mounted on top of a centrally located tower. Dish-engine systems, the third type of solar thermal system, continuously track the sun, providing concentrated sunlight to a thermal receiver and heat engine/generator located at the focus of the dish.

Trough Systems

Of the three solar thermal technologies, trough-electric systems are the most mature with 354 MW installed in the Mojave Desert of Southern California. Trough systems produce about 75 suns concentration and operate at temperatures of up to 400°C at annual efficiencies of about 12%. These systems use linear-parabolic concentrators to focus the sunlight on a glass-encapsulated tube that runs along the focal line of the collector, shown in [Figure 67.1](#). Troughs are usually oriented with their long axis north–south, tracking the sun from east to west, to have the highest collection efficiencies. The oil working fluid is heated as it circulates through the receiver tubes and before passing through a steam-generator heat exchanger. In the heat exchanger, water boils producing the steam that is used to drive a conventional Rankine-cycle turbine generator. The optimal size for a trough-electric system is thought to be about 200 megawatts, limited mainly by the size of the collector field.

A major challenge facing these plants has been to reduce the operating and maintenance costs, which represent about a quarter of the cost of the electricity they produce. The newer plants are designed to operate at 10 to 14% annual efficiency and to produce electricity for \$.08 to \$.14 a kilowatt-hour, depending on interest rates and tax incentives with maintenance costs estimated to be about \$.02 a

kilowatt hour. New systems are currently being designed for use in the Southwest U.S. that will utilize ongoing research and development addressing issues such as improved receiver tubes, advanced working/storage fluids, and molten-salt storage for trough plants.

Power Towers

In the Spring of 2003, the first commercial power towers are being designed for installation in Spain in response to a very attractive solar incentive program. Power towers, shown in Figure 67.2, are also known
