Most lidar systems are capable of recording multiple returns associated with each outgoing pulse. For example, in a forested area lidar can be used to discriminate not only such features as the top of the forest canopy and bare ground but also surfaces in between (such as the intermediate forest structure and the vegetation growing under the tree canopy). In urban areas, the first return of lidar data typically measures the elevations of tree canopies, building roofs, and other unobstructed surfaces. These data sets are easily acquired, processed, and made quickly available to support high-resolution contour production, and bare-earth surface elevation determination for DEM construction. A distinct advantage to lidar is that all the data are georeferenced from inception, making them inherently compatible with GIS applications.

169.4 Remote Sensing from Earth Orbit

The use of satellites as sensor platforms has made possible the routine acquisition of remotely sensed data of the Earth’s surface on a global basis. The field of space remote sensing is a rapidly changing one, with numerous countries and commercial firms developing and launching new systems on a regular basis. The application of satellite image interpretation has already been demonstrated in many fields, such as agriculture, botany, cartography, civil engineering, environmental modeling and monitoring, forestry, geography, geology, geophysics, habitat assessment, land resource analysis, land use planning, oceanography, range management, and water resources.

Land remote sensing from space began on an operational basis in the civilian sector with the launch of Landsat-1 in 1972. At the time of this writing (2003), the most recently launched satellite in the Landsat series is Landsat-7. This satellite images each spot on the Earth’s surface once each 16 days, providing for frequent, synoptic, repetitive, global coverage. The multispectral scanner onboard is the *Enhanced Thematic Mapper Plus (ETM+)*, which senses in six bands of the spectrum, from the blue through the midinfrared, with a ground resolution cell size of 30 m. A seventh band senses in the thermal infrared with a ground resolution cell size of 60 m. The system also incorporates an eighth b/w or panchromatic band having a resolution of 15 m.

Launched in 1986, SPOT-1 was the first in a series of Earth resource satellites conceived and designed by the French Centre National d’Etudes Spatiales (CNES). The most recently launched SPOT satellite, SPOT-5, carries multiple sensing systems. Together, these systems provide data ranging from panchromatic images with 2.5-m resolution and a 60-km swath, to multispectral data with a resolution of 1 km and a 2250-km swath. The SPOT-5 system also features fore-and-aft stereo image acquisition and across-track

pointable imaging at angles up to 31° either side of vertical. This allows both across-track stereoscopic imaging from side-by-side orbits, and more frequent opportunities to record images of any ground location.

While Landsat and SPOT data have the longest history of availability and use, many other Earth observation satellites have been operated or are planned for launch in the not-too-distant future. Those systems operating in the optical portion of the electromagnetic spectrum can be generally classified into the categories of moderate-resolution systems, high-resolution systems, and hyperspectral systems. These are complemented by existing or planned radar and lidar systems.

Moderate resolution systems include the Indian Remote Sensing (IRS) series of satellites, the RESURS series initiated by the former Soviet Union and continued by Russia, several systems launched by Japan, and the CBERS satellite systems jointly developed by China and Brazil. A partial list of countries (or agencies) operating, planning, or developing such systems includes Argentina, Australia, Brazil, Canada, China, the European Space Agency, France, Germany, India, Israel, Italy, Japan, Korea, Malaysia, Russia, South Africa, Spain, Taiwan, Thailand, United Kingdom, Ukraine, and the United States.

High-resolution systems have principally been developed and launched commercially. To date, those systems planned or launched by U.S. firms include Space Imaging’s IKONOS system, the QuickBird satellite operated by EarthWatch, Inc., and ORBIMAGE’s OrbView-3 system. ImageSat International has also launched the first of a planned series of EROS high-resolution satellites. Table 169.2 summarizes these systems. Except for EROS-A, all feature a panchromatic band with a spatial resolution of 1 m or better and four multispectral bands (blue, green, red, near infrared) with spatial resolution of 4 m or better. It should also be noted that it is possible to merge the finer-resolution panchromatic data with the coarser multispectral data digitally to synthesize a multispectral composite having the effective spatial resolution of the panchromatic data. This process is often called “pan-sharpening” and can be used to generate color composites very similar in appearance and utility to color and color infrared photographic images. In fact, such products are often used as a complement to, or replacement for, aerial photography in many applications.

Hyperspectral systems that have been operated from space include the Hyperion instrument carried on the EO-1 spacecraft launched by NASA. The Hyperion provides 242 spectral bands of data over the 0.36- to 2.6- μm range, each of which has a width of 0.010 to 0.011 μm . The spatial resolution of this experimental sensor is 30 m, and the swath width is 7.5 km.

TABLE 169.2 High-Resolution Earth Observation Satellite Systems

| Satellite | Launch Date | Spatial Resolution (m) | Spectral Bands (μm) | Swath Width (km) | Altitude (km) |
|-----------|----------------|------------------------|--|------------------|---------------|
| IKONOS | Sept. 24, 1999 | 1.0 | Pan: 0.45–0.90 | 11.0 | 681 |
| | | 4.0 | 1: 0.45–0.52 2: 0.52–0.60 3: 0.63–0.69 4: 0.76–0.90 | | |
| EROS-A | Dec. 5, 2000 | 1.8 | Pan: 0.50–0.90 | 13.5 | 480 |
| QuickBird | Oct. 18, 2001 | 0.6 | Pan: 0.45–0.90 | 16.5 | 450 |
| | | 2.4 | 1: 0.45–0.52 2: 0.52–0.60 3: 0.63–0.69 4: 0.76–0.90 | | |
| OrbView-3 | 2003 (planned) | 1.0 | Pan: 0.45–0.90 | 8.0 | 470 |

Several other hyperspectral systems have been proposed or are in development. These include, among others, the U.S. Navy's Naval EarthMap Observer (NEMO) satellite and the Australian Resource Information and Environmental Satellite (ARIES). The latter system is designed to include a hyperspectral imager with up to 105 bands located between 0.4 and 2.5 μm , 30-m resolution, a 15-km swath, up to 30° cross-track pointing, and a 7-day repetitive coverage period. The future for these and similar hyperspectral satellite systems is an extremely bright one.

Radar systems operated from space have included the Almaz-1 system of the former Soviet Union, the ERS-1, ERS-2, and Envisat systems of the European Space Agency, Japan's JERS-1 system, and Canada's Radarsat system. Japan also plans to launch the PALSAR system in the not-too-distant future.

Among the precursors to these systems were the experimental spaceborne systems Seasat-1 and three Shuttle Imaging Radar systems (SIR-A, SIR-B, and SIR-C). As mentioned earlier, the Shuttle Radar Topography Mission (SRTM) was a brief but highly productive operational program to map global topography using radar interferometry.

Present and future radar systems afford a wide range of data acquisition options. Among these are various wavelength bands, the plane of polarization (vertical or horizontal) of signal transmission and reception, swath width, viewing angle, and spatial resolution. For example, the planned PALSAR system will provide multiple polarization modes at look angles (relative to vertical) of 10 to 51°, at swath widths as large as 350 km, and resolutions of 10 to 100 m. Such systems will continue the application of radar data to such tasks as sea ice reconnaissance, coastal surveillance, land cover mapping, agriculture and forest monitoring, oil slick detection, and geologic mapping.

Lidar systems are still in their infancy in terms of their application from space. The first such system, the Ice, Cloud, and Land Elevation Satellite (ICESat) includes lidars operating both in the visible and near infrared, at 0.532 μm and 1.064 μm , respectively. These systems transmit pulses about 40 times per second and measure the timing of the received returns to within 1 nanosecond. The laser footprints at ground level are approximately 70 m in diameter, and are spaced 170 m apart along-track.

ICESat is a component of NASA's Earth Observing System Program (discussed in the next section). The primary purpose of ICESat is to collect precise measurements of the mass balance of polar ice sheets, and to study how the Earth's climate affects ice sheets and sea level. The ICESat lidar can measure changes of as small as 1.5 cm in the elevation of ice sheets, over areas of 100 km by 100 km. This should permit scientists to determine the contribution of the ice sheets of Greenland and Antarctica to global sea level change to within 0.1 cm per decade. In addition to measurements of surface elevation ICESat is designed to collect vertical profiles of clouds and aerosols within the atmosphere, using sensitive detectors to record backscatter from the 0.532 μm wavelength lasers.

169.5 Earth Observing System

No discussion of space remote sensing is complete without mention of the Earth Observing System (EOS), which is part of the NASA-initiated Earth Science Enterprise (ESE). The ESE is an international earth science program aimed at providing the observations, understanding, and modeling capabilities needed to assess the impacts of natural events and human-induced activities on the Earth's environment. The program incorporates both space- and ground-based measurement systems to provide the basis for documenting and understanding global change with an initial emphasis on climate change. The program also focuses on the necessary data and information systems to acquire, archive, and distribute the data and information collected about the Earth. The intent is to further international understanding of the Earth as a system.

The EOS component of the ESE includes currently operational observing systems (beginning with Landsat-7), new programs under development, and planned programs for the future. Clearly, programs of this magnitude, cost, and complexity are subject to change. Also, the EOS program includes numerous platforms and sensors that are outside the realm of land-oriented remote sensing. We make no attempt to describe the overall program, but only wish to highlight the Moderate Resolution Imaging Spectro-Radiometer (MODIS) included on the first two EOS-dedicated platforms, the Terra and Aqua spacecraft.

Terra and Aqua were launched in late 1999 and mid-2002, respectively. MODIS is a sensor that is intended to provide comprehensive data about land, ocean, and atmospheric processes simultaneously. MODIS provides 2-day repeat global coverage with moderate spatial resolution (250, 500, or 1000 m, depending on wavelength) in 36 carefully chosen spectral bands. The total field of view of MODIS is $\pm 55^\circ$, providing a swath width of 2330 km.

A large variety of data products can be derived from MODIS data. Among the principal data products available are the following:

- *Cloud mask* at 250 and 1000 m resolution during the day and 1000-m resolution at night.
- *Aerosol concentration and optical properties* at 5-km resolution over oceans and 10-km resolution over land during the day.
- *Cloud properties* (optical thickness, effective particle radius, thermodynamic phase, cloud top altitude, cloud top temperature) at 1- to 5-km resolution during the day and 5-km resolution at night.
- *Vegetation and land surface cover*, conditions, and productivity, defined as vegetation indices corrected for atmospheric effects; soil, polarization, and directional effects; surface reflectance; land cover type; and net primary productivity, leaf area index, and intercepted photosynthetically active radiation.
- *Snow and sea-ice cover and reflectance*.
- *Surface temperature* with 1-km resolution, day and night, with absolute accuracy goals of 0.3 to 0.5° over oceans and 1° over land.
- *Ocean color* (ocean-leaving spectral radiance measured to 5%), based on data acquired from the MODIS visible and nearinfrared channels.
- *Concentration of chlorophyll *a** (within 35%) from 0.05 to 50 mg/m^3 for case 1 (deep ocean) waters.
- *Chlorophyll fluorescence* (within 50%) at surface water concentration of 0.5 mg/m^3 of chlorophyll *a*.

169.6 Digital Image Processing

The digital data acquired by the systems described in this chapter are typically computer processed to produce images through *digital image processing*. Through various image-processing techniques, digital images can be enhanced for viewing and human image interpretation. Digital data can also be processed using computer-based image classification techniques to prepare various thematic maps, such as land cover maps. Digital image processing procedures are normally integrated with the functions of a GIS.

Defining Terms

Electromagnetic radiation — The transmission of energy in the form of waves having both an electric and a magnetic component.

Electromagnetic spectrum — Electromagnetic radiation is most simply characterized by its frequency or wavelength. The resulting array is called the *electromagnetic spectrum*. The spectrum is normally considered to be bounded by cosmic rays at short wavelengths and by radio waves at long wavelength.

Emitted energy — The energy radiated by an object resulting from its internal molecular motion (heat). All objects above “absolute zero” in temperature radiate energy.

Ground truth (or reference data) — Field observations or other information used to aid or verify the interpretation of remotely sensed data.

Photogrammetry — The science, art, and technology of obtaining reliable measurements, maps, digital elevation models, thematic geographic-information-system data, and other derived products from photographs.

Pixel — The cell representing each combination of row and column (picture element) in a digital image data set.

Reflected energy — That component of incident energy that is reflected from an object.

Remote sensing — Studying the characteristics of objects from a distance by recording and analyzing electromagnetic energy, typically from ultraviolet to microwave wavelengths.

Further Information

Two of the leading professional societies dealing with remote sensing and photogrammetry are the American Society for Photogrammetry and Remote Sensing (ASPRS, www.asprs.org) and the Canadian Remote Sensing Society (CRSS, www.casi.ca). The ASPRS publishes the monthly journal *Photogrammetric Engineering & Remote Sensing*, as well as many books and special publications. The CRSS publishes the *Canadian Journal of Remote Sensing*.

In contrast with the ASPRS and CRRS, the International Society for Photogrammetry and Remote Sensing (ISPRS) has no individual members. It has a membership of 50 sustaining members, such as ASPRS and CRRS. The ISPRS has seven technical commissions, each of which has many working groups. The ISPRS holds numerous meetings throughout the world, and publishes many journals, proceedings, and technical reports, such as the *International Archives of Photogrammetry and Remote Sensing* and the *ISPRS Journal of Photogrammetry and Remote Sensing*. For further information, see www.isprs.org.

Information on the availability of cartographic and image data throughout the United States, including aerial photographs and satellite images, can be obtained from the U.S. Geological Survey, Earth Science Information Center (<http://ask.usgs.gov>).

For information on the availability of Landsat data on a worldwide basis, see <http://edc.usgs.gov> or www.landsat.org.

For information on the availability of SPOT data on a worldwide basis, see www.spotimage.fr/home or www.spot.com.

Information on the availability of data from various other sensing systems can be found by using an Internet search engine.

170.1 Feedback Control in Engineering

170.2 Fundamentals of Feedback for Linear-Time-Invariant
Systems

Open Loop Control • Feedback Control • Stabilization •
Tracking • Disturbance Attenuation • Sensitivity

In this chapter, fundamental properties of feedback control are discussed with engineering applications in mind. However, feedback appears in many other disciplines, such as agriculture, biology, medicine, pharmaceuticals, economics, business management, political science, etc. A typical example of feedback control is steering of an automobile: we would like to keep the vehicle on the road (in the cruising lane). The road curvature determines the desired path to be followed. On the other hand, unpredictable gusting winds, bumps, or potholes on the road may move the vehicle off the cruising lane, unless corrective steering action is taken. As the driver (or autopilot) detects, using vision or other sensors, deviation from the desired path he/she can take the corrective steering action. Clearly, without the feedback from vision (or other sensory mechanism), the automobile cannot be kept on the road for a long time, even if we know the desired path *a priori*. In this example, the position of the vehicle relative to the center of the lane is the system *output* to be controlled, vision or another sensor provide a measured value of the output to the controller (human driver or automatic steering mechanism). This information is processed together with the desired path to be followed (i.e., *reference input*), and then steering angle (i.e., the *control input*) is determined by the controller. The immeasurable variables such as wind, bumps, potholes, as well as measurement errors due to imprecise sensing, represent the *disturbances* in this feedback system. The main goal of feedback control is to reduce the effect of uncertainty (i.e., disturbances in the above example) on the output of the system. In fact, it is widely accepted by control engineers that the only reason to use feedback is to cope with uncertainty.

170.1 Feedback Control in Engineering

Generalizing the steering example given above, a feedback control system contains a *process* (a cause–effect relation) whose operation depends on one or more variables (inputs) that cause changes in some other variables of interest (outputs). If an input can be manipulated, then it is said to be a control input; otherwise it is considered as a disturbance, or noise. The *controller* compares the measured output (which is obtained by a *sensor*) with the desired output (reference) and produces the control input for the process; hence the feedback loop is closed (Figure 170.1). In typical engineering applications, the controller is a computer, or a human interfacing with a computer. In this case, the control signal generated by a computer

FIGURE 170.1 Feedback control system.

needs to be converted to an input that the process takes. For example, in automatic steering applications discussed above, the computer generates a small electrical signal (in the form of a voltage or current) that needs to be converted to an angle of the steering column; typically, a DC motor does the job. Such a device is called an *actuator*. The sensors and the actuators are interface devices between the physical process and the controller. They are selected by the process engineer, depending on the physical application in mind, design specifications, and economic considerations. The physical process together with the actuators and sensors form the *plant* to be controlled.

In order to design a controller, a mathematical model of the plant (describing the dynamical behavior of the system) is derived. In the next section, I discuss systems represented by ordinary differential equations with constant coefficients, that is, finite-dimensional (lumped parameter) linear, time-invariant systems. Other types of mathematical models include infinite dimensional linear systems (e.g., systems with time delays, and spatially distributed systems described by partial differential equations), nonlinear dynamical systems, and fuzzy systems described by a set of logical rules. Control design techniques used depend on the type of dynamical equations representing the plant.

Typical goals in feedback controller design include:

- Stability of the closed loop system
- Reduction of sensitivity to modeling uncertainty
- Disturbance attenuation
- Tracking of a reference input

Clearly, in controller design the biggest concern is the first item in the above list. If the controller is not designed properly, a stable open-loop system (i.e., stable controller and stable plant connected in cascade with no feedback) may become unstable when the loop is closed with feedback. This is the main reason why feedback control is an important research area in engineering and applied mathematics.

In practice, after a controller is designed for a physical system, it is tested under different operating conditions by performing numerical simulations and laboratory experiments. If the results are satisfactory, then the controller is deployed and the feedback loop is formed around the actual physical system. Otherwise, the mathematical model is refined, and/or some of the design specifications are relaxed in order to satisfy all the design requirements. A summary of this process is shown in [Figure 170.2](#).

170.2 Fundamentals of Feedback for Linear-Time-Invariant Systems

In this section, to illustrate the benefits of feedback, we consider a simple control system, where the plant and the controller are single input–single output (SISO), linear, time-invariant systems whose transfer functions are rational functions. To further simplify the notation and discussion, we assume that the sensor is perfect (measured output is the same as the output of the process). Then, the feedback system shown in [Figure 170.1](#) reduces to the system shown in [Figure 170.3](#), where $C(s)$ and $P(s)$ are the transfer functions of the controller and the plant, respectively. (Plant transfer function is defined as $P(s) = Y(s)/U(s)$, where $Y(s)$ and $U(s)$ represent the Laplace transforms of the output $y(t)$, and the input $u(t)$, respectively.) The tracking error, e , is defined as the difference between the reference input r and the

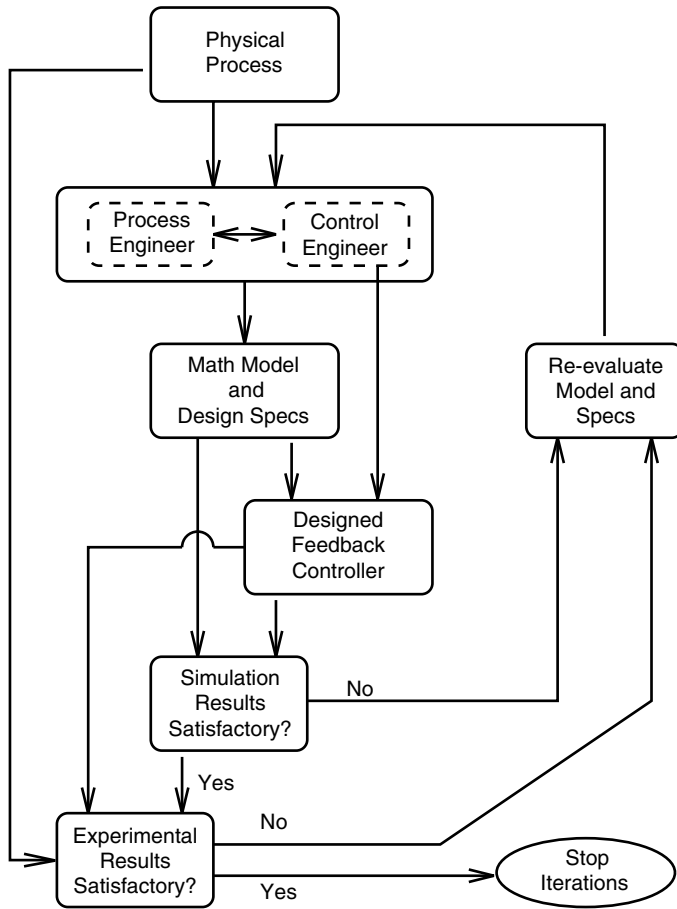

FIGURE 170.2 Controller design iterations.

FIGURE 170.3 Feedback system with controller C and plant P .

output y , that is, $e(t) = r(t) - y(t)$. In Figure 170.3, the control input is u , and the disturbance is v . We want to make the tracking error “small” in the presence of disturbance and modeling errors in the plant.

Open Loop Control

First, consider the open loop control, where the Laplace transform of the output is given by

$$Y(s) = P(s)C(s)R(s) + P(s)V(s)$$

Clearly, when the plant is unstable, a small disturbance may result in an unbounded output. (A system is stable if its transfer function has no poles in $\{s : \text{Re}(s) \geq 0\}$.) Even if we assume that $v(t) = 0$, to get a

bounded output, the unstable poles of the plant must be cancelled by the zeros of the controller. As an example, let $P(s) = 1/(s - 1)$, and consider a unit step reference input, $R(s) = 1/s$, with $V(s) = 0$. Then,

$$Y(s) = \frac{C(s)}{s(s-1)}$$

Assuming that $C(s)$ does not have poles or zeros at $s = 0$ and $s = 1$, partial fraction expansion and inverse Laplace transformation results in

$$y(t) = Ae^t + B + y_c(t), \text{ for } t > 0$$

where $A = C(1)$, $B = -C(0)$; and exponential decay, or growth, or oscillations in $y_c(t)$ depend on the location of the poles of $C(s)$. If the controller does not have a zero at $s = 1$, that is, if $C(1)$ is not equal to zero, $y(t)$ is unbounded. So, in order to prevent an unbounded output, we must choose $C(s)$ such that $C(1) = 0$. It is clear from this example that a slightest uncertainty in the pole location of the plant will lead to an unsuccessful controller design, and hence to an unbounded output. Thus, the open loop control is out of question when the plant is unstable; in this case, the uncertainty, either in the form of disturbance or in the form of modeling error, will lead to an unbounded output.

In light of the above discussion, now consider a stable plant, with no disturbance, $v = 0$. Then, in order to make $y(t) \approx r(t)$, we tend to choose the open loop controller as $C(s) = 1/P(s)$. There are two problems with this choice: controller might turn out to be *improper* or *unstable*. As an example of the first case, let $P(s) = 1/(s + 1)$, then $C(s) = (s + 1)$, which is improper, that is, it contains a differentiator, and hence cannot be exactly implemented in a causal fashion. The second case occurs when the plant has a zero in the right half-plane, such as $P(s) = (s - 1)/(s + 2)$. Taking the inverse of this plant leads to a controller whose pole is at $s = 1$, and again, the slightest uncertainty in the location of this right half-plane zero of the plant leads to an unbounded output.

Finally, for the open loop control, when $r(t) = 0$, and $v(t) \neq 0$, the system output is independent of the controller: $Y(s) = P(s)V(s)$. We see that by using feedback we can attenuate the effect of this disturbance.

Feedback Control

As shown in [Figure 170.3](#), feedback is formed by the equations

$$E(s) = R(s) - Y(s)$$

and

$$Y(s) = P(s)C(s)E(s) + P(s)V(s)$$

Therefore, the output is determined from the identity

$$(1 + P(s)C(s))Y(s) = P(s)C(s)R(s) + P(s)V(s)$$

Note that the right side of the above equality corresponds to the output of the open-loop control system discussed before. In order to determine $Y(s)$ uniquely, the operator $(1 + P(s)C(s))$ must be causally invertible; otherwise the feedback system is said to be ill-posed. For example, when $P(s) = K_p$ and $C(s) = -1/K_p$, the feedback system is ill-posed. Another example of an ill-posed systems is $P(s) = 2s/(s + 1)$, $C(s) = -1/2$, in which case the inverse of $(1 + P(s)C(s))$ is $(s + 1)$, an improper transfer function. In general, the *feedback system becomes ill-posed when*

$$1 + P(\infty)C(\infty) = 0$$

From now on we assume that the feedback system is well-posed; and we define the *sensitivity function*, $S(s)$, as the inverse of $(1 + P(s)C(s))$. The word sensitivity will be defined shortly, and hence this notation will be made clear.

In a well-posed feedback system the internal signals of interests are

$$E(s) = S(s)R(s) - S(s)P(s)V(s)$$

$$U(s) = C(s)S(s)R(s) + S(s)V(s)$$

Stabilization

We say that a feedback system is bounded input/bounded output (BIBO) stable if every bounded input pair $(r(t), v(t))$ leads to bounded internal signals $(e(t), u(t))$. (A signal $f(t)$ is said to be bounded if there exists a finite number M_f satisfying $|f(t)| < M_f$.)

It can be shown that the feedback system is BIBO stable if and only if transfer functions $S(s)$, $P(s)S(s)$, and $C(s)S(s)$, are stable, that is, they have no poles in the closed right half-plane, $\{s : \text{Re}(s) \geq 0\}$. It is important to note that stability of the plant and/or controller does not imply stability of the feedback system; conversely, stability of the feedback system does not imply stability of the plant nor the controller. In fact, one of the reasons to use feedback is to stabilize an unstable plant. For example, let $P(s) = 1/(s - p)$, with $p > 0$, and $C(s) = K_c$, it is a simple exercise to show that closed loop system poles, that is, the poles of S , PS , and CS , are the roots of

$$s - p + K_c = 0$$

Thus, with a simple gain $K_c > p$, we can stabilize the system using feedback. In order to have stability robustness against a possible uncertainty in p , we might want to choose K_c much greater than the maximum known value of p . Recall that with an open loop control scheme it is impossible to stabilize this system in the presence of uncertainty in p .

In general, feedback system stability can be determined by finding the closed loop system poles. Let $P = N_p/D_p$, and $C = N_c/D_c$, where N_p, D_p, N_c, D_c are polynomials, and the pairs (N_p, D_p) and (N_c, D_c) are coprime. (A pair of polynomials (N, D) is said to be coprime if $N(s)$ and $D(s)$ do not have common roots.) Then, it is easy to see that all the poles of S , PS , and CS are precisely the roots of the characteristic equation

$$D_p(s)D_c(s) + N_p(s)N_c(s) = 0$$

Once this equation is constructed, numerical root-finding tools can be used to calculate the closed-loop system poles. More discussion on stability analysis and controller design can be found in subsequent chapters of this handbook, where different design/analysis techniques are studied for more general classes of systems. In the remaining sections of this chapter on the fundamental properties of feedback, it is assumed that the feedback system is stable.

Tracking

One of the goals of feedback control is to make the output, $y(t)$, track the reference input, $r(t)$. Therefore, we would like to design the controller in such a way that the tracking error, $e(t) = r(t) - y(t)$, is "small." When $v(t) \equiv 0$, the Fourier transform of the error is $E(j\omega) = S(j\omega)R(j\omega)$. Unless $S \equiv 0$, the error cannot be zero. So, the best we can do is make $|S(j\omega)|$ "small" whenever $|R(j\omega)|$ is not. For example, consider a unit step reference, $R(s) = 1/s$, and let $P(s) = 1/(s - 1)$. Since $R(0) = \infty$, we need to have $S(0) = 0$, so that $E(0) \neq \infty$. Since the plant does not have a pole at $s = 0$, in order to make $S(0) = 0$ the controller needs

to have a pole at $s = 0$. Accordingly, we choose a PI (proportional plus integral) controller whose transfer function is in the form $C(s) = K(s + z)/s$. The characteristic equation is

$$s^2 + (K - 1)s + Kz = 0$$

For stability we need $K > 1$, and $z > 0$. Moreover, we can place the closed loop poles anywhere in the complex plane by properly selecting K and z . The tracking error is given by

$$E(s) = \frac{s - 1}{s^2 + (K - 1)s + Kz}$$

If we place one of the closed loop poles at $s = -1$, and the other one at $s = -r$, then we have

$$|E(j\omega)| = \left| \frac{1}{j\omega + r} \right| \leq 1/r$$

This is achieved when $K = r + 2$, and $z = r/(r + 2)$. Note that the right side of the above inequality can be made arbitrarily small by selecting large values of r ; hence, the tracking error can be made small. On the other hand, it is a simple exercise to check that for the above design

$$u(t) = -1 + A \exp(-rt) + B \exp(-t)$$

where $A = K(z - r)(r + 1)/(r(r - 1))$, and $B = 2K(1 - z)/(r - 1)$, and when r is large we have $A \approx K = r + 2$. That leads to large values of $|u(t)|$ in the transient response, possibly resulting in severe actuator damage or saturations. To summarize the discussion, in order to obtain good tracking performance we need use high gain controllers. However, the gain of the controller should not exceed a certain limit, determined by the actuator's capacity to handle large inputs.

Disturbance Attenuation

In this section we assume that $r(t) = 0$, and $v(t) \neq 0$. Recall that in open loop control the output is $Y(s) = P(s)V(s)$, and hence the controller does not play a role in reducing the effect of disturbance on the output. However, in feedback control, the output is $Y(s) = S(s)P(s)V(s)$. Compared to the open loop response the output is scaled by a factor of $|S(j\omega)|$ in the frequency domain. Therefore, as in the tracking discussion, whenever $|V(j\omega)|$ is "large" we need to make $|S(j\omega)|$ "small" by a proper choice of the controller $C(s)$. This way, the effect of the disturbance on the output can be reduced significantly. As an example, consider a unit step disturbance $V(s) = 1/s$, for the unstable plant $P(s) = 1/(s - 1)$, and let the feedback controller be the same PI controller defined above $C(s) = K(s + z)/s$. Then, the output due to disturbance v is obtained as $Y(s) = 1/(s^2 + (K - 1)s + Kz)$. Again, choosing $K = r + 2$ and $z = r/(r + 2)$, we have

$$|Y(j\omega)| = \left| \frac{1}{(j\omega + r)(j\omega + 1)} \right| \leq \frac{1}{r}$$

Hence the output can be made as small as desired, provided that the actuator is not pushed to its limits.

Sensitivity

Consider a function F , which depends on a parameter α . Sensitivity of F with respect to variations of α is defined as

$$S_F^\alpha = \frac{\Delta F / F}{\Delta \alpha / \alpha} = \frac{\alpha}{F} \frac{\partial F}{\partial \alpha}$$

where ΔF represents variations in F due to variations in α by an amount $\Delta\alpha$, at the nominal value of α . Therefore, the functions defined above need to be evaluated at the nominal value of α . Now let F be the transfer function from r to y , denoted by T , and the parameter α be the plant transfer function, P . In the open loop case we have $T = PC$, and in the feedback control case $T = 1 - S = PC/(1 + PC)$. Since P is simply a “model” of the plant, it does not capture the “true” behavior of the actual plant. Accordingly, assume that the “true” plant has a transfer function in the form $P + \Delta P$, where ΔP represents the modeling uncertainty. By applying the above definition of the sensitivity, we find that sensitivity of T with respect to variations in P is 1 for the open loop control, and it is equal to $1/(1 + PC)$ for feedback control. Recall that $1/(1 + PC) = S$, which we called the “sensitivity” function for the now obvious reason. Having unity sensitivity (open loop case) means that, any percentage variation of P will result in the same percentage variation in T . On the other hand, a properly designed controller can reduce the sensitivity (i.e., smaller than unity) in the frequency region of interest. Note that, by definition of the sensitivity, we have

$$\frac{\Delta T}{T} = S \frac{\Delta P}{P}$$

and hence

$$\Delta T = S \Delta P C S$$

Thus, we need to make the sensitivity $|S(j\omega)|$ “small” whenever $|\Delta P(j\omega)C(j\omega)|$ is “large.” This property is also needed for stability robustness in the presence of plant uncertainty. For details, see subsequent chapters in this volume, and sources listed below.

References and Further Reading

Principles of feedback control and basic feedback system analysis and design techniques can be found in all undergraduate level textbooks on feedback control systems. Some of the newer texts include detailed discussions on the links between sensitivity and robustness, a topic that has been traditionally left for a second course on feedback control. A partial list of introductory textbooks on feedback control systems is given below.

New developments in feedback control theory and their applications in many engineering disciplines are reported regularly in academic journals. The most prominent journals in this area, most of which are published monthly, are listed below.

- IEEE Transactions on Automatic Control*
- IEEE Transactions on Control Systems Technology*
- Automatica*, journal of IFAC

Control Engineering Practice, journal of IFAC
SIAM Journal on Control and Optimization
Systems & Control Letters
Mathematics of Control Signals and Systems
International Journal of Control
International Journal of Robust and Nonlinear Control
International Journal of Adaptive Control and Signal Processing
European Journal of Control
AIAA Journal of Guidance Control and Dynamics
ASME Journal of Dynamic Systems Measurement and Control

The two largest professional societies active in the control systems area are:

Control Systems Society of IEEE (Institute of Electrical and Electronics Engineers): www.ieeecss.org
IFAC, International Federation of Automatic Control: www.ifac-control.org

Besides publishing some of the academic journals listed above, these societies regularly hold meetings devoted to the latest developments in the control systems area. Some of the major control conferences are:

Conference on Decision and Control, held once a year in December
American Control Conference, held once a year in early summer
Conference on Control Applications, held once a year, typically in the summer
European Control Conference, held once a year late summer
IFAC World Congress, held once every 3 years, typically in the summer.

171.1 Introduction

In general, the root locus is the locus of the roots of an algebraic equation with constant coefficients when the value of a parameter of the equation is changed between two limits. With particular reference to the field of control system, the root locus was invented by Walter Evans during the 1950s [1–3] for which he was honored with the prestigious Bellman Control Heritage Award in 1988 by American Automatic Control Council (AACC) and the paper [2] was reprinted in the recent volume *Control Theory: Twenty-Five Seminal Papers (1932–1981)* [4]. Basically, the root locus method gives the information regarding closed-loop stability by showing the location of the closed-loop poles or the roots of characteristic equation of a closed-loop control system for variation of the values of a parameter of the system. The root locus technique was developed for both continuous-time systems described by ordinary differential equations and Laplace transforms with s as the complex variable and discrete-time systems described by ordinary difference equations and Z -transforms with z as the complex variable. This article is based on the author's teaching experience in the area of control systems and the well-known texts such as those found in References 5 through 7.

171.2 Concept and Definition of Root Locus

We first address root locus for continuous-time systems in detail and then briefly deal with the root locus for discrete-time system. Consider a negative feedback control system shown in [Figure 171.1](#). Here, a standard notation is used with $s = \sigma + j\omega$ as Laplace complex variable, $R(s)$ and $Y(s)$ are reference input and the actual output, respectively. Further, K is any parameter associated with the forward transfer function $G(s)$ and $H(s)$ is the feedback transfer function. It is well-known that

$$\frac{Y(s)}{R(s)} = M(s) = \frac{KG(s)}{1 + KG(s)H(s)} \quad (171.1)$$

FIGURE 171.1 Negative feedback control system.

The stability of this closed-loop system requires that the location of the poles of the transfer function $M(s)$ or the roots of the characteristic equation (C.E.)

$$F(s) = 1 + KG(s)H(s) = 0 \tag{171.2}$$

lie in the left half s plane. Let us note that if the original open-loop transfer function, say $G_1(s)H_1(s)$, is embedded with a parameter K , it can always be rewritten as $G_1(s)H_1(s) = KG(s)H(s)$. Also, if $KG(s)H(s)$ can be written as a rational function as

$$KG(s)H(s) = \frac{KP(s)}{Q(s)} \tag{171.3}$$

then, the C.E. (171.2) can be written as

$$Q(s) + KP(s) = 0. \tag{171.4}$$

Concept of Root Locus

In the context of systems and control, the root locus is *defined* as the locus (or trajectory) of the roots of the characteristic equation of a negative feedback control system for all positive (and/or negative) values of a parameter associated with the system transfer function.

Thus, the root locus for the negative-feedback control system (171.1) is the locus of the roots of the characteristic equation (171.2) for all positive (and/or negative) values of the parameter K . To illustrate the concept of the root locus, let us consider a simple second order system $G(s) = 1/s(s + 2)$ with open-loop poles at $s = 0, -2$ and $H(s) = 1$. Then the C.E. (171.2) becomes

$$F(s) = s^2 + 2s + K = 0. \tag{171.5}$$

The roots s_1 and s_2 of (171.5) can be easily found as

$$s_{1,2} = -1 \pm \sqrt{1 - K} \tag{171.6}$$

for various positive values of K tabulated as shown. The locus of the roots shown in Table 171.1 is sketched in Figure 171.2. It is clear from Figure 171.2 that the locus (trajectory) of the roots s_1 and s_2 (171.6) of the C.E. (171.5) for values of $K = 0$ to ∞ starts (corresponding to $K = 0$) at the open-loop poles located at $s = 0$ and $s = -2$ and travels through the values corresponding to $K = 0.5, 1, 2, 3, \infty$. Since

TABLE 171.1 Roots of the Characteristic Equation (171.5)

| K | 0 | 0.5 | 1 | 2 | 3 | ∞ |
|-------|----|---------------|-----------|-----------|---------------|----------------|
| s_1 | 0 | $-0.293 + j0$ | $-1 + j0$ | $-1 + j1$ | $-1 + j1.414$ | $-1 + j\infty$ |
| s_2 | -2 | $-1.707 - j0$ | $-1 - j0$ | $-1 - j1$ | $-1 - j1.414$ | $-1 - j\infty$ |

FIGURE 171.2 Root locus concept: Second order system.

the roots of the C.E. for all values of K lie in the left-half of the s -plane, the second-order, negative-feedback control system (171.1) is stable for all positive values of K . Thus, one of the most important useful characteristics of the root locus is to find the stability of the closed-loop system *once for all* for all values of $K = 0$ to ∞ .

Definition of Root Locus

The root locus is *defined* as the locus (trajectory) of the roots of the characteristic equation of a feedback control system. Note that the above procedure is given only to get the concept of the root locus and the root locus for any general feedback control system is not obtained *directly* by finding the roots of the C.E. and then plotting or sketching the same in the s -plane as shown above, but is done *indirectly* by developing some rules/steps for constructing or sketching the root locus as given next.

Rules/Steps for Constructing Root Locus

Let us reconsider the C.E. (171.2) written as

$$G(s)H(s) = -\frac{1}{K}. \tag{171.7}$$

and focus only on positive values of $0 \leq K \leq \infty$ noting that a similar treatment (called *complementary root locus*) can be developed for negative values $-\infty \leq K < 0$. Note that $G(s)H(s)$ is a complex number and as such has a *magnitude* and *angle* or *phase*. This leads us to write the *one* relation (171.7) in terms of *two* relations as [8] (where, $||$ indicates *magnitude* and \angle indicates the *angle*)

$$\begin{aligned} |G(s)H(s)| &= \left| -\frac{1}{K} \right| = \frac{1}{K}, & 0 \leq K < \infty, & \text{Magnitude Condition} \\ \angle G(s)H(s) &= \angle \left\{ -\frac{1}{K} \right\} = \angle \{-1 + j0\}, & 0 \leq K < \infty, & \text{Angle Condition} \\ &= \text{odd multiple of } \pi, & & \end{aligned} \tag{171.8}$$

FIGURE 171.3 Magnitude and angle conditions of root locus.

$$= (2r + 1)\pi, \quad r = 0, \pm 1, \pm 2, \dots \quad (171.9)$$

To further illustrate the above magnitude and angle conditions, consider a feedback control system

$$KG(s)H(s) = \frac{K(s+2)}{s(s+4)(s^2+4s+13)} = \frac{K(s+2)}{s(s+4)(s+2-j\beta)(s+2+j\beta)} \quad (171.10)$$

and any point s_1 on the root locus in the s -plane as shown in Figure 171.3. Note that the distances from s_1 to various open-loop poles and zero are given as $D_0 = s_1$, $D_1 = s_1 + 2$, $D_2 = s_1 + 4$, $D_3 = s_1 + 2 - j\beta$, $D_4 = s_1 + 2 + j\beta$ and the corresponding angles are shown as $\theta_0, \theta_1, \dots, \theta_4$. Then the magnitude condition (171.8) implies that

$$\begin{aligned} \left| \frac{1}{K} \right| &= \left| \frac{(s_1+2)}{s_1(s_1+4)(s_1+2-j\beta)(s_1+2+j\beta)} \right| \rightarrow \\ K &= \left| \frac{s_1(s_1+4)(s_1+2-j\beta)(s_1+2+j\beta)}{(s_1+2)} \right| = \frac{D_0 D_2 D_3 D_4}{D_1} \quad (171.11) \\ &= \frac{\text{Product of the distances from all the poles of } G(s)H(s) \text{ to the point } s_1}{\text{Product of the distances from all the zeros of } G(s)H(s) \text{ to the point } s_1} \end{aligned}$$

Similarly, with respect to the Figure 171.3 the angle condition (171.9) implies that

$$\begin{aligned} \angle G(s_1)H(s_1) &= \angle \left\{ \frac{(s_1+2)}{s_1(s_1+4)(s_1+2-j\beta)(s_1+2+j\beta)} \right\} \\ &= \theta_1 - [\theta_0 + \theta_2 + \theta_3 + \theta_4] \quad (171.12) \\ &= \text{odd multiple of } \pi \end{aligned}$$

Next, we develop various rules/steps required for constructing the root locus. Also, we first consider an illustrative (or running) example described by

$$KG(s)H(s) = \frac{K(s+2)}{s(s+4)(s+6)(s^2+6s+34)} = \frac{K(s+2)}{s(s+4)(s+6)(s+3-j5)(s+3+j5)} \quad (171.13)$$

which will be used to demonstrate the various rules/steps involved in the construction of the root locus. The reason for selecting a high-order system (171.13) is that this example illustrates most of the rules, steps, or properties of root locus. Also, note that the root locus and root loci will be used interchangeably.

Rule/Step 1: Starting Points of Root Locus

From the magnitude condition (171.8), the starting points of the root locus which correspond to the value of $K = 0$ are given by

$$|G(s)H(s)| = \frac{1}{K=0} = \infty \quad (171.14)$$

meaning that the starting points of the root loci are those values of s for which $G(s)H(s)$ becomes infinity or the *poles* of $G(s)H(s)$.

In the illustrative example (171.13), the starting points of the root locus are at the poles of $G(s)H(s)$ or at $s = 0, -4, -6, -3 + j5, -3 - j5$, which also means that there are 5 (as many as there are poles) branches of root loci. A branch of root locus is the locus of one root of the C.E. as K changes from zero to infinity.

Statement of Step 1: The root locus starts at the poles of the open-loop transfer function $KG(s)H(s)$.

Rule/Step 2: Ending Points of Root Locus

From the magnitude condition (171.8), the ending points which correspond to the value of $K = \infty$ are given by

$$|G(s)H(s)| = \frac{1}{K=\infty} = 0 \quad (171.15)$$

meaning that the ending points of the root loci are those values of s for which $G(s)H(s)$ becomes zero or the *zeros* of $G(s)H(s)$. In the illustrative example (171.13), the ending points of the root locus are at the zeros of $G(s)H(s)$ or at $s = 2$. Note that if there are 5 branches of root loci as per (171.14), then all these 5 branches need to end at 5 zeros. This means that if there is only 1 finite zero (at $s = 2$) for the system (171.13), then the remaining 4 branches of root loci starting at the poles of $G(s)H(s)$ end at 4 zeros located at infinity.

Statement of Step 2: The root locus ends at the zeros (both finite and infinite) of the open-loop transfer function $KG(s)H(s)$.

Rule/Step 3: Number of Branches of Root Locus

Since the number of branches must equal the number of roots or the order of the C.E., the number of branches of root locus must equal the *order* of the C.E. or the number of open-loop poles or zeros, whichever is higher.

In this particular example (171.13), the total number of branches is 5 the number of open-loop poles.

Statement of Step 3: The total number of branches of the root locus is equal to the number of open-loop poles or zeros, whichever is higher.

Step/Rule 4: Root Locus on Real Axis

Considering any point s_1 on the real axis of the s -plane, it can be easily seen that the angle condition (171.9) or (171.12) is satisfied only for that section on the real axis for which the *total* number of poles and zeros of $G(s)H(s)$ to the *right* of that section is *odd*.

In the present example (171.13), the root locus exists on the real axis on the sections between $s = 0$ and $s = -2$ and $s = -4$ and $s = -6$ as shown in [Figure 171.4](#).

FIGURE 171.4 Root locus on real axis.

Statement of Step 4: *The root locus exists on a section of the real axis if the total number of poles and zeros of $KG(s)H(s)$ to the right of the section is odd.*

Rule/Step 5: Symmetry of Root Locus

Since the root locus is drawn in complex (s -) plane, and the roots not on the real axis are always complex-conjugates, the root locus is symmetrical w.r.t. the real axis of the s -plane.

Statement of Step 5: *The root locus is symmetrical w.r.t. the real axis in s plane.*

Rule/Step 6: Asymptotes of Root Locus

The nature of the root locus near infinity in the s -plane is determined by the asymptotes. There are two properties of the asymptotes: (i) angles of asymptotes and (ii) intersection of asymptotes with real axis.

(i) Angles of Asymptotes

These angles for $s \rightarrow \infty$ are given by

$$\theta_r = \frac{(2r+1)\pi}{|n-m|}, \quad r = 0, 1, 2, \dots, |n-m|-1, \quad (171.16)$$

where, n and m refer to the number of finite poles and zeros respectively of $KG(s)H(s)$.

In the present example (171.13), we have $n = 5$ and $m = 1$ and $n - m - 1 = 3$, so that the angles for asymptotes (171.16) are given by (stopping at $\theta_r = \theta_3$)

$$\theta_0 = \frac{\pi}{4} = 45^\circ, \theta_1 = \frac{3\pi}{4} = 135^\circ, \theta_2 = \frac{5\pi}{4} = 225^\circ = -135^\circ, \theta_3 = \frac{7\pi}{4} = 315^\circ = -45^\circ \quad (171.17)$$

(ii) Intersection of Asymptotes with Real Axis

The intersection σ_a of the asymptotes on the real axis of the s -plane is given by

$$\sigma_a = \frac{\text{Sum of finite poles of } G(s)H(s) - \text{Sum of finite zeros of } G(s)H(s)}{n-m} \quad (171.18)$$

For the running example (171.13), we have

FIGURE 171.5 Asymptotes of root locus.

FIGURE 171.6 Angles of departure for root locus.

$$\sigma_a = \frac{[0 - 4 - 6 - 3 + j5 - 3 - j5] - [-2]}{5 - 1} = -3.5 \quad (171.19)$$

The situation at this stage is depicted in Figure 171.5.

Statement of Step 6: The angles and the intersection of asymptotes are given by (171.16) and (171.18).

Rule/Step 7: Angles of Departure and Arrival

The method of finding the starting and ending points of the root locus on the real axis or from the real poles and zeros is straight forward and is clearly found from the earlier Steps 1–2, whereas the method of finding starting and ending points for the root locus from the complex-conjugate poles and zeros is not that straightforward. The angles of departure (from the complex poles) and the angles of arrival (at complex zeros) are found by considering a point s_1 very close to these complex-conjugate poles/zeros and applying the angle condition (171.9). Thus, consider a point s_1 very close to the complex pole at $-3 + j5$ as shown in Figure 171.6. Applying the angle condition (171.9) to the point s_1 , we have

$$\begin{aligned} \angle(s_1 + 2) - [\angle s_1 + \angle(s_1 + 4) + \angle(s_1 + 6) + \theta + \angle(s_1 + 3 + j5)] &= \text{odd multiple of } \pi, \\ \theta_2 - [\theta_1 + \theta_3 + \theta_4 + \theta + \theta_5] &= \text{odd multiple of } \pi, \\ 180 - \tan^{-1}\left(\frac{5}{3-2}\right) - \left[180 - \tan^{-1}\left(\frac{5}{3}\right) + \tan^{-1}\left(\frac{5}{4-3}\right) + \tan^{-1}\left(\frac{5}{6-3}\right) + \theta + 90^\circ\right] &= \pi, \\ \theta &= -67.4^\circ \end{aligned} \quad (171.20)$$

Statement of Step 7: The angles of departure from the complex poles and the angles of arrival at complex zeros are found using the angle condition (171.9).

Rule/Step 8: Break-Away or Break-In Points on Real Axis

The root locus, starting from a pair of poles (ending at a pair of zeros) on the real axis, for some values of K , will break away (break in) from (to) a point s_1 . This is found using the fact that the value of K is maximum (or minimum) at the break away (or break in) point. This is easily found first by rewriting the C.E. (171.2) in terms of K and then using simple calculus of finding the maximum (or minimum) of K at the point s_1 as

$$K = -\frac{1}{G(s_1)H(s_1)} \rightarrow \frac{dK}{ds_1} = 0 \rightarrow \frac{d}{ds_1} \{G(s_1)H(s_1)\} = 0 \quad (171.21)$$

The break away point s_1 , for the illustrative example (171.13) becomes

$$\frac{d}{ds_1} \left\{ \frac{(s_1 + 2)}{s_1(s_1 + 4)(s_1 + 6)(s_1^2 + 6s_1 + 34)} \right\} = 0 \rightarrow s_1 = -5.0024. \quad (171.22)$$

Note: Use of MATLAB[®] greatly simplifies the procedure for finding the maximum (minimum) at s_1 .

Statement of Step 8: The break away (break in) point at s_1 is found by using the fact that at s_1 , the value of K attains maximum (minimum).

Rule/Step 9: Intersection of Root Locus with $j\omega$ Axis

The value of $K = Kc$ corresponding to the point of intersection of the root locus with the $j\omega$ axis in the s -plane indicates the critical point for stability of the closed-loop system. Beyond this value of Kc (or for some range of values of Kc), the roots of the C.E. lie in the right-half of the s plane leading to instability. This critical point is easily found using the well-known Routh-Hurwitz test for the C.E. (171.2). For this example (171.13), the C.E. (171.2) is

$$s^5 + 15s^4 + 118s^3 + 484s^2 + (816 + K)s + 2K = 0 \quad (171.23)$$

Using the Routh-Hurwitz [6], we get the following three conditions

$$K > 0; K < 2101.07; K < 1356.16 \text{ or } K < -1444.83 \quad (171.24)$$

yielding the result as

$$0 < K_c < 1356.16. \quad (171.25)$$

Also, using this value of $Kc = 1356.16$ in the row above the row determining the critical value of Kc , the points of intersection with the $j\omega$ axis are found to be $\pm j4.7773$.

Statement of Step 9: The intersection of root locus with the $j\omega$ axis in the s plane is found using the Routh-Hurwitz test.

Rule/Step 10: Calculation of the value of K on Root Locus

The value of K on the root locus is found using the basic magnitude condition (171.8). Let us calculate the value of K at the crossing of the root locus with the $j\omega$ axis so that the result can be easily verified with that obtained by using Routh-Hurwitz test used in Step 9. Thus, using (171.8) or (171.11) at the point $s_1 = j4.7773$, we have

$$K = \frac{D_0 D_2 D_3 D_4 D_5}{D_1} = \frac{4.7773 \times 6.231 \times 7.67 \times 3.0083 \times 10.2272}{5.179} = 1356.34 \quad (171.26)$$

The small difference between this value of K and the value of Kc calculated under Step 9 may be attributed to numerical approximation.

Statement of Step 10: The value of K at any point on the root locus is found using the magnitude condition (171.8).

171.5 Software for Root Locus

The first semi-automatic plotting device for root locus was called “Spirule”, invented by The Spirule Company in 1950s [3] for measuring and adding/subtracting angles and for measuring and multiplying/dividing magnitudes. However, with the introduction of computers, the root locus can now be easily obtained using various software packages available [9, 10], notable among them being MATLAB® and SIMULINK®. For this example, the following MATLAB (*m*) file is used to generate the Figure 171.7.

```

171.6 Design Using Root Locus

Root locus is a useful tool for design of controllers for feedback control systems. The design of a controller or compensator essentially amounts to adding poles and/or zeros to the original system transfer function. Hence, we briefly study the effect of adding a pole and a zero on the root locus of the original transfer function. For example, if the original transfer function

$$KG(s)H(s) = \frac{K}{s(s+2)} \quad (171.27)$$

then with the addition of a finite pole, say at $s = -3$, the new transfer function becomes

$$KG(s)H(s) = \frac{K}{s(s+2)(s+3)} \quad (171.28)$$

The corresponding root loci for these transfer functions (171.27) and (171.28) is shown in [Figure 171.8](#). On the other hand, with the addition of a zero, say at $s = -3$, the new transfer function becomes

$$KG(s)H(s) = \frac{K(s+3)}{s(s+2)} \quad (171.29)$$

and the corresponding root loci for (171.27) and (171.29) is shown in [Figure 171.9](#). By proper choice of the pole and/or zero at $s = -3$, we can have a desired shape for the root locus to satisfy the design specifications.

171.7 Root Locus for Discrete-Time Systems

The root locus procedure for discrete-time systems described by Z transforms is similar to the above procedure for continuous-time systems described by Laplace transforms. The one main difference between the two procedures is the stability boundary, that is, the stable region for a discrete-time system in z domain is the unit circle. For example, for a discrete-time system described by the open-loop transfer function

$$KG(z)H(z) = \frac{K(z+0.5)}{(z^2 - 1.4z + 0.48)} \quad (171.20)$$

the root locus plot is shown in [Figure 171.10](#).

171.8 Conclusions

The root locus technique is a very powerful tool for analysis and design of automatic control systems and other systems where one is interested in finding the effect of variation of a particular parameter. Even after more than half a century since its invention, the root locus is still an interesting area of research [11–17].

172.6 Stability via Separate Magnitude and Phase Plots
(Bode Plots)

Frequency response methods for the analysis and design of control systems were developed by H. Nyquist and H. W. Bode in the 1930s. These methods are older than, but not as intuitive as, the root locus, which was discovered by W. R. Evans in 1948. Frequency response yields a new vantage point from which to view feedback control systems. This technique possesses distinct advantages (1) when modeling transfer functions from physical data, (2) when designing lead compensators to meet a steady-state error requirement and a transient response requirement, (3) when determining the stability of nonlinear systems, and (4) in setting ambiguities when sketching a root locus. This chapter introduces frequency response concepts and the determination of stability using the Nyquist criterion.

172.1 Concept and Definition of Frequency Response

In the steady state, sinusoidal inputs to a linear system generate sinusoidal responses of the same frequency. Even though these responses are of the same frequency as the input, they differ in amplitude and phase angle from the input. These differences are a function of frequency.

Sinusoids can be represented as complex numbers, or vectors, called *phasors*. The magnitude of the complex number is the amplitude of the sinusoid and the angle of the complex number is the phase angle of the sinusoid. Thus, $M_1 \cos(\omega t + \phi_1)$ can be represented as $M_1 \angle \phi_1$, where the frequency, ω , is implicit.

Since a system causes both the amplitude and phase angle of the input to be changed, we can therefore think of the system itself as represented by a complex number defined so that the product of the input phasor and the system function yields the phasor representation of the output.

Consider the system in [Figure 172.1](#). Assume that the system is represented by the complex number, $M(\omega) \angle \phi(\omega)$. The output steady-state sinusoid is found by multiplying the complex number representation of the input by the complex number representation of the system. Thus, the steady-state output sinusoid is

FIGURE 172.1 Steady-state sinusoidal frequency response function.

$$M_o(\omega) \angle \phi_o(\omega) = M_i(\omega) M(\omega) \angle (\phi_i(\omega) + \phi(\omega)) \quad (172.1)$$

From Equation(172.1), we see that the system function is given by

$$M(\omega) = \frac{M_o(\omega)}{M_i(\omega)} \quad (172.2)$$

and

$$\phi(\omega) = \phi_o(\omega) - \phi_i(\omega) \quad (172.3)$$

Equations (172.2) and (172.3) form the definition of frequency response. We call $M(\omega)$ the *magnitude frequency response*, and $\phi(\omega)$ the *phase frequency response*. The combination of the magnitude and phase frequency responses is called the *frequency response* and is $M(\omega) \angle \phi(\omega) = G(j\omega)$.

If we know the transfer function, $G(s)$, of a system, we can find $G(j\omega)$ by using the relationship [Nilsson, 1990].

$$G(j\omega) = G(s) \Big|_{s \rightarrow +j\omega} = M(\omega) \angle \phi(\omega) \quad (172.4)$$

172.2 Plotting Frequency Response

$G(j\omega) = M(\omega) \angle \phi(\omega)$ can be plotted in several ways. Two of these ways are (1) as a function of frequency with separate magnitude and phase plots, or (2) as a polar plot, where the phasor length is the magnitude and the phasor angle is the phase. When plotting separate magnitude and phase plots, the magnitude curve can be plotted in decibels (dB) vs. $\log \omega$, where $\text{dB} = 20 \log M$. The phase curve is plotted as phase angle vs. $\log \omega$. Plots that use dB and log frequency are called *Bode plots*. Bode plots can be easily drawn using asymptotic approximations [Nise, 2000].

As an example, find the analytical expression for the frequency response of the system, $G(s) = 1/(s + 2)$. Then, plot the separate magnitude and phase diagrams, as well as the polar plot.

First, substitute $s = j\omega$ in the system function and obtain $G(j\omega) = 1/(j\omega + 2) = (2 - j\omega)/(\omega^2 + 4)$. The magnitude of this complex function, $|G(j\omega)| = M(\omega) = 1/\sqrt{\omega^2 + 4}$, is the magnitude frequency response. The phase angle of $G(j\omega)$, $\phi(\omega) = -\tan^{-1}(\omega/2)$, is the phase frequency response.

$G(j\omega)$ can be plotted in two ways — Bode plots and a polar plot. The Bode plots are shown in Figure 172.2(a), where the magnitude diagram is $20 \log M(\omega) = 20 \log(1/\sqrt{\omega^2 + 4})$ vs. $\log \omega$, and the phase diagram is $\phi(\omega) = -\tan^{-1}(\omega/2)$ vs. $\log \omega$. The polar plot, shown in Figure 172.2(b), is a plot of $M(\omega) \angle \phi(\omega) = 1/\sqrt{\omega^2 + 4} \angle -\tan^{-1}(\omega/2)$ for different ω .

172.3 Stability

A linear, time-invariant system is *stable* if the natural response approaches zero as time approaches infinity. A linear, time-invariant system is *unstable* if the natural response grows without bound as time approaches infinity. Finally, a linear, time-invariant system is *marginally stable* if the natural response neither decays nor grows, but remains constant or oscillates as time approaches infinity.

FIGURE 172.2 Frequency response plots for $G(s) = 1/(s + 2)$: (a) Bode plots, and (b) polar plot.

From the point of view of the transfer function, stable systems have closed-loop transfer functions with only left half-plane *poles*, where a pole is defined as a value of s that causes $F(s)$ to be infinite, such as a root of the denominator of a transfer function. Unstable systems have closed-loop transfer functions with at least one right half-plane pole and/or poles of multiplicity greater than one on the imaginary axis. Marginally stable systems have closed-loop transfer functions with only imaginary axis poles of multiplicity one and left half-plane poles. Stability is the most important system specification. An unstable system cannot be designed for a specific transient response or steady-state error requirement. Physically, instability can cause damage to a system, adjacent property, and human life. Many times, systems are designed with limit stops to prevent total runaway.

FIGURE 172.3 Closed-loop control system.

172.4 Nyquist Criterion for Stability

The Nyquist criterion relates the stability of a closed-loop system to the open-loop frequency response and open-loop pole location. Consider the system of Figure 172.3. The Nyquist criterion can tell us how many closed-loop poles are in the right half-plane.

Before stating the Nyquist criterion, let us discuss the concept of *mapping*. If we take a complex number on the s plane and substitute it into a function, $F(s)$, another complex number will result. This process is called mapping. For example, substituting $s = 4 + j3$ into the function $(s^2 + 2s + 1)$ yields $16 + j30$. We say that $4 + j3$ maps into $16 + j30$ through the function $(s^2 + 2s + 1)$.

Now consider a collection of points, called a *contour*, shown in Figure 172.4 as contour A. Also, assume that

$$F(s) = \frac{(s - z_1)(s - z_2) \cdots}{(s - p_1)(s - p_2) \cdots} \quad (172.5)$$

Contour A can be mapped through $F(s)$ into contour B by substituting each point of contour A into the function $F(s)$ and plotting the resulting complex numbers. For example, point P in Figure 172.4 maps into point Q through the function $F(s)$. Let us now put these concepts together and state the Nyquist criterion for stability (see [Nise, 2000] for derivation).

Assume the system of Figure 172.3, where the open-loop transfer function is $G(s)H(s)$ and the closed-loop transfer function is $T(s) = G(s)/[1 + G(s)H(s)]$. If a contour A that encircles the entire right half-plane, as shown in Figure 172.5, is mapped through $G(s)H(s)$ into contour B, then $Z = P - N$. Z is the number of closed-loop poles (the poles of $T(s)$) in the right half-plane, P is the number of open-loop poles (the poles of $G(s)H(s)$) in the right half-plane, and N is the number of counterclockwise encirclements of -1 of contour B. The mapping, contour B, is called the *Nyquist diagram*.

The Nyquist criterion is classified as a frequency response technique because, around contour A in Figure 172.5, the mapping of the points on the $j\omega$ axis through the function $G(s)H(s)$ is the same as substituting $s = j\omega$ into $G(s)H(s)$ forming the frequency response function, $G(j\omega)H(j\omega)$. Thus, part of the Nyquist diagram is the polar plot of the frequency response of $G(s)H(s)$. Let us look at two examples that illustrate the application of the Nyquist criterion.

FIGURE 172.4 Mapping contour A through function $F(s)$ to contour B.

FIGURE 172.5 Contour enclosing right half-plane to determine stability.

In Figure 172.6(a), contour A maps through $G(s)H(s)$ into a Nyquist diagram that does not encircle -1 . Hence, $P = 0$, $N = 0$, and $Z = P - N = 0$. Because $Z = 0$ is the number of closed-loop poles inside contour A , which encircles the right half-plane, this system does not have any right half-plane poles and is stable.

On the other hand, Figure 172.6(b) shows a contour A that generates two clockwise encirclements of -1 when mapped through the function $G(s)H(s)$. Thus, $P = 0$, $N = -2$, and $Z = P - N = 2$. The system is unstable because it has two closed-loop poles in the right half-plane ($Z = 2$). The two closed-loop poles are shown inside contour A in Figure 172.6(b) as zeros of $1 + G(s)H(s)$. The reader should keep in mind that the existence of these poles is not known *a priori*.

In this example, note that clockwise encirclements imply a negative value for N . The number of encirclements can be determined by drawing a test radius from -1 in any convenient direction and

FIGURE 172.6 Examples of mapping for the Nyquist criterion: (a) contour A does not enclose closed-loop poles; and (b) contour A encloses closed-loop poles.

counting the number of times the Nyquist diagram crosses the test radius. Counterclockwise crossings are positive and clockwise crossings are negative. For example, in Figure 172.6(b), contour *B* crosses the test radius twice in a clockwise direction. Hence, there are -2 encirclements of the point -1 .

172.5 Gain Design for Stability via the Nyquist Criterion

We now use the Nyquist criterion to design a system's gain for stability. The general approach is to set the loop gain equal to unity and draw the Nyquist diagram. Since gain is simply a multiplying factor, the effect of the gain is to multiply the resultant by a constant anywhere along the Nyquist diagram. For example, consider Figure 172.7, which summarizes the Nyquist approach for a system with variable gain K . As the gain is varied, we can visualize the Nyquist diagram (Figure 172.7(c)) expanding (increased gain) or shrinking (decreased gain) like a balloon. This motion could move the Nyquist diagram past the -1 point and change the stability picture. For this system, since $P = 2$, the critical point must be encircled two times in the counterclockwise direction by the Nyquist diagram to yield $N = 2$ and a stable system. A reduction in gain would place the critical point outside the Nyquist diagram where $N = 0$ yielding $Z = 2$, an unstable system.

From another perspective, we can think of the Nyquist diagram as remaining stationary and the -1 point moving along the real axis. In order to do this, we set the gain to unity and position the critical point at $-1/K$ rather than -1 . Thus, the critical point appears to move closer to the origin as K increases.

Finally, if the Nyquist diagram intersects the real axis at -1 , then $G(j\omega)H(j\omega) = -1$. From the root locus, when $G(s)H(s) = -1$, the variables s is a closed-loop pole of the system. Thus, the frequency at which the Nyquist diagram intersects -1 is the same frequency at which the root locus crosses the $j\omega$ axis. Hence, the system is marginally stable if the Nyquist diagram intersects the real axis at -1 .

In summary, if the open-loop system contains a variable gain K , set $K = 1$ and sketch the Nyquist diagram. Consider the critical point to be at $-1/K$ rather than -1 . Adjust the value of gain K to yield stability based upon the Nyquist criterion.

Let us look at an example. For a unity feedback system, where $G(s) = K/[s(s+3)(s+5)]$, find the range of gain K for stability, instability, and marginal stability. For marginal stability, also find the frequency of oscillation.

FIGURE 172.7 Feedback control system to demonstrate Nyquist stability: (a) system, (b) contour, and (c) Nyquist diagram.

FIGURE 172.8 (a) Contour for example; and (b) Nyquist diagram.

First, set $K = 1$ and sketch the Nyquist diagram for the system using the contour shown in Figure 172.8(a). Conceptually, the Nyquist diagram is plotted by substituting the points of the contour shown in Figure 172.8(a) into $G(s) = 1/[s(s + 3)(s + 5)]$. The contour, as shown, must detour around open-loop imaginary axis poles in order to plot a continuous Nyquist diagram. The detour, however, is epsilon close to the open-loop poles to ensure that any closed-loop right half-plane poles close to the imaginary open-loop poles are still inside the contour and are counted.

From A to B, we use

$$G(j\omega) = \frac{1}{s(s+3)(s+5)} \Big|_{s \rightarrow j\omega} = \frac{-8\omega^2 - j\omega(15 - \omega^2)}{64\omega^4 + \omega^2(15 - \omega^2)^2} \quad (172.6)$$

and let ω vary from $0 +$ to ∞ . The mapping in Figure 172.8(b) goes from A' at ∞ to B' at the origin.

Around the infinite circle from B through C to D, the mapping is found by replacing each complex factor in $G(s)$ by its polar form. Thus,

$$G(s) = \frac{1}{(R_0 \angle \theta_0)(R_3 \angle \theta_3)(R_5 \angle \theta_5)} \quad (172.7)$$

The angles are drawn from the respective poles to a point on the infinite circle. The R_i 's are the vector lengths (in this case, infinite). Hence, all points on the infinite circle map into the origin.

The negative imaginary axis from D to E maps into a mirror image of the mapping from A to B, because $G(j\omega)$ has an even real part and an odd imaginary part. From E through F to A, we can again use Equation(172.7). R_0 is zero. Thus, the resultant magnitude is infinite. At E, the angles add to -90° . Hence, the resultant is $+90^\circ$. Similar reasoning yields the mapping of F and A to F' and A' , respectively.

Finally, let us find the point where the Nyquist diagram intersects the negative real axis. We set the imaginary part of Equation(172.6) equal to zero using $\omega = \sqrt{15}$. Then we substitute this value of ω back into Equation(172.6) and find that the real part equals -0.0083 .

From the contour of Figure 172.8(a), $P = 0$ and, for stability, N then must be equal to zero. From Figure 172.8(b), the system is stable if the critical point lies outside the contour ($N = 0$) so that $Z = P - N = 0$. Thus, K can be increased by $1/0.0083 = 120.48$ before the Nyquist diagram encircles -1 . Hence, for stability, $K < 120.48$. For marginal stability, $K = 120.48$. At this gain, the Nyquist diagram intersects -1 , and the frequency of oscillation is $\sqrt{15}$ rad/s.

Now that we have used the Nyquist diagram to determine stability, we can develop a simplified approach that uses only the mapping of the positive $j\omega$ axis.

172.6 Stability via Separate Magnitude and Phase Plots (Bode Plots)

In many cases, stability can be determined from just a mapping of the positive $j\omega$ axis, or, in other words, stability can be determined from the frequency response of the open-loop transfer function. Consider a stable open-loop system, such as that shown in Figure 172.6(a). Since the open-loop system does not have right half-plane poles, $P = 0$. For the closed-loop system to be stable, $N = 0$ yields $Z = P - N = 0$. $N = 0$ (i.e., no encirclements of -1) implies that the Nyquist diagram passes to the right of -1 . Stated another way, the gain of the open-loop transfer function is less than unity at 180° . Thus, if we use Bode plots, we can determine stability from the open-loop frequency response by looking at the magnitude response curve where the phase is 180° . If the gain is less than unity at this frequency, the closed-loop system is stable.

Let us look at an example and determine the range of gain for stability of a system by implementing the Nyquist stability criterion using asymptotic log-magnitude and phase plots. From the log-magnitude plot, we will determine the value of gain that ensures that the magnitude is less than 0 dB (unity gain) at the frequency where the phase is $\pm 180^\circ$.

Shown in Figure 172.9 are the asymptotic approximations to the frequency response of $G(s) = K/[(s + 2)(s + 4)(s + 5)]$, scaled to $K = 40$. Since this system has all of its open-loop poles in the left half-plane, the open-loop system is stable. Hence, the closed-loop system will be stable if the open-loop frequency response has a gain less than unity when the phase is 180° . Accordingly, we see that at a frequency of approximately 7 rad/s, when the phase plot is 180° , the magnitude plot is -20 dB. Therefore, an increase in gain of $+20$ dB is possible before the system becomes unstable. Since the gain plot was scaled for a gain of 40, $+20$ dB (a gain of 10) represents the required increase in gain above 40. Hence, the gain for instability is $40 \times 10 = 400$. The final result is $0 < K < 400$ for stability. This result, obtained by

FIGURE 172.9 Log-magnitude and phase plots.

approximating the frequency response by Bode asymptotes, can be compared to the result obtained from the actual frequency response, which yields a gain of 378 at a frequency of 6.16 rad/s.

In this chapter, we discussed the concept of frequency response, including the Nyquist criterion and its application to the stability of linear feedback control systems. The concept of frequency response can be further applied to transient response analysis and design. Frequency response techniques can also be applied to digital and nonlinear control systems.

Defining Terms

Bode plot — A sinusoidal frequency response plot where the magnitude response is plotted separately from the phase response. The magnitude plot is decibels vs. log frequency, and the phase plot is phase vs. log frequency. In control systems, the Bode plot is usually made for the open-loop transfer function.

Frequency response — The combination of magnitude and phase frequency responses expressed as separate magnitude and phase responses, or as a complex function of frequency.

Magnitude frequency response — The ratio of the magnitude of the steady-state sinusoidal response to the magnitude of the sinusoidal input as a function of frequency. The ratio can be expressed in decibels.

Nyquist criterion for stability — Assume a feedback system where the open-loop transfer function is $G(s)H(s)$ and the closed-loop transfer function is $T(s) = G(s)/[1 + G(s)H(s)]$. If a contour A that encircles the entire right half-plane is mapped through $G(s)H(s)$ into contour B , then $Z = P - N$. Z is the number of closed-loop poles (the poles of $T(s)$) in the right half-plane, P is the number of open-loop poles (the poles of $G(s)H(s)$) in the right half-plane, and N is the number of counterclockwise encirclements of -1 of contour B . The mapping, contour B , is called the Nyquist diagram.

Nyquist diagram — A mapping of a closed contour on the s plane that encloses the right half-plane.

Phase frequency response — The difference between the phase angle of the steady-state sinusoidal response and the phase angle of the input sinusoid as a function of frequency.

Phasor — A complex number or vector representing a sinusoid.

Pole — A value of s that causes $F(s)$ to be infinite, such as a root of the denominator of a transfer function.

Stability of a linear, time-invariant system — That characteristic of a linear, time-invariant system defined by a natural response that decays to zero as time approaches infinity.

The frequency response of a control system may be determined experimentally. Since this is the frequency response for the actual system, correlation criteria that relate transient response to frequency response may then be used to ascertain the transient behavior of the system. Various system **compensation** techniques are available for changing the frequency response so as to improve the transient behavior of the system.

173.1 Correlation between Transient and Frequency Response

Figure 173.1 shows a second-order, type 1 system. For this system, the **natural frequency** is $\omega_n = \sqrt{K_1/\tau}$ and the **damping ratio** is $\zeta = 1/(2\sqrt{K_1\tau})$. The transient behavior is completely described by ζ and ω_n [Raven, 1995]. For a sinusoidal input $r(t) = r_o \sin \omega t$, after the initial transients have died out, the response will be $c(t) = c_o \sin(\omega t + \phi)$. The ratio of the amplitude of the output sinusoidal c_o to the input sinusoidal r_o is $M = c_o/r_o$. The value of ω at which M is a maximum is

$$\omega_p = \omega_n \sqrt{1 - \zeta^2} \quad 0 \leq \zeta \leq 0.707 \quad (173.1)$$

where ω_p is the value of ω at which M attains its peak or maximum value. The corresponding peak or maximum value of M which is designated M_p is

$$M_p = \frac{1}{2\zeta\sqrt{1 - \zeta^2}} \quad 0 \leq \zeta \leq 0.707 \quad (173.2)$$

The preceding result has significance only for $0 \leq \zeta \leq 0.707$, in which case, $M_p \geq 1$. Solving Equation (173.2) for the damping ratio ζ gives

$$\zeta = [(1 - \sqrt{1 - 1/M_p^2})/2]^{1/2} \quad M_p \geq 1 \quad (173.3)$$

The transient behavior of higher-order, type 1 systems is closely approximated by the preceding correlation criteria. For the case in which $M_p < 1$, the transient response is described by a first-order, type 1 system whose time constant τ_c is

$$\tau_c = 1/\omega_c \quad M_p < 1 \quad (173.4)$$

where ω_c is the value of ω at which the $G(j\omega)H(j\omega)$ plot crosses the unit circle. That is, $|G(j\omega)H(j\omega)| = 1$.

Figure 173.2 shows a second-order, type 0 system. For this system, the natural frequency is $\omega_n = \sqrt{(1 + K_o)/b}$, and the damping ratio is $\zeta = a/(2\sqrt{(1 + K_o)b})$. The value of ω at which M is a maximum is the same as that given by Equation (173.1). The corresponding peak or maximum value of M is

$$\frac{M_p}{K_o/(1 + K_o)} = \frac{1}{2\zeta\sqrt{1 - \zeta^2}} \quad 0 \leq \zeta \leq 0.707 \quad (173.5)$$

For large values of K_o , then $K_o/(1 + K_o) \approx 1$, and this criterion becomes the same as that for a type 1 system. Solving Equation (173.5) for the damping ratio ζ gives

$$\zeta = \left\{ \left[1 - \sqrt{1 - (K/M_p)^2} \right] / 2 \right\}^{1/2} \quad M_p/K \geq 1 \quad (173.6)$$

where

$$K = K_o/(1 + K_o)$$

For the case in which $M_p/K = M_p/[K_o/(1 + K_o)] < 1$, the transient response is described by a first-order, type 0 system whose time constant τ_c is

$$\tau_c = 1/\omega_c \quad (173.7)$$

where ω_c is the value of ω at which the $G(j\omega)H(j\omega)$ plot crosses the circle whose radius is

$$r = \frac{K_o}{\sqrt{1 + (1 + K_o)^2}} \quad (173.8)$$

For large values of K_o , the radius r approaches the unit circle and the preceding criterion becomes the same as that for a type 1 system.

FIGURE 173.1 Second order, type 1 system.

FIGURE 173.2 Second order, type 0 system.

FIGURE 173.3 Typical polar plot.

173.2 Determining K to Yield a Desired M_p

Figure 173.3 shows a typical polar plot of $G(j\omega)H(j\omega)$. If the gain K of the system is doubled, the value $G(j\omega)H(j\omega)$ is doubled at every point. Multiplying the old scale by a factor of 2 yields the polar plot for the system in which the gain K has been doubled. Values of this new scale are shown in parentheses. Changing the gain K does not affect the shape of the polar plot.

An M circle is shown in Figure 173.4. The center of the circle is located on the real axis at $-M^2/(M^2 - 1)$, and the radius is $M/(M^2 - 1)$. The line drawn from the origin, tangent to the M circle at the point P , has an included angle of ψ . The value of $\sin \psi$ is

$$\sin \psi = 1 / M \tag{173.9}$$

A characteristic feature of the point of tangency P is that a line drawn from the point P perpendicular to the negative axis intersects this axis at the -1 point.

The procedure for determining the gain K so that the $G(j\omega)H(j\omega)$ plot will have a desired value of M_p is as follows.

1. Draw the polar plot for $G(j\omega)H(j\omega)/K$.
2. Draw the tangent line to the desired M_p circle [$\psi = \sin^{-1}(1/M_p)$].
3. Draw the circle with center on the negative real axis that is tangent to both the $G(j\omega)H(j\omega)/K$ plot and the tangent line, as is shown in Figure 173.5.
4. Erect the perpendicular to the negative real axis from point P . This perpendicular intersects the negative real axis at the point $-A = -0.05$.

FIGURE 173.4 Tangent to an M circle.

FIGURE 173.5 Determination of K to yield a desired M_p .

5. In order that the circle drawn in Step 3 is the desired M_p circle, this point should be -1 rather than $-A$. The required gain is that value of K which changes the scale so that this becomes the -1 point. Thus $K(-A) = -1$ or $K = 1/A$.

As illustrated in Figure 173.5, the perpendicular drawn from point P to the negative real axis intersects the axis at the value $-A = -0.05$. Multiplication of the scale by a factor of 20, as is shown in Figure 173.5 by the numbers in parentheses, converts this point to the -1 point. Thus, the required value of the gain K is 20, such that the polar plot $G(j\omega)H(j\omega)$ is tangent to the desired M_p circle.

The plot $G(j\omega)H(j\omega)/K$ is the plot for the case in which K is 1. By constructing the plot for $G(j\omega)H(j\omega)$ rather than $G(j\omega)H(j\omega)/K$, the resulting value of $1/A$ represents the required factor K_c by which the gain should be changed such that the resulting polar plot will be tangent to the desired M_p circle. That is,

$$\text{New gain} = K_c (\text{original gain}) \quad (173.10)$$

Another method for representing frequency response information is the log-modulus or Nichols plot [Nichols, 1947]. A log-modulus plot is a plot of $\log |G(j\omega)H(j\omega)|$ versus $\angle G(j\omega)H(j\omega)$. Lines of constant M and constant α , where

$$M = |C(j\omega)/R(j\omega)| \text{ and } \alpha = \angle C(j\omega)/R(\omega) \quad (173.11)$$

are circles on the polar plot, become contours when drawn on the log-modulus plot. These M and α contours are shown in Figure 173.6.

Changing the gain K does not affect the phase angle, but merely moves the log-modulus plot $G(j\omega)H(j\omega)/K$ for a system vertically up for $K > 1$ and vertically down for $K < 1$. The M_p contour shown in Figure 173.7 is the desired value of M_p . The solid curve is the log-modulus plot of $G(j\omega)H(j\omega)/K$ for the system. The vertical distance that this curve must be raised such that it is tangent to the desired M_p contour is $\log K$. The dashed curve is the resultant frequency response $G(j\omega)H(j\omega)$. The frequency at the point of tangency is ω_p .

173.3 Gain Margin and Phase Margin

The -1 point of the $G(s)H(s)$ map has great significance with regard to the stability of a system. Figure 173.8 shows a typical $G(j\omega)H(j\omega)$ plot in the vicinity of the -1 point. If the gain were multiplied by an

FIGURE 173.6 Log-modulus representation for lines of constant M and lines of constant α .

FIGURE 173.7 Determination of K for a desired M_p .

amount K_M , called the **gain margin**, the $G(j\omega)H(j\omega)$ plot would go through the -1 point. Thus, the gain margin is an indication of how much the gain can be increased before the $G(j\omega)H(j\omega)$ plot goes through the critical point.

The angle γ in Figure 173.8 is the angle measured from the negative real axis to the radial line through the point where the polar plot crosses the unit circle. If the angle γ were zero, the polar plot would go through the -1 point. The angle γ , called the **phase margin**, is a measure of the closeness of the polar plot to the critical point. A positive phase margin indicates a stable system, as does a gain margin greater than one.

FIGURE 173.8 Gain margin K_M and phase margin γ on the polar plot.

For the system shown in [Figure 173.1](#), the relationship between the damping ratio ζ and the phase margin γ is

$$\zeta = \frac{\tan \gamma \sqrt{\cos \gamma}}{2} \quad (173.12)$$

A plot of this relationship is shown in [Figure 173.9\(a\)](#). The frequency ω_c at which the open-loop frequency response crosses the unit circle is

$$\omega_c / \omega_n = \left[\sqrt{4\zeta^4 + 1} - 2\zeta^2 \right]^{1/2} \quad (173.13)$$

The relationship is shown in [Figure 173.9\(b\)](#). By knowing the phase margin γ , the damping ratio ζ may be determined from [Figure 173.9\(a\)](#). From [Figure 173.9\(b\)](#), the ratio ω_c/ω_n can be found. Thus, by knowing ω_c , the natural frequency ω_n can now be calculated. This method for ascertaining the damping

FIGURE 173.9 Correlation between ζ , ω_n , and phase margin γ : (a) plot of γ versus ζ , and (b) plot of (ω_c/ω_n) versus ζ .

FIGURE 173.10 Series compensator $G_c(j\omega)$.

FIGURE 173.11 Bode diagram for a phase lead compensator.

ratio ζ and natural frequency from the phase margin γ and the frequency ω_c at which the open-loop frequency response crosses the unit circle yields good approximations for systems other than that shown in Figure 173.1.

173.4 Series Compensation

A change in the gain K changes the scale factor of the polar plot, but does not affect the basic shape of the plot. In the design of control systems, it is often necessary to change the shape of the polar plot in order to achieve the desired dynamic performance. A common way of doing this is to insert elements in series with the feed-forward portion of the control, as is illustrated by the elements $G_c(j\omega)$ shown in Figure 173.10. This method of compensating the performance of a control system is called **cascade** or **series compensation**.

Lead Compensation

The frequency response of a phase lead compensator is

$$\frac{1 + j\tau_1\omega}{1 + j\tau_2\omega} \quad \tau_1 > \tau_2 \quad (173.14)$$

The asymptotic approximation to the Bode diagram [Bode, 1945] for $(1 + j\tau_1\omega)/(1 + j\tau_2\omega)$ is shown in Figure 173.11. The frequency at which the maximum phase lead occurs is at

$$\omega_m = 1/\sqrt{\tau_1\tau_2} \quad (173.15)$$

The value of the maximum phase lead is

$$\phi_m = \tan^{-1} \frac{(\tau_1/\tau_2) - 1}{2\sqrt{\tau_1/\tau_2}} \quad (173.16)$$

Figure 173.12 shows a plot of ϕ_m versus both $\log \tau_1/\tau_2$ and τ_1/τ_2 .

The effect of using a phase lead compensator in series with the feed-forward portion of a control system is illustrated in Figure 173.13. The dashed curve is the frequency response $G(j\omega)H(j\omega)$ for the uncompensated control system. This system is unstable. The addition of the lead compensation $G_c(j\omega)$ to reshape the high-frequency portion of the polar plot is shown by the solid line curve. Note that lead compensation rotates a typical vector such as that for $\omega = 2$ in a counterclockwise direction away from the -1 point. Because of the counterclockwise rotation, lead compensation has the very desirable effect of increasing the natural frequency, which increases the speed of the system's response.

To select a lead compensator, it is necessary to specify the values of both τ_1 and τ_2 . Because of the two unknowns τ_1 and τ_2 , the selection of a lead compensator to achieve desired design specifications is basically a trial-and-error process. However, a systematic procedure that rapidly converges is described in the following steps:

1. Determine the phase margin for the uncompensated system.
2. Select a value for ϕ_m , which is the difference between the desired phase margin and the value obtained in step 1, plus a small additional amount, such as 5° .
3. Determine the ratio τ_1/τ_2 from Figure 173.12.
4. Determine the frequency where the log magnitude for the uncompensated system is $-0.5 \log(\tau_1/\tau_2)$. Use this frequency for ω_m .
5. Because the phase lead compensator provides a gain of $0.5 \log(\tau_1/\tau_2)$ at $\omega_m = 1/\sqrt{\tau_1\tau_2}$, this will be the frequency where the compensated system crosses the unit circle. Determine the resulting phase margin for the compensated system.

FIGURE 173.12 Lead compensator characteristics: maximum phase shift ϕ_m versus $\log \tau_1/\tau_2$.

FIGURE 173.13 Use of phase lead to reshape a polar plot.

If the phase margin is too small, increase the value τ_1/τ_2 and, if it is too large, decrease the ratio τ_1/τ_2 and then repeat the steps.

Lag Compensation

The frequency response for a phase lag compensator is

$$\frac{1 + j\tau_2\omega}{1 + j\tau_1\omega} \quad \tau_1 > \tau_2 \tag{173.17}$$

The Bode diagram for $(1 + j\tau_2\omega)/(1 + j\tau_1\omega)$ is shown in Figure 173.14. Note that when $\omega = 10/\tau_2$, the negative phase shift ϕ_c is very small. The negative phase shift associated with lag compensation is usually undesirable. The effectiveness of lag compensation is attributed to the attenuation ($-\log \tau_1/\tau_2$) that occurs at high frequencies.

FIGURE 173.14 Bode diagram for a lag compensator.

FIGURE 173.15 Use of phase lag to reshape a polar plot.

The effect of using a phase lag compensator in series with the feed-forward portion of a control system is illustrated in Figure 173.15. The dashed curve is the frequency response of the uncompensated system. Note that the effect of lag compensation is to shorten a typical vector, such as that for $\omega = 0.5$, and to rotate it slightly in a counterclockwise direction. A procedure for determining the lag compensator for obtaining a desired dynamic performance is described in the following steps.

1. Add 5° to the desired phase margin and then subtract 180° from this result.
2. For the uncompensated system, determine the value of the $\log|G(j\omega)H(j\omega)|$ at the angle determined in step 1.
3. Set this value of $\log|G(j\omega)H(j\omega)|$ equal to $\log \tau_1/\tau_2$. When the lag compensator is added to the uncompensated system, this will be the point where the resultant system crosses the unit circle (i.e., $\log|G(j\omega)H(j\omega)| - \log \tau_1/\tau_2 = 0$). This will be the $10/\tau_2$ frequency.

Lag-lead Compensation

A lag-lead compensator is a series combination of a lag and a lead network. The general transfer function for **lag-lead compensation** is

$$\frac{1 + j\tau_2\omega}{1 + j\tau_1\omega} \frac{1 + j\tau_1\omega}{1 + j\tau_2\omega} \quad \tau_1 > \tau_2 \quad (173.18)$$

Rather than using a lag and a lead compensator in series, it is possible to use a single compensator. The Bode diagram for a typical lag-lead compensator is shown in Figure 173.16 [Palm, 1986]. Because $c\tau_1 > \tau_2 > \tau_1 > \tau_2$, the **lag compensation** takes place before and at lower frequency than the **lead compensation**. A factor of five provides a reasonable separation between the lag and lead compensations:

$$\frac{1}{\tau_1} = 5 \frac{1}{c\tau_2}$$

or

FIGURE 173.16 Bode diagram for a lag-lead compensator.

$$c = 5 \frac{\tau_1}{\tau_2} \quad (173.19)$$

The maximum phase shift ϕ_m occurs at $\omega = 1/\sqrt{\tau_1\tau_2}$, and the corresponding gain is $-0.5\log\tau_1/\tau_2$. This is the same as for a lead compensator, except that the sign of the gain $0.5\log\tau_1/\tau_2$ is negative. This feature makes the lag-lead compensator considerably more effective than the lead compensator only.

173.5 Internal Feedback

Another method commonly used to alter frequency response characteristics is that of providing a separate **internal feedback** path about certain components [D'Souza, 1988]. A plot of the function $G^{-1}(j\omega) = 1/G(j\omega)$ is called an inverse polar plot. Figure 173.17 shows a typical inverse polar plot for the function $G^{-1}(j\omega)$. At any frequency ω , the vector from the origin to a point on the plot defines the vector $G^{-1}(j\omega)$ for that frequency. The length of the vector is $|G^{-1}(j\omega)| = 1/|G(j\omega)|$, and the angle is

$$\angle G^{-1}(j\omega) = \angle \frac{1}{G(j\omega)} = -\angle G(j\omega) \quad (173.20)$$

On the inverse plane, lines of constant M are circles of radius $1/M$. The center of these concentric M circles is at the point $x = -1$ and $y = 0$ (e.g., the -1 point). A plot of the M circles on the inverse plane is shown in Figure 173.18. Because the reciprocal of -1 is still -1 , this point has the same significance for an inverse polar plot as for a direct polar plot. The lines of constant $\alpha = \angle [C(j\omega)/R(j\omega)] = -\angle [R(j\omega)/C(j\omega)]$ are radial straight lines (rays) which pass through the -1 point.

FIGURE 173.17 Typical inverse polar plot $G^{-1}(j\omega)$.

FIGURE 173.18 M circles and α rays on the inverse plane.

FIGURE 173.19 Tangent line to an M circle.

As illustrated in Figure 173.19, the angle ψ of a radial line drawn from the origin and tangent to any M circle is

$$\sin \psi = 1 / M \tag{173.21}$$

The general procedure for determining the required gain K to yield a desired M_p is as follows:

1. Plot the inverse function $KG^{-1}(j\omega)H^{-1}(j\omega)$.
2. Construct the tangent line at the angle $\psi = \sin^{-1}(1/M_p)$.
3. Construct the circle which is tangent to both the $KG^{-1}(j\omega)H^{-1}(j\omega)$ plot and the tangent line.
4. The center of the circle is at the point $-A$. The desired gain is $K = A$.

When the function $G^{-1}(j\omega)H^{-1}(j\omega)$ is plotted rather than $KG^{-1}(j\omega)H^{-1}(j\omega)$, then A is equal to the factor K_c by which the gain should be changed to yield the desired M_p .

The major advantage of using the inverse plane is realized for systems with internal feedback. For the system of Figure 173.20,

$$G^{-1}(j\omega) = \frac{1 + G_1(j\omega)H_1(j\omega)}{G_1(j\omega)} = G_1^{-1}(j\omega) + H_1(j\omega) \tag{173.22}$$

As illustrated in Figure 173.21, the vectors $G_1^{-1}(j\omega)$ and $H_1(j\omega)$ may be added as vector quantities to yield $G^{-1}(j\omega)$. For a given $G_1^{-1}(j\omega)$ plot, $H_1(j\omega)$ may be determined to move any given point to a desired location, such as a point of tangency with an M_p circle, or to yield a desired phase margin.

FIGURE 173.20 Internal feedback $H_1(s)$ placed about $G_1(s)$.

FIGURE 173.21 Vector addition of $G_1^{-1}(j\omega)$ and $H_1(j\omega)$ to yield $G^{-1}(j\omega)$. **FIGURE 173.22** (a) Root locus plot for $s(s - r_1)(s - r_2) + K = 0$, and (b) addition of phase lead compensation.

If $H_1(s) = \alpha$, a constant, then the $G^{-1}(j\omega)$ plot is shifted to the right by the distance α . If $H_1(s) = \beta s$, then $H_1(j\omega) = j\beta\omega$, and the $G^{-1}(j\omega)$ plot is shifted upwards vertically in proportion to the frequency ω . If $H(s) = \alpha + \beta s$, then the $G^{-1}(j\omega)$ plot is shifted both to the right and upwards vertically.

173.6 Compensation on the S Plane

The transfer function for a phase lead compensator may be written in the form

$$\frac{1 + \tau_1 s}{1 + \tau_2 s} = \frac{s + 1/\tau_1}{s + 1/\tau_2} = \frac{s - z}{s - p} \quad \tau_1 > \tau_2 \quad (173.23)$$

where $z = -1/\tau_1$ is a zero, and $p = -1/\tau_2$ is a pole. The root locus plot for the system whose characteristic equation is $s(s - r_1)(s - r_2) + K = 0$ is shown in Figure 173.22(a). Assume that the root locus plot goes through the root location for the dominant roots (point $a \pm jb$) shown in Figure 173.22(b). The zero is drawn directly under the point $a + jb$. Application of the angle condition gives

$$\phi_1 + \phi_2 + \phi_3 + \phi_p - 90^\circ = 180^\circ$$

Hence,

$$\phi_p = 270^\circ - (\phi_1 + \phi_2 + \phi_3)$$

The angle ϕ_p determines the location of the pole. Similarly, phase lag and lag-lead compensators [Dorf, 1989] may be designed on the s plane.

Defining Terms

Cascade compensation — Insertion of elements in series with the feed-forward portion of a control system in order to obtain the desired performance.

Compensation — Method of improving the performance of a control system by inserting an additional component within the structure of the system.

Damping ratio — Dimensionless number that is a measure of the amount of damping in a system.

Gain margin — If the gain of a system were changed by this factor, called the gain margin, the $G(j\omega)H(j\omega)$ plot would go through the -1 point.

Internal feedback — Method of system compensation in which an internal feedback path is provided about certain components.

Lag compensation — A component that provides significant attenuation over the frequency range of interest.

Lag-lead compensation — A component that provides both significant positive phase angle and attenuation over the frequency range of interest.

Lead compensation — A component that provides significant positive phase angle over the frequency range of interest.

Natural frequency — Frequency at which a system would oscillate if there was no damping.

Phase margin — Angle measured from the negative real axis to the radial line where the polar plot crosses the unit circle.

Series compensation — The insertion of elements in series with the feed-forward portion of a control system in order to obtain the desired performance.

Thomas E. Marlin
McMaster University

Process control addresses the application of automatic control theory to the process industries. These industries typically involve the continuous processing of fluids and slurries in chemical reactors, physical separation units, combustion processes, and heat exchangers in industries such as chemicals, petroleum, pulp and paper, food, steel, and electrical power generation. Generally, the goal of process control is to reduce the variability of key process variables that influence safety, equipment protection, product quality, and production rate. To achieve reduced variability in these key variables, we must adjust selected manipulated variables. As a result, the “*total variability*” is not reduced, but it is transferred from important to less important areas of the process, such as cooling water, steam systems, and fuel distribution systems.

174.1 Defining the Process Control Design Problem

Process control design involves the following decisions: (1) selecting sensors that reflect process performance, (2) selecting final elements with good dynamic responses and sufficient range, (3) ensuring that the feedback process dynamics are favorable for good control performance, (4) selecting a structure for linking controlled and manipulated variables, and (5) selecting algorithms and tuning parameters to give robust performance. Note that key decisions such as process flexibility and locations of sensors and final elements involve the structure of the process, and the linking of measured and manipulated variables involves the structure of the control system. If these structural decisions are made poorly, even the best control algorithms will not provide acceptable performance.

Before beginning the design process, the engineer must thoroughly define the control objectives using the following categories:

- Safety
 - Environmental protection
 - Equipment protection
 - Smooth, easy operation
 - Product quality
-

- Efficiency and profit
- Monitoring and diagnosis

Each of these objectives should be defined as quantitatively as possible; for example, the temperature of the reactor will not exceed 400 K for a feed rate change of $\pm 20\%$ or a feed temperature step change of 20 K. Clearly, the thorough understanding of the process, including disturbed situations, is required to define the design problem. A simplified statement of objectives for distillation control is given in Table 174.1 with sensors and control designs. Several more complete examples are available in Marlin (2000), and methods for estimating economic benefits from control are presented by Marlin et al. (1991).

An important step is the definition of the desired dynamic performance of the key variables. This definition will be used in the initial design and can also be used to monitor and evaluate the achieved performance of the operating plant. In evaluating control performance, many factors are relevant, as shown in Figure 174.2. First, the controlled variable should have a small deviation from its set point (or

FIGURE 174.2 Example of control-loop dynamic response.

reference value); this can be measured by the integral of the error squared for short data sets and by the standard deviation of the error for long data sets. Note that the contribution of this deviation due to sensor noise cannot be eliminated by control. Second, the behavior of the manipulated variable is crucial in many processes. Large rapid changes in the manipulated variable could lead to damage of process equipment; an example is adjustments to the fuel to a fired heater, where large, long-term fuel variations could lead to excessive thermal stresses. In other cases, disturbances could be propagated to other important units; an example is tight level control that could lead to excessive flow fluctuations through

the plant. Third, the stability and performance should be robust, that is, dynamic performance should remain acceptable for expected changes in the plant operation. As the operation changes, the process dynamics change and control performance could suffer. Thus, the application of process control must satisfy a complex, multiobjective performance measure.

174.2 Single-Variable Control

Most complex control systems involve multiple, single-loop controllers; thus, the principles of single-loop control must be mastered as a basis for realistic, multivariable control systems. In single-variable systems, one measured variable is regulated by adjusting one manipulated variable. The algorithm most commonly used is the proportional-integral-derivative (PID) controller, which is given for a continuous system:

$$MV(t) = K_c \left(E(t) + \frac{1}{T_i} \int_0^t E(t') dt' - T_D \frac{dCV(t)}{dt} \right) + I \quad (174.1)$$

with the error, $E = SP - CV$ and the initialization bias, I . The process, sensor, final element, and controller appear in the closed-loop system and influence the control performance. To consider the behavior of the system, see the simple block diagram in Figure 174.3. The transfer functions describing the relationship between the input forcing and the controlled variable are given in the following equations.

Disturbance response:
$$\frac{CV(s)}{D(s)} = \frac{G_D(s)}{1 + G_p(s)G_v(s)G_c(s)G_f(s)G_s(s)} \quad (174.2)$$

Set point response:
$$\frac{CV(s)}{SP(s)} = \frac{G_p(s)G_v(s)G_c(s)G_f(s)}{1 + G_p(s)G_v(s)G_c(s)G_f(s)G_s(s)} \quad (174.3)$$

The stability of the closed-loop system depends on the terms in the characteristic equation, the denominator of the closed-loop transfer function.

The single control algorithm is matched or “tuned” to the specific process by selecting values for the adjustable parameters: the controller gain, K_c ; the integral time, T_i ; and the derivative time, T_d . In all tuning approaches, the parameters depend upon the feedback dynamics, and in some methods, the

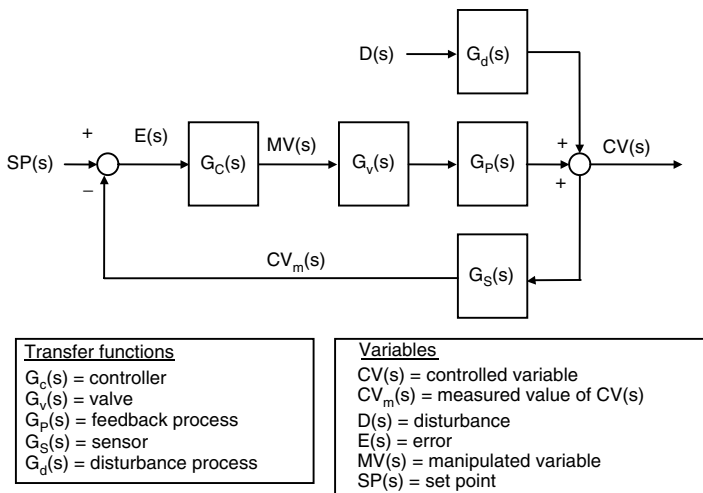

FIGURE 174.3 Single-loop block diagram.

disturbance dynamics are also considered. The method based on a stability margin developed by Ziegler-Nichols (1942) was used for many years; this method established a stability margin for proportional-only feedback and estimated tuning constant values based on heuristics. When digital computing was available to optimize tuning, methods based on closed-loop dynamic performance were developed. The success and generality of these methods depended on the definition of control performance measures and scenarios considered. Initial methods considered only controlled variable performance for perfect models (Lopez et al., 1969), while later methods included sensor noise (Fertik, 1975).

Newer tuning methods are available, such as Morari and Zafiriou (1989) and Marlin (2000), which provide a better balance of performance and robustness. The tuning correlations presented here are restricted to processes that have stable, monotonic step responses, so that they can be adequately modeled using first-order with dead-time models (Brosilow and Joseph, 2002).

$$\text{Feedback process:} \quad \frac{CV(s)}{MV(s)} = \frac{K_p e^{-\theta s}}{\tau s + 1} \quad (174.4)$$

$$\text{Disturbance process:} \quad \frac{CV(s)}{D(s)} = \frac{K_D e^{-\theta_D s}}{\tau_D s + 1} \quad (174.5)$$

The following IMC tuning correlations provide tuning values to achieve a user-specified closed-loop response time, τ_{CL} .

$$K_p K_c = \frac{2\tau + \theta}{2\tau_{CL}} \quad T_I = \tau + \frac{\theta}{2} \quad (174.6)$$

The smaller the value of the closed-loop time constant (τ_{CL}), the more aggressive the controller. As guidelines, the closed-loop time constant should be greater than 1.7θ and always greater than 0.2τ . Details on the development of IMC tuning rules and more general correlations are provided in Rivera et al. (1986) and Morari and Zafiriou (1989).

The tuning charts in [Figure 174.4](#) give PI tuning that provides robust control with moderate adjustments to the manipulated variable. Details on their development and more general correlations are provided in the tuning charts in Marlin (2000). Regardless of the tuning correlation, the resulting values should be considered as *initial estimates* to be modified to achieve the desired performance for a specific process.

The same single-loop PI controller can be successfully applied to level control, or more generally, inventory control. However, because of the unique process dynamics and control objectives, special tuning approaches are required. The dynamic response for the level in [Figure 174.5](#) is an integrator, which is open-loop unstable. In addition, we usually select from two different objectives for control. Tight level control seeks to maintain the level close to its set point; it is appropriate for controlling small levels and for processes in which the inventory affects process performance, such as chemical reactors. Loose or averaging level control seeks to achieve moderate changes to the manipulated flow rate, while maintaining the level within acceptable limits; it is appropriate for most tank and drum levels, when preventing downstream disturbances is important. Tuning for linear PI level control is given in [Figure 174.5](#). Derivations for these expressions and an approach for nonlinear PI control are available in Marlin (2000), and more background and correlations on level control are given by Cheung and Luyben (1978).

Single-Loop Control Performance

Using a well-tuned feedback algorithm does not ensure acceptable control performance because control performance depends on all elements in the closed-loop system, as seen in Equation (174.2). Important insights can be obtained by considering the frequency response of Equation (174.2), $|CV(j\omega)|/|D(j\omega)|$, shown in [Figure 174.6](#). For disturbances with very low frequencies, feedback control is much faster than the

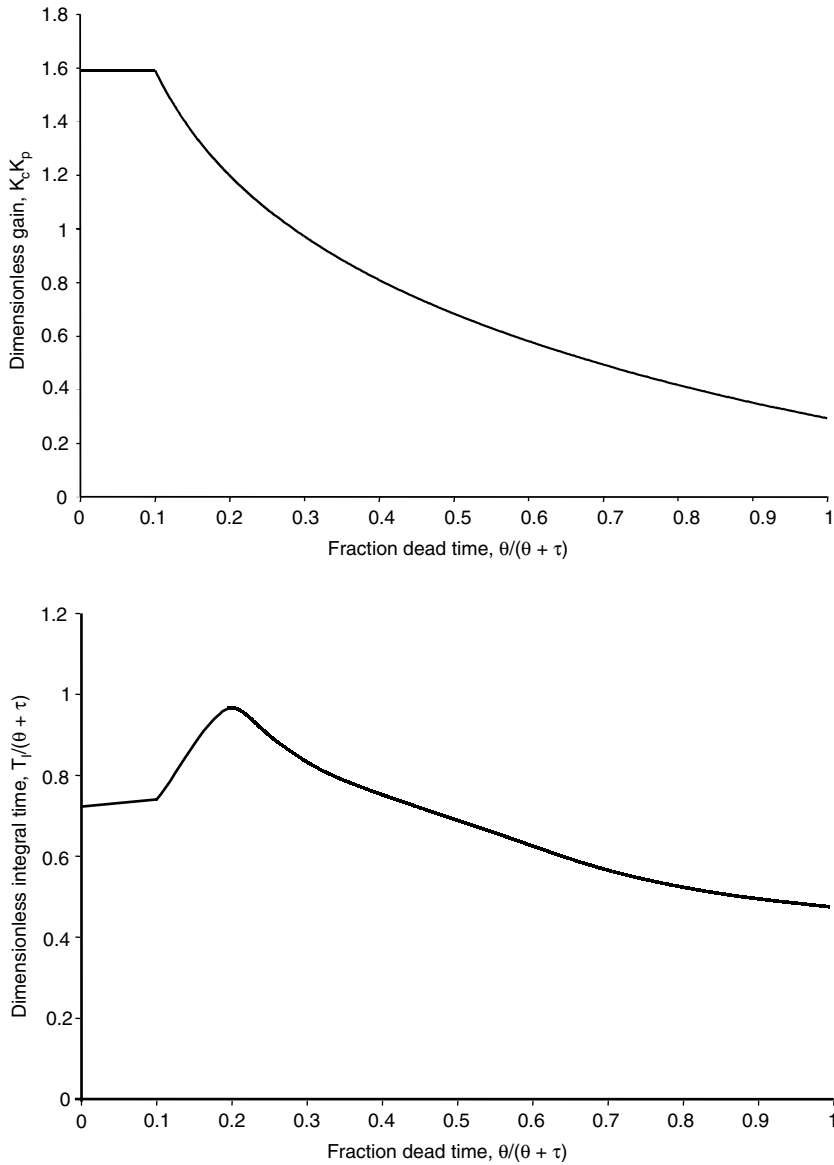

FIGURE 174.4 Proportional integral tuning correlations. (Source: Marlin, T. 2000. *Process control: designing processes and control systems for dynamic performance*. McGraw-Hill, New York. With permission.)

disturbance, and is thus quite effective. For very high frequencies, the disturbance time constant attenuates the effect of the disturbance on the controlled variable, and the performance is quite good, although not due to feedback compensation. In some intermediate range of frequencies, resonance occurs and feedback control performance is poor. The location of the resonance peak depends primarily on the feedback dynamics for a (stable, well-tuned) feedback control system. Therefore, the dynamics of the feedback system (process, sensor, and final element) impose a fundamental limitation to feedback performance.

The effects of various elements in the feedback loop on the performance of single-loop control are summarized in [Table 174.2](#). This table provides the basis for design decisions to improve control performance. It is important to note that large dead times and time constants in the feedback loop are always detrimental, whereas large time constants in the disturbance path, which is not in the feedback loop, can improve control performance.

$$K_c = \frac{-0.737\Delta F_{\max}}{\Delta L_{\max}}$$

$$T_i = \frac{4A}{-K_c}$$

ΔL = maximum allowable change in level (m)
 ΔF = maximum flow disturbance magnitude (m³/min)
 A = cross sectional area (m²)
 For both controls, set point = 50% of range
 For averaging level control, $\Delta L \approx 40\%$ of range
 For tight level control, $\Delta L \approx 5\%$ of range

FIGURE 174.5 Level control design with tuning for averaging and tight level control.

FIGURE 174.6 Typical closed-loop frequency response.

Instrumentation provides the essential measurements and final elements for process control. Important features of the sensor include accuracy, reproducibility, reliability, and dynamics; these issues are discussed in Hughes (2002). Important features of the final element, which is usually a valve, include stiction, hysteresis, characteristic dynamics, tight shutoff, and failure position; these issues are discussed in Driskell (1983).

Single-Loop Control Improvement Through Process Modifications

The principles in Table 174.2 can be used in designing high-performance single-variable control loops by modifying the process dynamics, either feedback or disturbance as appropriate. In the heat exchanger example in Figure 174.7a, the initial design has slow feedback dynamics because of the heat exchanger

TABLE 174.2 Summary of Factors Affecting Single-Loop PID Controller Performance

| Key Factor | Typical Parameter | Effect on Control Performance |
|--|---|--|
| Feedback process gain | K_p | The key factor is the product of the process and controller gains. For example, a small process gain can be compensated by a larger controller gain. Note that the manipulated variable must have sufficient range. |
| Feedback process “speed” | $\theta + \tau$ | Control performance is always better when this term is small. |
| Feedback fraction process dead time | $\theta/(\theta + \tau)$ | Control performance is always better when this term is small. |
| Inverse response | Numerator term in transfer function, $(\tau s + 1)$ with $\tau < 0$ | Control performance degrades for large inverse response. |
| Magnitude of disturbance effect | $K_d \Delta D $ | Control performance is always better when this term is small. |
| Disturbance dynamics | τ_D | Control performance is best when the disturbance is slow, that is, the time constant is large. |
| | ω_D | Feedback control is effective for low-frequency disturbances and is least effective at the resonant frequency. |
| | θ_D | Disturbance dead time does not influence performance. |
| Sensor | | Measurement should be accurate as operating conditions change. Dynamics should be fast with little noise. |
| Filter, $1/(1 + \tau_f s)$ | $\tau_f/(\theta + \tau)$ | Filters higher-frequency components of measurement. Reduces the variability of the manipulated variable but degrades control as filter time constant is increased. |
| Final element | | Dynamics should be fast without sticking or hysteresis. Range should be large enough for response to demands. |
| Controller execution period (Δt) | $\Delta t/(\theta + \tau)$ | Control performance is best when this parameter is small. Continuous PID tuning correlations can be used by modifying the dead time, $\theta' = \theta + \Delta t/2$. |
| Controller tuning | $K_c K_d$ $T_I/(\theta + \tau)$ $T_D/(\theta + \tau)$ | Determined from tuning correlations based on control objectives. The tuning should provide robust performance, that is, should provide reasonable performance for the expected range of process dynamics experienced in the plant. |
| Modeling errors | | Errors in identifying the process model parameters lead to poorer control performance and, potentially, instability. Tuning should consider the estimate of model errors. K_p must not change sign. |
| Limitations on manipulated variable | $\min < mv(t) < \max$ | Limitations on manipulated variables reduce the operating window, that is, the range of achievable conditions. An active limit would cause steady-state offset from the set point. |

being in the feedback loop. The improved design in Figure 174.7b involves rapid mixing of a bypass stream to shorten the feedback dynamics, thus providing better performance. In addition, the cooling stream flow rate in Figure 174.7b can be manipulated independently, which is essential when it is a process stream from another section of the plant.

In the distillation example in Figure 174.1, the feed flow rate and composition experience variation at frequencies near the resonant frequency of the composition control loop. The design includes features

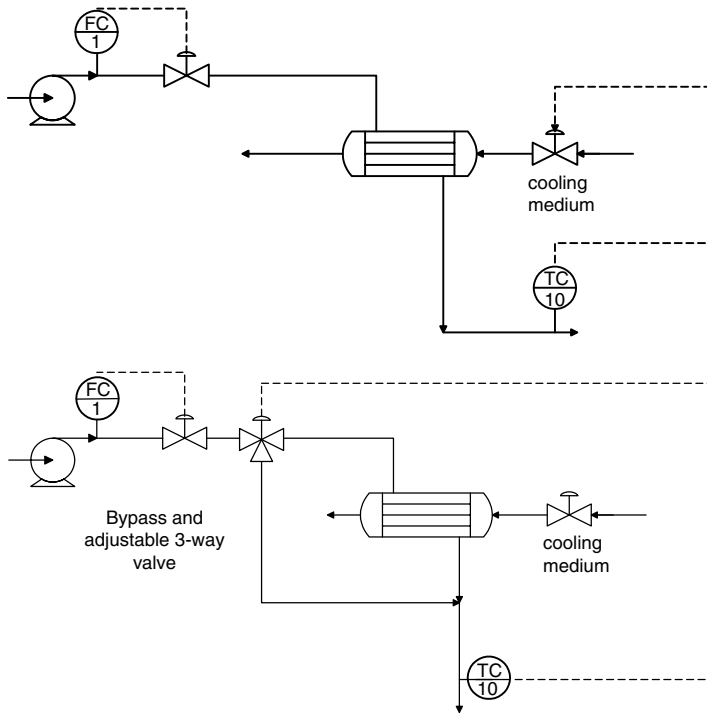

FIGURE 174.7 Heat exchanger control with (a) slow and (b) fast feedback dynamics.

to moderate the effects of disturbances. The feed flow rate disturbance has been attenuated by the addition of a feed storage drum with averaging level control, and the feed composition disturbance is attenuated by mixing in the feed storage drum. As a result, the disturbances experienced by the distillation tower are smaller in magnitude, and the control performance is substantially improved.

Single-Loop Control Improvements Through Control Structure Modifications

The control performance of a single variable can be improved, without changing the process, by modifying the control structure. Four common control structure modifications are presented here. The first new structure is cascade control, which uses a secondary measured variable to provide an early indication of selected disturbances. As shown in Figure 174.8, the secondary variable, the measured heating medium flow rate is controlled using feedback principles, and the set point of the flow controller is adjusted via feedback to achieve the desired outlet temperature. Each of the controllers can use the standard PID controller algorithm, and the inner or secondary controller must be tuned first. The cascade design provides good performance for only some disturbances; for example, the design in Figure 174.8 gives good performance for disturbances in the pressure of the heating medium source, but it does not improve performance for feed temperature disturbances.

Cascade control must conform to specific design criteria. In particular, the secondary variable must (1) be measured, (2) indicate the occurrence of an important disturbance, (3) be causally affected by the final element, and (4) have feedback dynamics much faster than the primary variable (Marlin, 2000). A multiple-layer cascade control design is common to compensate for several disturbances; however, each layer must conform to the four design criteria above.

The second control structure provides an alternative to feedback by measuring the disturbance before it influences the process. This *feed-forward* modification, shown in Figure 174.9, eliminates the feedback dynamics from the control compensation for the measured disturbance and can theoretically provide excellent control. The feed-forward control algorithm to give perfect feed-forward compensation can be

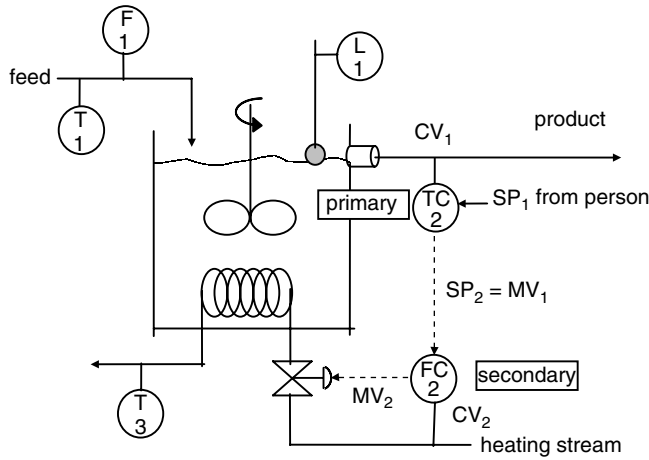

FIGURE 174.8 Cascade control system.

determined from block diagram algebra to be $G_{ff}(s) = -G_D(s)/G_p(s)$; thus, the feed-forward algorithm depends on the models of the process dynamics. When both the process and disturbance transfer functions can be well approximated by first-order with dead-time transfer functions in Equations (174.4) and (174.5), the feed-forward controller is

Feedforward controller:
$$G_{ff}(s) = \frac{MV_{ff}(s)}{D(s)} = -\frac{K_d}{K_p} \left(\frac{\tau s + 1}{\tau_D s + 1} \right) e^{-(\theta_D - \theta)s} \quad (174.7)$$

Equation (174.7) is often used for feed-forward control and can be realized using standard gain, dead-time, and lead/lag algorithms.

Feed-forward control must conform to specific design criteria. In particular, the measured disturbance variable must (1) be measured, (2) indicate the occurrence of an important disturbance, (3) not be causally affected by the final element, and (4) have disturbance dynamics not faster than the compensation dynamics (Marlin, 2000). Usually, feedback control is retained because feed-forward compensates for only the measured disturbance(s) and because the feed-forward control is not perfect due to model mismatch. The feed-forward and feedback adjustments can be added, as in Figure 174.9, using the property of linearity.

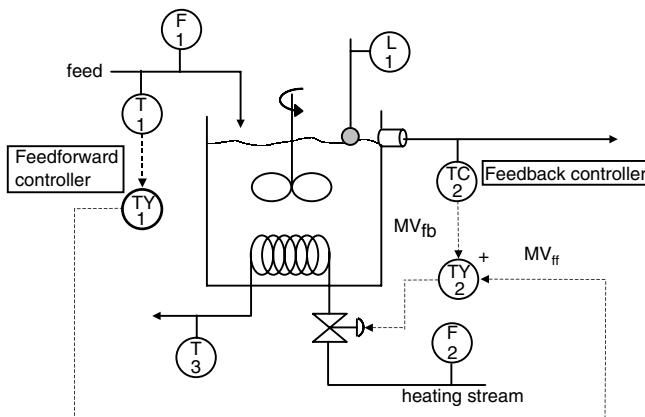

FIGURE 174.9 Feed-forward feedback control system.

FIGURE 174.10 Pressure control using a split range strategy.

The third control structure is split range control, which enables one controller to adjust more than one final element. Split range can be used to (1) improve the speed of response, (2) expand the range of the manipulation, or (3) utilize the most economically attractive manipulated variable. An application involving an economic objective is shown in Figure 174.10, in which a pressure controller adjusts two sources of material to satisfy demands in the plant. The controller calculates only one output (x) that is transmitted to two final elements. The final elements are calibrated to respond to the controller output as shown in the figure, so that only one valve is moving for any value of x . Under normal operation, v_A is adjusted and v_B is fully closed; this represents the case in which flow A is less expensive. When the controller requests a large flow of material and the controller output (x) is over 50%, v_A is fully opened and v_B is adjusted. In general, the feedback dynamics, at least the process gain, can change when the valves are switched, and the engineer should investigate the need for adjusting the controller tuning based on the controller output value.

The fourth control structure is *signal select*, which is explained here for an application in which three controllers adjust only one final element, as shown for a chemical reactor in Figure 174.11. We want to

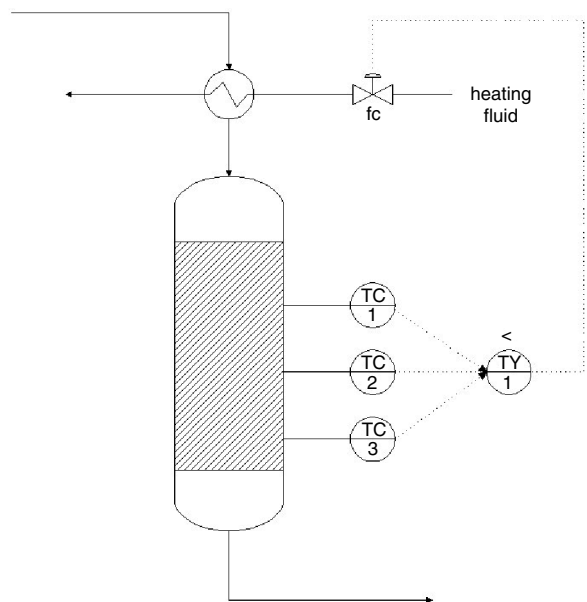

FIGURE 174.11 Reactor temperature control using a signal select strategy.

control the temperature but also ensure that the hottest temperature in the packed bed reactor remains below a maximum limit. Thus, we implement several single-loop PID controllers, one for each temperature measurement. The outputs from all controllers are transmitted to a calculation that selects the signal that results in the “safest” opening of the heating flow valve. Since the valve is fail closed, this safest operation is the smallest of the controller output values; thus, a low signal select is employed. The value from the signal select is transmitted to the control valve.

174.3 Principles of Multiple Input-Output Control

Most industrial processes involve many manipulated and controlled variables, which dramatically complicates control design and implementation. Multivariable control will be presented in three subsections covering (1) principles of multivariable control, (2) control using multiple PID controllers, and (3) control using a centralized algorithm. In this section, the required conditions for degrees of freedom, controllability, and rangeability are discussed.

The selection of variables to be controlled is based on the control objectives; that is, we control what is required for safety, product quality, production rate, and so forth; refer again to [Table 174.1](#) for an example of the relationships between control objectives and control variable selection. After the controlled and manipulated variables have been defined, we must ensure that control is possible, that is, that we have sufficient *degrees of freedom*. A simple test is to compare the number of manipulated and controlled variables. Clearly, to achieve desired (independent) values of the controlled variables, the plant must have at least as many manipulated (final elements) as controlled variables. If this condition is not satisfied, the process design must be modified to include additional flexibility and final elements.

The final elements must also be able to be controlled, which is referred to as *controllability*. Because of the complex nature of chemical processes, final elements do not influence only one controlled variable. Thus, *interaction* exists, with interaction resulting from the effect of a manipulated variable on many controlled variables. Because of interaction, the engineer cannot determine whether control is possible by observation. Several methods are available to determine whether a selection of controlled and manipulated variables is controllable; the method should be matched to the specific application and dynamic behavior required, continuous tracking, continuous regulation, batch control, and so on. Rosenbrock (1974) provides an excellent discussion with calculation methods. For continuous processes, a relevant controllability test is given in the following for the two input/two output system shown in [Figure 174.12a](#).

$$\begin{bmatrix} CV_1(s) \\ CV_2(s) \end{bmatrix} = \begin{bmatrix} G_{11}(s) & G_{12}(s) \\ G_{21}(s) & G_{22}(s) \end{bmatrix} \begin{bmatrix} MV_1(s) \\ MV_2(s) \end{bmatrix} + \begin{bmatrix} G_{d1}(s) \\ G_{d2}(s) \end{bmatrix} D(s) \quad (174.8)$$

The controlled variables can be maintained exactly at their desired values if the feedback process can be inverted at all frequencies (Rosenbrock, 1974); that is,

$$\det \begin{bmatrix} G_{11}(j\omega) & G_{12}(j\omega) \\ G_{21}(j\omega) & G_{22}(j\omega) \end{bmatrix} \neq 0 \quad (174.9)$$

Usually, the exact inverse cannot be taken because of the process dynamics (e.g., dead times), so perfect control is not possible. If the requirement is only that the controlled variables can be maintained at their desired values in the steady state, the requirement for controllability is

$$\det \begin{bmatrix} G_{11}(0) & G_{12}(0) \\ G_{21}(0) & G_{22}(0) \end{bmatrix} = \begin{bmatrix} K_{11} & K_{12} \\ K_{21} & K_{22} \end{bmatrix} \neq 0 \quad (174.10)$$

Therefore, the controllability test in Equation (174.10) requires that the steady-state gain matrix must be invertible, that is, its determinant must not be zero. This serves as a useful controllability test for

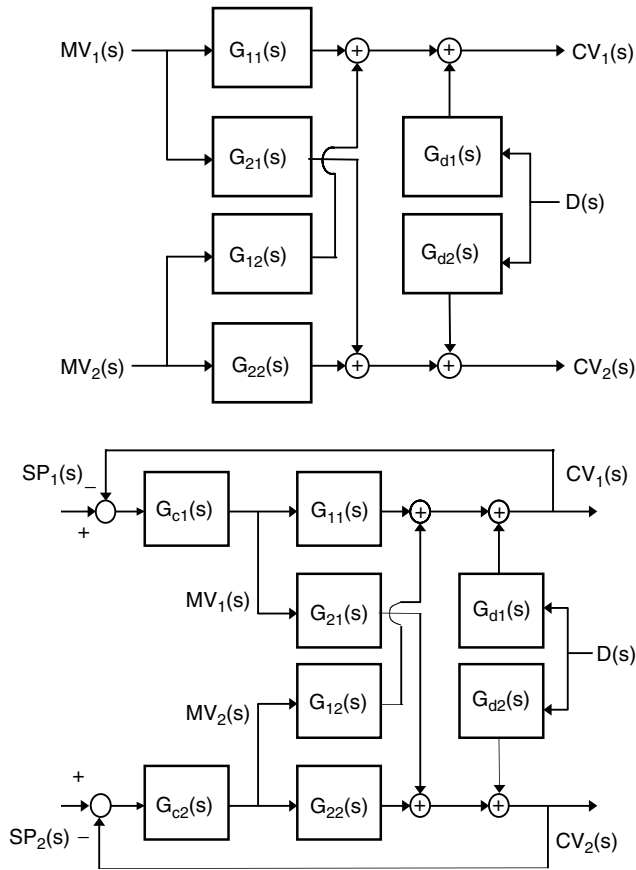

FIGURE 174.12 Multiloop (2×2) block diagram for (a) process only and (b) multiloop control.

continuous processes that must be satisfied before the design of the control system begins. Note that this test is only valid at the linearization point and does not ensure that the dynamic performance is satisfactory at all operating conditions.

A final process requirement involves the ability of the system to maintain controlled variables at their set points as the values of the set points and process disturbances vary within expected limits. The acceptable range of plant operation is often referred to as the *operating window* or the *feasible region*. Qualitatively, the process must be able to adjust the manipulated variables over a wide enough range of values to reach the set points and reject the expected range of disturbances.

When a process design satisfies the three essential requirements (degrees of freedom, controllability, and rangeability) the design procedure can continue to address the feedback strategy to achieve good dynamic performance. If the process is deficient in any of these areas, the process must be modified by, for example, increasing the final element capacity or adding an additional manipulated variable. In the following subsections, the two major multivariable control approaches are introduced: multiloop control and centralized multivariable control.

174.4 Multiloop Multivariable Control

Often, multiple single-loop controllers are used to automate a multivariable process, but the existence of *interactions* between loops dramatically increases the challenges in analysis and design. For the simple two input/two output system in Figure 174.12b, each input can influence both outputs (when $G_{ij}(s) \neq 0$ for $i \neq j$). As a result the closed-loop transfer function is

$$\frac{CV_1(s)}{SP_1(s)} = \frac{G_{c1}(s)G_{11}(s) + G_{c1}(s)G_{c2}[G_{11}(s)G_{22}(s) - G_{12}(s)G_{21}(s)]}{CE(s)} \quad (174.11)$$

with the characteristic equation, $CE(s) = 1 + G_{c1}(s)G_{11}(s) + G_{c2}(s)G_{22}(s) + G_{c1}(s)G_{c2}(s)[G_{11}(s)G_{22}(s) - G_{12}(s)G_{21}(s)]$.

Since all process models and both controllers appear in the denominator, interaction affects the stability of the closed-loop system, requiring modifications to the controller tuning. No reliable, general multiloop tuning method has been widely accepted. Since interaction often requires less aggressive tuning, one approach recommends beginning multi-loop tuning with the single-loop tuning modified by reducing the controller gains by a factor of 0.5 (Marino-Galarraga et al., 1987), while an alternative uses a log-modulus criterion (Monica et al., 1988) to determine the detuning. Usually, multiloop tuning requires trial and error, which can be performed on a dynamic simulation before implementation in a plant.

The most important multi-loop control design decision is the manner in which the controllers link the controlled and manipulated variables, which is termed *loop pairing*. The proper loop pairing should yield a control system that can (1) achieve the desired rangeability, (2) provide good dynamic performance for the most likely disturbances, and (3) provide acceptable performance when some loops are not functioning. A loop will not function, that is, not provide feedback, when the controller is in manual (off) or has its output (final element) saturated. Since each controller is an independent algorithm, any one or a group of controllers can be off while the remaining controllers are functioning. When this occurs, the input-output process experienced by the functioning controllers will change, that is, the characteristic equation changes. A desirable feature of a multiloop design would be that a control system would be stable (without retuning) even if an arbitrary selection of its loop(s) were turned off. This feature is termed decentralized integral stabilizability, and unfortunately, no rigorous method exists to ensure a control design has this feature (Campo and Morari, 1994). A less restrictive feature is that the sign of the feedback controller gain is the same for stable single-loop and multiloop control. If this criterion is satisfied for every controller in a multiloop design, the design has integrity.

A test for integrity uses a quantitative measure of interaction, the *relative gain array* (Bristol, 1966; McAvoy, 1983). The relative gain is defined as

$$\lambda_{ij} = \frac{\left\{ \frac{\partial CV_i}{\partial MV_j} \right\}_{MV_k = \text{const} \neq j}}{\left\{ \frac{\partial CV_i}{\partial MV_j} \right\}_{CV_k, \text{const} \neq i}} = \frac{\left\{ \frac{\partial CV_i}{\partial MV_j} \right\}_{\text{other loops open}}}{\left\{ \frac{\partial CV_i}{\partial MV_j} \right\}_{\text{other loops closed}}} \quad (174.12)$$

The relative gain array is formed as a two-dimensional matrix of elements, λ_{ij} . Each relative gain element indicates how interaction influences the steady-state gain of a specific input-output pairing, with a value of 1.0 indicating no influence and large deviations from 1.0 indicating strong influence. The relative gain can be evaluated using only the open-loop steady-state gains (McAvoy, 1983).

Clearly, control is simpler when the process gain “seen” by every controller never changes sign; this good property is characterized by positive relative gains. A multiloop control design with an input-output ($M_j - CV_i$) pairings having a negative relative gain (λ_{ij}) will have one of the following properties (McAvoy, 1983; Morari and Zafriou, 1989):

- Unstable with all controllers in automatic
- Unstable when only one controller ($MV_j - CV_i$) is in automatic
- Unstable when one controller ($MV_j - CV_i$) is in manual and all others in automatic

Each of these situations is undesirable. Thus, if a design has a negative relative gain pairing, its is said to have *poor integrity*. Note that the results presented here are for stable processes; modified results are available for open-loop unstable processes (Hovd and Skogestad, 1994).

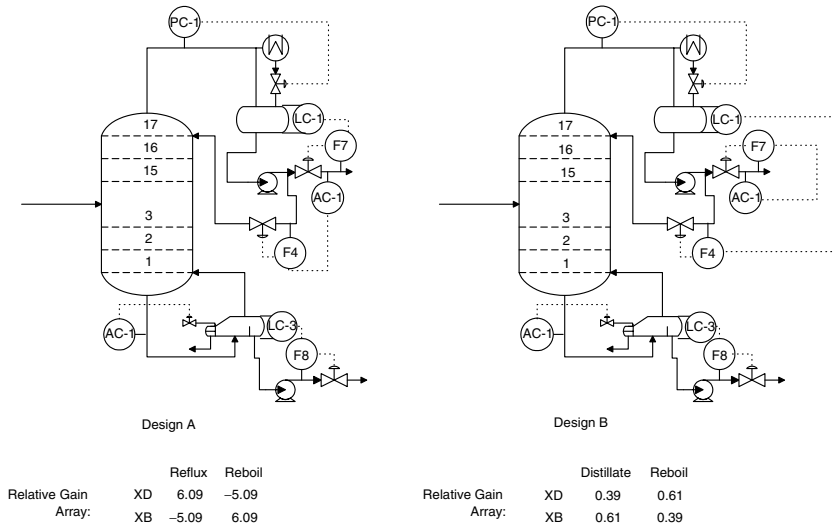

FIGURE 174.13 Alternative multiloop distillation control designs with relative gain arrays.

Naturally, good dynamic performance is the overall goal; unfortunately, no rigorous shortcut test is available to ensure good dynamic control performance. However, several useful guidelines exist. First, the most important variables should be paired with manipulated variables that have sufficient range, that is, variables that can be adjusted to compensate for all expected disturbances. Second, the most important variables should be paired with manipulated variables that provide fast feedback compensation. Third, the process equipment and control structures should be selected to attenuate disturbances; this could include tankage before sensitive units and enhancements such as cascade and feed-forward control. Also, inventories (liquid level and solid mass) should be controlled in a manner that attenuates flow variation to integrated sections of the plant.

Fourth, the loop pairing should not have strongly unfavorable interaction. The effects of favorable and unfavorable interaction will be demonstrated through a two-product distillation tower example. Distillation affects a separation of feed components based on differences in volatility, and the reboiler consumes a large amount of energy at high temperature. The tower in Figure 174.13 is considered; this tower has a conventional pressure control design (Sloley, 2001). The two designs considered differ in the variables adjusted to control the product qualities. Data regarding this case study are available (Marlin, 2000:161). Both designs have loop pairings on positive values of relative gain. In spite of the seemingly small changes in loop pairings, the relative gains are very different, with Design B having the relative gain closer to 1.0.

The control performances of the two designs are shown in Figures 174.14 for changes in one set point and for a feed composition disturbance. Clearly, Design B is better for the set point change, while Design A is better for the disturbance response. An important observation is that control design rules based solely on relative gains being near 1.0, as has been suggested, are not reliable. Since the feedback dynamics are similar for the two cases, the very different performances are not due to dynamics.

The key principle demonstrated by this example is that the directionality of interactions and disturbances strongly affects multiloop control performance. Favorable interaction can occur where one loop, while controlling a variable, introduces adjustments that also tend to reduce the variability of other interacting controlled variables. Both favorable and unfavorable interactions are possible; thus, the proper pairing selection is crucial. Short-cut methods are available for analyzing the likely effects of interaction (Stanley et al., 1985; Skogestad and Morari, 1987). The methods calculate an estimate of the effect of a specific disturbance on closed-loop performance using some simplifying assumption about the dynamics. The following equations summarize the key results for the relative disturbance gain method, which calculates an estimate of the multiloop performance, IE, dt , for the system in Figure 174.12b.

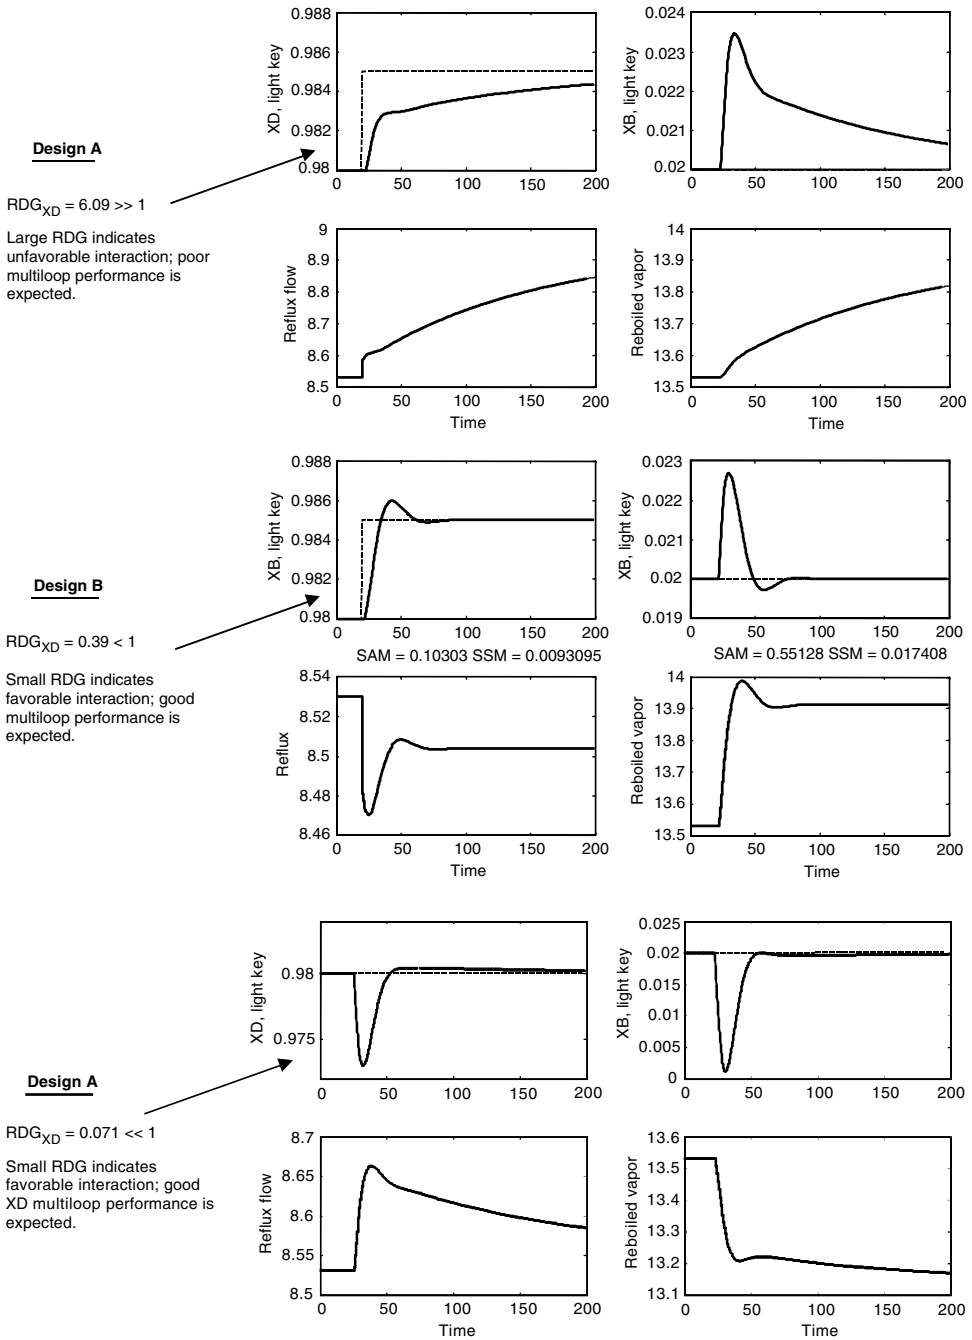

FIGURE 174.14 Dynamic performance of multiloop distillation control for (a) set point change and (b) feed composition disturbance. *Continued on facing page.*

FIGURE 174.14 Continued.

$$\text{Multiloop control performance: } \int_0^{\infty} (E_1(t))_{ML} dt = RDG f_{tune} \int_0^{\infty} (E_1(t))_{SL} dt \quad (174.13)$$

$$\text{Relative disturbance gain: } RDG = \left(1 - \frac{K_{d2} K_{12}}{K_{d1} K_{22}} \right) \lambda_{11} \quad (174.14)$$

$$\text{Detuning factor: } f_1 \left(\frac{K_{c1}}{T_{I1}} \right)_{SL} \left(\frac{K_{c1}}{T_{I1}} \right)_{ML}^{-1} \quad (174.15)$$

$$\text{Single-loop performance: } (E_1)_{SL} = \frac{K_D T_{I1}}{K_{11} K_{c1}} \quad (174.16)$$

Some important results demonstrated by this method (Marino et al., 1985) follow:

- The performance is estimated using only steady-state gains.
- The ratio of the disturbance gains (direction) has a strong effect on performance.
- The effect of the process gains is captured by the relative disturbance gain, which includes the relative gain and the disturbance direction.
- Controller tuning has a relatively small effect on the controller performance, because the detuning factor (f_i) often has a relatively small range (Marino et al., 1987).
- Multiloop performance is proportional to single-loop performance. If single-loop is poor, it is unlikely that multiloop will be acceptable.

Much can be deduced from the relative disturbance gain. If it is much greater than 1.0, interaction degrades control performance; if it is much smaller than 1.0, interaction likely improves performance (with the caveat that plus/minus error cancellation can also lead to a small integral error).

Note that the values calculated for the distillation performance in Figure 174.14 predict the relative control performances between Designs A and B. These shortcut methods are generally reliable for indicating the relative performance of multiloop systems, which is very useful when selecting a good design from many candidates.

In summary, multiloop designs must satisfy key criteria of degrees of freedom, controllability, and rangeability. From candidates that satisfy these requirements, a good design is selected to achieve the following characteristics:

1. Good integrity (positive relative gains)
2. Fast feedback dynamics (especially for the important controlled variables)
3. Large ranges for manipulated variables paired with important controlled variables (large rangeability)
4. Favorable interaction directions (small relative disturbance gain)
5. Good performance over an expected range of plant operation (robustness)
6. Profitable plant operation.

When these six characteristics are all satisfied, the control performance is generally good. However, achieving all characteristics in the same design is often not possible; in such cases, the designer must balance the needs for performance, integrity, and robustness.

- When items 2 and 3 are in conflict, two manipulated variables can be included in the process design. Good performance is achieved with split range and signal select to provide fast feedback dynamics (with a small range) and a slower correction to maintain the fast final element away from saturation.
- When items 1 and 2 are in conflict, some industrial systems achieve good performance by designing control systems paired on zero or negative relative gains (McAvoy, 1983b; Arbel et al., 1996). When a pairing on a zero or negative relative gain is selected, the possibility exists for unstable control to occur when a loop is off. Therefore, the plant personnel should be thoroughly trained and the automation system should have interlock features to disable controllers when interacting loops are not functioning.
- When item 6 is not consistent with the other characteristics, the control system is usually designed to achieve good dynamic operation and provide slow compensation to approach high profitability. The concept of constraint control is often used to improve profitability.

Unfortunately, no systematic procedure is available for designing the structure for multiloop control that includes all options; the skill and experience of the engineer strongly influences the design. The final design should be checked by dynamic simulation.

174.5 Centralized Multivariable Control

Multiloop control involves independent, decentralized controllers applied to a process with interactions. It seems reasonable to provide more information to the controller by allowing it to calculate all manipulated variables using a model of the entire process, with all input-output dynamics. Such a controller cannot be achieved by extending the PID algorithm, but several algorithms are available for centralized, multivariable feedback control. Here, model predictive control (MPC) is presented. This method addresses many practical issues in industrial applications, can be extended to a high-order system (many manipulated and controlled variables), and involves reasonable real-time computing. As a result, it is the dominant centralized control method used in the process industries.

As with most centralized controllers, the algorithm optimizes the dynamic response. The optimization is based on a model of the open-loop process, so that the (estimated) process interactions are considered explicitly in the controller algorithm. Thus, at each controller execution, the adjustments in the manipulated variables are determined that optimize an appropriate objective function measuring closed-loop control performance. Some of the important objectives in centralized process control include the following:

- The controlled variables should quickly return to their set points.
- The manipulated variable adjustments should not be too rapid. This objective protects process equipment; for example, large, rapid adjustments to the fuel to a fired heater could damage the metal tubes and brick refractory.
- The manipulated variables must observe hard constraints on their allowed values. For example, the adjustment of valve openings must remain between 0% and 100%, even if values outside of this range would result in a (predicted) performance improvement.

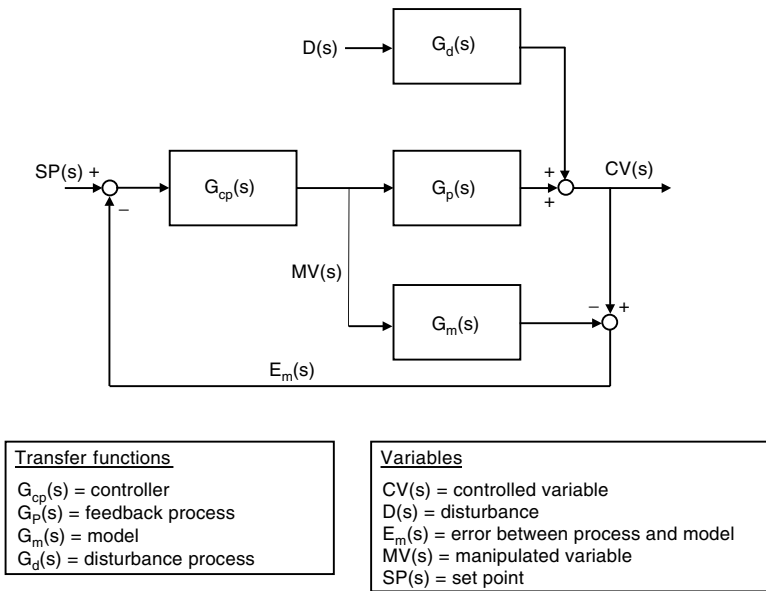

FIGURE 174.15 Block diagram of internal model control (IMC).

- The controlled variables should observe soft constraints on their allowed values. Note that feedback control cannot eliminate constraint violations in the dependent variables in all circumstances, because of slow feedback dynamics, potentially fast, large disturbances, and limitations to the adjustments in manipulated variables.
- The feedback system should perform well, that is, be stable and provide reasonable dynamic performance, over a range of process dynamics. This robustness requirement is needed because of plant-model mismatch, even at a nominal operation, and these errors increase due to changes in operation of non-linear plants.
- The preceding objectives should be achieved as the degrees of freedom for control change. For example, one or more of the manipulated variables can be fixed at their current values because an operator places the variables on “manual,” that is, removes the variable from the control problem.

These objectives, especially the need to observe limitations in a problem with changing variable limitations, require solving an optimization every time the controller is executed. The controller to achieve this performance will be explained using the IMC (internal model control) structure shown in Figure 174.15.

At each execution, the controller performs an open-loop optimization to calculate future controller outputs that provide good performance for the controlled and manipulated variables, as shown in Figure 174.16. Only the first controller output is transmitted to the plant. This adjustment is also used as the input to a linear model of the process. Since the controller bases its results on a dynamic plant model, the difference between the measured plant outputs and the model predictions is the feedback signal, which is used to correct the model prediction. All controller and model calculations are performed at each execution, and the dynamic transient is optimized using a rolling horizon approach.

The calculations of the controller are based on the following problem, which is solved at every controller execution:

$$\min_{\Delta MV_j^c} \sum_{i=1}^I w_i \sum_{n=1}^N (SP_{i,n} - CV_{i,n} - (E_{mm})_i)^2 + \sum_{i=1}^I \rho_i \sum_{n=1}^N (V_{i,n}^+ + V_{i,n}^-)^2 + \sum_{j=1}^I q_j \sum_{m=1}^M (\Delta MV_{j,m}^c)^2 \quad (174.17)$$

The problem is subject to the dynamic plant model (given here for CV_i and MV_j)

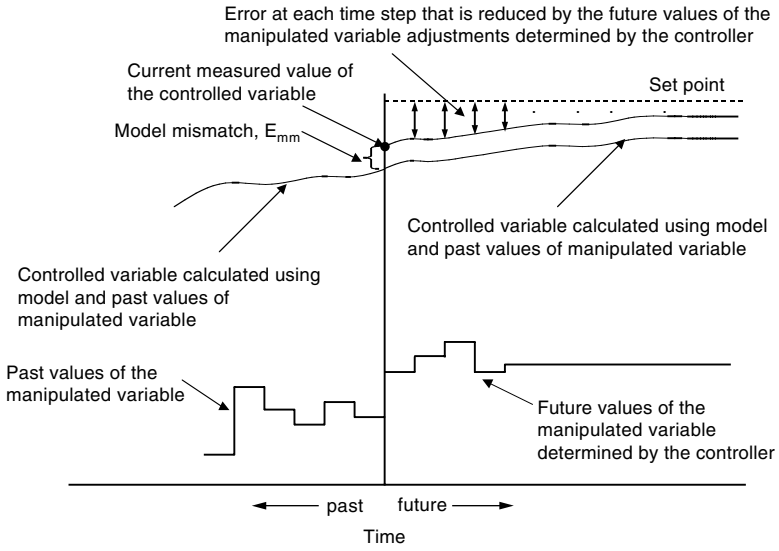

FIGURE 174.16 Typical MPC dynamic variables for single input–single output system.

$$\begin{bmatrix} CV_{i,1} \\ CV_{i,2} \\ \dots \\ CV_{i,N} \end{bmatrix} = \begin{bmatrix} a_{11} & a_{12} & \dots & \dots & a_{1M} \\ \dots & \dots & \dots & \dots & \dots \\ \dots & \dots & \dots & \dots & \dots \\ \dots & \dots & \dots & \dots & \dots \\ a_{N1} & \dots & \dots & \dots & a_{NM} \end{bmatrix} \begin{bmatrix} \Delta MV_{j,1}^c \\ \Delta MV_{j,2}^c \\ \dots \\ \Delta MV_{j,M}^c \end{bmatrix} \quad (174.18)$$

$$+ \begin{bmatrix} a_{1,M+1} & a_{1,M+2} & \dots & \dots & \dots \\ \dots & \dots & \dots & \dots & \dots \\ \dots & \dots & \dots & \dots & \dots \\ \dots & \dots & \dots & \dots & \dots \\ a_{M,M+1} & \dots & \dots & \dots & \dots \end{bmatrix} \begin{bmatrix} \Delta MV_{j,M+1}^{past} \\ \Delta MV_{j,M+2}^{past} \\ \dots \\ \dots \end{bmatrix}$$

and feedback error:

$$\begin{bmatrix} (E_{mm})_1 \\ (E_{mm})_2 \\ \dots \\ (E_{mm})_I \end{bmatrix} = \begin{bmatrix} (CV_{measured} - CV_{model})_1 \\ (CV_{measured} - CV_{model})_2 \\ \dots \\ (CV_{measured} - CV_{model})_I \end{bmatrix} \quad (174.19)$$

The bounds on manipulated variables (change per execution and value at each execution) are

$$(\Delta MV_j)_{\min} \leq \Delta MV_{j,m}^c \leq (\Delta MV_j)_{\max} \quad (174.20)$$

$$(MV_j)_{\min} \leq MV_{current} + \sum_{m=1}^K \Delta MV_{j,m}^c \leq (MV_j)_{\max} \quad \text{for } K = 1, M \quad (174.21)$$

Violations of controlled variable bounds follow:

$$(CV_i)_{\max} - CV_{i,n} + V_{i,n}^+ \geq 0 \quad \text{for } V_{i,n}^+ \geq 0 \quad (174.22)$$

$$(CV_i)_{\min} - CV_{i,n} - V_{i,n}^- \leq 0 \quad \text{for } V_{i,n}^- \geq 0 \quad (174.23)$$

The objective function in Equation (174.17) has three terms that are minimized for good performance. The first term sums the deviations between the future controlled variables and their set points. The second term represents the violations of controlled variable limits that are penalized; the values for the violations are determined in Equations (174.22) and (174.23). A penalty is used in place of strict bounds because imposing strict bounds could lead to infeasibilities. The third term involves the changes in the manipulated variables that are penalized for two reasons. First, large changes might be undesirable in the plant; second, more moderate adjustments lead to a robust controller that provides acceptable performance over a range of plant-model mismatch. This third term in the objective is often referred to as “move suppression.”

The dynamic model in Equation (174.18) represents the effects of all past and future controller output adjustments calculated by the controller over the input horizon. Naturally, the past adjustments (ΔMV^{past}) are not affected by the current controller calculation, which determines only the future adjustments (ΔMV^c). A step-weight model represents the effects of the manipulated variable adjustments on the controlled variables. An example of the model for one $MV_j - CV_i$ pair is given in the following for changes in manipulated variables from an initial steady state:

$$CV_{i,n} = [a_{n,1} \quad a_{n,2} \quad \cdots \quad a_{n,M}] \begin{bmatrix} \Delta MV_{j,1}^c \\ \cdots \\ \Delta MV_{j,M}^c \end{bmatrix} \quad (174.24)$$

The step weights (a_{nm}) are determined from empirical modeling (e.g., Cryor, 1986). Note that the separate values for the model step weights (a_{nm}) exist for every input-output ($MV_j - CV_i$) model.

Feedback is included by the $(E_{mm})_i$ corrections in Equation (174.19). Since the controller adjustments are based on a dynamic model, the feedback is the mismatch between the model and the plant. A common assumption is that the feedback (E_{mm}) for all samples in the future output horizon has the same value as the value at the time of the controller execution.

Bounds on the future manipulated variable values can be included; recall that the past manipulated variable values are known but not adjustable. Bounds can be enforced on the change per execution period (ΔMV_{jm}^c) and on the total value of the manipulated variable.

The adjustments for the manipulated variables at the current time are implemented; the remainder of the calculation is discarded, and the dynamic model is integrated one time step. The controller then waits until its next execution.

This formulation has several important features. First, it involves an open-loop control calculation that is updated through feedback; thus, the control involves a rolling horizon that looks ahead to the steady state achieved by the closed-loop system. Second, it is a convex quadratic program that can be solved efficiently to a global optimum (Reklaitis et al., 1983). Third, the controller ensures that bounds on the manipulated variables are strictly observed. Fourth, although bounds on the controlled variables cannot be strictly observed with assurance, the bounds on the controlled variables are expressed using goal programming (Williams, 1999) to penalize violations. Fifth, the controller is easily extended to high-dimensional, multivariable systems, including systems with unequal number of manipulated and controlled variables. Sixth and finally, feed-forward control is easily implemented for multivariable systems.

Further details on the widely applied QDMC algorithm are provided by Garcia and Morshedi (1986). A thorough presentation of model-predictive control is given in Maciejowski (2003). The historical development of model-predictive control along with industrial experiences is reported in Qin and Badgwell (1997), and the classic introduction of model predictive control was presented by Cutler and Raymaker (1979).

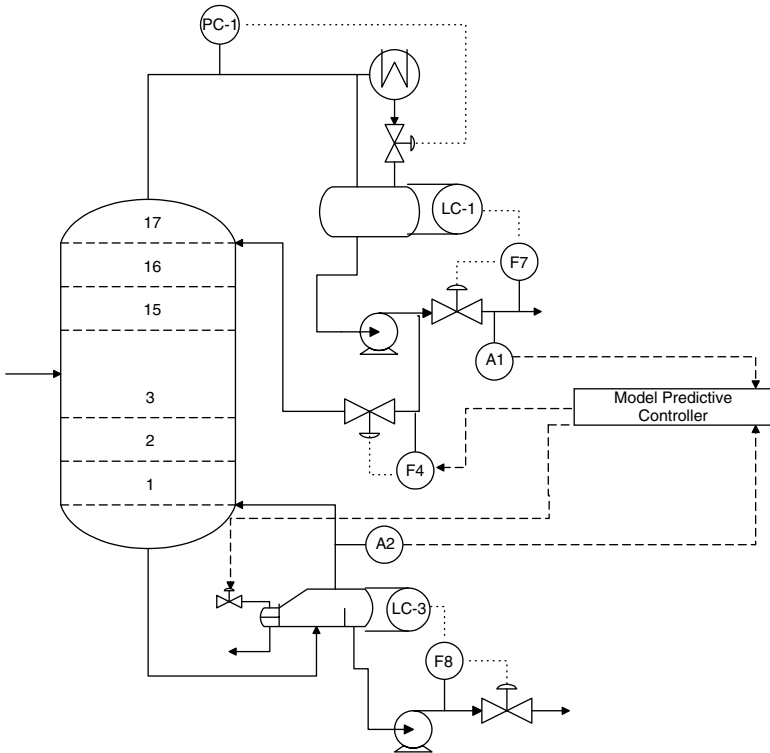

FIGURE 174.17 Distillation tower composition control with model predictive control.

The dynamic performance possible with model-predictive control is demonstrated with an example of distillation control shown in Figure 174.17. Model-predictive control is applied to the distillation tower for situations with constraints.

- Manipulated variable constraint:* In this situation, the reboiler duty is limited because of a maximum possible heating medium flow rate. The maximum amount of reboiled vapor is 14.1 kmol/min. The results are given in Figure 174.18a for a set point change in the X_D controlled variable. Because one of the manipulated variables encounters a constraint, both controlled variables cannot be maintained at their set points. Since the controller objective (Equation (174.17)) considers both controlled variables, the controller adjusts the one remaining, unconstrained manipulated variable to minimize the sum of the (squared) errors for the distillate and bottoms compositions. Neither controlled variable achieves its set point, but each is maintained “close” to its set point. Modifications can be made to implement a priority ranking for controlled variables so that the more important can be returned to their set points when all controller variables cannot be returned to their set points (Swartz, 1995).
- Controlled variable constraint:* Again, the set point response for a change in the X_D set is considered. In this situation, the light key in the bottoms should be maintained below a specified limit or costly economic penalties would occur. The maximum value for X_B is 0.0205, and this limitation is included in the controller through a very severe penalty on any X_B values that exceed the limit. The results are given in Figure 174.18b. To reduce the disturbance to X_B due to interactions, the controller has slowed the adjustment to the manipulated variables slightly. Therefore, slightly more time is required to change the distillate composition, X_D . However, the controller achieves the dual goals of reasonably fast X_D response while X_B is maintained within its specified upper limit. This excellent performance is due to the capability of the controller and the perfect model used in this simulation example. Such excellent performance would not be expected for a realistic nonlinear

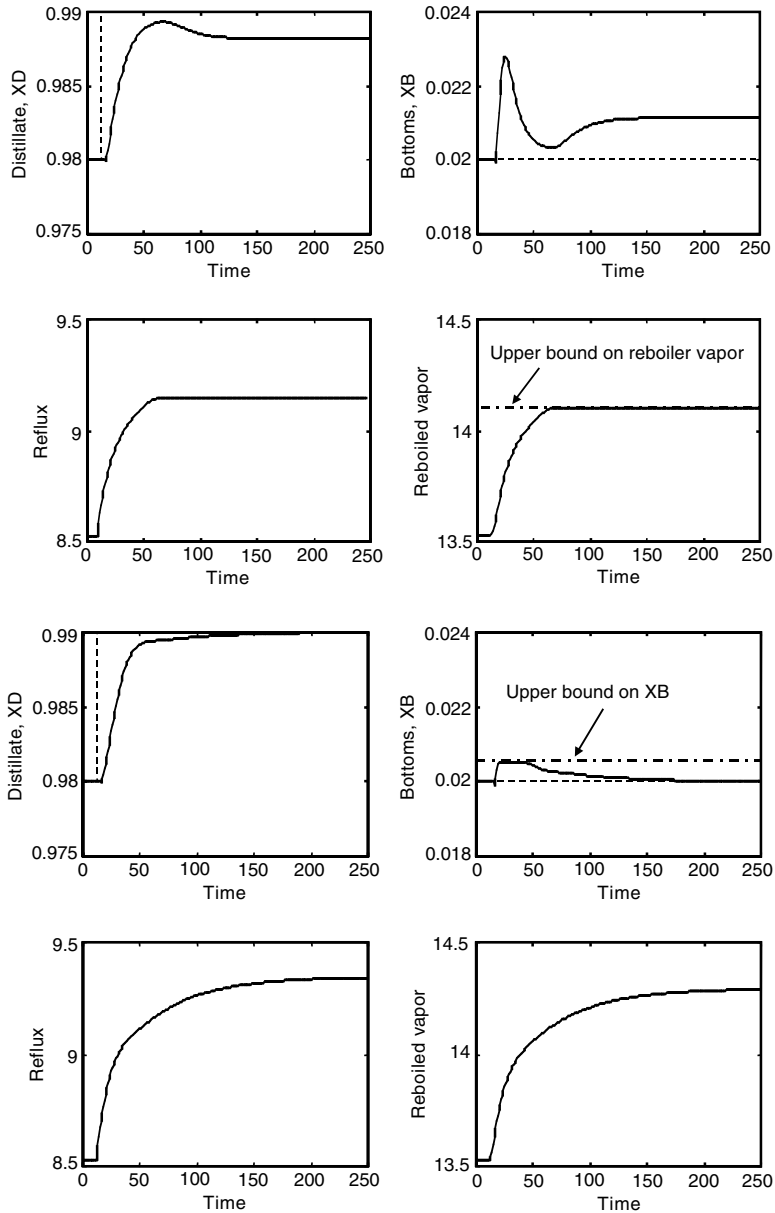

FIGURE 174.18 Dynamic performance of MPC distillation control designs for constraints on (a) reboiler and (b) bottoms product composition. (Source: Marlin, T. 2000. *Process control: designing processes and control systems for dynamic performance*. McGraw-Hill, New York. With permission.)

process with dynamics changing due to alterations in operating conditions, but quite good performance can be achieved using centralized model predictive control.

Given the success of centralized control, the reader may wonder about using this technology for centralized control of large plants having hundreds to thousands of variables. Although theoretically possible, such large MPC controllers are not now used because of (1) the difficulty in building the models, (2) the computation time for solving the optimization problem, and (3) the challenge to the plant personnel in understanding the controller results. Typically, centralized MPC is applied to blocks of variables that have substantial interaction among themselves and weak effects on the remainder of the

plant. Thus, plants can have multiple centralized, multivariable MPC, and many single-loop controllers. Also single-loop controllers remain as lower-level, secondary controllers whose set points are adjusted by the higher level MPC controllers. Thus, even in the age of block centralized MPC, knowledge of single-loop control is essential to the engineer.

This brief summary provides some guidance on key aspects of applying automatic control in the process industries. Citations in the References and Further Information sections provide details essential for successful process control design and application.

Defining Terms

Cascade — A control structure in which one (primary) feedback controller sends its output to the set point of another (secondary) feedback controller.

Controllability — The ability of a specific set of manipulated and controlled variables to achieve the specified dynamic behavior in the controlled variables.

CV, MV, SP — Symbols used for the controlled variable, manipulated variable, and the set point (reference value), respectively.

Feed forward — A control approach in which the adjustments to the manipulated variable are based on a measured input to maintain a system output unchanged.

IAE — Integral of the absolute value of error (small values indicate good controlled variable performance).

Interaction — The situation in a multi-input, multioutput system where the inputs affect more than one output variable.

Model-predictive control — A centralized control algorithm that optimizes the future trajectory of the variables using the assumption of a perfect model and applying a model correction via feedback.

Signal select — A calculation that selects the higher (or lower) of several control signals; it can be applied to measurements or controller outputs.

Split-range control — A control structure that enables one controller to adjust more than one valve in a fixed priority order.

Control is defined as the art and science of transferring sources of variations that would otherwise result in deviation from a desired dynamic response to the input of the system. As an example, consider the speed control of an automobile set to keep the car moving at 60 miles per hour. If the automobile encounters a hill, the automobile would slow down if the controller did not make an appropriate adjustment. If the device providing the manipulating inputs to the dynamic system is digital in nature, we say that the system is being controlled digitally.

Figure 175.1 illustrates a digital control system. The objective of the control system is to choose inputs to the system to be controlled so that controlled output, $y(t)$ matches some reference input, $r(t)$. The analog-to-digital converter, A/D, takes analog inputs and converts them to a sequence of sampled values every clock tick or T_s seconds. The signal marked $r(t)$ is the desired response of the dynamic system output, $y(t)$. The digital processor computes the input to the dynamic system based on the sampled values of $r(t)$ and $y(t)$ so as to correct for any deviations between the two. The processor output is then converted back to an analog signal through the digital-to-analog converter, D/A, that is then used to drive the dynamic system to be controlled, often referred to as the plant. A clock drives the A/D, the processor and the D/A. At each clock tick, the sampled output is compared to the desired output, and a corrective input is applied to the system. Nothing happens again until the next clock tick, leaving the system blind between sampling times.

Digital control systems are both nonlinear and time varying even if the plant to be controlled is linear and time invariant. The nonlinearity results from the fact that A/D converter must quantize the input signal into a finite number of bits, and hence multiple analog signal values convert into the same digital signal. The time-varying behavior is due to the clock. Imagine that the reference input changes instantaneously at some time t . Depending on when this change occurs, different behaviors result. If the change occurs at the beginning of the sampling interval, it is caught immediately; whereas, if it occurs in the middle of the interval, a different time response of the output would eventually result because the input would not be seen until the next clock tick.

Despite these difficulties, a digital controller is almost always used in practice. There are many reasons for this:

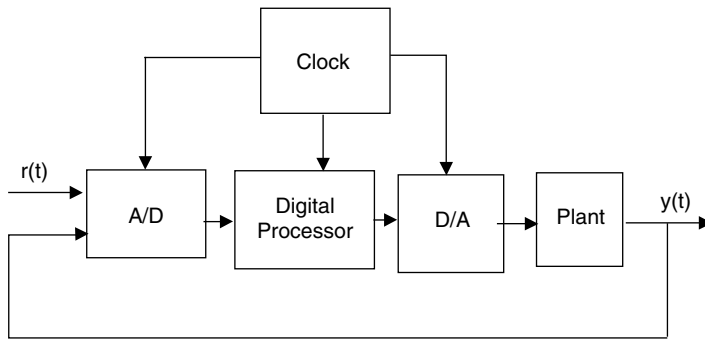

FIGURE 175.1 Digital control system.

1. Since we are dealing with digital hardware, there are none of the drifting effects in either age or temperature that occurs with analog hardware. The same input sequence operated on by an algorithm produces the same output sequence independent of time and temperature.
2. Exact reproducibility is possible for multiple applications since the same inputs always produce the same outputs.
3. There is a high degree of accuracy. More accuracy is always possible by using more bits in the processor or if necessary in the A/D and/or the D/A.
4. There is flexibility in that one processor can control multiple loops or perform additional tasks beside control.
5. Significant performance enhancement is possible by using digital control. Model-based control approaches such as optimal control, adaptive control and model predictive control can only be effectively implemented digitally.

Digital control systems can be developed two different ways. In the first, we recognize that the dynamic system to be controlled is analog in nature, design an analog controller, and then mimic its performance digitally. The second way is to view the world from the perspective of the digital processor. The digital processor observes a sequence of numbers that corresponds to the sampled values of the output of the plant and produces a sequence of numbers that corresponds to the eventual inputs to the plants. Suppose that we were to find a discrete-time system whose output is the same sequence of numbers as that generated from sampled values of $y(t)$ when the analog system input is the output of the D/A due to the sequence of numbers computed by the digital processor. Such a discrete-time system would provide the sampled values for the output, and the algorithm that controls how that sequence is generated, would be the digital controller shown in Figure 175.1 used to control the plant.

This chapter is organized as follows. Section 175.1 is a review of the representation and analysis of discrete time system. Section 175.2 discusses the use of digital simulation as a tool for implementing an analog controller digitally. Section 175.3 focuses on the design of digital controller directly using root locus methodology for which a short review is provided. The pulse transfer function is developed as a means of generating the digital system representation of the analog plant that is the model for designing the controller.

175.1 Discrete Time Systems

Digital controller design is based on the behavior of linear, shift-variant, discrete-time systems. An understanding as to how these systems behave is crucial to the design of digital controller. In many ways, there are a number of similarities between the behavior of linear time-invariant analog systems and linear shift-invariant, discrete-time systems. The behavior of such systems depends on the solution of the describing difference equation or equivalently, on the location of the poles and zeros of its transfer function.

Difference Equations

Linear, time or shift-invariant, discrete-time systems are characterized by linear difference equations with constant coefficients. The general equation that describes any linear, shift-invariant system is

$$y_k = a_{n-1}y_{k-1} + \dots + a_0y_{k-n} + b_mx_k + b_{m-1}x_{k-1} + \dots + b_0x_{k-m} \quad (175.1)$$

The solution of this equation defines the behavior of the system for a given input. There are two components to the total solution: the homogeneous and particular parts. The homogeneous solution is the solution to the difference equation with zero input and defines the underlying characteristic behavior of the system. If the input is zero, Equation (175.1) reduces to:

$$y_{h,k} = a_{n-1}y_{h,k-1} + \dots + a_0y_{h,k-n} \quad (175.2)$$

where the subscript h refers to the homogeneous part. Assume that solution is of the form of $y_{h,k} = Kp^k$. Substituting into Equation (175.2) results in the characteristic equation that defines the necessary condition that p must satisfy.

$$p^n - a_{n-1}p^{n-1} - \dots - a_0 = 0 \quad (175.3)$$

If the n roots of Equation (175.3) are p_1, p_2, \dots, p_n , then the homogenous solution is

$$y_{h,k} = K_1p_1^k + K_2p_2^k + \dots + K_np_n^k \quad (175.4)$$

Note that $y_{h,n}$ will tend to zero if magnitude of each root of the characteristic equation is less than 1. If any p_i has magnitude greater than 1, the homogeneous solution will grow without bound, resulting in an *unstable* system.

The particular solution, $y_{p,k}$, is the component of y_k that is due solely to the forcing input x_k . For a linear shift-invariant system, the particular solution will take the same form as the input provided that the input is not of the same form as one of the components of the homogeneous solution. Thus, if the input is a sinusoidal, the particular solution is a sinusoidal of the same frequency with only the amplitude and phase changing. If the input is a polynomial in time, the particular solution is a polynomial of the same order as the input.

From a control system perspective, we desire the particular solution to match the reference input because the objective of the system is to force the plant output to match the reference. What keeps that from happening is the homogeneous solution. The faster the homogeneous solution tends to zero, the faster the controlled output approaches the reference input. This implies that the smaller p_i is in magnitude, the faster that contribution to the homogeneous solution tends to zero.

Transfer Functions

An alternative way of representing discrete-time systems represented by equation is developed through Z-transforms. The Z-transform is a one-to-one mapping of a sequence of numbers into a function of the complex variable z . The one-sided Z-transform is defined as

$$F(z) = \sum_{n=0}^{\infty} f_n z^{-n} \quad (175.5)$$

Knowledge of the Z-transform is equivalent to knowledge of the sequence of numbers and vice versa.

Note that the Z-transform of a sequence delayed by m samples is z^{-m} times the Z-transform of undelayed sequence provided that the sampled values of the sequence are zero for negative arguments. Applying the Z-transform to Equation (175.1) results in

$$\frac{Y(z)}{X(z)} = \frac{b_m + b_{m-1}z^{-1} + \dots + b_0z^{-m}}{1 - a_{n-1}z^{-1} - \dots - a_0z^{-n}} \quad (175.6)$$

Note that this representation of a system is completely equivalent to the difference equation representation of Equation (175.1). This is clear from the fact if input sequence and the system are known, then the Z-transform of the output sequence can be computed from Equation (175.6). A knowledge of $Y(z)$ is equivalent to a knowledge of the output sequence $y(k)$.

The system represented by Equation (175.6) is causal. That is, all outputs are computable from knowledge of present and past inputs and past outputs only. If we multiply the right side of equation (175.6) by z^n , the numerator and denominator become polynomials in z instead of z^{-1} provided that $n \geq m$:

$$H(z) = \frac{b_m z^n + b_{m-1} z^{n-1} + \dots + b_0 z^{n-m}}{z^n - a_{n-1} z^{n-1} - \dots - a_0} = \frac{B(z)}{A(z)} \quad (175.7)$$

Equation (175.6) and Equation (175.7) are equivalent transfer functions of the system defined by the difference equation (175.1). Note that by inspection, the transfer function can be written from knowledge of the difference equation and vice versa.

Also, Equation (175.3), the characteristic equation of the system defined by Equation (175.1), is the same equation that define the roots of the denominator polynomial, $A(z)$. The roots of the denominator polynomial are the poles of the system. The roots of the numerator polynomial are the zeros. Knowledge of the poles provides the same information as to the homogeneous solution of the difference equation as does the roots of the characteristic equation. For the system to be stable, the magnitude of the poles must be less than one. This implies that the poles must be located inside a circle of radius 1 in the z -plane. The z -plane is the representation of the complex values of z that are candidates for substitution into Equation (175.7).

Using transfer functions to represent discrete-time systems has many advantages. Difference equations need not be solved, and the transfer function of the interconnections between dynamic systems can be easily computed. As an example, consider the closed-loop system shown in Figure 175.2 with $G_c(z)$ and $G_p(z)$ being the controller and plant transfer function, respectively. The transfer function between the reference input and controlled output, called the closed-loop transfer function, is

$$\frac{Y(z)}{R(z)} = G_{CL}(z) = \frac{G_c(z)G_p(z)}{1 + G_c(z)G_p(z)} \quad (175.8)$$

FIGURE 175.2 Closed-loop system.

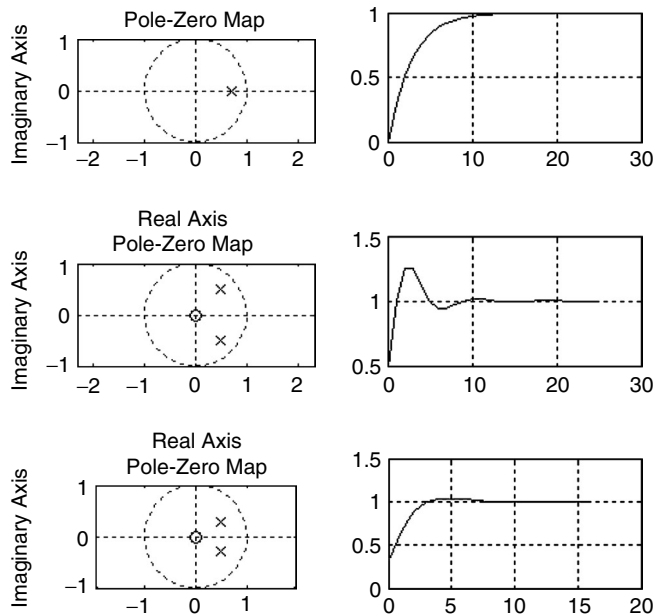

FIGURE 175.3 Relationship between pole and zeros and the corresponding step responses.

System Response

To design a controller, one must understand the dynamic response of both the plant and the closed-loop system — that is, the system response from reference input to output. The response to any input is the sum of the particular and homogeneous responses. The form of the homogeneous response is known from the pole location, and that provides an understanding as to how the homogeneous solution for a stable system decays to zero.

For example, consider a system with a pole at $z = 0.5$. The homogeneous solution would be proportional to 0.5^k . If the pole were located at $z = 0.2$ instead of $z = 0.5$, the system would settle faster to the particular solution because the homogeneous part of the response decays away faster. For $z = 0.8$, the system would be slower. In general, the response of a system with poles closer to origin of the Z-plane is faster than ones with poles farther away.

Figure 175.3 illustrates several examples of the effect of poles and zeros on system response. The left column gives the pole and zero location in the z-plane of three systems, while the right column shows the step response of each system. The system in the top row is a first order with transfer function

$$G(z) = \frac{0.3}{z - 0.7} \quad (175.9)$$

Shown for reference in the figures on the left is a circle of radius 1, called the unit circle. Since the poles are inside this circle, the system is stable. For this example, there is no zero and a pole at $z = 0.7$. This will produce a homogeneous solution of 0.7^k , which, as it dies away, the output reaches the particular solution or the steady-state output value of 1. Note that the first output of the system response is 0. Mathematically, this results from having more poles than zeros. The difference between the number of poles and the number of zeros is the pole excess. In this case, there is one pole and no zeros. If there had been three poles and one zero, the first two values, or the pole excess, of the step response would have been zero.

The middle and bottom rows show two related second-order systems. The system in the middle row has the transfer function:

$$G(z) = \frac{0.5z^2}{z^2 - z + 0.5} \quad (175.10)$$

This system has two zeros at the origin of the z -plane and two complex poles a distance of 0.707 from the origin. The step response is shown to the right of the pole/zero plot. Note that the output of this system exceeds the steady-state value and oscillates. This is characteristic of what are called an *under-damped* systems. Furthermore, note that the pole excess is zero, resulting in an immediate output response to a step input. The system in the bottom row is similar to the system in the middle row in that the poles are complex and there are two zeros at $z = 0$. However, the distance from the origin is now 0.5774 and the angle with respect to the real axis is smaller. Note that the response is somewhat faster in settling to the 1. This is because the poles are closer to the origin and decay away faster. Again, the system response is immediate because the pole excess is zero.

Characterization of Closed-Loop Systems

To design a control system, one must have a specification that defines how the closed-loop system is to respond. The closed-loop poles are chosen with the anticipation that if they are the dominant ones, the system will meet the specification. The dominant poles of a stable system are those that are closest to the unit circle. These poles take the longest to decay to zero since they are the largest distance from the origin of the z -plane. Hence, the dominant poles are the slowest decaying away to zero and have the biggest influence on determining the time for settling to the steady-state solution.

Specifications for the closed-loop system typically center on the speed and amount of overshoot of the system response. A system may be fast enough in terms of reaching the target value or in settling to a desired result, but if the overshoot or the amount by which the output exceeds the target value is too large, then the overall response may be unacceptable. If the overshoot is acceptable but the system takes too long to reach the desired level or to settle, then the overall response will be unacceptable. The typical performance specifications usually center on the closed-loop response to a step input. The specifications that relate to speed of response are:

1. *Rise time, T_R* : Typically defined as the time required going from 10 to 90% of the final value. The 10% lower limit is used so that any time delay in the system is not directly counted as part of the system response. Time delays cannot be controlled away, and hence they do not reflect the speed of response of the system
2. *Time to peak, T_P* : The time to peak is the time at which the output peaks. This is the time to reach the first overshoot peak.
3. *Settling time, T_S* : The time required for the output to be within a guaranteed level of the final value. Typically, this is measured as being within 5% or 2% of the final value.

The overshoot, M_p , is the difference between the peak and the steady-state values divided by the steady-state value multiplied by 100 to make it a percent. Typical values are 3 to 20%. Most often, some overshoot is desired. The reason is that the speed in getting to the target value can be greatly improved if the system output is allowed to overshoot the steady-state value by a small amount.

Given a set of specifications, the question becomes where the dominant poles of the closed-loop should be located so that the system is likely to meet that specification. The location is determined by approximating the closed loop as a second-order system without any finite zeros and defining the poles of that system so that the specifications are met. If the assumption that such a second-order approximation is a good model for the closed loop is valid, then the results would be nearly as predicted. If it is not valid, then the approximation may or may not completely satisfy the system requirement. If the specifications are not met, the closed-loop poles need to be altered, a new controller designed and the system retested.

To understand how a second-order system behaves, consider the step response of the analog system:

FIGURE 175.4 Complex poles in the s-plane.

$$G(s) = \frac{\omega_n^2}{s^2 + 2\zeta\omega_n s + \omega_n^2} \quad (175.11)$$

where ζ is the damping ratio and ω_n is the natural frequency. If the damping ratio is less than 1, the poles of this system are located at $s_{1,2} = -\zeta\omega_n \pm j\omega_n\sqrt{1-\zeta^2}$. Figure 175.4 illustrates the pole location in the s-plane. Note that the complex pole defines a right triangle with the two arms of length $\zeta\omega_n$ and $\omega_n\sqrt{1-\zeta^2}$. The hypotenuse is of length ω_n , and the cosine of the angle θ is just the damping ratio, ζ . Note that the locus of points in the s-plane corresponding to constant damping ratio between 0 and 1 (ω_n varies) is a ray emanating from the origin for which the cosine of the angle of the ray with respect to the negative real axis is the damping ratio. Likewise, the locus of points for fixed natural frequency, ω_n , (damping ratio varying from 0 to 1) is a semicircle in the left s-plane or radius, ω_n .

The step response of the second-order system of Equation (175.11) is given by

$$y(t) = 1 - \frac{e^{-\zeta\omega_n t}}{\sqrt{1-\zeta^2}} \sin(\omega_n\sqrt{1-\zeta^2}t + \theta) \quad (175.12)$$

$$\text{with } \theta = \tan^{-1}\left(\frac{\sqrt{1-\zeta^2}}{\zeta}\right)$$

Given this response, the time to peak and percent overshoot are calculated by taking the derivative of Equation (175.12), setting it equal to zero and solving for the values of time for which $y(t)$ has local maxima and minima. Putting the time for the peak into Equation (175.12), the percent overshoot can be found. The values of the time to peak and the percent overshoot are, respectively,

$$T_p = \frac{\pi}{\omega_n\sqrt{1-\zeta^2}} \quad (175.13)$$

and

$$M_p = 100 \exp\left(-\frac{\pi\zeta}{\sqrt{1-\zeta^2}}\right) \quad (175.14)$$

Note that the peak overshoot does not depend on the natural frequency, but only on the damping ratio. With a damping ratio of zero, the percent overshoot is 100, and with a value of 1 or greater, it is zero. In addition to peak overshoot and time to peak, the settling time is often of interest. For analog systems, the 5% settling time for complex poles is approximately $3/\zeta\omega_n$ and the 2% is $4/\zeta\omega_n$.

To illustrate how the specification determines the closed-loop poles, consider a case where a 5% settling time of 3 sec is sought with 5% overshoot to step inputs. The 4% overshoot defines the damping ratio found by solving Equation (175.13). In this case, ζ is 0.7. Typical values of ζ are between 0.5 and 1. The 5% settling time is found by $3/\zeta\omega_n = 3$ or $\zeta\omega_n = 1$. The closed loop poles are approximately $-1 \pm j$.

Characterization of Discrete Time Systems

The mapping from the analog s-plane to digital z-plane illustrates how the natural frequency and damping ratio in the analog world manifest itself in the digital world. A pole in the s-plane at $s = s_0$ produces a transient of the form $e^{s_0 t}$. Sampling every T seconds generates a sequence whose Z-transform has to a pole at $z = z_0 = e^{s_0 T}$ where T is the sampling time. Figure 175.5 illustrates the z-plane that is used to locate the pole and zeros. The circle of radius one is known as the unit circle. For stability, all the poles of the discrete time system must be within this circle. The heart-shaped curves are the ones that correspond to constant damping ratio. For a damping ratio close to 1, the curves are close to the real axis. If the points corresponding to a constant damping ratio are mapped into the digital world as shown above, they produce this set of heart-shaped curves. As the damping ratio decreases towards 0, the constant damping ratio curves move toward the unit circle. Alternatively, the points on the locus of constant natural frequency are the curves that begin and end on the unit circle. The values of the natural frequency are given in steps of the 0.1 times pi divided by the sampling time.

Figure 175.5 can be used to define the desired closed-loop pole locations for a given specification. A specification, such as the peak overshoot, specifies only one parameter, namely the damping ratio. Another constraint is needed to specify the other parameter ω_n . The specification that is most often given for a digital control system is the settling time. For discrete time systems, the distance from the origin to the pole location determines this as was noted earlier. For a 5% settling time, the homogeneous solution must

FIGURE 175.5 Grid with curves of constant damping ratio and constant natural frequency.

decay away 95% of its maximum effect. To determine an approximate settling time, take the dominant pole (the one closest to the unit circle) and solve for the smallest sample number, N , that satisfies $R^N \leq 0.05$ where R is the distance from the origin to the pole location. The actual settling time is closer to the value N plus the pole excess because the number of samples of response delay is the pole excess.

In the design problem, the inequality above must be solved for R knowing the desired settling time. For example, suppose that we want 2-sec settling and have a sampling time 0.25 sec. This corresponds to eight samples, and if there is a pole excess of two, we need to have the dominant poles of the closed-loop system be located a distance R from the center of the z -plane so that the transient due to that pole settles in six samples after the pole-excess delay. Solving $R^6 = 0.05$, yields desired closed-loop poles at a distance of approximately 0.6 from the center of the z -plane. The actual location for the dominant poles should be at those points corresponding to a distance of 0.6 from the origin and intersecting the desired damping ratio. If the desired damping ratio was 0.7, the location of the dominant poles should be at $z = 0.52 \pm j0.3$.

175.2 Digital Simulation of Analog Controllers

Analog systems can be implemented using only integrators together with appropriate feedback. To approximate such systems digitally means finding an appropriate digital simulation of the analog integrator which will, in turn, define a specific transformation from the s -domain to the z -domain. There are a number of different ways of approximating an integrator or measuring the area under a function. Consider the one shown in Figure 175.6. An approximation to the area under a curve can be estimated by taking the sampled value at time kT and holding it constant until a new sample is available at time $(k + 1) * T$. This produces a set of rectangles and forms what is called forward Euler integration.

The difference equation describing this approximation to an analog integrator is found by noting that the area under the curve at time nT is the area under the curve at time $(n - 1)T$ plus the area under the rectangle formed at time $(n - 1)T$.

$$S_n = S_{n-1} + T * x((n-1)T) \tag{175.15}$$

where S_n is the approximate area under the curve at time nT . The transfer function of the system corresponding to Equation (175.15) is $T/(z - 1)$. Since the transfer of an integrator is $1/s$, a comparison of the two suggest that a substitution of s by $(z - 1)/T$ would convert an analog system transfer function into a digital system that corresponds to the simulation with a forward Euler integration scheme.

FIGURE 175.6 Forward Euler integration.

FIGURE 175.7 Backward Euler integration.

Alternatively, the rectangles could be generated by taking samples at time nT and projecting them backwards one sample interval forming a backward Euler integration approximation. Figure 175.7 illustrates this, and in this case, the approximate area under the curve is given by

$$S_n = S_{n-1} + T * x(nT) \tag{175.16}$$

The transfer function of this integrator is $Tz/(z - 1)$. The substitution for s that would correspond to backward Euler integration is $(z - 1)/Tz$.

A better approximation would be to join samples, $x(nT)$ and $x((n - 1)T)$ by a straight line and measure the areas under the resulting trapezoids, leading to trapezoidal integration. This is also known as Tustin approximation and is illustrated in Figure 175.8. The equation describing this approximation is

$$S_n = S_{n-1} + \frac{T}{2} * (x(nT) + x((n-1)T)) \tag{175.17}$$

This corresponds to a substitution for s by $2/T[(z - 1)/(z + 1)]$.

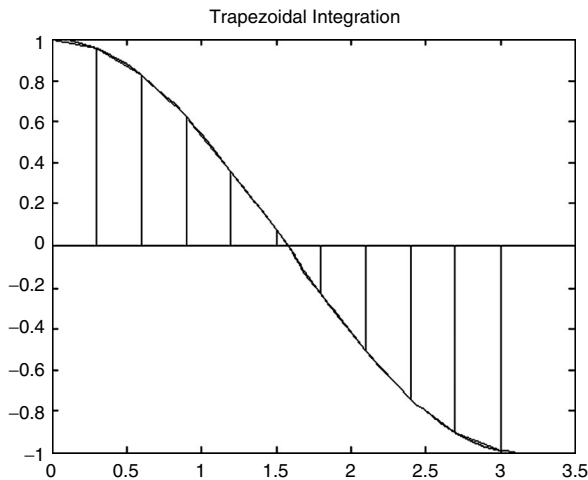

FIGURE 175.8 Trapezoidal integration or Tustin approximation.

FIGURE 175.9 Tustin approximation with two different sampling times.

Each of these methods provides an adequate approximation provided that the sampling time is chosen sufficiently small. The sampling time should be chosen as large as possible without sacrificing performance too much. For very small sampling time, the changes in the controller output becomes small, creating computational accuracy problems. Choosing a good sampling time is important. A rule of thumb suggested by Astrom and Wittenmark (1997) is to choose the sampling time so that the product of the sampling time and the gain crossover frequency (in radians per second), $T\omega_c$, of the loop gain (i.e., the product of the controller and plant transfer function), is between 0.15 and 0.5. As the sampling time increases, the trapezoidal method tends to offer the most robustness because of its improved accuracy. In fact, the Tustin approximation has the property of mapping the left or the stable region of the s-plane onto the area inside the unit circle, the stable region in the digital world. The frequency axis in the analog domain, the $j\omega$ axis, is mapped onto the frequency axis in the digital world, the unit circle.

The procedure is very simple. Given an analog controller and its transfer function, convert it to a discrete time system by choosing a sampling time T and substituting for s the relationship corresponding to which approximation is chosen: forward, backward, or Tustin integrator approximations. This then gives a discrete transfer function from which a difference equation can be extracted and implemented.

As an example, consider a lead compensator with transfer function $4[(s + 1)/(s + 2)]$ for a system with a transfer function $1/s(s + 1)$. The gain crossover frequency is approximately 1.6 radians per second. Thus an appropriate sampling time is between 0.1 to 0.3 sec. Figure 175.9 illustrates the results of using a Tustin approximation with the two extremes in the choice of the sampling time. The solid curve is the result with an analog controller, the dashed line corresponds to a sampling time of 0.1 sec and the dotted line corresponds to 0.3 sec.

175.3 Design of Digital Controllers

Digital controllers can be generated either by designing an analog controller and simulating it or by designing a digital controller directly. Designing a digital controller directly requires that the plant be discrete time, not analog. Fortunately, there is a way to convert an analog system directly into a meaningful digital one. Figure 175.1 illustrates that the output of the processor goes directly to a D/A converter. The output of the D/A is held to its input value until a new input is applied. This produces a staircase-like function to the input of the plant. The output of the plant is sampled by the A/D and inputted to the processor. From the perspective of the processor, a digital value is being applied to some system and another digital value is being returned as an output of that system. This looks like a digital system, and

in fact, the transfer function can be defined that will produce the sampled values of the analog output when it is excited by a staircase input generated by a D/A converter.

The digital system can be determined by taking the Z-transform of the sampled values of the analog output when the processor outputs a discrete-time impulse function, namely a sequence that is 1 at $n = 0$ and 0 elsewhere. With that input, the D/A converter produces a pulse of height 1 and duration of T seconds that then excites the analog system. The output is given by

$$L^{-1}\left\{\frac{1-e^{-sT}}{s}G_p(s)\right\}$$

where L^{-1} represents the inverse Laplace transform and $G_p(s)$ is the transfer function of the analog system being controlled. Taking the Z-transform of the samples every T seconds of the resulting time signal produces the transfer function of a discrete-time system that is the discrete model for the plant. This system is called the pulse transfer function or the zero-order hold model of the analog plant. It forms the basis for the digital controller design.

Note that the transfer function depends on the sample time T . The poles of the discrete transfer function are located at e^{s_0T} where s_0 is the location of the analog plant pole. If T is chosen very small, all the poles of the analog system map into values very close to 1. This creates problems from a design perspective. The desired closed-loop poles are also going to be near 1. The reason can be seen by the discussion above concerning settling time. If we desire a system with a certain settling, the number of samples that this corresponds to is that time divided by the sampling time. If the sampling time is small, the number of samples is large. A large number of samples imply that the distance from the origin to the pole location, R , must be near 1 so that R^N is 0.05, where N is the number of samples desired for the settling time.

Clearly, the choice of the sampling time, T , is an important consideration for the design of a digital controller. If T is very large, then the controller would not be able to respond in a timely fashion to unmeasured disturbances. Astrom and Wittenmark (1997) point out several rules of thumb that one can employ in choosing T . If T_r is the 10 to 90% rise time, the sampling time can be chosen so that there are four to ten samples per rise time. Alternatively, the choice can be related to the closed-loop bandwidth. Choose the sampling rate so that the sampling frequency is 10 to 30 times the closed-loop bandwidth in hertz.

Relatively slow sampling rates are tolerable in control systems because the closed loop is a low-pass filter. Thus, the higher frequencies are attenuated, eliminating the need for a higher sampling frequency. Furthermore, the nature of the game in control is the performance of the closed-loop system, not information. Thus, we can tolerate slower sampling rates than might be suggested from a consideration of the issues centered on digital signal processing.

Root Locus Design

The pulse transfer function provides us with a model for designing a controller. There are a number of different techniques that can be employed. Here, we will discuss the use of root locus. Root locus is an algebraic methodology for plotting the location of the roots of the denominator polynomial, or the poles, of the closed-loop transfer function as a function of a multiplicative parameter K . These roots are given by the characteristic equation,

$$1 + KG(z) = 0 \tag{175.18}$$

where $G(z) = N(z)/D(z)$ and $N(z)$ and $D(z)$ are the numerator and denominator polynomials, respectively. We seek the solution for Equation (175.18) as a function of positive K . We will not examine negative K because in the vast majority of control problems, K will be positive. In order to find a solution, $G(z)$ must be negative real. If it is, there is always a positive K to satisfy Equation (175.18). Thus, the necessary and sufficient condition for a point to be on the root locus and a solution to Equation (175.18) is that

$G(z)$ be negative real or that the angle of $G(z)$ be an odd integer of 180° . Every point on the root locus satisfies this condition.

The art of designing a controller is to find dynamics in the controller such that the desired closed-loop poles are dominant (closest to the unit circle) and on a root locus. This means that the angle of $G(z)$ is an odd integer multiple of 180° at the desired location of the z -plane. This angle can be computed from the difference of the angle associated with $N(z)$ and the angle associated with $D(z)$. The angle of a polynomial is the sum of angles from each root to the desired location. This angle is measured with respect to the positive real axis. The gain that K needed, so that $z = z_0$ is a closed-loop pole, is

$$K = \frac{1}{|G(z_0)|} = \frac{|D(z_0)|}{|N(z_0)|} \quad (175.19)$$

where z_0 is a point on the root locus. The magnitude of a polynomial evaluated at a complex value z_0 is the product of the distances from each root to the point in question, z_0 .

Controller Design Using Root Locus

Controller design using root locus is an art and must be often done iteratively. First, one needs a model of the system to be the controller. The specifications imply the locations for the dominant closed-loop poles. A design is then developed and simulated to determine if specifications are met. If specifications are not met, then a modification of the design is required to achieve the desired requirements. When the specifications are met in the simulation, a controller can be implemented and tested. If this fails to meet specifications, then a more accurate model is required for design. Figure 175.10 presents a flow diagram that illustrates this concept.

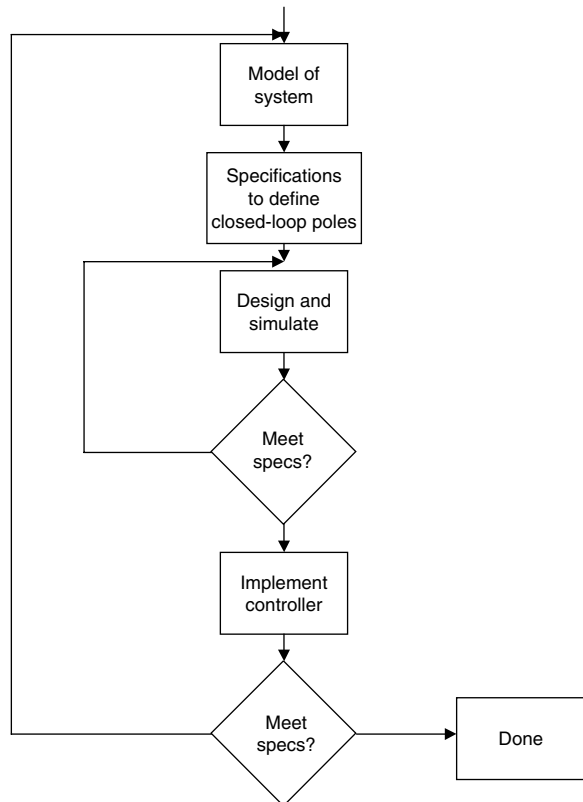

FIGURE 175.10 Flow diagram for controller design.

FIGURE 175.11 Closed-loop pole location for design example.

Assume that we have a DC motor to control with transfer function $G_p(s) = 1/(s+1)$. The specifications are that the 5% settling time is no more than 3 sec, with a damping ratio of 0.5. The 5% settling is given by $3/\zeta\omega_n$, yielding $\zeta\omega_n = 1$, from Equation (175.14). A sampling rate of 0.3 would meet the criteria set by the rules of thumb defined earlier. The pulse transfer function model for the analog system with sampling time of 0.3 is $G_z(z) = 0.0408(z + 0.9049)/z^2 - 1.7408z + 0.7408$. Note that the pole excess is 1. The number of samples required to have a 3-sec settling time is 10. However, because of the pole excess, we need to design for nine samples to achieve 3 sec of settling time. Solving $R^9 = 0.05$ for R gives $R = 0.717$. If we draw a circle on the grid with the unit circle of radius 0.717 on the grid of Figure 175.5 and seek the intersection of the damping ratio of 0.5 with a circle of radius 0.717, we find that the desired location of the closed-loop poles are at $z = 0.6 \pm j0.39$. Figure 175.11 shows the unit circle in the z -plane with a circle of radius 0.717. The X's mark the spot on the circle of radius 0.717 that intersects the 0.5 damping-ratio curve.

To achieve the specified behavior, dynamics in the compensator must be such that the sum of the angles of the zeros to the point location minus the sum of the angles of the poles to pole location must be an odd integer of 180° . The angle from the pole at $z = 1$ to the location of one of the complex closed-loop poles, $0.6 + j0.39$ is 135.7252° , and the angle from the pole at $z = 0.7408$ is 109.8509° . The sum of the angles of the poles is 245.5761° . There is a zero at -0.9049 that contributes a phase of 14.5288° . Thus the compensator needs to provide a positive 51.0473° of phase so that the sum of angles of the plant and compensator totals -180 . If we position a pole at $z = 0$, we can compute the position of a zero so that the angle of the compensator is 51.0473° . The zero will need to provide 84.0712° , and its location is 0.5595 . The compensator transfer function is $G_c(z) = K(z - 0.5595/z)$. Recall that our choice of the compensator ensures that $G_z(z)G_c(z)$ is negative when evaluated at $0.6 + j0.39$, and is in fact, -0.1501 . This implies that K must be $1/0.1501 = 6.624$.

The step response of the closed-loop system is shown in Figure 175.12. Superimposed are the two lines representing the 5% deviations from steady-state output. The dashed line is the actual analog output of the system being controlled. Note also that the desired settling time is achieved. Furthermore, observe that the pulse transfer function gives us the sampled values of the analog output.

Defining Terms

Discrete time systems — Systems whose inputs and outputs change only at discrete points in time.

Z transforms — A transformation from the discrete time domain to a complex variable domain such that knowledge of the time domain behavior completely defines the complex variable domain and vice versa.

FIGURE 175.12 Step response of the digitally controlled system.

Simulation of analog controllers — A digital controller design technique in which an analog controller is designed and then converted to a discrete time system whose behavior approximates the analog controller.

Pulse transfer function — The discrete time system whose time outputs are the samples at a prespecified rate of the output of a corresponding analog system that is being driven by a zero-order hold analog-to-digital converter.

Root locus design — A technique for design controllers based on positioning the dominant poles of the closed-loop system at a prescribed location.

Credit for bringing robots to life is given to two individuals, Karel Capek and Isaac Asimov. In 1922, Capek wrote a play called *Rossum's Universal Robots* (RUR) describing how robots would turn on mankind and eventually take over the world. In the 1940s, Asimov, who is credited with coining the term “robotics,” freed us from a view of robots as malevolent beings, painting a view of robots as our helpmates, improving our lives and making us more productive.

176.1 Robot Definition

The term “robot” is defined by The Robotics Industry Association as a “reprogrammable multifunctional manipulator designed to move material, parts, tools, or specialized devices, through variable programmed motions for the performance of a variety of tasks.” It consists of mechanical links, often in a serial chain with one link grounded or attached to a frame, that are connected via revolute (i.e., hinge) or prismatic (i.e., sliding) joints and actuated via gear trains or directly by electric motors or hydraulic or pneumatic drives. A robot will generally include position sensors (such as potentiometers or optical encoders) and may include contact, tactile, force/torque, proximity, or vision sensors. At its distal end, a robotic manipulator is typically fitted with an end-effector, such as a gripper, enabling it to accomplish desired tasks. An example of an industrial robot is the Case Packer from CAMotion, Inc. shown in [Figure 176.1](#).

176.2 Robot Control Problem

The fundamental control problem in robotics is to determine the actuator signals required to achieve the desired motion and specified performance criteria. If the robot is to perform a task while in contact with a surface, it is also necessary to control the contact force applied by the manipulator. Although the control problem can be stated simply, its solution may be quite complicated due to robot nonlinearities. For example, because of coupling among links, the robot dynamics in a serial link robot design are described mathematically by a set of coupled nonlinear differential equations, making the controls problem challenging. The controls problem becomes even more difficult if the links exhibit flexibility, and hence cannot be modeled as rigid.

FIGURE 176.1 Case Packer Cartesian Robot. (Courtesy of CAMotion, Inc.)

To achieve the desired motion and possibly contact force characteristics, the planning of the manipulator trajectory is integrally linked to the control problem. The position of the robot can be described by a set of joint coordinates in *joint space* or by the position and orientation of the end-effector using coordinates along orthogonal axes in *Cartesian or task space*. The two representations are related, that is, the Cartesian position and orientation can be computed from the joint positions via a mapping (or function) known as *forward kinematics*. The motion required to realize the desired task is generally specified in Cartesian space. The joint positions required to achieve the desired end-effector position and orientation can be found by a mapping known as the *inverse kinematics*. This inverse kinematics problem may have more than one solution, and a closed-form solution may not be possible, depending on the geometric configuration of the robot. The desired motion may be specified as point to point, in which the end-effector moves from one point to another without regard to the path, or it may be specified as a continuous path, in which the end-effector follows a desired path between the points. A trajectory planner generally interpolates the desired path and generates a sequence of set points for the controller. The interpolation may be done in joint or Cartesian space.

Some of the robot control schemes in use today include independent joint control [Luh, 1983]; Cartesian-space control [Luh et al., 1980]; and force control strategies such as hybrid position/force control [Raibert and Craig, 1981] and impedance control [Hogan, 1985]. In independent joint control, each joint is considered as a separate system and the coupling effects between the links are treated as disturbances to be rejected by the controller. Performance can be enhanced by compensating for robot nonlinearities and interlink coupling using the method of computed torque or inverse dynamics. In Cartesian-space control, the error signals are computed in Cartesian space and the inverse kinematics problem need not be solved. In this chapter, independent joint control is analyzed in depth to provide insight into the use of various controllers for joint position control. Information on force control schemes can be found in the references cited above as well in Bonitz [1995].

176.3 Basic Joint Position Dynamic Model

Many industrial robots operate at slow speeds, employing large gear reductions that significantly reduce the coupling effects between the links. For slowly varying command inputs, the drive system dominates

FIGURE 176.2 Simple actuator model for a single-link robot.

the dynamics of each joint and each link can be considered rigid. Under these conditions, each joint can be controlled as an independent system using linear system control techniques. Figure 176.2 is a model of a single actuator-link model, representative of a single link robot. The model includes an effective inertia, J ,

$$J = J_m + r^2 J_l \quad (176.1)$$

where r is the gear ratio of the joint, J_m is the motor inertia, and J_l is the link inertia. The model also includes an effective damping coefficient, B , and a motor armature inductance and resistance, L and R , respectively. The relationship between the motor input voltage and the rotational speed is given by the second-order differential equation,

$$\ddot{\omega}(t) + (JR + BL)\dot{\omega}(t) + \left(\frac{RB}{JL} + \frac{K_t^2}{JL} \right) \omega(t) = \frac{K_t}{JL} e_{in}(t) \quad (176.2)$$

where $e_{in}(t)$ is the motor input voltage, $\omega(t)$ is the link angular velocity or rotational speed, and K_p is a motor torque constant (torque per current ratio). Assuming zero initial conditions and defining the Laplace transformations,

$$\mathfrak{S}\{\omega(t)\} \equiv \Omega(s) \quad \mathfrak{S}\{e_{in}(t)\} \equiv E_{in}(s)$$

the transfer function between the input voltage, $E_{in}(s)$ and the link rotational velocity, $\Omega(s)$, can be written as

$$\frac{\Omega(s)}{E_{in}(s)} = \frac{\frac{K_t}{JL}}{s^2 + (JR + BL)s + \left(\frac{RB}{JL} + \frac{K_t^2}{JL} \right)} \quad (176.3)$$

For most motor systems, the overall system dynamics are dominated by the mechanical dynamics rather than the electrical “dynamics,” that is, the effect of L is small in comparison to the other system parameters. Assuming negligible L in equation (176.3), the following first-order transfer function can be developed:

$$\lim_{L \rightarrow 0} \left[\frac{\Omega(s)}{E_{in}(s)} \right] = \lim_{L \rightarrow 0} \left[\frac{\frac{K_t}{JL}}{s^2 + (JR + BL)s + \left(\frac{RB}{JL} + \frac{K_t^2}{JL} \right)} \right] = \frac{K_t}{JR s + \left(RB + \frac{K_t^2}{JL} \right)} \quad (176.4)$$

Defining the open-loop joint time constant, T_m , as

$$T_m = \frac{JR}{RB + \left(\frac{K_t^2}{JL} \right)} \quad (176.5)$$

and the open-loop link gain as

$$K_m \equiv \frac{K_t}{RB + \left(\frac{K_t^2}{JL} \right)} \quad (176.6)$$

Equation (176.4) can be rewritten as

$$\frac{\Omega(s)}{E_{in}(s)} = \frac{K_m}{T_m s + 1} \quad (176.7)$$

The assumption of the motor inductance being small, resulting in negligible electrical dynamics is considered reasonable if the negative real part of the single pole from the electrical dynamics is approximately three times larger than the negative real part of the mechanical dynamics. This is known as the dominant pole theory, and is valid for most motors. However, for small motors, such as those used in micro-electromechanical systems (MEMS) devices, this assumption may not be valid.

Equation (176.7) provides a relationship between joint angular velocity and input motor voltage, and is a useful first-order model for velocity control. However, for most robot applications, position control rather than velocity control is desired. For the typical case of lower velocities, the dynamics of the individual joints can be considered to be decoupled. Recognizing that the position of the joint is the integral of the joint velocity, a transfer function between position, $\Theta(s)$, which is the Laplace transform of $\theta(t)$, and the input voltage can be developed:

$$G(s) = \frac{\Theta(s)}{E_{in}(s)} = \frac{1}{s} \frac{\Omega(s)}{E_{in}(s)} = \left(\frac{1}{s} \right) \frac{K_m}{T_m s + 1} = \frac{K_m}{s(T_m s + 1)} \quad (178.8)$$

where $G(s)$ is the plant transfer function for the single link. Equation (176.8) is a model for position control, and the same simple dynamics can be used to model a variety of systems including high precision machine tools, which are essentially multi-axis Cartesian robots [Kurfess and Jenkins, 2000].

176.4 Independent Joint Position Control

For many applications, the assumption of negligible link coupling is reasonable and independent joint position control can be a successful strategy. Two classical control methods — proportional derivative (PD) control and proportional integral derivative (PID) control — are typically implemented. This

FIGURE 176.3 Generalized closed-loop system configuration.

section develops design strategies for both types, and, for completeness, considers the even simpler proportional (P) controller. Figure 176.3 represents the closed-loop feedback configuration for the single link model, where $G(s)$ represents the link or plant dynamics given by Equation (176.8), $K(s)$ represents the controller that is to be designed, and $H(s)$ represents the feedback sensor dynamics. In general, the relationship between the desired angular position, $\Theta_d(s)$, and the actual angular position of the link, $\Theta(s)$, is given by Black's Law (1934a, 1934b),

$$G_{CL}(s) = \frac{\Theta(s)}{\Theta_d(s)} = \frac{K(s)G(s)}{1 + K(s)G(s)H(s)} \quad (176.9)$$

The angular error, $E(s)$, is given by the difference between the desired angle and the actual angle. The transfer function between $\Theta_d(s)$ and $E(s)$ is given by

$$\frac{E(s)}{\Theta_d(s)} = \frac{\Theta_d(s) - \Theta(s)}{\Theta_d(s)} = \frac{1}{1 + K(s)G(s)H(s)} \quad (176.10)$$

The controller typically includes a power amplifier that provides the power to drive the system. In this example, the output of the controller is a voltage, that is, the power amplifier's function is to provide sufficient current at the desired voltage to drive the system. Saturation occurs when the desired input voltage exceeds the maximum amplifier voltage output capacity, or when the product of the voltage and current exceeds the amplifier's rated power capacity. The effect of saturation is ignored in the following examples. Finally, the controller output voltage can be related to the input command signal via the following transfer function,

$$\frac{E_{in}(s)}{\Theta_d(s)} = \frac{E(s)}{\Theta_d(s)} K(s) = \frac{\Theta_d(s) - \Theta(s)}{\Theta_d(s)} K(s) = \frac{K(s)}{1 + K(s)G(s)H(s)} \quad (176.11)$$

Equation (176.11) can be used to determine the motor command voltage as a function of the desired angular trajectory.

Definition of Specifications

Specifications are generally provided to ensure that the desired system behavior is achieved. The specifications define the closed-loop system characteristics, and the usual practice is to tune the controller gains to achieve the desired performance. For this exercise, a 2% settling time, t_s , and a maximum percent overshoot, M_p , are specified. These two quantities (and others) are visualized in the typical second-order response shown in Figure 176.4. They define a desired dynamic response of the closed-loop system described by a second-order model of the form,

$$G_{CL}(s) = \frac{\omega_{nd}^2}{s^2 + 2\zeta_d \omega_{nd} s + \omega_{nd}^2} \quad (176.12)$$

FIGURE 176.4 A typical second-order response.

where ζ_d and ω_{nd} are the desired damping ratio and (undamped) natural frequency, respectively, and are related to the desired overshoot M_{pd} and desired settling time t_{sd} of the target closed-loop system by the expressions,

$$M_{pd} = e^{-\left(\frac{\zeta_d}{\sqrt{1-\zeta_d^2}}\right)\pi} \quad (176.13)$$

$$t_{sd} \approx \frac{4}{\zeta_d \omega_{nd}} \quad (176.14)$$

where the latter is a conservative approximation of the settling time. Solving for ζ_d in Equation (176.13) yields

$$\zeta_d = \sqrt{\frac{\ln(2M_{pd})}{\pi^2 + \ln(2M_{pd})}} = \frac{\ln(M_{pd})}{\sqrt{\pi^2 + \ln(2M_{pd})}} \quad (176.15)$$

From Equations (176.14) and (176.15), ω_{nd} can be expressed as

$$\omega_{nd} \approx \frac{4\sqrt{\pi^2 + \ln(2M_p)}}{t_{sd} \ln(M_p)} \quad (176.16)$$

From Equation (176.12), the characteristic equation that defines the system response is given by

$$s^2 + 2\zeta_d \omega_{nd} s + \omega_{nd}^2 = 0 \quad (176.17)$$

This equation can be used for the design of various controllers. The poles of the closed-loop system are shown in Figure 176.5 for a variety of desired damping ratios, ζ_d . Nominally, for joint position control a damping ratio of 1, corresponding to a critically damped system, is desired. This places both poles in

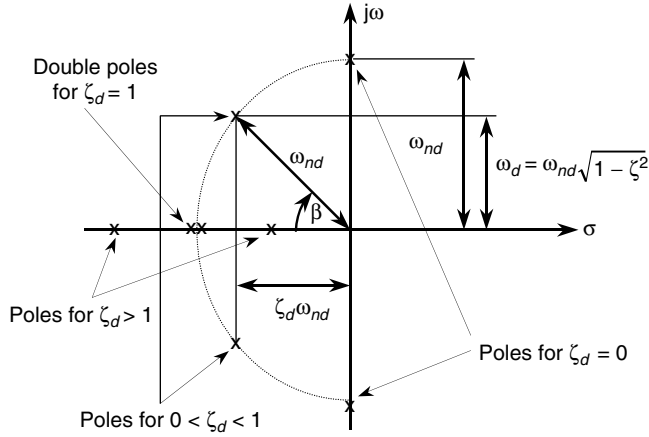

FIGURE 176.5 Pole locations for desired closed-loop system dynamics.

the same location on the real axis, and yields the fastest system response without overshoot. For generality in the control design examples, the variables ζ_d and ω_{nd} are used rather than specific values for these variables [Nagurka and Kurfess, 1992].

Proportional (P) Control

In P control, the simplest analog control algorithm, the control signal is proportionally related to the error signal by a constant gain, K_p . Thus, the transfer function for a proportional controller is a constant,

$$K(s) = K_p \quad (176.18)$$

The closed-loop transfer function of the single actuator-link system with a proportional controller is

$$G_{CL}(s) = \frac{K_p K_m / T_m}{s^2 + (1/T_m)s + K_p K_m / T_m} \quad (176.19)$$

from Equations (176.8), (176.9), and (176.18). The characteristic equation for the transfer function given in Equation (176.19) is

$$s^2 + (1/T_m)s + K_p K_m / T_m = 0 \quad (176.20)$$

With one free design parameter, the proportional gain, K_p , the target closed-loop system dynamics will be virtually impossible to achieve. By equating the actual closed-loop characteristic Equation (176.20) to the desired closed-loop characteristic Equation (176.17),

$$s^2 + (1/T_m)s + K_p K_m / T_m = 0 = s^2 + 2\zeta_d \omega_{nd} s + \omega_{nd}^2 \quad (176.21)$$

only ω_{nd} can be specified directly, giving the value of K_p by

$$K_p = \omega_{nd}^2 \frac{T_m}{K_m} \quad (176.22)$$

(found by equating the coefficients of s^0). Once ω_{nd} has been chosen, ζ_d is fixed to be

$$\zeta_d = \frac{1}{2\omega_{nd}T_m} \quad (176.23)$$

It is useful to investigate the location of the closed-loop poles as a function of K_p . The pole locations on the s-plane can be computed by solving for s in Equation (176.21) via the quadratic formula,

$$s = \frac{-\frac{1}{T_m} \pm \sqrt{\left(\frac{1}{T_m}\right)^2 - 4\frac{K_p K_m}{T_m}}}{2} \quad (176.24)$$

Two values of K_p provide insight. When $K_p = 0$, the closed-loop poles are located at

$$s = \begin{cases} 0 \\ -\frac{1}{T_m} \end{cases} \quad (176.25)$$

corresponding to the open-loop pole locations. When K_p is selected such that the radical in Equation 176.24 vanishes,

$$K_p = \frac{1}{4K_m T_m} \quad (176.26)$$

the two roots are located at

$$s = \begin{cases} -\frac{1}{2T_m} \\ -\frac{1}{2T_m} \end{cases} \quad (176.27)$$

When $0 \leq K_p \leq 1/(4K_m T_m)$, the closed-loop poles of the system are purely real. When $K_p > 1/(4K_m T_m)$, the closed-loop poles of the system are complex conjugates with a constant real part of $-1/(2T_m)$. Increasing the proportional gain beyond $1/(4K_m T_m)$ only increases the imaginary component of the poles; the real part does not change. A graphical portrayal of the pole locations of the system under proportional control is shown in the root locus plot of [Figure 176.6](#). The poles start at their open-loop positions when $K_p = 0$, and transition to a break point at $-1/(2T_m)$ when $K_p = 1/(4K_m T_m)$. After the break point, they travel parallel to the imaginary axis with only their imaginary parts increasing while their real parts remain constant at $-1/(2T_m)$. It is clear from [Figure 176.6](#) that only specific combinations of ω_{nd} and ζ_d can be achieved with the proportional control configuration. Such relationships can be observed directly via a variety of controls design tools for both single-variable and multivariable systems [Kurfess and Nagurka, 1993, 1994].

Proportional Derivative (PD) Control

To improve performance beyond that available by proportional control, PD control can be employed. The dynamics for the PD controller are given by

$$K(s) = K_D s + K_p \quad (176.28)$$

FIGURE 176.6 Root locus for proportional control on a single link.

where the constants K_p and K_D are the proportional and derivative gains, respectively. Employing Black's Law with the PD controller, the closed-loop transfer function for the single actuator-link model is

$$G_{cl}(s) = \frac{\frac{K_m}{T_m}(K_D s + K_p)}{s^2 + \left(\frac{K_m K_D + 1}{T_m}\right)s + K_m K_p / T_m} \quad (176.29)$$

There are now additional dynamics associated with the zero (root of the transfer function numerator) located at

$$s = -\frac{K_p}{K_D} \quad (176.30)$$

These dynamics can affect the final closed-loop response. Ideally, the zero given in Equation (176.30) will be far enough to the left of the system poles on the s -plane that the dominant pole theory applies. (This would mean the dynamics corresponding to the zero are sufficiently fast in comparison to the closed-loop pole dynamics that their effect is negligible.)

Expressions for K_p and K_D can be found by equating the closed-loop characteristic Equation (176.29),

$$s^2 + \left(\frac{K_m K_D + 1}{T_m}\right)s + K_m K_p / T_m = 0 \quad (176.31)$$

to the target closed-loop characteristic equation that possesses the desired natural frequency and damping ratio, Equation (176.17). Equating the coefficients of s^0 and solving for K_p yields

$$K_p = \omega_{nd}^2 \frac{T_m}{K_m} \quad (176.32)$$

Similarly, equating the coefficients of s^1 and solving for K_D yields

FIGURE 176.7 Root locus for PD control on a single link.

$$K_D = \frac{2\zeta_d \omega_{nd} T_m - 1}{K_m} \quad (176.33)$$

This approach of solving for control gains is known as pole placement. As with all control design methods, the gains derived using Equations (176.32) and (176.33) should be checked to ensure that they are realistic.

Figure 176.7 presents a typical root locus plot for a single actuator-link model using a PD controller where the forward loop gain is varied. The location of the single zero ($s = -K_p/K_D$) can be seen on the real axis in the left of the s -plane. For this design, the zero dynamics will be insignificant in comparison to the pole dynamics. It is noted that the break point for the root locus presented in Figure 176.7 is slightly to the left of the break point in Figure 176.6 ($s = -1/2T_m$). Furthermore, the locus of the complex conjugates poles is circular and centered at the zero.

Classical control tools such as the root locus are critical in control design. Without such tools the designer could use the relationships given by Equations (176.32) and (176.33) to place the poles at any location. However, the resulting location of the zero may have been too close to the closed-loop poles resulting in system dynamics that do not behave as desired. This is described in detail in the following section.

Effect of Zero Dynamics

To demonstrate the effect of a zero, consider two systems that have the same damping ratios (ζ) and natural frequencies (ω_n). The first system is given by

$$G_1(s) = \frac{R_1(s)}{C(s)} = \frac{\omega_n^2}{s^2 + 2\zeta\omega_n s + \omega_n^2} \quad (176.34)$$

and the second system is

$$G_2(s) = \frac{R_2(s)}{C(s)} = \frac{s + \omega_n^2}{s^2 + 2\zeta\omega_n s + \omega_n^2} \quad (176.35)$$

where the input is $c(t)$ and the output is $r_i(t)$ ($i = 1, 2$). The difference between the two systems is the zero located at $s = -\omega_n^2$ for the system described by Equation (176.35). For a unit step input,

$$C(s) = \frac{1}{s} \quad (176.36)$$

the unit step responses of the two systems are

$$R_1(s) = \frac{\omega_n^2}{s^2 + 2\zeta\omega_n s + \omega_n^2} \left(\frac{1}{s} \right) \quad (176.37)$$

and

$$R_2(s) = \frac{s + \omega_n^2}{s^2 + 2\zeta\omega_n s + \omega_n^2} \left(\frac{1}{s} \right) = \frac{s}{s^2 + 2\zeta\omega_n s + \omega_n^2} \left(\frac{1}{s} \right) + \frac{\omega_n^2}{s^2 + 2\zeta\omega_n s + \omega_n^2} \left(\frac{1}{s} \right) \quad (176.38)$$

The difference between the two responses is the derivative term, corresponding to the first term on the right side of Equation (176.38):

$$\frac{s}{s^2 + 2\zeta\omega_n s + \omega_n^2} \left(\frac{1}{s} \right)$$

The time domain responses for Equations (176.37) and (176.38), respectively, are

$$r_1(t) = 1 - e^{-\zeta\omega_n t} \left[\left(\frac{\zeta}{\sqrt{1-\zeta^2}} \right) \sin(\omega_d t) + \cos(\omega_d t) \right] \quad (176.39)$$

and

$$r_2(t) = \left\{ 1 - e^{-\zeta\omega_n t} \left[\left(\frac{\zeta}{\sqrt{1-\zeta^2}} \right) \sin(\omega_d t) + \cos(\omega_d t) \right] \right\} + \left\{ e^{-\zeta\omega_n t} \left(\frac{1}{\omega_n \sqrt{1-\zeta^2}} \right) \sin(\omega_d t) \right\} \quad (176.40)$$

where ω_d , the damped natural frequency, is given by

$$\omega_d = \omega_n \sqrt{1-\zeta^2} \quad (176.41)$$

Several items are worth noting. First, Equations (176.39) and (176.40) are valid for $0 \leq \zeta < 1$. Second, the difference between the two responses is

$$\left\{ e^{-\zeta\omega_n t} \left(\frac{1}{\omega_n \sqrt{1-\zeta^2}} \right) \sin(\omega_d t) \right\} \quad (176.42)$$

which is the impulse response of the system given by Equation (176.34). For the initial transient of the step response, the impulse response is positive and, therefore, adds to the overall system response. This indicates that the overshoot may be increased, which is the case for the example shown in [Figure 176.8](#) for $\omega_n = 1$ rad/s and $\zeta = 0.707$. In [Figure 176.8](#), the proportional term is the step response given by Equation (176.39), the derivative term is given by expression (176.42), and the total response is given by the sum of the two expressions in Equation (176.40).

From this example, the addition of the zero results in increased overshoot. The real part of the poles is

$$s = \zeta\omega_n = 0.707 \quad (176.43)$$

FIGURE 176.8 Step response of two systems.

and the location of the zero is

$$s = 1 \tag{176.44}$$

Thus, the dominant pole theorem does not hold and the dynamics of the zero cannot be ignored. Again, this is demonstrated by the increased overshoot illustrated in Figure 176.8.

Proportional Integral Derivative (PID) Control

A PID controller can be designed to provide better steady-state disturbance rejection capabilities compared to PD or P controllers. The form of the PID controller is given by

$$K(s) = K_D s + K_P + \frac{K_I}{s} = \frac{K_D s^2 + K_P s + K_I}{s} \tag{176.45}$$

For the single actuator-link model, the closed-loop transfer function using a PID controller is given by

$$G_{CL}(s) = \frac{\frac{K_m}{T_m} (K_D s^2 + K_P s + K_I)}{s^3 + \left(\frac{K_m K_D + 1}{T_m} \right) s^2 + \frac{K_m K_P}{T_m} s + \frac{K_m K_I}{T_m}} \tag{176.46}$$

The closed-loop dynamics are third order and, in comparison to the second-order PD case, the control design has an extra gain that must be determined and an additional pole, located at $s = -d$, added to the target dynamics. The closed-loop characteristic equation,

$$s^3 + \left(\frac{K_m K_D + 1}{T_m} \right) s^2 + \frac{K_m K_P}{T_m} s + \frac{K_m K_I}{T_m} = 0, \tag{176.47}$$

is equated to the new target closed-loop characteristic equation,

$$(s^2 + 2\zeta_d \omega_{nd} s + \omega_{nd}^2)(s + d) = 0 \tag{176.48}$$

FIGURE 176.9 Root locus for PID control on a single link.

As with the PD controller, the location of the zeros in Equation (176.46) as well as the extra pole at $s = -d$, should have a negative real parts that are at least three times as negative as the target closed-loop pole locations.

Figure 176.9 presents a possible root locus plot for the single actuator-link model with a PID controller where the forward loop gain is varied. The two zeros and extra pole can be seen on the real axis to the left in the s -plane. As with the PD control design, the gains used for achieving the target dynamics must be well understood. It is easy to pick gains that move both zeros and the extra pole far to the left in the s -plane. However, it should be noted that the further left the dynamics are shifted in the s -plane, the faster they become, influencing less the overall response of the system. However, to increase the response speed of these dynamics requires higher gains that ultimately result in higher power requirements (and the possibility of instability). As such, while designing for higher gains is rather straightforward mathematically, the implementation may be limited by the physical constraints of the system.

Unlike the locus of the complex conjugate poles for the model employing PD control (Figure 176.6), the locus here need not be circular. Also, given the increased number of closed-loop system parameters (including the control gains and design parameters such as d , the sensitivity of the closed-loop dynamics to changes of these parameters may be important and should be investigated. For example, if the proportional gain changes a small amount (which is bound to happen in a real system), the impact in the overall system performance must be understood. Mathematically, sensitivity can formally be shown to be a complex quantity (having both magnitude and angle), and a variety of techniques can be used to explore sensitivity to parameter changes [Kurfess and Nagurka, 1994].

176.5 Method of Computed Torque

If the robot is a direct-drive type without gear reduction or if the command inputs are not slowly varying, the control scheme of the previous section may exhibit poor performance characteristics and instability may even result. One method of compensating for the effects of link coupling is to use feed-forward disturbance cancellation. The disturbance torque is computed from the robot dynamic equation, summarized in vector-matrix form as

$$\tau = D(\theta)\ddot{\theta} + C(\theta, \dot{\theta}) + G(\theta) + F(\dot{\theta}) \quad (176.49)$$

where τ is the $n \times 1$ vector of joint torques (forces), $D(\theta)$ is the $n \times n$ inertia matrix, $C(\theta, \dot{\theta})$ is the $n \times 1$ vector of Coriolis and centrifugal torques (forces), $G(\theta)$ is the $n \times 1$ vector of torques (forces) due to gravity, and $F(\dot{\theta})$ is the $n \times 1$ vector of torques (forces) due to friction. In the feed-forward disturbance

cancellation scheme, the right side of Equation (176.49) is computed using the desired value of the joint variables and injected as a compensating “disturbance.” If the plant is minimum phase (has no right-half s -plane zeros), its inverse is also fed forward to achieve tracking of any reference trajectory.

Another version of computed-torque control, known as *inverse dynamics control*, involves setting the control torque to

$$\tau = D(\theta)v + C(\theta, \dot{\theta}) + G(\theta) + F(\dot{\theta}) \quad (176.50)$$

which results in $\ddot{\theta} = v$, a double integrator system. The value of v is now chosen as $v = \ddot{\theta}_d + K_D(\dot{\theta}_d - \dot{\theta}) + K_P(\theta_d - \theta)$ where subscript d denotes desired. This results in the tracking error, $e = \theta_d - \theta$, which satisfies

$$\ddot{e} + K_D\dot{e} + K_Pe = 0 \quad (176.51)$$

The gains K_P and K_D can be chosen for the desired error dynamics (damping and natural frequency). In general, computed-torque control schemes are computationally intensive due to the complicated nature of Equation (176.49), and require accurate knowledge of the robot model [Bonitz, 1995].

176.6 Cartesian Space Control

The basic concept of Cartesian space control is that the error signals used in the control algorithm are computed in Cartesian space, obviating the solution of the inverse kinematics. The position and orientation of the robot end-effector can be described by a 3×1 position vector, p , and the three orthogonal axes of an imaginary frame attached to the end effector. (The axes are known as the normal (n), sliding (s), and approach (a) vectors.) The control torque is computed from

$$\tau = D(\theta)\ddot{\theta} + C(\theta, \dot{\theta}) + G(\theta) + F(\dot{\theta}) \quad (176.52)$$

$$\ddot{\theta} = J(\theta)^{-1}[\ddot{x}_d + K_D\dot{e} + K_Pe - \dot{J}(\theta, \dot{\theta})\dot{\theta}] \quad (176.53)$$

where $J(\theta)$ is the manipulator *Jacobian* that maps the joint velocity vector to the Cartesian velocity vector, \ddot{x}_d is the 6×1 desired acceleration vector, $e = [e_p^T e_o^T]^T$, e_p is the 3×1 position error vector, e_o is the 3×1 orientation error vector, K_D is the 6×6 positive-definite matrix of velocity gains, and K_P is the 6×6 positive-definite matrix of position gains. The actual position and orientation of the end-effector is computed from the joint positions via the forward kinematics. The position error is computed from $e_p = \theta_d - \theta$ and, for small error, the orientation error is computed from $e_o = \frac{1}{2}[n \times n_d + s \times s_d + a \times a_d]$. The control law of Equations (176.52) and (176.53) results in the Cartesian error equation,

$$\ddot{e} + K_D\dot{e} + K_Pe = 0 \quad (176.54)$$

The gain matrices K_D and K_P can be chosen to be diagonal to achieve the desired error dynamics along each Cartesian direction [Spong and Vidyasagar, 1989].

The Cartesian space controller has the disadvantage that the inverse of the Jacobian is required, which does not exist at *singular configurations*. The planned trajectory must avoid singularities, or alternative methods such as the SR pseudoinverse [Nakamura, 1991] must be used to compute the Jacobian inverse [Bonitz, 1995].

Defining Terms

Cartesian or task space — The set of vectors describing the position and orientation of the end-effector using coordinates along orthogonal axes. The position is specified by a 3×1 vector of the

coordinates of the end-effector frame origin. The orientation is specified by the 3×1 normal, sliding, and approach vectors describing the directions of the orthogonal axes of the frame. Alternately, the orientation may be described by Euler angles, roll/pitch/yaw angles, or an axis/angle representation.

Forward kinematics — The function that maps the position of the joints to the Cartesian position and orientation of the end-effector. It maps the joint space of the manipulator to Cartesian space.

Inverse kinematics — The function that maps the Cartesian position and orientation of the end-effector to the joint positions. It is generally a one-to-many mapping, and a closed-form solution may not always be possible.

Jacobian — The function that maps the joint velocity vector to the Cartesian translational and angular velocity vector of the end-effector $\dot{x} = J(\theta)\dot{\theta}$.

Singular configuration — A configuration of the manipulator in which the manipulator Jacobian loses full rank. It represents configurations from which certain directions of motion are not possible or when two or more joint axes line up and there is an infinity of solutions to the inverse kinematics problem.

State Variable Feedback

Thomas L. Vincent

University of Arizona

[177.1 Linear State Space Control Systems](#)

[177.2 Controllability and Observability](#)

[177.3 Eigenvalue Placement](#)

[177.4 Observer Design](#)

The fundamental concept of control system design deals with creating a feedback loop between the output and the input of a dynamical system. This is done to improve the stability characteristics of the system. State variable feedback is associated with the idea of using every state variable in the feedback loop, and is used in both nonlinear and linear systems. However, it is only with linear systems that a relatively complete theory is available, with some of the results given in this chapter. The advantage of using state variable feedback for linear control system design is its simplicity. However, in order to use state variable feedback, every state variable must be either measured directly or estimated. Since measuring every state variable is impractical for many control applications, a state estimator must usually be included as a part of the state variable feedback control system design.

177.1 Linear State Space Control Systems

A linear state space model of a control system is given by

$$\dot{\mathbf{x}} = \mathbf{Ax} + \mathbf{Bu} \quad (177.1)$$

$$\mathbf{y} = \mathbf{Cx} + \mathbf{Du} \quad (177.2)$$

where the dot denotes differentiation with respect to time, \mathbf{x} is an $N_x \times 1$ dimensional state vector, \mathbf{u} is an $N_u \times 1$ dimensional control vector, \mathbf{y} is an $N_y \times 1$ dimensional output vector, \mathbf{A} is a square $N_x \times N_x$ matrix, \mathbf{B} is $N_x \times N_u$, \mathbf{C} is $N_y \times N_x$, and \mathbf{D} is $N_y \times N_u$. The matrices \mathbf{A} , \mathbf{B} , \mathbf{C} , and \mathbf{D} are composed of system constants. Nonlinear systems are often approximated by this same linear system in the neighborhood of some steady-state equilibrium point.

The state vector

$$\mathbf{x} = [x_1 \cdots x_{N_x}]^T \quad (177.3)$$

where $()^T$ denotes transpose, is defined by the solution to the differential Equation (177.1). All control inputs to the system are given by the vector

$$\mathbf{u} = [u_1 \cdots u_{N_u}]^T. \quad (177.4)$$

Control inputs include both open-loop command inputs external to the system and closed-loop control inputs internal to the system. Control is ultimately transmitted to the system through the use of actuators that may or may not be modeled in Equation (177.1). It follows from Equation (177.1) that the state of the system cannot be determined until all inputs, along with initial conditions for the state, have been specified. All of the system quantities measured by means of sensors are given by the output vector

$$\mathbf{y} = [y_1 \cdots y_{N_y}]^T \quad (177.5)$$

The sensor output may be of the general form of Equation (177.2), where it is a function of both the state and control inputs (e.g., accelerometer) or it may be simply one or more of the state variables (e.g., position sensor, tachometer). The control system design problem is to determine an automatic control algorithm such that the relationship between a command input $r(t)$ and the output $y(t)$ yields acceptable performance in terms of tracking, stability, uncertain inputs, and so forth. These qualitative performance criteria are determined by the controlled system eigenvalues.

177.2 Controllability and Observability

The concepts of controllability and observability are fundamental to state space design. If a system is controllable, then it is always possible, using state variable feedback, to design a stable controlled system. In fact, the controlled systems eigenvalues may be arbitrarily placed. If a system is observable, then it will always be possible to design an estimator for the state.

The system in Equation (177.1) is controllable if for every initial state $\mathbf{x}(0)$ there exists a control $\mathbf{u}(t)$, $t \in [0, T]$, where T is some finite time interval, that will drive the system to any other point in state space. The system in Equations (177.1) and (177.2) is observable if, given a control $\mathbf{u}(t)$, $t \in [0, T]$, the initial state $\mathbf{x}(0)$ can be determined from the observation history $\mathbf{y}(t)$, $t \in [0, T]$.

Controllability and observability for linear systems in the form of Equations (177.1) and (177.2) may be checked using the Kalman controllability and observability criteria. The Kalman controllability criterion is that the system in Equation (177.1) is controllable if and only if

$$\text{rank}[\mathbf{P}] = N_x \quad (177.6)$$

where \mathbf{P} is the controllability matrix

$$\mathbf{P} = [\mathbf{B}, \mathbf{A}\mathbf{B}, \dots, \mathbf{A}^{N_x-1}\mathbf{B}]. \quad (177.7)$$

According to the Kalman observability criterion, the system in Equations (177.1) and (177.2) is observable if and only if

$$\text{rank}[\mathbf{Q}] = N_x \quad (177.8)$$

where \mathbf{Q} is the observability matrix,

$$\mathbf{Q} = \begin{bmatrix} \mathbf{C} \\ \mathbf{C}\mathbf{A} \\ \mathbf{C}\mathbf{A}^2 \\ \vdots \\ \mathbf{C}\mathbf{A}^{N_x-1} \end{bmatrix} \quad (177.9)$$

State variable feedback design requires that both the controllability and observability criteria be satisfied, which will be assumed in the following discussion. State space design may be broken into two parts: eigenvalue placement (assuming full state information is available) and observer design to supply any missing state information.

177.3 Eigenvalue Placement

If every component of the state x is measured then $C = I$ and $D = 0$ so that $y = x$. Given that the desired controlled system eigenvalues are known, the design problem is reduced to finding an $N_u \times N_x$ feedback gain matrix K such that Equation (177.1) under state variable feedback of the form

$$\mathbf{u} = \mathbf{F}\mathbf{r}(t) - \mathbf{K}\mathbf{x}(t) \quad (177.10)$$

will have the prescribed eigenvalues. Here, $\mathbf{r}(t)$ is an $N_x \times 1$ vector of command inputs and \mathbf{F} is an $N_x \times N_r$ input matrix. The \mathbf{F} matrix will in general be required, since the dimension of the command inputs may not equal the dimension of the control vector. It also provides for scaling of the command input. Substituting Equation (177.10) into Equation (177.1) yields

$$\dot{\mathbf{x}} = \bar{\mathbf{A}}\mathbf{x} + \bar{\mathbf{B}}\mathbf{r} \quad (177.11)$$

where

$$\bar{\mathbf{A}} = \mathbf{A} - \mathbf{B}\mathbf{K} \quad (177.12)$$

$$\bar{\mathbf{B}} = \mathbf{B}\mathbf{F} \quad (177.13)$$

The controlled system of Equation (177.11) is of the same form as the original system in Equation (177.1), except the matrix $\bar{\mathbf{A}}$ now depends on the matrix of feedback gains \mathbf{K} , and the control input, \mathbf{u} , is now the command input \mathbf{r} . For a constant command input, the equilibrium solutions to Equation (177.11) depend on both \mathbf{F} and \mathbf{K} . However, \mathbf{K} alone affects the eigenvalues of the controlled system. If Equation (177.1) is completely controllable, then any desired set of eigenvalues for $\bar{\mathbf{A}}$ can be obtained through an appropriate choice for \mathbf{K} [Davison, 1968; Wonham, 1967].

For single-input systems (u is a scalar) of low dimensions, determining \mathbf{K} for direct eigenvalue placement is easy to do. For example, consider a second-order system of the form of Equation (177.1) with

$$\mathbf{A} = \begin{bmatrix} 0 & 1 \\ a_1 & a_2 \end{bmatrix} \quad \mathbf{B} = \begin{bmatrix} 0 \\ b \end{bmatrix} \quad (177.14)$$

This system satisfies Equation (177.6) so that state space design is possible. Under state variable feedback,

$$\bar{\mathbf{A}} = \begin{bmatrix} 0 & 1 \\ a_1 - bk_1 & a_2 - bk_2 \end{bmatrix} \quad (177.15)$$

that has the characteristic equation

$$\lambda^2 + (bk_2 - a_2)\lambda + (bk_1 - a_1) = 0 \quad (177.16)$$

This system can now be made to behave like a second-order system with eigenvalues $\bar{\lambda}_1$ and $\bar{\lambda}_2$ satisfying the characteristic equation

$$(\lambda - \bar{\lambda}_1)(\lambda - \bar{\lambda}_2) = \lambda^2 + 2\zeta\omega_n\lambda + \omega_n^2 = 0 \quad (177.17)$$

by matching coefficients to yield

$$k_1 = (a_1 + \omega_n^2)/b; \quad k_2 = (a_2 + 2\zeta\omega_n)/b \quad (177.18)$$

This procedure is also applicable when u is a vector, but it is complicated by the fact that the gain matrix K is not unique. However, a general procedure to handle this situation is available [Wonham, 1985]. The procedure can also be readily adapted for numerical solution so that higher dimensional problems can be handled as well.

Unless one is certain about what eigenvalues to use, the question of where to place the controlled system eigenvalues remains a fundamental design problem. There are methods available for handling this aspect of state variable feedback design as well. Some of the more commonly used methods are the linear-quadratic-regulator design [Bryson and Ho, 1975] and robust control design [Green and Limebeer, 1994]. These methods focus on other system performance criteria for determining the feedback gain matrix K , which, in turn, indirectly determine the controlled system eigenvalues. Software is available, based on these methods, for doing control design on a PC [Shahian and Hassul, 1993].

177.4 Observer Design

Even if every component of the state vector x is not directly measured, it is possible to build a device called an *observer* [Luenberger, 1971] that will approximate x . An observer that reconstructs the entire state vector is called an *identity observer*. One that only reconstructs states not directly measured is called a *reduced-order observer*. Identity observers are of a simpler form.

An observer uses the system model with an additional output feedback term to generate an estimate for the state. If we let \hat{x} denote the estimate of x , then an identity observer is obtained from

$$\dot{\hat{x}} = \mathbf{A}\hat{x} + \mathbf{B}u - \mathbf{G}[\hat{y} - y] \quad (177.19)$$

where $\hat{x}(0) = 0$, \mathbf{G} is an $N_x \times N_y$ matrix to be determined, and

$$\hat{y} = \mathbf{C}\hat{x} + \mathbf{D}u \quad (177.20)$$

is the predicted measurement in accordance with Equation (177.2). The structure of the state estimator from Equations (177.19) and (177.20) is the same as a Kalman filter [Kalman, 1960], which is used for state estimation in the presence of Gaussian random noise inputs.

Substituting (177.20) into (177.19) and rearranging terms yields the identity observer,

$$\dot{\hat{x}} = [\mathbf{A} - \mathbf{GC}]\hat{x} + [\mathbf{B} - \mathbf{GD}]u + \mathbf{G}y \quad (177.21)$$

The components of the \mathbf{G} matrix are chosen so that the error equation

$$\dot{\mathbf{e}} = \dot{\hat{x}} - \dot{x} = [\mathbf{A} - \mathbf{GC}]\mathbf{e} \quad (177.22)$$

is stable. The *return time* of the error equation should be chosen so that it is faster than the return time of the controlled system. The stability properties of the error equation are completely under the designer's control, provided that the system in Equations (177.1) and (177.2) is observable. For controllable and observable linear systems, observers do not change the closed-loop eigenvalues of the controlled system.

Rather, they simply adjoin their own eigenvalues. That is, the eigenvalues for the controlled system using an identity observer are those associated with $[A - BK]$ and $[A - GC]$, respectively.

As an example, consider the second-order system given by Equation (177.14), in which the output is the first state variable x_1 , that is,

$$C = [1 \quad 0] \quad D = 0 \quad (177.23)$$

The observability criterion of Equation (177.8) is satisfied by this system so that an observer can be built. In this case,

$$A - GC = \begin{bmatrix} -g_1 & 1 \\ a_1 - g_2 & a_2 \end{bmatrix} \quad (177.24)$$

which has the characteristic equation,

$$\lambda^2 + (g_1 - a_2)\lambda + (g_2 - a_2g_1 - a_1) = 0 \quad (177.25)$$

By choosing the constants g_1 and g_2 , the observer can now be made to behave like a second-order system with eigenvalues $\hat{\lambda}_1$ and $\hat{\lambda}_2$ satisfying the characteristic equation,

$$(\lambda - \hat{\lambda}_1)(\lambda - \hat{\lambda}_2) = \lambda^2 + 2\hat{\zeta}\hat{\omega}_n\lambda + \hat{\omega}_n^2 = 0 \quad (177.26)$$

Equating coefficients between Equations (177.25) and (177.26) yields

$$g_1 = a_2 + 2\hat{\zeta}\hat{\omega}_n; \quad g_2 = a_1 + a_2g_1 + \hat{\omega}_n^2 \quad (177.27)$$

The observer in this case is of the form

$$\dot{\hat{x}}_1 = \hat{x}_2 + g_1(y - \hat{x}_1) \quad (177.28)$$

$$\dot{\hat{x}}_2 = a_1\hat{x}_1 + a_2\hat{x}_2 + g_2(y - \hat{x}_1) + bu \quad (177.29)$$

These equations must be solved on-line to yield \hat{x}_1 and \hat{x}_2 . The resulting controller is

$$u = r - k_1\hat{x}_1 - k_2\hat{x}_2 \quad (177.30)$$

In this case the actual measurement $y = x_1$ could be used in Equation (177.30) instead of \hat{x}_1 . However, if the measurement of y contains noise, this noise can be filtered through the observer by using the full state estimate \hat{x} as used in Equation (177.30).

The observer differential equations may be solved on-line by either digital or analog methods. The initial conditions for solving these equations will generally not be known. However, in most situations, this does not present difficulties with a properly designed observer. Any error resulting from setting all the initial conditions equal to zero will rapidly become small according to the error equation.

Defining Terms

Closed-loop control inputs — Inputs to a control system, given as a function of the output, that are determined by an automatic control algorithm within the system (usually computed by an analog or digital device).

Feedback loop — Any connection between the input and the output of a dynamical system.

Input — The inputs to a dynamical system are quantities that can affect the evolution of the state of the system.

Open-loop command inputs — Inputs to a control system, given as a function of time, that are initiated by a human operator or some other external device used to specify a desired output.

Output — Those functions of the state and control, possibly the states themselves, that can be measured.

Return time — For asymptotically stable systems, with eigenvalues λ_i , the return time is defined by $T = 1/\min|\operatorname{Re}(\lambda_i)|$, $i = 1, \dots, N_x$ and the eigenvalue(s) corresponding to T is called the *dominant eigenvalue(s)*. The dominant eigenvalue(s) corresponds to the slowest time constant in the system.

State variables — Those variables that identify the state of a system. The states of a dynamical system are those dynamical components of a system that completely identify it at any moment in time.

Andrea Serrani

The Ohio State University

In the last 20 years nonlinear control has reached the level of a mature discipline, both in its theoretical developments and in engineering applications. Examples of successful application of modern nonlinear control theory are widespread, and range from aerospace to robotics, and from electrical and mechanical to biomedical engineering. The advantage of nonlinear control systems design versus more conventional (i.e., linear) design methodologies lies in the fact that the fundamentally nonlinear nature of the plant to be controlled is taken directly into account (and, sometimes, exploited) rather than neglected or ignored. The price to pay, however, is the lack of a general design methodology that is applicable to *all* nonlinear systems, and a substantial complexity of the mathematical tools required for the analysis and the synthesis of nonlinear control systems. The first drawback is intrinsic to the nature of the problem, and it is alleviated by the fact that most nonlinear design techniques indeed apply to entire *classes* of nonlinear systems sharing a common structure and properties. The second requires the modern control engineer to acquire the mathematical tool necessary to master the discipline, and meet the challenges for more demanding applications.

178.1 Differential Geometric Methods

Feedback Linearization

The application of concepts and methodologies from differential geometry lies at the foundation of modern nonlinear control theory. The widely popular nonlinear design technique known as *linearization by feedback* is one of the most important results due to the differential geometric approach. Given a nonlinear system in the form

$$\dot{x} = f(x) + \sum_{i=1}^m g_i(x)u_i = f(x) + g(x)u \quad (178.1)$$

with state $x \in \mathfrak{R}^n$ and control input $u \in \mathfrak{R}^m$, the problem of *feedback linearization* amounts to finding a state feedback control

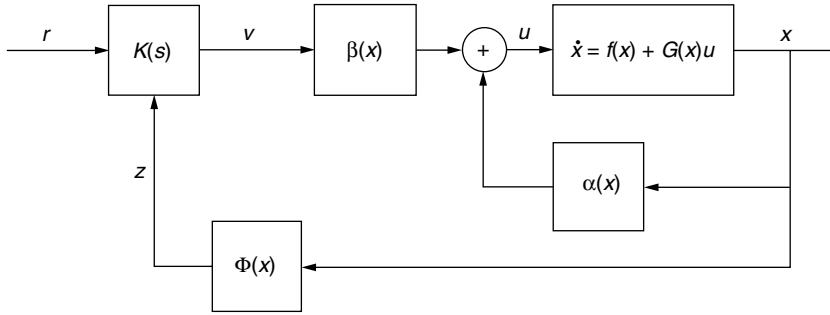

FIGURE 178.1 Inner-loop and outer-loop control based on feedback linearization.

$$u = \alpha(x) + \beta(x)v \quad (178.2)$$

and a change of coordinates in the state space $z = \Phi(x)$ such that the resulting closed-loop system $\dot{x} = f(x) + g(x)\alpha(x) + g(x)\beta(x)v$, when expressed in the new set of coordinates $z(t)$, coincides with the minimal state-space realization of m decoupled linear systems with transfer function

$$G_i(s) = \frac{1}{s^{r_i}}, \quad i = 1, \dots, m \quad (178.3)$$

and $r_1 + r_2 + \dots + r_m = n$. If this is the case, a linear controller $K(s)$ can then be design for Equation (178.3) to obtain the desired response, with the feedback linearizing control Equation (178.2) playing the role of an *inner loop controller* in a multiloop controller design (see Figure 178.1).

In general, the functions $\alpha(x)$, $\beta(x)$, and the transformation $\Phi(x)$ may be defined or remain valid only in a neighborhood $W \subset \mathfrak{R}^n$ of a given point $x_0 \in \mathfrak{R}^n$. If this is the case, the control Equation (178.2) and the change of coordinates $x \mapsto z$ are said to solve the *local* feedback linearization problem; otherwise, if $W \equiv \mathfrak{R}^n$, the Equation (178.1) system is said to be *globally linearizable by state feedback*. Given any nonlinear systems of the form in Equation (178.1), the solvability of the feedback linearization problem (both local and global) can be given a complete characterization in terms of properties of certain *distributions* generated by the vector fields $f(x), g_1(x), \dots, g_m(x)$, that is, properties of nonlinear equivalents of the invariant and controlled-invariant subspaces found in geometric linear systems theory. It is worth noting that the condition of local (global) existence of a linearizing state-feedback transformation does not depend on the choice of the coordinates, that is, on the choice of the state-space representation of the system model. Crucial, in this regard, is the concept of *nonlinear relative degree*. Given m output functions $y_i = h_i(x)$, the Equation (178.1) system is said to have (vector) relative degrees at a point x_0 with respect to the output $y = (y_1 \dots y_m)'$ if there exists an m -tuple of integers $\{r_1, r_2, \dots, r_m\}$ such that

1. $L_{g_j}^k L_f^{r_i} h_i(x) = 0$ for all $j = 1, \dots, m$, for all $k = 1, \dots, r_i - 2$, for all $i = 1, \dots, m$, and for all x in a neighborhood of x_0 .

2. The matrix $A(x) = \begin{pmatrix} L_{g_1} L_f^{r_1-1} h_1(x) & \dots & L_{g_m} L_f^{r_1-1} h_1(x) \\ \vdots & \ddots & \vdots \\ L_{g_1} L_f^{r_m-1} h_m(x) & \dots & L_{g_m} L_f^{r_m-1} h_m(x) \end{pmatrix}$ is nonsingular at x_0

Then, the system in Equation (178.1) is feedback linearizable in a neighborhood of x_0 if it is possible to find m functions such that, when equipped with the “dummy output” $\phi_1(x), \phi_2(x), \dots, \phi_m(x)$, the system in Equation (178.1) has vector relative degree at $y = (\phi_1 \dots \phi_m)'$ and, in addition,

$$3. \quad r_1 + r_2 + r_m = n.$$

Note: The notation $L_f \lambda(x) = \frac{\partial \lambda}{\partial x} f(x)$ stands for the Lie derivative of the smooth function $\lambda(x)$ along

$$\text{the vector field } f(x), \text{ with } L_f^k \lambda(x) = \frac{\partial (L_f^{k-1} \lambda)}{\partial x} f(x).$$

Although their existence can be completely determined a priori, finding such functions is in general a very difficult task, since it amounts in solving a system of nonlinear partial differential equations. However, important classes of nonlinear systems can be easily shown to be feedback linearizable, and the linearizing feedback computed quite effortlessly. Among these latter, the most notable example is the class of fully actuated *Euler-Lagrange systems*, that is, mechanical systems described by equations of the form

$$\frac{d}{dt} \frac{\partial L(q, \dot{q})}{\partial \dot{q}_i} - \frac{\partial L(q, \dot{q})}{\partial q_i} = u_i, \quad i = 1, \dots, n$$

in which each degree of freedom q_i is controlled independently. In the specific case of a fully actuated rigid robotic manipulator, the Euler-Lagrange equations read as

$$M(q)\ddot{q} + C(q, \dot{q})\dot{q} + g(q) = u \quad (178.4)$$

where $q \in \mathfrak{R}^n$ is the vector of joint positions, $M(q)$ is the $n \times n$ inertia matrix, $C(q, \dot{q})$ accounts for the centripetal and Coriolis forces, $g(q)$ is the gravitational force, and $u \in \mathfrak{R}^n$ is the control torque at each joint. It is easy to check this since the inertia matrix is nonsingular for any $q \in \mathfrak{R}^n$, Equation (178.4) has a (global) vector relative degree $\{2, 2, \dots, 2\}$ with respect to the output $y = q$, and the linearizing feedback $u = M(q)[\ddot{v} - C(q, \dot{q})\dot{q} - g(q)]$ yields the closed-loop system $\ddot{q} = \ddot{v}$, that is, a system of n decoupled double integrators. The application of a feedback-linearizing loop in the control of rigid manipulators is commonly referred to as a *computed-torque control*.

Input-Output Linearization

In many cases, it may be impossible to find a set of functions $\phi_1(x), \phi_2(x), \dots, \phi_m(x)$ satisfying the above conditions 1 and 2 for which the additional condition 3 holds, or the system may already be endowed with an output function $y = h(x) \in \mathfrak{R}^m$ for which the system has vector relative degree $\{r_1, r_2, \dots, r_m\}$, but $r_1 + r_2 + r_m < n$. In this case, it is still possible to simplify the nonlinear system to its maximum extent, applying a state feedback of the kind in Equation (178.2) and a coordinate transformation $z = \Phi(x)$ such that, in a closed loop, the resulting input/output map $v \mapsto y$ is that of a linear system, but the closed-loop system itself is not a minimal realization of this map. Specifically, consider for simplicity the case of a SISO nonlinear system in the form

$$\begin{aligned} \dot{x} &= f(x) + g(x)u \\ y &= h(x) \quad x \in \mathfrak{R}^n \end{aligned} \quad (178.5)$$

and assume that the system has relative degree $r < n$ at a point x_0 , that is, $L_g^k L_f^k h(x) = 0$ for all x in a neighborhood of x_0 and all $k < r - 1$, and $L_g L_f^{r-1} h(x_0) \neq 0$. Then, it is possible to find a change of coordinates $\Phi(x): x \mapsto z = (\xi, \eta)$, with $\xi \in \mathfrak{R}^r$, $\eta \in \mathfrak{R}^{n-r}$, such that in the new coordinates the systems has the form

$$\begin{aligned}
\dot{\xi}_1 &= \xi_2 \\
\dot{\xi}_2 &= \xi_3 \\
&\dots \\
\dot{\xi}_r &= a(z) + b(z)u \\
\dot{\eta}_1 &= q_1(z) + p_1(z)u \\
&\dots \\
\dot{\eta}_{n-r} &= q_{n-r}(z) + p_{n-r}(z)u \\
y &= \xi_1
\end{aligned} \tag{178.6}$$

with $b(z) \neq 0$ in a neighborhood of $z_0 = \Phi(x_0)$. Systems of the kind in Equation (178.6) are said to be in *normal form*.

The feedback law

$$u = \frac{v - a(z)}{b(z)} = \frac{v - L_f^r h(x)}{L_g L_f^{r-1} h(x)} \tag{178.7}$$

yields a closed-loop system in which the input-output map is that of a chain of r integrators, $y(s) = \frac{1}{s^r} v(s)$, which is precisely a system of the form

$$\begin{aligned}
\dot{\xi}_1 &= \xi_2 \\
\dot{\xi}_2 &= \xi_3 \\
&\dots \\
\dot{\xi}_r &= v \\
\dot{\eta}_1 &= \bar{q}_1(\eta, \xi) + \bar{p}_1(\eta, \xi)v \\
&\dots \\
\dot{\eta}_{n-r} &= \bar{q}_{n-r}(\eta, \xi) + \bar{p}_{n-r}(\eta, \xi)v \\
y &= \xi_1
\end{aligned} \tag{178.8}$$

The application of the linearizing control renders the $n-r$ states $\eta_1, \dots, \eta_{n-r}$ *unobservable* from the output y . If the system in Equation (178.8) is to be controlled closing an outer-loop controller between y and v , particular care must be taken in ensuring that the internal dynamics $\dot{\eta}(t) = \bar{q}(\eta(t), \xi(t)) + \bar{p}(\eta(t), \xi(t))v(t)$ remains well behaved, that is, the unobservable trajectory $\eta(t)$ remains bounded for all time t .

Example

The kinematic model of a cart-like mobile robot is given by

$$\begin{aligned}
\dot{x} &= v \cos(\theta) \\
\dot{y} &= v \sin(\theta) \\
\dot{\theta} &= \omega
\end{aligned}$$

FIGURE 178.2 Cart-like mobile robot.

where (x,y) are the Cartesian coordinates of the center of the vehicle's center of rotation, θ is the vehicle attitude with respect to a reference frame, and (v,ω) are the linear and angular velocities respectively, playing the role of control inputs (Figure 178.2). It can be easily verified that the system does not have relative degree with respect to the output function $h = (x,y)'$; hence the input-output map between the control input and the Cartesian coordinates cannot be rendered linear. However, the system has relative degree with respect to the output

$$\bar{h} = \begin{pmatrix} \xi_1 \\ \xi_2 \end{pmatrix} = \begin{pmatrix} x + d \cos(\theta) \\ y + d \sin(\theta) \end{pmatrix}$$

which corresponds to the position of some point on the cart away from the center of rotation. Application of the globally defined feedback law

$$\begin{pmatrix} v \\ \omega \end{pmatrix} = \begin{pmatrix} \cos(\theta) & \sin(\theta) \\ -\frac{\sin(\theta)}{d} & \frac{\cos(\theta)}{d} \end{pmatrix} \begin{pmatrix} u_1 \\ u_2 \end{pmatrix}$$

yields the system

$$\begin{aligned} \dot{\xi}_1 &= u_1 \\ \dot{\xi}_2 &= u_2 \\ \phi &= -\frac{\sin(\theta)}{d} u_1 + \frac{\cos(\theta)}{d} u_2 \end{aligned}$$

in which the input-output relationship, in the Laplace domain, is precisely $\bar{h}(s) = \begin{pmatrix} \frac{1}{s} & 0 \\ 0 & \frac{1}{s} \end{pmatrix} \begin{pmatrix} u_1(s) \\ u_2(s) \end{pmatrix}$.

Zero Dynamics

The notion of *zero dynamics* plays a fundamental role in the design of feedback control laws aiming at rendering asymptotically stable an equilibrium point for a nonlinear system. Its importance stems from the fact that it constitutes a nonlinear equivalent of the familiar notion of a transmission zero of a linear system, and, to a certain extent, accounts for the definition of a nonlinear version of the celebrated Evans root-locus design technique. Consider again the SISO nonlinear system in Equation (178.5) and assume that the origin $x = 0$ is an equilibrium of the unforced system, that is, $f(0) = 0$. Without loss of generality, assume also that $h(0) = 0$. The problem of *zeroing the output* is that of finding all possible pairs $(x_*, u_*(\cdot))$ consisting of initial conditions and input functions other than the trivial pair $(x_*, u_*(\cdot)) = (0, 0)$, such that the trajectory of the system

$$\begin{aligned}\dot{x}(t) &= f(x(t)) + g(x(t))u_*(t) \\ x(0) &= x_*\end{aligned}$$

yields an identically zero output. If Equation (178.5) has relative degree r at the origin, the characterization of the solution problem of zeroing the output is derived directly from the normal form of Equation (178.6), from which it is evident that

$$x_* \in \{x = \Phi^{-1}(z); \xi = 0\}, \quad u_*(t) = -\frac{a(z)}{b(z)}$$

and the resulting nontrivial system dynamics are given by

$$\begin{aligned}\dot{\eta}_1 &= \bar{q}_1(\eta, 0) \\ &\dots \\ \dot{\eta}_{n-r} &= \bar{q}_{n-r}(\eta, 0)\end{aligned}\tag{178.9}$$

Equation (178.9), which characterizes the dynamics of systems when the output is forced to be identically zero, is referred to as *the zero dynamics* of Equation (178.5). Note that the zero dynamics is not intrinsic to the unforced system, rather it is imposed by a particular choice of an input function $u(t)$ and an initial condition $x(0)$ forcing the trajectories of the systems to evolve on an invariant hypersurface of the state space.

The role played by the zero dynamics of Equation (178.9) in the local stabilization of the equilibrium at the origin can be explained as follows. Since, without loss of generality, the change of coordinate $(\xi, \eta) = \Phi(x)$ can be always chosen to preserve the origin, Equation (178.9) has an equilibrium at $\eta = 0$. If the equilibrium in question is known to be asymptotically stable, a simple strategy to stabilize the origin of Equation (178.5) is that of designing a feedback control law that drives asymptotically the trajectories of the system to the zero dynamics of Equation (178.9). In this regard, application of the linearizing control of Equation (178.7) yields Equation (178.8), which reads as

$$\begin{aligned}\dot{\xi} &= A_c \xi + B_c v \\ \dot{\eta} &= \bar{q}(\eta, \xi) + \bar{p}(\eta, \xi)v\end{aligned}$$

where (A_c, B_c) are in controllable companion form. Then, choosing the additional control $n = F\xi$, where $F = (-c_0 \ -c_1 \ \dots \ -c_{r-1})$ is a feedback matrix such that $A_c + B_c F$ has all eigenvalues with a negative real part, yields the desired asymptotic convergence of $\xi(t)$ to the origin. Trajectories of the system will then be attracted to the zero dynamics of the systems, and convergence to the origin is implied by asymptotic stability of $\eta = 0$. It is worth noting that the method guarantees only *local* stabilization, valid in general only for trajectory originating from initial conditions in a neighborhood of the origin. On the other hand, asymptotic stability of $\eta = 0$ for Equation (178.9) is not required to be exponential, that is, stabilizability of the Jacobian linearization of the Equation (178.5) is not assumed. The method resembles the classic root-locus design technique for minimum-phase linear systems, where stabilization of the closed-loop system is achieved forcing the closed-loop poles to approach the stable open loop transmission zeros of the plant by means of dynamic output feedback.

Local Output Tracking

The problem of letting the output of a system to track a specified reference trajectory occupies a central role in nonlinear control theory. One of the most common scenarios occurs when the reference trajectory

$y_R(t)$ to be tracked by the output $y(t)$ of Equation (178.5) is generated by a *reference model*, which is usually given as a stable linear system of the form

$$\begin{aligned}\dot{x}_R &= Ax_R + Bu_R \\ y_R &= Cx_R\end{aligned}$$

where $u_R(t)$ is an exogenous input. The role of the reference model is that of shaping the commanded variables so that a desired response in terms of settling time and overshoot during transient is achieved. Again, the role of relative degree and zero dynamics of the plant are crucial in finding a constructive solution. Assume that the plant Equation (178.5) has relative degree r , and that the reference model is chosen in such a way that the relative degree between u_R and y_R is greater or equal to r , that is,

$$CB = CAB = \dots = CA^{r-2}B = 0$$

It is now easy to see that a control which forces the tracking error $e(t) = y(t) - y_R(t)$ to converge asymptotically to zero is given by the multiloop dynamic feedback law

$$\begin{aligned}\dot{\zeta} &= A\zeta + Bu_R \\ u &= \frac{v - L_f^r h(x)}{L_g L_f^{r-1} h(x)} \\ v &= CA^r \zeta - \sum_{i=1}^r c_{i-1} (\zeta_i - CA^{i-1} \zeta) + CA^{r-1} Bu_R\end{aligned}\tag{178.10}$$

where $c_i, i = 0, \dots, r-1$ are the coefficients of the gain matrix F defined in the previous section. To see why the control in Equation (178.10) achieves local tracking of the reference trajectory, note that the inner-loop feedback of Equation (178.7), together with the change of coordinates $z = (\xi, \eta)$, puts the system into the form of Equation (178.8). Then, the additional change of coordinates $\tilde{\xi}_i = \xi_i - CA^{i-1} \zeta, i = 1, \dots, r$, and the application of the outer-loop control v defined in Equation (178.10) yields a closed-loop system of the form

$$\begin{aligned}\dot{\tilde{\xi}} &= (A_c + FB_c) \tilde{\xi} \\ \dot{\eta} &= \varphi(\eta, \tilde{\xi}, \zeta, u_R) \\ \dot{\zeta} &= A\zeta + Bu_R \\ e &= \tilde{\xi}_1\end{aligned}$$

in which the trajectory $\tilde{\xi}(t)$ converges asymptotically to the origin, as the matrix $A_c + B_c F$ has, by design, all eigenvalues with a negative real part. Again, particular care must be taken in ensuring that the trajectories of the “unobservable subsystem”

$$\dot{\eta}(t) = \varphi(\eta(t), \tilde{\xi}(t), \zeta(t), u_R(t))$$

remain bounded in the operating range. The closed-loop system is shown in [Figure 178.3](#).

A somewhat different situation occurs when the trajectory to be tracked by the plant of Equation (178.5) is generated by an *autonomous* system of the form

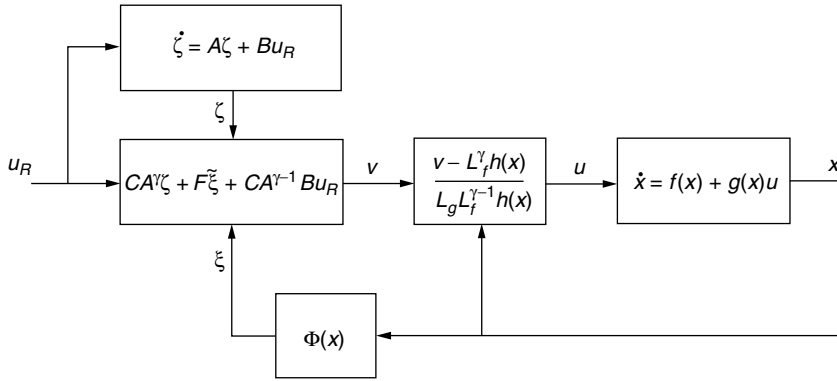

FIGURE 178.3 Model-reference tracking controller.

$$\begin{aligned} \dot{w} &= s(w) \\ y_R &= r(w) \end{aligned} \tag{178.11}$$

with state $w \in \mathfrak{R}^q$, and such that the equilibrium at $w = 0$ is stable, and the Jacobian linearization at the origin $S = \left. \frac{\partial s}{\partial w} \right|_{w=0}$ has all eigenvalues on the imaginary axis. This ensures that the reference Equation (178.11), for initial conditions in a neighborhood of the origin, generates trajectories which are bounded, but do not vanish asymptotically. (If, for some initial conditions, the reference trajectory was such that $y_R(t) = r(w(t)) \rightarrow 0$ as $t \rightarrow \infty$, the problem of asymptotic output tracking would be reduced to the problem of zeroing the output of the plant.) This setup of the problem includes common situations in which the reference signals to be tracked are constant or sinusoidal signals. If the equilibrium at the origin $x = 0$ for the plant in Equation (178.5) is stabilizable in the first approximation, that is, the pair (F, G) defined as

$$F = \left. \frac{\partial f}{\partial x} \right|_{x=0}, \quad G = \left. \frac{\partial g}{\partial x} \right|_{x=0}$$

is stabilizable, then asymptotic stability of the origin of the unforced closed-loop system (i.e., when $w = 0$) is usually imposed as an additional control objective. If this is the case, the solution of the problem of local output tracking with local exponential stability is obtained without requiring the existence of a relative degree for the plant, or even asymptotic stability of its zero dynamics. As a matter of fact, it can be shown that the solvability of the problem is equivalent to the existence of a controlled-invariant submanifold of the extended state space $X = \mathfrak{R}^q \times \mathfrak{R}^n$, which can be locally described by the graph of a mapping, on which the tracking error vanishes identically. In other words, the problem is solvable if and only if there exists mappings $x = \pi(w)$ and $u = c(w)$, defined in a neighborhood of $(w, x) = (0, 0)$, which solve the *nonlinear regulator equation*

$$\begin{aligned} \frac{\partial x}{\partial w} s(w) &= f(\pi(w)) + g(\pi(w))c(w) \\ h(\pi(w)) &= r(w) \end{aligned}$$

The set $\{(w, x): x = \pi(w)\}$ is called an *error-zeroing manifold*, since at each point in this set the error $e = h(x) - r(w)$ is identically zero. The pair $x = \pi(w)$, $u = c(w)$ can therefore be viewed as a solution of the problem of zeroing the output of the augmented system

FIGURE 178.4 Tracking controller with autonomous reference model.

$$\begin{aligned} \dot{w} &= s(w) \\ \dot{x} &= f(x) + g(x)u \\ e &= h(x) - r(w) \end{aligned}$$

whose zero dynamics are precisely given by the trajectories of Equation (178.11). If the solution of the regulator equation is available, the control law which solves the problem of local output tracking is obtained as a combination of the “feed-forward” control $u_{ff} = c(w)$, required to render the error-zeroing manifold invariant under the trajectories of the closed-loop system, and of a “feedback” term of the form $u_{fb} = K[x - \pi(w)]$, which has the role of rendering the error-zeroing manifold locally exponentially attractive. The feedback gain K must be selected in such a way that $F + GK$ has all eigenvalues with a negative real part. The resulting control-loop system is shown in Figure 178.4.

178.2 Lyapunov Techniques

Control Lyapunov Functions

A fundamental tool for the analysis of the stability of a fixed point of a nonlinear system is the celebrated *direct method of Lyapunov*. A fixed point x_0 of a nonlinear system of the form $\dot{x} = f(x)$, $x \in \mathfrak{R}^n$, is stable if there exists a continuously differentiable function $V: \mathfrak{R}^n \rightarrow \mathfrak{R}_{\geq 0}$, called a Lyapunov function, that is positive definite in a neighborhood W of x_0 , that is,

$$V(x_0) = 0$$

and

$$V(x) > 0$$

for each

$$x \in W, x \neq x_0$$

and such that the Lie derivative of V along the vector field $f(x)$ is negative semi-definite in W , that is,

$$L_f V(x) \leq 0$$

for any

$$x \in W$$

If, in addition, $L_f V(x) < 0$ for any $x \in W$, $x \neq x_0$ the equilibrium $x = x_0$ is (locally) asymptotically stable. Global asymptotic stability of $x = x_0$ is established if $W \equiv \mathfrak{R}^n$, and the function is *radially unbounded*, that is,

$$\lim_{\|x\| \rightarrow \infty} V(x) = \infty$$

A natural application of Lyapunov direct method for the stabilization of a fixed point x_0 of a nonlinear control system by means of state-feedback

$$\dot{x} = f(x) + g(x)u$$

consists of choosing a *candidate Lyapunov function* $V(x)$ and finding a feedback control $u = \alpha(x)$, with $\alpha(x_0) = 0$, such that

$$\dot{V}(x) := L_f V(x) + L_g V(x)\alpha(x) < 0$$

for all

$$x \in W, x \neq x_0$$

Again, if global asymptotic stability is the property of interest, $V(x)$ must be chosen to be radially unbounded and $u = \alpha(x)$ must guarantee that $V(x) < 0$ on $\mathfrak{R}^n - \{x_0\}$. Clearly, the existence of such a feedback law depends on the choice of the candidate Lyapunov function $V(x)$. If the fixed point x_0 is stabilizable by means of state feedback, that is, if there exists $u = \alpha(x)$ such that $x = x_0$ is an asymptotically stable equilibrium of

$$\dot{x} = f(x) + g(x)\alpha(x)$$

then, existence of a Lyapunov function $V(x)$ is guaranteed by the *converse Lyapunov theorem*. On the other hand, in solving the feedback stabilization problem, it is of primary importance to recognize *a priori* whether the choice of a candidate Lyapunov function is appropriate or not, in the sense that a corresponding stabilizing law $u = \alpha(x)$ exists for a given $V(x)$. A candidate Lyapunov function is a *control Lyapunov function (CLF)* if

$$L_f V(x) < 0$$

for each

$$x \neq x_0$$

such that

$$L_g V(x) = 0$$

It is quite obvious that functions $V(x)$, which are such that

$$L_f V(x) > 0$$

for some

$$x \neq x_0$$

such that

$$L_g V(x) = 0$$

cannot be used at all for feedback stabilization by Lyapunov direct method. Note that the CLF property can be checked *a priori*. Once a CLF is found, there are several methods to design the stabilizing control $u = \alpha(x)$, the most famous being the *Artstein–Sontag universal formula*,

$$\alpha(x) = \begin{cases} -\frac{L_f V(x) + \sqrt{[L_f V(x)]^2 + [L_g V(x)]^4}}{L_g V(x)} & \text{if } L_g V(x) \neq 0 \\ 0 & \text{if } L_g V(x) = 0 \end{cases}$$

In some cases, when a Lyapunov function $V(x)$ is known such that

$$L_f V(x) \leq 0$$

for any

$$x \in W$$

which means that $x = x_0$ is a stable equilibrium for the uncontrolled system, a control law yielding asymptotic stability of x_0 can still be found, even if $V(x)$ fails to be a CLF. Assume, in addition, that the set

$$Q = \{x \in \mathfrak{R}^n : L_f V(x) = 0 \text{ and } L_f^k L_g V(x) = 0 \text{ for all } k = 0, 1, 2, \dots\}$$

is such that

$$Q = \{x_0\}$$

Then, it can be shown by means of a simple application of *La Salle's invariance principle* (see Khalil [2002], section 4.2), that the so-called *Jurdjević–Quinn control*

$$\alpha(x) = -L_g V(x)$$

succeeds in stabilizing asymptotically the equilibrium $x = x_0$. A typical example of the application of the Jurdjević–Quinn control is given by damping control of mechanical systems, in which $V(x)$ is an energy function, and $\alpha(x) = -L_g V(x)$ plays the role of adding a dissipation term. Consider, for example, the model of the rotational dynamics of a fully actuated rigid body

$$I\dot{\omega} = -\omega \times I\omega + u$$

where $I \in \mathfrak{R}^{3 \times 3}$ is the positive definite inertia matrix, $\omega \in \mathfrak{R}^3$ is the angular velocity about the body-fixed axes, and $u \in \mathfrak{R}^3$ is the control torque. Choosing the Lyapunov function candidate $V(\omega) = \frac{1}{2} \omega' I \omega$, one obtains

$$L_f V(\omega) = 0 \text{ for any } \omega \in \mathfrak{R}^3$$

Hence, $V(\omega)$ is not a CLF. Application of the Jurdjević–Quinn control $u = -\omega$ yields

$$\dot{V}(\omega) = -\|\omega\|^2$$

which implies global asymptotic stability of the origin.

Backstepping

Lyapunov-based techniques are instrumental in the design of stabilizing control law for interconnected systems. Typically, the design is accomplished in a recursive fashion, building a new CLF at each step of the recursion, and finding the corresponding control. One such method is commonly known as *backstepping*, and it is applicable to systems exhibiting a triangular structure of the form

$$\begin{aligned}\dot{z} &= f_0(z) + g_0(z)x_1 \\ \dot{x}_1 &= x_2 + f_1(z, x_1) \\ \dot{x}_2 &= x_3 + f_2(z, x_1, x_2) \\ &\dots \\ \dot{x}_r &= u + f_r(z, x_1, \dots, x_r)\end{aligned}$$

which are said to be in *strict-feedback form*. Let $z \in \mathfrak{R}^{n-r}$ and $x = (x_1, x_2, \dots, x_r)'$, and assume that the equilibrium $z = 0$ of the system

$$\dot{z} = f_0(z) + g_0(z)v$$

is stabilizable by means of a smooth state feedback law $v = \alpha_1(z)$; that is, assume that a radially unbounded CLF $V_0(z)$ is known such that

$$L_{f_0} V(z) + L_{g_0} V(z)\alpha(z) < 0$$

for all

$$z \neq 0$$

Then, it can be shown that the function

$$V_1(z, x_1) = V_0(z) + \frac{1}{2}(x_1 - \alpha_1(z))^2$$

is a CLF for the system

$$\begin{aligned}\dot{z} &= f_0(z) + g_0(z)x_1 \\ \dot{x}_1 &= v + f_1(z, x_1)\end{aligned} \tag{178.12}$$

with corresponding globally stabilizing control

$$\alpha_2(z, x_1) = -(x_1 - \alpha_0(z)) - f_1(z, x_1) - L_{g_0} V_0(z)(x_1 - \alpha_0(z)) + L_{f_0} \alpha_1(z) + L_{g_0} \alpha_1(z)x_1 \tag{178.13}$$

The procedure can obviously be iterated, until a CLF and a corresponding stabilizing feedback for the original system is found. It is worth noting that the method has an interesting interpretation related to

the concept of zero dynamics discussed previously. As a matter of fact, the zero dynamics of Equation (178.12) with respect to the “dummy output” $y_1 = x_1 - \alpha_1(z)$ that was obtained choosing the initial conditions $x_1(0) = \alpha_1(z(0))$ and the control input $v_* = -f_1(z, x_1) + L_{f_0} \alpha_1(z) + L_{g_0} \alpha_1(z) x_1$, reads as

$$\dot{z} = f_0(z) + g_0(z)\alpha(z)$$

and, by assumption, possesses a globally asymptotically stable equilibrium at the origin. The control law of Equation (178.13) is completed by the term $-L_{g_0} V_0(z)(x_1 - \alpha_0(z))$, ensuring that the trajectories of the closed-loop systems of Equations (178.12) and (178.13) remain bounded, while the term $-(x_1 - \alpha_0(z))$ drives asymptotically the trajectories toward the zero dynamics.

Adaptive Control

Concepts and techniques from Lyapunov theory are also central in adaptive control of uncertain nonlinear systems. Given a parameter-dependent single-input nonlinear systems in the form

$$\dot{x} = f(x, \theta) + g(x, \theta)u$$

where $f(0, \theta) = 0$ regardless of the value of the unknown parameter vector $\theta \in \mathfrak{R}^p$, we consider the problem of designing a parameter-independent dynamic feedback law of the form

$$\dot{\xi} = \varphi(\xi, x)$$

$$u = \beta(\xi, x)$$

with state $\xi \in \mathfrak{R}^v$, such that the trajectories of the closed-loop system

$$\dot{x} = f(x, \theta) + g(x, \theta)\alpha(\xi, x)$$

$$\dot{\xi} = \varphi(\xi, x)$$

are globally bounded, and $x(t) \rightarrow 0$, as $t \rightarrow \infty$. Assume that a parameter-dependent CLF $V(x, \theta)$ is given, and that the following hold:

$L_g V(x, \theta)$ is independent of θ .

The stabilizing control $u = \alpha(x, \theta)$ associated with the CLF $V(x, \theta)$ is *affine* in θ , that is, $\alpha(x, \theta) = \alpha_0(x) + \alpha_1(x)\theta$ for some *known* functions $\alpha_0(x)$, $\alpha_1(x)$.

Then, the stabilizing dynamic feedback can be found by appealing to the principle of *certainty-equivalence*, replacing the unknown parameter vector in the control $u = \alpha(x, \theta)$ with an estimate $\hat{\theta}(t)$ generated by the update law

$$\dot{\hat{\theta}} = -(L_g V(x)\alpha_1(x))'$$

In this case, evaluation of the Lyapunov function candidate

$$W(x, \hat{\theta}, \theta) = V(x, \theta) + \frac{1}{2} \|\hat{\theta} - \theta\|^2$$

along with solutions of the closed-loop system

$$\begin{aligned}\dot{x} &= f(x, \theta) + g(x, \theta)\alpha_0(x) + g(x, \theta)\alpha_1(x)\hat{\theta} \\ \dot{\hat{\theta}} &= -(L_g V(x)\alpha_1(x))'\end{aligned}$$

yields

$$\dot{W}(x, \hat{\theta}, \theta) = \frac{\partial V}{\partial x} [f(x, \theta) + g(x, \theta)\alpha(x, \theta)] \leq 0$$

Thus, application of La Salle's invariance theorem yields global boundedness of all trajectories and regulation of $x(t)$ to the origin. If the first property above does not hold, the principle of certainty equivalence cannot be applied, as the update law cannot be computed. If this is the case, a Lyapunov function that depends on the estimate $\hat{\theta}$ rather than on θ must necessarily be employed in analyzing the asymptotic properties of the closed-loop system. In the simpler case in which the plant model depends linearly on the unknown parameter, that is, for systems in the form

$$\dot{x} = f(x) + F(x)\theta + g(x)u \quad (178.13)$$

a solution to the adaptive stabilization problem follows from the existence of an *adaptive control Lyapunov function (ACLf)*. A Lyapunov function candidate $V(x, \theta)$ is an ACLf for Equation (178.13) if there exists a parameter-dependent control $u = \alpha(x, \theta)$ such that

$$\frac{\partial V}{\partial x} \left[f(x) + F(x) \left(\theta + \frac{\partial V'}{\partial \theta} \right) + g(x)\alpha(x, \theta) \right] < 0$$

for all $x \neq 0$ and for all θ . Then, an adaptive controller is obtained as

$$\begin{aligned}\dot{\hat{\theta}} &= F'(x) \frac{\partial V'(x, \hat{\theta})}{\partial x} \\ u &= \alpha(x, \hat{\theta})\end{aligned}$$

The asymptotic properties of the closed-loop systems are evaluated with the aid of the Lyapunov function

$$W(x, \hat{\theta}) = V(x, \hat{\theta}) + \frac{1}{2} \|\hat{\theta} - \theta\|^2$$

which is independent of the actual unknown parameter vector θ . A remarkable feature of the ACLf-based method is that it is amenable to backstepping design. As a matter of fact, for the augmented system

$$\begin{aligned}\dot{x} &= f(x) + F(x)\theta + g(x)\xi \\ \dot{\xi} &= u\end{aligned} \quad (178.14)$$

an ACLf is readily available as

$$V_2(x, \xi, \theta) = V(x, \theta) + \frac{1}{2} (\xi - \alpha(x, \theta))^2$$

for which a control $u = \beta(x, \xi, \theta)$, yielding

$$\frac{\partial V_2}{\partial(x, \xi)} \left[\begin{array}{c} f(x) + F(x) \left(\theta + \frac{\partial V_2'}{\partial \theta} \right) + g(x)\xi \\ \beta(x, \xi, \theta) \end{array} \right] < 0$$

for all

$$x \neq 0, \quad \xi \neq 0 \text{ and for all } \theta$$

can be easily computed. Then, an adaptive controller for Equation (178.14) is given by

$$\begin{aligned} \dot{\hat{\theta}} &= F'(x) \frac{\partial V'(x, \hat{\theta})}{\partial x} - \frac{\partial \alpha'}{\partial x} (\xi - \alpha(x, \hat{\theta})) \\ u &= \beta(x, \xi, \hat{\theta}) \end{aligned}$$

178.3 Input-Output and Dissipative Systems Techniques

Dissipative Systems

A useful tool for the analysis and design of nonlinear control systems is offered by the theory of *dissipative systems*. A nonlinear system of the form

$$\begin{aligned} \dot{x} &= f(x) + g(x)u \\ y &= h(x) \end{aligned} \tag{178.15}$$

with $u \in \mathfrak{R}^m$, $y \in \mathfrak{R}^m$ is said to be *dissipative* with respect to a *supply rate* if there exists a continuous positive definite function $S(x)$, called a *storage function*, such that along solutions of Equation (178.15) the following *dissipation inequality*

$$S(x(t; x_0)) - S(x_0) \leq \int_0^t q(u(s), h(x(s))) ds, \quad t \geq 0$$

holds for any initial condition x_0 and all input functions $u(\cdot)$. (Although in principle this is not required for the definition of dissipativity, assumption of positive definiteness of the storage function $S(x)$ helps to simplify the statement of the stability results described in this section.) Of particular interest is the case in which $S(x)$ is continuously differentiable, so that the dissipation inequality can be given the infinitesimal form

$$\dot{S}(x) \leq q(u, h(x))$$

for all

$$x \in \mathfrak{R}^n, u \in \mathfrak{R}$$

In addition, a system is said to be *strictly dissipative* if there exists a positive definite function $a(x)$ such that

$$\dot{S}(x) \leq -a(x) + q(u, h(x))$$

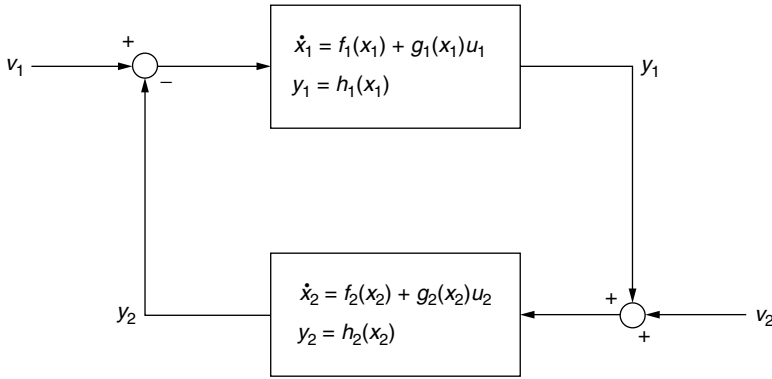

FIGURE 178.5 Feedback loop interconnection.

for all

$$x \in \mathfrak{X}^n, u \in \mathfrak{X}$$

Loosely speaking, if we interpret the storage function as some sort of “energy” of the system, and the supply rate as the power supplied to the system by an external source, the dissipation inequality establishes the property that the rate of change of the energy stored by the system does not exceed the supplied power at any time.

Passive Systems

Among dissipative systems, an important role is played by *passive* systems, for which $q(u, y) = u'y$, and by *strictly output passive* systems, for which $q(u, y) = u'y - \epsilon y'y$, for some $\epsilon > 0$. Clearly, a passive system can be rendered strictly output passive through application of the output feedback $u = v - \epsilon y$, where $v \in \mathfrak{X}^m$ is a new input. Passive systems possess a stable equilibrium at the origin when the input is identically zero, while strictly output passive systems satisfy, in addition,

$$u(t) \equiv 0 \Rightarrow \lim_{t \rightarrow 0} y(t) = 0$$

as a result of La Salle’s invariance theorem. If, in addition to being strictly output passive, a system is *zero-state detectable*, that is, if

$$u(t) \equiv 0 \text{ and } y(t) \equiv 0 \Rightarrow \lim_{t \rightarrow 0} x(t) = 0$$

then the origin is an asymptotically stable equilibrium of the systems. Strict output passivity, in combination with zero-state detectability, is a powerful tool for the analysis of the stability of complex interconnected systems. As a matter of fact, the properties of passivity and strict output passivity are preserved under feedback interconnection: given the system interconnection depicted in Figure 178.5, with

$$\begin{aligned} \dot{x}_1 &= f_1(x_1) + g_1(x_1)u_1 \\ y_1 &= h_1(x_1) \\ \dot{x}_2 &= f_2(x_2) + g_2(x_2)u_2 \\ y_2 &= h_2(x_2) \end{aligned}$$

and $u_1 = v_1 - y_2$, $u_2 = v_2 + y_1$, if the two systems are passive or strictly output passive with storage functions $S_1(x_1)$ and $S_2(x_2)$ respectively, the overall system with input $v = (v_1, v_2)'$ and output $y = (y_1, y_2)'$ is passive with storage function $S_1(x_1) + S_2(x_2)$, and strictly output passive if both systems are strictly output passive. Strictly output passive systems enjoy the property of having a *finite L_2 -gain*, which means that, if the input is a square-integrable signal, then the output of the system is defined for all time, is square-integrable, and satisfies $\|y\|_{L_2} \leq \gamma \|u\|_{L_2}$, for some $\gamma > 0$. It is easy to see that finite L_2 -gain systems are dissipative with respect to the supply rate $q(u, y) = \gamma^2 \|u\|^2 - \|y\|^2$. Stability of feedback interconnections of finite L_2 -gain systems (not necessarily strictly output passive) can be determined by means of the celebrated *small gain theorem*. Suppose that the systems in [Figure 178.4](#) have finite L_2 -gain γ_1 and γ_2 , respectively, and that $\gamma_1\gamma_2 < 1$. Then, the interconnection is stable, and all trajectories converge to the origin if the overall system is zero-state detectable.

Passivity-based techniques are also instrumental in solving the problem of stabilizing cascade systems of the form

$$\begin{aligned} \dot{z} &= f(z, \xi) \\ \dot{\xi} &= a(\xi) + b(\xi)u \end{aligned} \tag{178.16}$$

where, for the sake of simplicity, we take $u \in \mathfrak{R}$. Let $V(z)$ be a Lyapunov function such that

$$\frac{\partial V}{\partial z} f(z, 0) \leq 0, \quad \text{for all } z \in \mathfrak{R}^n$$

which implies that the subsystem

$$\dot{z} = f(z, 0)$$

has a stable, but not necessarily asymptotically stable, equilibrium at the origin. Assume that there exists a “dummy output” $y = h(\xi)$ such that the driven subsystem can be written as

$$\dot{z} = f(z, 0) + p(z, \xi)y$$

and such that the driving subsystem with output $y = h(\xi)$ is passive with storage function $S(\xi)$, and zero-state detectable. Then, the feedback

$$u = -\frac{\partial V}{\partial z} p(z, \xi) + v$$

transforms Equation (178.16) into a passive system with input v , output y , and storage function $V(z) + S(\xi)$. Application of the control $v = -h(\xi)$ yields convergence of all trajectories $\xi(t)$ to zero, while trajectories $z(t)$ are guaranteed to remain bounded. Convergence of $z(t)$ to the origin is, in turn, established if the driven subsystem is zero-state detectable with respect to y , or if

$$\frac{\partial V}{\partial z} f(z, 0) < 0, \quad \text{for all } z \in \mathfrak{R}^n, z \neq 0$$

The one described above is an example of a general methodology called *feedback passivation design*, which aims at rendering a given systems passive with respect to a certain output by means of feedback. The concepts of zero dynamics and relative degree play again a fundamental role in feedback passivation design. As a matter of fact, a system of the form of Equation (178.15) can be rendered passive with respect to a given output $y = h(x)$ only if the system has a vector relative degree $\{1, 1, \dots, 1\}$ with respect to y , and

the corresponding zero dynamics have a stable equilibrium at the origin. The next example (taken from Van der Schaft [2000]) helps clarify the matter.

Example

The attitude dynamics of a rigid body can be described by the equations

$$\begin{aligned}\dot{\eta} &= -\frac{1}{2}\varepsilon'\omega \\ \dot{\varepsilon} &= \frac{1}{2}\eta\omega + \varepsilon \times \omega \\ I\dot{\omega} &= -\omega \times I\omega + u\end{aligned}\tag{178.17}$$

where $\eta \in \mathfrak{R}$, $\varepsilon \in \mathfrak{R}^3$ are the *Euler parameters*

$$\eta = \cos\left(\frac{\varphi}{2}\right), \quad \varepsilon = \sin\left(\frac{\varphi}{2}\right)k$$

corresponding to a rotation of an angle φ about the axis $k \in \mathfrak{R}^3$, $\|k\|=1$. The (η, ε) dynamics is passive with respect to the input/output pair (ω, ε) , with storage function $S(\eta) = 2(1 - \eta)$, while the angular velocity dynamics is passive with respect to the input-output pair (u, ω) , with the storage function given by the kinetic energy $T(\omega) = \frac{1}{2}\omega'I\omega$. The attitude dynamics is therefore the cascade of two passive systems. Choosing the control $u = -\varepsilon + v$, the cascade system is rendered passive with respect to the new input v and the output ω , with storage function $V(\eta, \omega) = S(\eta) + T(\omega)$. Note that the system has relative degree $\{1, 1, \dots, 1\}$ with respect to the output $y = \omega$, and that the corresponding zero-dynamics is

$$\begin{aligned}\dot{\eta} &= 0 \\ \dot{\varepsilon} &= 0\end{aligned}$$

which has a stable equilibrium at the origin. Application of the additional output-feedback control $v = -\omega$ renders $\omega = 0$ attractive, yielding $(\varepsilon(t), \omega(t)) \rightarrow (0, 0)$ by virtue of zero-state detectability of ε with respect to the output ω .

Input-to-State Stability

A nonlinear system of the form

$$\dot{x} = f(x, u)\tag{178.18}$$

is said to be input-to-state stable (ISS), if there exists a continuously differentiable function $V(x): \mathfrak{R}^n \rightarrow \mathfrak{R}_{\geq 0}$, class- K_∞ functions $\alpha_1(\cdot)$, $\alpha_2(\cdot)$, $\sigma(\cdot)$, and a class- K function $\theta(\cdot)$ such that

$$\begin{aligned}\alpha_1(\|x\|) &\leq V(x) \leq \alpha_2(\|x\|) \\ \frac{\partial V}{\partial x} f(x, u) &\leq -\sigma(\|x\|) + \theta(\|u\|)\end{aligned}$$

for all $x \in \mathfrak{R}^n$ and all $u \in \mathfrak{R}^m$. (A class- K function $\lambda: \mathfrak{R}_{\geq 0} \rightarrow \mathfrak{R}_{\geq 0}$ is a continuous and strictly increasing function satisfying $\lambda(0) = 0$. A class- K_∞ function is a class- K function such that $\lim_{s \rightarrow \infty} \lambda(s) = +\infty$.)

Therefore, an ISS system is dissipative with respect to a supply rate of the form $q(u, y) = \theta(\|u\|) - \sigma(\|x\|)$, with a continuously differentiable, positive, definite, and radially unbounded storage function. An ISS system clearly possesses a globally asymptotically stable equilibrium at the origin, when the input is identically zero. Conversely, global asymptotic stability of the origin for the unforced system (in short, 0-GAS) does not, in general, imply ISS. However, 0-GAS systems are feedback equivalent to ISS systems, in the sense that if Equation (178.18) is 0-GAS, then there exists a feedback law of the form

$$u = \alpha(x) + \beta(x)v$$

with $\beta(x)$ invertible everywhere, such that the closed-loop system with input v

$$\dot{x} = f(x, \alpha(x) + \beta(x)v)$$

is ISS. As a result, it is in principle possible, by means of state feedback, to enforce the desirable property of ISS on a system that is globally asymptotically *stabilizable*. Since the ISS property is preserved under series interconnection, enforcing ISS by feedback proves to be a powerful tool for the *global* stabilization of cascade systems. Consider again the cascade system of Equation (178.16), and assume that there exists a function $\xi = \kappa(z)$ such that the system

$$\dot{z} = f(z, \kappa(z))$$

has a globally asymptotically stable equilibrium at the origin. Then, a “feedback law” $\xi = \alpha(z) + \beta(z)v$ exists such that the system with input v

$$\dot{z} = f(z, \alpha(z) + \beta(z)v)$$

is ISS. The change of coordinates $\beta^{-1}(z)[\xi - \alpha(z)]$ transforms Equation (178.16) into a system of the form

$$\dot{z} = f(z, \alpha(z) + \beta(z)v)$$

$$\dot{v} = \bar{a}(z, v) + \bar{b}(z, v)u$$

Since the cascade of two ISS systems is ISS, necessarily the cascade of an ISS system with a 0-GAS system is 0-GAS. Therefore, to globally stabilize Equation (178.16), it suffices to globally stabilize the origin of the driving subsystem $\dot{v} = \bar{a}(z, v) + \bar{b}(z, v)u$.

The ISS property is also instrumental in analyzing stability of loop interconnections of systems. As a matter of fact, ISS systems possess an *asymptotic gain* with respect to the input, in the sense that there exists a class- K function $\gamma(\cdot)$ such that

$$\limsup_{t \rightarrow \infty} \|x(t)\| \leq \gamma(\|u\|_{\infty})$$

for any

$$u(\cdot) \in L_{\infty}$$

A version of the *small-gain* theorem for ISS systems involving asymptotic gains states that the loop interconnection of two ISS systems

$$\dot{x}_1 = f_1(x_1, u_1)$$

$$\dot{x}_2 = f_2(x_2, u_2)$$

$$u_1 = x_2$$

$$u_2 = x_1 + v$$

each having asymptotic gain $\gamma_1(\cdot)$ and $\gamma_2(\cdot)$, respectively, is ISS with respect to the overall input v if the composition $\gamma_1 \times \gamma_2(\cdot)$ is a simple contraction, that is, if $\gamma_1 \times \gamma_2(s) < s$, for any $s \geq 0$. Several versions, characterizations, extensions, and applications of the ISS have flourished in the last decade, and have contributed to the success of the ISS framework as a powerful analysis and design tool for nonlinear systems. For a survey, see Sontag [1995].

Introduction to Mechatronics

Robert H. Bishop
University of Texas at Austin

- [179.1 Basic Definitions](#)
- [179.2 Key Elements of Mechatronics](#)
- [179.3 Historical Perspective](#)
- [179.4 Future of Mechatronics](#)

Mechatronics is a natural stage in the evolutionary process of modern engineering design. The development of the computer, and then the microcomputer, embedded computers, and associated information technologies and software advances, made mechatronics an imperative in the latter part of the 20th century. Standing on the threshold of the 21st century, with expected advances in integrated bio-electro-mechanical systems, quantum computers, nano- and pico-systems, and other unforeseen developments, the future of mechatronics is full of potential and bright possibilities. The *Handbook of Mechatronics* [1] contains a complete description of the field of mechatronics and is an excellent resource for further reading.

179.1 Basic Definitions

The definition of mechatronics has evolved since the original definition by the Yasakawa Electric Company. In trademark application documents, Yasakawa defined mechatronics in this way [2,3]: “The word, Mechatronics, is composed of ‘mecha’ from mechanism and the ‘tronics’ from electronics. In other words, technologies and developed products will be incorporating electronics more and more into mechanisms, intimately and organically, and making it impossible to tell where one ends and the other begins.”

The definition of mechatronics continued to evolve after Yasakawa suggested the original definition. One oft-quoted definition of mechatronics was presented by Harashima, Tomizuka, and Fukada in 1996 [4]. In their words, mechatronics is defined as “the synergistic integration of mechanical engineering, with electronics and intelligent computer control in the design and manufacturing of industrial products and processes.”

That same year, another definition was suggested by Auslander and Kempf [5]: “Mechatronics is the application of complex decision making to the operation of physical systems.” Yet another definition due to Shetty and Kolk appeared in 1997 [6]: Mechatronics is a methodology used for the optimal design of electromechanical products. More recently, we find the suggestion by Bolton [7] that “[a] mechatronic system is not just a marriage of electrical and mechanical systems and is more than just a control system; it is a complete integration of all of them.”

All of these definitions and statements about mechatronics are accurate and informative, yet each one in and of itself fails to capture the totality of mechatronics. Despite continuing efforts to define mechatronics, to classify mechatronic products, and to develop a standard mechatronics curriculum, a consensus

opinion on an all-encompassing description of “what is mechatronics” eludes us. This lack of consensus is a healthy sign. It says that the field is alive, that it is a youthful subject. Even without an unarguably definitive description of mechatronics, engineers understand from the definitions given above and from their own personal experiences the essence of the *philosophy* of mechatronics.

For many practicing engineers on the front line of engineering design, mechatronics is nothing new. Many engineering products of the last 25 years integrated mechanical, electrical, and computer systems, yet were designed by engineers that were never formally trained in mechatronics *per se*. It appears that modern concurrent engineering design practices, now formally viewed as part of the mechatronics specialty, are natural design processes. What is evident is that the study of mechatronics provides a mechanism for scholars interested in understanding and explaining the engineering design process to define, classify, organize, and integrate the many aspects of product design into a coherent package. As the historical divisions between mechanical, electrical, aerospace, chemical, civil, and computer engineering become less clearly defined, we should take comfort in the existence of mechatronics as a field of study in academia. The mechatronics specialty provides an educational path, that is, a road map, for engineering students studying within the traditional structure of most engineering colleges. Mechatronics is generally recognized worldwide as a vibrant area of study. Undergraduate and graduate programs in mechatronic engineering are now offered in many universities. Refereed journals are being published and dedicated conferences are being organized and are generally highly attended.

It should be understood that mechatronics is not just a convenient structure for investigative studies by academicians; it is a way of life in modern engineering practice. The introduction of the microprocessor in the early 1980s and the ever increasing desired performance to cost ratio revolutionized the paradigm of engineering design. The number of new products being developed at the intersection of traditional disciplines of engineering, computer science, and the natural sciences is ever increasing. New developments in these traditional disciplines are being absorbed into mechatronics design at an ever-increasing pace. The ongoing information technology revolution, advances in wireless communication, smart sensors design (enabled by MEMS technology), and embedded systems engineering insures that the engineering design paradigm will continue to evolve in the early 21st century.

179.2 Key Elements of Mechatronics

The study of mechatronic systems can be divided into the following areas of specialty:

- Physical systems modeling
- Sensors and actuators
- Signals and systems
- Computers and logic systems
- Software and data acquisition

The key elements of mechatronics are illustrated in [Figure 179.1](#). As the field of mechatronics continues to mature, the list of relevant topics associated with the area will most certainly expand and evolve.

Central to mechatronics is the integration of physical systems (e.g., mechanical and electrical systems) utilizing various sensors and actuators connected to computers and software. The connections are illustrated in [Figure 179.2](#). In the design process, it is necessary to represent the physical world utilizing mathematical models; hence physical system modeling is essential to the mechatronic design process. Fundamental principles of science and engineering (such as the dynamical principles of Newton, Maxwell, and Kirchoff) are employed in the development of physical system models of mechanical and dynamical systems, electrical systems, electromechanical systems, fluid systems, thermodynamical systems, and microelectromechanical (MEMS) systems. Mechatronic systems utilize a variety of sensors to measure the external environment and actuators to manipulate the physical systems to achieve the desired goals. The sensors measure linear and rotational motion, acceleration, force, torque and power, flow, temperature, distance and proximity, and light and images. Sensors are becoming increasingly smaller, lighter, and in many instances, less expensive. The trend to micro- and nano-scales supports the continued

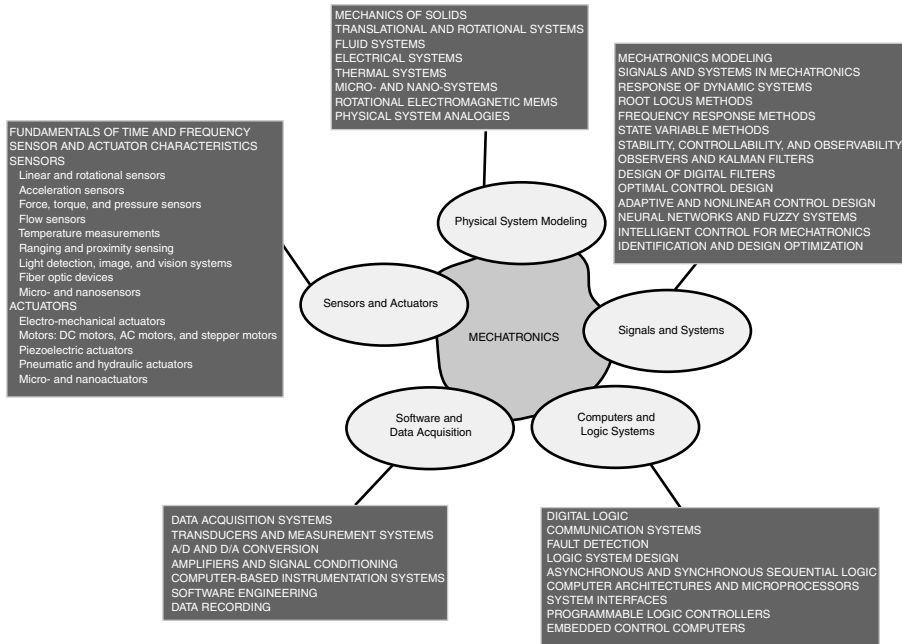

FIGURE 179.1 The key elements of mechatronics.

FIGURE 179.2 Mechatronic system connections between the physical processes and the information processing through the sensors and actuators.

evolution of mechatronic system design. Actuators are following the same trends as sensors in reduced size and cost, and can be grouped into electromechanical actuators, electrical actuators, piezoelectric actuators, hydraulic and pneumatic actuators, and microelectromechanical MEMS (microtransducers).

As noted, an important step in the design process is to accurately represent the system with mathematical models. What are the mathematical models used for? They are employed in the design and analysis of appropriate control systems. The historic subject of systems and controls is central to mechatronic system design. The application of control system design to mechatronic systems runs the gamut from classical frequency domain design (using linear, time-invariant system models) to modern multi-input, multioutput (MIMO) state space methods (again assuming linear, time-invariant models) to nonlinear, time-varying methods. The classical design methods use transfer function models in conjunction with root locus methods or frequency-response methods, such as Bode, Nyquist, and Nichols. Although the transfer function approach generally uses single-input, single-output (SISO) models, it is possible to perform MIMO analysis in the frequency domain. Modern state space analysis and design techniques can be readily applied to SISO and MIMO systems. Pole placement techniques are used to design the controllers. Optimal control methods, such as linear quadratic regulators (LQR), have been discussed in the literature since the 1960s and are in common use today. Robust optimal control design strategies, such

as H_2 and H_∞ , are applicable to mechatronic systems, especially in situations where there is considerable uncertainty in the plant and disturbance models. Other design methodologies include fuzzy control, control, adaptive control, and nonlinear control (using Lyapunov methods and feedback linearization).

Once the control system is designed, it must be implemented on the mechatronic system. This is the stage in the design process wherein issues of software and computer hardware, logic systems, and data acquisition take center stage. The development of the microcomputer, and associated information technologies and software, has impacted the field of mechatronics. The integration of computers and electromechanical systems has led to a whole new generation of consumer products.

The evolution of modern mechatronics can be illustrated with the example of the automobile. An overview of the automobile as a mechatronic system can be found in *The Mechatronics Handbook* [1]. To illustrate the impact of computer technology on the automobile, consider that until the 1960s, the radio was the only significant electronics in an automobile. All other functions were entirely mechanical or electrical. Today, there are about 30 to 60 micro controllers in a car. The automotive electronics market in North America was expected to reach \$28 billion by 2004 [8].

179.3 Historical Perspective

Attempts to construct automated mechanical systems have an interesting history. Actually, the term “automation” was not popularized until the 1940s when it was coined by the Ford Motor Company to denote a process in which a machine transferred a subassembly item from one station to another and then positioned the item precisely for additional assembly operations. But successful development of automated mechanical systems occurred long before then. For example, early applications of automatic control systems appeared in Greece from 300 to 1 B.C. with the development of float regulator mechanisms [9]. Two important examples include the water clock of Ktesibios that used a float regulator, and an oil lamp devised by Philon, which also used a float regulator to maintain a constant level of fuel oil. Later, in the first century, Heron of Alexandria published a book entitled *Pneumatica* that described different types of water-level mechanisms using float regulators.

In Europe and Russia in the 17th to 19th centuries, many important devices were invented that would eventually contribute to mechatronics. Cornelis Drebbel (1572–1633) of Holland devised the temperature regulator representing one of the first feedback systems of that era. Subsequently, Dennis Papin (1647–1712) invented a pressure safety regulator for steam boilers in 1681. Papin’s pressure regulator is similar to a modern-day pressure-cooker valve. The first mechanical calculating machine was invented by Pascal in 1642 [10]. The first historical feedback system claimed by Russia was developed by Polzunov in 1765 [11]. Polzunov’s water-level float regulator, illustrated in Figure 179.3, employs a float that rises and lowers in relation to the water level, thereby controlling the valve that covers the water inlet in the boiler.

Further evolution in automation was enabled by advancements in control theory traced back to the Watt flyball governor of 1769. The flyball governor, illustrated in Figure 179.4, was used to control the speed of a steam engine [12]. Employing a measurement of the speed of the output shaft and utilizing the motion of the flyball to control the valve, the amount of steam entering the engine is controlled. As

FIGURE 179.3 Water-level float regulator. (From R. C. Dorf and R. H. Bishop, Eds., *Modern Control Systems*, 9th ed., Prentice Hall, New York, 2000. With permission.)

FIGURE 179.4 Watt's flyball governor. (From R. C. Dorf and R. H. Bishop, Eds., *Modern Control Systems*, 9th ed., Prentice Hall, New York, 2000. With permission.)

the speed of the engine increases, the metal spheres on the governor apparatus rise and extend away from the shaft axis, thereby closing the valve. This is an example of a feedback control system where the feedback signal and the control actuation are completely coupled in the mechanical hardware.

These early successful automation developments were achieved through intuition, application of practical skills, and persistence. The next step in the evolution of automation required a *theory* of automatic control. The precursor to the numerically controlled (NC) machines for automated manufacturing (to be developed in the 1950s and 1960s at the Massachusetts Institute of Technology) appeared in the early 1800s with the invention of feed-forward control of weaving looms by Joseph Jacquard of France. In the late 1800s, the subject now known as control theory was initiated by J. C. Maxwell through analysis of the set of differential equations describing the flyball governor [13]. Maxwell investigated the effect that various system parameters had on the system performance. At about the same time, Vyshnegradskii formulated a mathematical theory of regulators [14]. In the 1830s, Michael Faraday described the law of induction that would form the basis of the electric motor and the electric dynamo. Subsequently, in the late 1880s, Nikola Tesla invented the alternating-current induction motor. The basic idea of controlling a mechanical system automatically was firmly established by the end of the 1800s. The evolution of automation would accelerate significantly in the 20th century.

The development of pneumatic control elements in the 1930s matured to a point of finding applications in the process industries. However, before 1940, the design of control systems remained an art generally characterized by trial-and-error methods. During the 1940s, continued advances in mathematical and analytical methods solidified the notion of control engineering as an independent engineering discipline. In the United States, the development of the telephone system and electronic feedback amplifiers spurred the use of feedback by Bode, Nyquist, and Black at Bell Telephone Laboratories [15–19]. The operation of the feedback amplifiers was described in the frequency domain and the ensuing design and analysis practices are now generally classified as “classical control.” During the same time period, control theory was also developing in Russia and Eastern Europe. Mathematicians and applied mechanics in the former Soviet Union dominated the field of controls and concentrated on time domain formulations and differential equation models of systems. Further developments of time domain formulations using state variable system representations occurred in the 1960s and led to design and analysis practices now generally classified as “modern control.”

The World War II mobilization led to further advances in the theory and practice of automatic control in an effort to design and construct automatic airplane pilots, gun-positioning systems, radar antenna

control systems, and other military systems. The complexity and expected performance of these military systems necessitated an extension of the available control techniques and fostered interest in control systems and the development of new insights and methods. Frequency domain techniques continued to dominate the field of controls following World War II with the increased use of the Laplace transform, and the use of the so-called s -plane methods, such as designing control systems using root locus.

On the commercial side, driven by cost savings achieved through mass production, automation of the production process was a high priority beginning in the 1940s. During the 1950s, the invention of the cam, linkages, and chain drives became the major enabling technologies for the invention of new products and high-speed precision manufacturing and assembly. Examples include textile and printing machines, paper converting machinery, and sewing machines. High-volume precision manufacturing became a reality during this period. An example of high-volume automated manufacturing of paperboard containers for packaging [20]. The automated paperboard container-manufacturing machine employs a sheet-fed process wherein the paperboard is cut into a fan shape to form the tapered sidewall, and wrapped around a mandrel. The seam is heat sealed and cured while another sheet-fed source of paperboard is used to cut out the plate to form the bottom of the paperboard container, formed into a shallow dish and assembled to the cup shell. The lower edge of the cup shell is bent inwards over the edge of the bottom plate sidewall. A heat-sealing process is used to prevent leaks and provide a level edge for standup while the brim is formed on the top to provide the required stiffness. All of these operations are carried out while the work piece undergoes a precision transfer from one turret to another and is then ejected. The production rate of a typical machine averages over 200 cups per minute. Automated paperboard-container manufacturing did not involve any nonmechanical system except an electric motor for driving the line shaft. These machines are typical of paper-converting and textile machinery and represent automated systems significantly more complex than their predecessors.

The development of the microprocessor in the late 1960s led to early forms of computer control in process and product design. Examples include NC machines and aircraft control systems. Yet the manufacturing processes were still entirely mechanical in nature and the automation and control systems were implemented only as an afterthought. The launch of Sputnik and the advent of the space age provided yet another impetus to the continued development of controlled mechanical systems. Missiles and space probes necessitated the development of complex, highly accurate control systems. Furthermore, the need

to minimize satellite mass (i.e., to minimize the amount of fuel required for the mission) while providing accurate control encouraged advancements in the important field of optimal control. Time domain methods developed by Liapunov, Minorsky, and others, as well as the theories of optimal control developed by Pontryagin in the former Soviet Union and Bellman in the United States, were well matched with the increasing availability of high-speed computers and new programming languages for scientific use.

Advancements in semiconductor and integrated circuits manufacturing led to the development of a new class of products that incorporated mechanical and electronics in the system and required the two together for their functionality. The term *mechatronics* was introduced by Yasakawa Electric in 1969 to represent such systems. Yasakawa was granted a trademark in 1972, but after widespread usage of the term, released its trademark rights in 1982 [2–4]. Initially, mechatronics referred to systems with only mechanical systems and electrical components — no computation was involved. Examples of such systems include the automatic sliding door, vending machines, and garage door openers.

In the late 1970s, the Japan Society for the Promotion of Machine Industry (JSPMI) classified mechatronics products into four categories [2]:

- Class I: Primarily mechanical products with electronics incorporated to enhance functionality. Examples include numerically controlled machine tools and variable-speed drives in manufacturing machines.
- Class II: Traditional mechanical systems with significantly updated internal devices incorporating electronics. The external user interfaces are unaltered. Examples include the modern sewing machine and automated manufacturing systems.
- Class III: Systems that retain the functionality of the traditional mechanical system, but the internal mechanisms are replaced by electronics. An example is the digital watch.
- Class IV: Products designed with mechanical and electronic technologies through synergistic integration. Examples include photocopiers, intelligent washers and dryers, rice cookers, and automatic ovens.

The enabling technologies for each mechatronic product class illustrate the progression of electromechanical products in stride with developments in control theory, computation technologies, and microprocessors. Class I products were enabled by servo technology, power electronics, and control theory. Class II products were enabled by the availability of early computational and memory devices and custom circuit design capabilities. Class III products relied heavily on the microprocessor and integrated circuits to replace mechanical systems. Finally, Class IV products marked the beginning of true mechatronic systems, through integration of mechanical systems and electronics. It was not until the 1970s with the development of the microprocessor by the Intel Corporation that integration of computational systems with mechanical systems became practical.

The divide between classical control and modern control was significantly reduced in the 1980s with the advent of “robust control” theory. It is now generally accepted that control engineering must consider both the time domain and the frequency domain approaches simultaneously in the analysis and design of control systems. In addition, during the 1980s the utilization of digital computers as integral components of control systems became routine. There are literally hundreds of thousands of digital process-control computers installed worldwide [21–22]. Whatever definition of mechatronics one chooses to adopt, it is evident that modern mechatronics involves computation as the central element. In fact, the incorporation of the microprocessor to precisely modulate mechanical power and to adapt to changes in environment are the essence of modern mechatronics and smart products.

179.4 Future of Mechatronics

Mechatronics, the term coined in Japan in the 1970s, has evolved over the past 25 years and has led to a special breed of intelligent products. What is mechatronics? It is a natural stage in the evolutionary process of modern engineering design. For some engineers, mechatronics is nothing new, and for others it is a philosophical approach to design that serves as a guide for their activities. Certainly, mechatronics

is an evolutionary process, not a revolutionary one. It is clear that an all-encompassing definition of mechatronics does not exist, but in reality, one is not needed. It is understood that mechatronics is about the synergistic integration of mechanical, electrical, and computer systems. One can understand the extent that mechatronics reaches into various disciplines by characterizing the constituent components comprising mechatronics, which include (1) physical systems modeling, (2) sensors and actuators, (3) signals and systems, (4) computers and logic systems, and (5) software and data acquisition. Engineers and scientists from all walks of life and fields of study can contribute to mechatronics. As engineering and science boundaries become less well defined, more students will seek a multidisciplinary education with a strong design component. Academia should be moving toward a curriculum that includes coverage of mechatronic systems.

In the future, growth in mechatronic systems will be fueled by growth in constituent areas. Advancements in traditional disciplines fuel the growth of mechatronics systems by providing “enabling technologies.” For example, the invention of the microprocessor had a profound effect on the redesign of mechanical systems and design of new mechatronics systems. We should expect continued advancements in cost-effective microprocessors and micro controllers, sensor and actuator development enabled by advancements in applications of MEMS, adaptive control methodologies and real-time programming methods, networking and wireless technologies, mature CAE technologies for advanced system modeling, virtual prototyping, and testing. The continued rapid development in these areas will only accelerate the pace of smart product development. The Internet is a technology that, when utilized in combination with wireless technology, may also lead to new mechatronic products. While developments in automobiles provide vivid examples of mechatronics development, there are numerous examples of intelligent systems in all walks of life, including smart home appliances such as dishwashers, vacuum cleaners, microwaves, and wireless network enabled devices. In the area of “human-friendly machines” (a term used by H. Kobayashi [23]), we can expect advances in robot-assisted surgery, and implantable sensors and actuators. Other areas that will benefit from mechatronic advances may include robotics, manufacturing, space technology, and transportation. The future of mechatronics is wide open.

Types of Manufacturing

Richard J. Schonberger
Schonberger e/ Associates, Inc.

- [180.1 Job-Shop and Batch Production](#)
- [180.2 Mass Production](#)
- [180.3 Continuous Production](#)
- [180.4 Mixtures and Gray Areas](#)
- [180.5 Capital Investment, Automation, Advanced Technology, Skills, and Layout](#)

Although there are many ways to categorize manufacturing, three general categories stand out (which probably have emerged from production planning and control lines of thought):

1. *Job-shop production.* A job shop produces in small lots or batches.
2. *Mass production.* Mass production involves machines or assembly lines that manufacture discrete units repetitively.
3. *Continuous production.* The process industries produce in a continuous flow.

Primary differences among the three types center on output volume and variety and process flexibility. [Table 180.1](#) matches these characteristics with the types of manufacturing and gives examples of each type. The following discussion begins by elaborating on [Table 180.1](#). Next are comments on hybrid and uncertain types of manufacturing. Finally, five secondary characteristics of the three manufacturing types are presented.

180.1 Job-Shop and Batch Production

As [Table 180.1](#) shows, job-shop manufacturing is very low in volume but is highest in output variety and process flexibility. In this mode, the processes — a set of resources including labor and equipment — are reset intermittently to make a variety of products. (Product variety requires flexibility to frequently reset the process.)

In tool and die making, the first example, the volume is generally one unit — for example, a single die set or mold. Since every job is different, output variety is at a maximum, and operators continually reset the equipment for the next job.

Casting in a foundry has the same characteristics, except that the volume is sometimes more than one. That is, a given job order may be to cast one, five, ten, or more pieces. The multipiece jobs are sometimes called lots or batches.

A bakery makes a variety of products, each requiring a new series of steps to set up the process — for example, mixing and baking a batch of sourdough bread, followed by a batch of cinnamon rolls.

TABLE 180.1 Types of Manufacturing — Characteristics and Examples

| | Job-Shop Production | Mass Production | Continuous Production |
|-------------|---|--|------------------------------------|
| Volume | Very low | High | Highest |
| Variety | Highest | Low | Lowest |
| Flexibility | Highest | Low | Lowest |
| Examples | Tool and die making, casting (foundry), baking (bakery) | Auto assembly, bottling, apparel manufacturing | Paper milling, refining, extrusion |

180.2 Mass Production

Second in Table 180.1 is mass production. Output volume, in discrete units, is high. Product variety is low, entailing low flexibility to reset the process.

Mass production of automobiles is an example. A typical automobile plant will assemble two or three hundred thousand cars a year. In some plants just one model is made per assembly line; variety is low (except for option packages). In other plants, assembly lines produce mixed models. Still, this is considered mass production since assembly continues without interruption for model changes.

In bottling, volumes are much higher, sometimes in the millions per year. Changing from one bottled product to another requires a line stoppage, but between changeovers production volumes are high (e.g., thousands). Flexibility, such as changing from small to large bottles, is low; more commonly, large and small bottles are filled on different lines.

Similarly, mass production of apparel can employ production lines, with stoppages for pattern changes. More conventionally, the industry has used a very different version of mass production: Cutters, sewers, and others in separate departments each work independently, and material handlers move components from department to department to completion. Thus, existence of an assembly line or production line is not a necessary characteristic of mass production.

180.3 Continuous Production

Products that flow — liquids, gases, powders, grains, slurries — are continuously produced, the third type in Table 180.1. In continuous process plants, product volumes are very high (relative to, for example, a job-shop method of making the same product). Because of designed-in process limitations (pumps, pipes, valves, etc.) product variety and process flexibility are very low.

In a paper mill, a meshed belt begins pulp on its journey through a high-speed multistage paper-making machine. The last stage puts the paper on reels holding thousands of linear meters. Since a major product changeover can take hours, plants often limit themselves to incremental product changes. Special-purpose equipment design also poses limitations. For example, a tissue machine cannot produce newsprint, and a newsprint machine cannot produce stationery. Thus, in paper making, flexibility and product variety for a given machine are very low.

Whereas a paper mill produces a solid product, a refinery keeps the substance in a liquid (or sometimes gaseous) state. Continuous refining of fats, for example, involves centrifuging to remove undesirable properties to yield industrial or food oils. As in paper making, specialized equipment design and lengthy product changeovers (including cleaning of pipes, tanks, and vessels) limit process flexibility; product volumes between changeovers are very high, sometimes filling multiple massive tanks in a tank farm.

Extrusion, the third example of continuous processing in Table 180.1, yields such products as polyvinyl chloride (PVC) pipe, polyethylene film, and reels of wire. High process speeds produce high product volumes, such as multiple racks of pipe, rolls of film, or reels of wire per day. Stoppages for changing extrusion heads and many other adjustments limit process flexibility and lead to long production runs between changeovers. Equipment limitations (e.g., physical dimensions of equipment components) keep product variety low.

180.4 Mixtures and Gray Areas

Many plants contain a mixture of manufacturing types. A prominent example can be found in the process industries, where production usually is only partially continuous. Batch mixing of pulp, fats, or plastic granules precedes continuous paper making, refining of oils, and extrusion of pipe. Further processing may be in the job-shop mode: slitting and length-cutting paper to customer order, secondary mixing and drumming of basic oils to order, and length cutting and packing of pipe to order.

Mixed production also often occurs in mass production factories. An assembly line (e.g., assembling cars or trucks) may be fed by parts, such as axles, machined in the job-shop mode from castings that are also job-shop produced. Uniform mass-made products (e.g., molded plastic hard hats) may go to storage where they await a customer order for final finishing (e.g., decals) in the job-shop mode. An apparel plant may mass produce sportswear on the one hand, and produce custom uniforms for professional sports figures in the job-shop mode on the other.

More than one type of manufacturing in the same plant requires more than one type of production planning, scheduling, and production. The added complexity in management may be offset, however, by demand-side advantages of offering a fuller range of products.

Sometimes a manufacturing process does not fit neatly into one of the three basic categories. One gray area occurs between mass production and continuous production. Some very small products — screws, nuts, paper clips, toothpicks — are made in discrete units. But because of small size, high volumes, and uniformity of output, production may be scheduled and controlled not in discrete units but by volume, thus approximating continuous manufacturing. Production of cookies, crackers, potato chips, and candy resembles continuous forming or extrusion of sheet stock on wide belts, except that the process includes die cutting or other separation into discrete units — like mass production. Link sausages are physically continuous, but links are countable in whole units.

Another common gray area is between mass and job-shop production. A notable example is high-volume production of highly configured products made to order. Products made for industrial uses — such as specialty motors, pumps, hydraulics, controllers, test equipment, and work tables — are usually made in volumes that would qualify as mass production, except that end-product variety is high, not low.

These types of manufacturing with unclear categories do not necessarily create extra complexity in production planning and control. The difficulty and ambiguity are mainly terminological.

180.5 Capital Investment, Automation, Advanced Technology, Skills, and Layout

The three characteristics used to categorize manufacturing — volume, variety, and flexibility — are dominant but not exhaustive. To some extent, the manufacturing categories also differ with respect to capital investment, automation, technology, skills, and layout.

Typically, continuous production is highly capital intensive, whereas mass production is often labor intensive. The trend toward automated, robotic assembly, however, is more capital intensive and less labor intensive, which erodes the distinction. Job-shop production on conventional machines is intermediate as to capital investment and labor intensiveness. However, computer numerically controlled (CNC) machines and related advanced technology in the job shop erode this distinction as well.

As technology distinctions blur, so do skill levels of factory operatives. In conventional high-volume assembly, skill levels are relatively low, whereas those of machine operators in job shops — such as machinists and welders — tend to be high. But in automated assembly, skill levels of employees tending the production lines elevate toward technician levels — more like machinists and welders. In continuous production, skill levels range widely — from low-skilled carton handlers and magazine fillers to highly skilled process technicians and troubleshooters.

Layout of equipment and related resources is also becoming less of a distinction than it once was. The classical job shop is laid out by type of equipment: all milling machines in one area, all grinding machines

in another. Mass and continuous production have been laid out by the way the product flows: serially and linearly. Many job shops, however, have been converted to cellular layouts — groupings of diverse machines that produce a family of similar products. In most work cells, the flow pattern is serial from machine to machine, but the shape of the cell is not linear; it is U-shaped or, for some larger cells, serpentine. Compact U and serpentine shapes are thought to provide advantages in teamwork, material handling, and labor flexibility.

To some degree, such thinking has carried over to mass production. That is, the trend is to lay out assembly and production lines in U and serpentine shapes instead of straight lines, which was the nearly universal practice in the past. In continuous production of fluids, the tendency has always been toward compact facilities interconnected by serpentine networks of pipes. Continuous production of solid and semisolid products (wide sheets, extrusions, etc.), on the other hand, generally must move in straight lines, in view of the technical difficulties in making direction changes.

Defining Terms

Batch — A quantity (lot) of a single item.

Changeover (setup) — Setting up or resetting a process (equipment) for a new product or batch.

Continuous production — Perpetual production of goods that flow and are measured by area or volume; usually very high in product volume, very low in product variety, and very low in process flexibility.

Job-shop production — Intermittent production with frequent resetting of the process for a different product or batch; usually low in product volume, high in product variety, and high in process flexibility.

Mass production — Repetitive production of discrete units on an assembly line or production line; usually high in product volume, low in product variety, and low in process flexibility.

Process — A set of resources and procedures that produces a definable product (or service).

Process industry — Manufacturing sector involved in continuous production.

Control Charts for Variables • Control Charts for Attributes

181.3 Tolerances and Capability

Although no universally accepted definition of *quality* exists, in its broadest sense quality has been described as “conformance to requirements,” “freedom from deficiencies,” or “the degree of excellence which a thing possesses.” Taken within the context of the manufacturing enterprise, quality — or, more specifically, manufacturing quality — shall be defined as “conformance to requirements.” This chapter focuses on the evaluation of product quality, with particular emphasis directed at statistical methods used in the measurement, control, and tolerances needed to achieve the desired quality. Factors that define product quality are ultimately determined by the customer and include such traits as reliability, affordability or cost, availability, user friendliness, and ease of repair and disposal. To ensure that quality goals are met, manufacturing firms have initiated a variety of measures that go beyond traditional product inspection and record keeping, which, by and large, were the mainstays of quality control departments for decades. One such initiative is total quality management (TQM) [Saylor, 1992], which focuses on the customer, both inside and outside the firm. It consists of a disciplined approach using quantitative methods to continuously improve all functions within an organization. Another initiative is registration under the ISO 9000 series [Lamprecht, 1993], which provides a basis for U.S. manufacturing firms to qualify their finished products and processes to specified requirements. More recently, the U.S. government has formally recognized outstanding firms through the coveted Malcolm Baldrige Award [ASQC, 1994] for top quality among U.S. manufacturing companies. One of the stipulations of the award is that recipient companies share information on successful quality strategies with their manufacturing counterparts.

181.1 Measurement

The inherent nature of the manufacturing process is variation. Variation is present due to any one or a combination of factors including materials, equipment, operators, or the environment. Controlling variation is an essential step in realizing product quality. To successfully control variation, manufacturing firms rely on the measurement of carefully chosen parameters. Because measurement of the entire population of products or components is seldom possible or desirable, *samples* from the *population* are chosen. The extent to which sample data represent the population depends largely on such items as sample size, method of sampling, and time-dependent variations.

Measured data from samples taken during a manufacturing process can be plotted in order to determine the shape of the *frequency distribution*. The frequency distribution can give a visual clue to the process average and dispersion. The latter is referred to as *standard deviation*. [Figure 181.1](#) shows a

FIGURE 181.1 Coded pin lengths.

frequency distribution plot of 40 coded pin lengths expressed in thousands of an inch greater than 1 in. Thus, the coded length 6 represents an actual length of 1.006 in. For the data shown, average coded pin length is 8.475 and standard deviation is 1.585.

Normal Distribution

Although there is an infinite variety of frequency distributions, the variation of measured parameters typically found in the manufacturing industry follows that of the normal curve. The normal distribution is a continuous bell-shaped plot of frequency versus some parameter of interest, and is an extension of a histogram whose basis is a large population of data points. Figure 181.2 shows a normal distribution plot superimposed on a histogram. Some important properties of the normal distribution curve are:

- The distribution is symmetrical about the population mean μ .
- The curve can be described by a specific mathematical function of population mean μ and population standard deviation σ .

An important relationship exists between standard deviation and area under the normal distribution curve. Such a relationship is shown in [Figure 181.3](#) and may be interpreted as follows: 68.26% of the

FIGURE 181.2 Normal distribution curve.

FIGURE 181.3 Percentages under the normal curve.

readings (or area under the curve) will be between $\pm 1\sigma$ limits, 95.46% of the readings will be between $\pm 2\sigma$ limits, and 99.73% of the readings will be between $\pm 3\sigma$ limits. The significance of this relationship is that the standard deviation can be used to calculate the percentage of the population that falls between any two given values in the distribution.

181.2 Statistical Quality Control

Statistical quality control (SQC) deals with collection, analysis, and interpretation of data to monitor a particular manufacturing or service process and ensure that the process remains within its capacity. In order to understand process capability, it is necessary to realize that variation is a natural phenomenon that will occur in any process. Parts will appear identical only due to the limitation of the inspection or measurement instrument. The sources of these variations may be the material, process, operator, time of the operation, or any other significant variables. When these factors are kept constant, the minor variations inherent in the process are called *natural* (or *chance*) *variations*, as opposed to variations due to *assignable causes*.

Control charts are utilized to determine when a given process variation is within the expected or natural limits. When the magnitude of variation exceeds these predetermined limits, the process is said to be *out of control*. The causes for out-of-control conditions are investigated and the process is brought back in control. Control charts or the control limits for the natural or chance-cause variations are constructed based on the relationship between the normal distribution and the standard deviation of the distribution. The property of normal distribution and its relationship to the standard deviation of the distribution was discussed in [Chapter 180](#). As stated earlier, since approximately 99.73% of a normal distribution is expected to fall between $\pm 3\sigma$ of the distribution, control limits are established at $\bar{X} \pm 3\sigma$ for the process. Therefore, any sample taken from the process is expected to fall between the control limits or the $\bar{X} \pm 3\sigma$ of the process 99.73% of the time. Any sample not within these limits is assumed to indicate an out-of-control condition for which an assignable cause is suspected.

Control charts can be divided into two major categories: control charts for variables (measurable quality characteristics, i.e., dimension, weight, hardness, etc.), and control charts for attributes (quality characteristics not easily measurable and therefore classified as conforming or not conforming, good or bad, etc.).

Control Charts for Variables

The most common charts used for variables are the \bar{X} and R charts. The charts are used as a pair for a given quality characteristic. In order to construct control charts for variables, the following steps may be followed:

1. Define the quality characteristic that is of interest. Control charts for variables deal with only one quality characteristic; therefore, if multiple properties of the product of the process are to be monitored, multiple charts should be constructed.

- Determine the sample (also called the *subgroup*) size. When using control charts, individual measurements or observations are not plotted, but, rather, sample averages are utilized. One major reason is the nature of the statistics and their underlying assumptions. Normal statistics, as the term implies, assumes a normal distribution of the observations. Although many phenomena may be normally distributed, this is not true of all distributions. A major statistical theory called the *central limit theorem* states that the distribution of sample averages will tend toward normality as the sample size increases, regardless of the shape of the parent population. Therefore, plotting sample averages ensures a reasonable normal distribution so that the underlying assumption of normality of the applied statistics is met. The sample size (two or larger) is a function of cost and other considerations, such as ease of measurement, whether the test is destructive, and the required sensitivity of the control charts. As the sample size increases, the standard deviation decreases; therefore, the control limits will become tighter and more sensitive to process variation.
- For each sample calculate the sample average, \bar{X} , and the sample **range**. For each sample, record any unusual settings (e.g., new operator, problem with raw material) that may cause an out-of-control condition.
- After about 20 to 30 subgroups have been collected, calculate

$$\bar{\bar{X}} = \frac{\sum \bar{X}}{g}; \quad \bar{R} = \frac{\sum R}{g}$$

where $\bar{\bar{X}}$ is the average of averages, \bar{R} is the average of range, and g is the number of samples or subgroups.

- Trial upper and lower control limits for the \bar{X} and R chart are calculated as follows:

$$\begin{aligned} \text{UCL}_{\bar{X}} &= \bar{\bar{X}} + A_2 \bar{R}; & \text{UCL}_R &= D_4 \bar{R} \\ \text{LCL}_{\bar{X}} &= \bar{\bar{X}} - A_2 \bar{R}; & \text{LCL}_R &= D_3 \bar{R} \end{aligned}$$

A_2 , D_3 , and D_4 are constants and are functions of sample sizes used. These constants are used to approximate process standard deviation from the range. Tables of these constants are provided in Banks [1989], De Vor et al. [1992], Grant and Leavenworth [1988], and Montgomery [1991].

- Plot the sample averages and ranges on the \bar{X} and the R chart, respectively. Any out-of-control point that has an assignable cause (new operator, etc.) is discarded.
- Calculate the revised control limits as follows:

$$\begin{aligned} \bar{\bar{X}}_o &= \frac{\sum \bar{X} - \sum \bar{X}_d}{g - g_d}; & \bar{R}_o &= \frac{\sum R - \sum R_d}{g - g_d}; & \sigma_o &= \frac{R_o}{D_2} \\ \text{UCL}_{\bar{X}_o} &= \bar{\bar{X}}_o + A\sigma_o & \text{UCL}_R &= D_2\sigma_o \\ \text{LCL}_{\bar{X}_o} &= \bar{\bar{X}}_o - A\sigma_o & \text{LCL}_R &= D_1\sigma_o \end{aligned}$$

The subscripts o and d stand for revised and discarded terms, respectively. The revised control charts will be used for the next production period by taking samples of the same size and plotting the sample average and sample range on the appropriate chart. The control limits will remain in effect until one or more factors in the process change. [Figure 181.4](#) shows control charts of \bar{X} and R values for ten subgroups. Each subgroup contained five observations because none of the ten data points lie outside of either upper and lower control limits; the process is designated “in control.”

The control charts can be used to monitor the out-of-control conditions of the process. It is imperative to realize that patterns of variation as plotted on the charts should give clear indications to a process that

FIGURE 181.4 Control charts for \bar{X} and R .

is headed for an out-of-control condition or one that displays an abnormal pattern of variations. Whereas no point may actually fall out of the limits, variation patterns can often point to some unusual process behavior that requires careful study of the process.

Control Charts for Attributes

For those quality characteristics that are not easily measured — or in such cases where count of defects of defective items are involved or go-no-go gages are used — control charts for attributes are used. These charts can be grouped into two major categories:

- Charts for defectives or nonconforming items
- Charts for defects or nonconformities

Charts for Nonconforming Items

The basic charts in this group are the fraction **nonconforming** chart (p chart), percent nonconforming chart ($100p$ chart), and count of nonconforming chart (np chart). The procedure for the construction, revision, and the interpretation of control charts for attributes is similar to that for \bar{X} and R charts. The following steps may be used to construct a p chart:

1. Once sample size has been established, fraction nonconforming, p , is determined for each sample by

$$p = \frac{np}{n}$$

where n is the sample size and np is the count of defectives or nonconforming items in the sample.

2. After roughly 20 to 30 subgroups have been collected, calculate \bar{p} , the value of the central line, or the average fraction defective.

$$\bar{p} = \frac{\sum np}{\sum n}$$

3. Trial control limits are calculated as follows:

$$UCL = \bar{p} + 3\sqrt{\frac{\bar{p}(1-\bar{p})}{n}}$$

$$LCL = \bar{p} - 3\sqrt{\frac{\bar{p}(1-\bar{p})}{n}}$$

4. Plot the fraction defective for each subgroup. The out-of-control subgroups that have assignable causes are discarded, and revised limits are calculated as follows:

$$p_o = \frac{\sum np - \sum np_d}{\sum n - n_d}$$

$$UCL = p_o + 3\sqrt{\frac{p_o(1-p_o)}{n}}$$

$$LCL = p_o - 3\sqrt{\frac{p_o(1-p_o)}{n}}$$

5. If the lower control limit is a negative number, it is set to zero. Sample points that fall above the upper limit indicate a process that is out of control. However, samples that fall below the lower limit, when the lower control limit is greater than zero, indicate a product that is better than expected. In other words, if a sample contains fewer nonconforming items than the process is capable of producing, the sample fraction defective will fall below the lower control limit. For this reason, some practitioners may choose to set the lower limit of the attribute charts to zero. This practice, however, may mask other problems or potentials for process improvements.

Other charts for nonconforming items are simple variations of the p chart. In the case of the 100 p chart, all values of the p chart are expressed as percentages. In the case of the np chart, instead of plotting fraction or percent defectives, actual counts of nonconforming or defective items are plotted. See Banks [1989], De Vor et al. [1992], Grant and Leavenworth [1988], and Montgomery [1991] for greater detail. The formulas for the central line and the control limits for an np chart are given below. It is assumed that the revised value for universe fraction defective, p_o , is known. If p is not known, then the procedure for the p chart must be carried out to determine the revised value for the universe fraction defective:

$$\text{Central line} = np_o$$

$$\text{Control limits} = np_o \pm 3\sqrt{np_o(1-p_o)}$$

where n is the sample size and p_o is the universe fraction defective.

Charts for Defects or Nonconformities

Whereas the charts for defective or nonconforming items are concerned with the overall quality of an item or sample, charts for defects look at each defect (i.e., blemish, scratch, etc.) in each item or sample. One may consider an item a nonconforming item based on its overall condition. A defect or **nonconformity** is that condition that makes an item a nonconforming or defective item.

In this category are c charts and u charts. The basic difference between the two is the sample size. The sample size, n , for a c chart is equal to one. In this case the number of nonconformities or defects are counted per a single item. For a u chart, however, $n > 1$. See Banks [1989], De Vor et al. [1992], Grant and Leavenworth [1988], and Montgomery [1991] for the formulas and construction procedures.

181.3 Tolerances and Capability

As stated earlier, *process capability* refers to the range of process variation that is due to chance or natural process deviations. This was defined as $\bar{X} \pm 3\sigma$ (also referred to as 6σ), which is the expected or natural process variation. *Specifications* or *tolerances* are dictated by design engineering and are the maximum amount of acceptable variation. These specifications are often stated without regard to process spread. The relationships between the process spread or the natural process variation and the engineering specifications or requirements are the subject of process capability studies. Process capability can be expressed as:

$$C_p = \frac{US - LS}{6\sigma}$$

where

- C_p = process capability index
- US = upper engineering specification value
- LS = lower engineering specification value

A companion index, C_{pk} , is also used to describe process capability, where

$$C_{pk} = \frac{US - \bar{X}}{3\sigma}$$

or

$$C_{pk} = \frac{\bar{X} - LS}{3\sigma}$$

The lesser of the two values indicates the process capability. The C_{pk} ratio is used to indicate whether a process is capable of meeting engineering tolerances and whether the process is centered around the target value \bar{X} . If the process is centered between the upper and the lower specifications, C_p and C_{pk} are equal. However, if the process is not centered, C_{pk} will be lower than C_p and is the true process capability index. See De Vor et al. [1992], Grant and Leavenworth [1988], and Montgomery [1991] for additional information.

A capability index less than one indicates that the specification limits are much tighter than the process spread. Hence, although the process may be in control, the parts may well be out of specification. Thus, the process does not meet engineering requirements. A capability index of one means that as long as the process is in control, parts are also within specifications. The most desirable situation is to have a process capability index greater than one. In such cases, not only are approximately 99.73% of the parts within specifications when the process is in control, but even if the process should go out of control, the product may still be within the engineering specifications. Process improvement efforts are often concerned with reducing the process spread and, therefore, increasing the process capability indices.

An extremely powerful tool for isolating and determining those factors that significantly contribute to process variation is statistical design and analysis of experiments. Referred to as “design of experiments,” the methodology enables the researcher to examine the factors and determine how to control these factors

in order to reduce process variation and therefore increase process capability index. For greater detail, see Box et al. [1978].

Defining Terms

Assignable causes — Any element that can cause a significant variation in a process.

Frequency distribution — Usually a graphical or tabular representation of data. When scores or measurements are arranged, usually in an ascending order, and the occurrence (frequency) of each score or measurement is also indicated, a frequency distribution results. The frequency distribution in the following table indicates that ten samples were found containing zero defectives.

| No. of Defectives | Frequency |
|-------------------|-----------|
| 0 | 10 |
| 1 | 8 |
| 2 | 7 |
| 3 | 8 |
| 4 | 6 |
| 5 | 4 |
| 6 | 2 |
| 7 | 1 |
| 8 | 1 |
| 9 | 0 |

Nonconforming — A condition in which a part does not meet all specifications or customer requirements. This term can be used interchangeably with *defective*.

Nonconformity — Any deviation from standards, specifications, or expectation; also called a *defect*. Defects or nonconformities are classified into three major categories critical, major, and minor. A critical nonconformity renders a product inoperable or dangerous to operate. A major nonconformity may affect the operation of the unit, whereas a minor defect does not affect the operation of the product.

Population — An entire group of people, objects, or phenomena having at least one common characteristic. For example, all registered voters constitute a population.

Quality — Quality within the framework of manufacturing is defined as conformance to requirements.

Range — A measure of variability or spread in a data set. The range of a data set, R , is the difference between the highest and the lowest values in the set.

Sample — A small segment or subgroup taken from a complete population. Because of the large size of most populations, it is impossible or impractical to measure, examine, or test every member of a given population.

Specifications — Expected part dimensions as stated on engineering drawings.

Standard deviation — A measure of dispersion or variation in the data. Given a set of numbers, all of equal value, the standard deviation of the data set would be equal to zero.

Tolerances — Allowable variations in part dimension as stated on engineering drawings.

Flexible Manufacturing

Andrew Kusiak

University of Iowa

Chang-Xue (Jack) Feng

Bradley University

182.1 Flexible Machining

182.2 Flexible Assembly

182.3 The Economic Justification of Flexibility

Flexible manufacturing systems (FMSs) have emerged to meet frequently changing market demands for products. The distinguishing feature of an FMS is in its software (e.g., numerical control programs) rather than the hardware (using, for example, relays and position switches). Fixed automation, programmable automation, and flexible automation are the three different forms of automation [Groover, 2001]. Numerical control (NC) and computer numerical control (CNC) technologies are essential in FMSs. Developments in robotics, automated guided vehicles (AGVs), programmable controllers (PCs), computer vision, group technology (GT), and statistical quality control (SQC) have accelerated the applications of FMSs. The computer technology (hardware and software) is a critical factor in determining the performance of flexible manufacturing systems. An FMS is frequently defined as a set of CNC machine tools and other equipment that are connected by an automated material-handling system, all controlled by a computer system [Askin and Standridge, 1993].

The FMS concept has been applied to the following manufacturing areas [Kusiak, 1986]: (1) fabrication, (2) machining, and (3) assembly. An FMS can be divided into three subsystems [Kusiak, 1985]: (1) management system, (2) production system, and (3) material-handling system. The management system incorporates computer control at various levels; the production system includes CNC machine tools and other equipment (e.g., inspection stations, washing stations); the material handling system includes AGVs, robots, and automated storage/retrieval systems (AS/RSs).

The planning, design, modeling, and control of an FMS differs from the classical manufacturing system. The structure and taxonomy of an FMS has been studied in Kusiak [1985]. Some planning tools — for example, IDEF (the U.S. Air Force ICAM definition language) [U.S. Air Force, 1981] — have been proposed for modeling of material flow, information flow, and dynamic (simulation) modeling of an FMS. Numerous mathematical models of FMSs are discussed in Askin and Standridge [1993]. An FMS can be structured as a five-level hierarchical control model [Jones and McLean, 1986] (see [Table 182.1](#)).

Manufacturing concepts such as just-in-time (JIT) manufacturing, lean manufacturing, time-based manufacturing, quick response manufacturing, synchronous manufacturing, and agile manufacturing relate to the flexible manufacturing approach. Here the term *flexible* describes the system's ability to adjust to customers' preferences; JIT reduces the throughput time and the level of inventory; "lean" stresses efficiency and cost reduction; and "agile," "time-based," "quick response," and "synchronous" all address the speed of a manufacturing system in responding to frequently changing market demands. Other terms such as flexible manufacturing cells (FMCs), computer-aided manufacturing (CAM), and computer-integrated manufacturing (CIM) are frequently used to describe flexible manufacturing.

TABLE 182.1 FMS Control Architecture (National Institute of Standards and Technology)

182.1 Flexible Machining

The basic features of a flexible machining system (FMS), as well as the differences between a flexible machining system and the equivalent classical machining system, are presented in Kusiak [1990] in the form of eight observations. These observations are based on the analysis of over 50 flexible machining systems.

An Example of FMS

Figure 182.1 illustrates one type of flexible machining system (FMS). The FMS produces parts for a family of DC motors used in the FANUC CNC system. The parts are of two types: rotational (e.g., a motor shaft) and prismatic (e.g., a supporting house). The production system includes a CNC turning machine tool, a CNC grinding machine tool, a vertical machining center, and a horizontal machining center, as well as two coordinate-measuring machines (CMMs). Programmable controllers (PCs) are also used in the CNC control system to perform some auxiliary functions. Quite frequently, a PC can be used as an independent CNC control device in a position control mode (as opposed to a path control mode), for example, in a CNC drilling machine to directly drive the servo motor. A CMM measures automatically the precision of the machined parts, including their nominal values and tolerances. It includes a moving head, a probe, a microcomputer, and input/output (I/O) devices. It is controlled by an NC program, and it feeds the measured data to the corresponding CNC system and records them for the purpose of statistical quality control (SQC). The essential function of the SQC system in an FMS is to analyze the data from the on-line measuring of the CNC machine or CMM and to construct a set of X-bar and R charts, which shows the measured values in their means and ranges based on a predetermined sample size and grouping. These mean and range values are then compared to the designed nominal value and control limits, respectively, to determine whether the process is under statistical control.

The automated material handling system in Figure 182.1 includes an AGV, three robots, two part buffers, and the automated storage and retrieval system (AS/RS). The function of the AGV in Figure

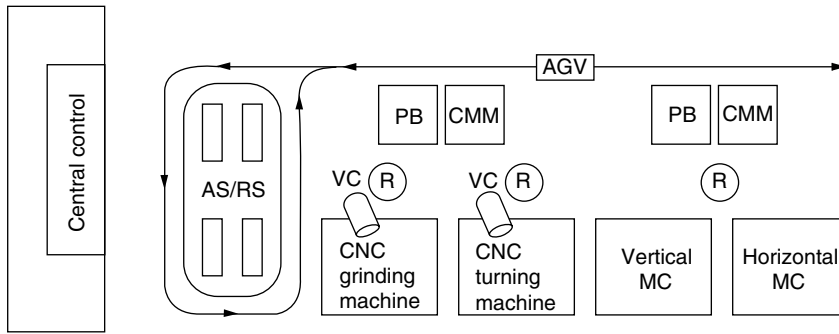

FIGURE 182.1 Physical layout of a flexible machining system. AS/RS: automated storage and retrieval system; PB: part buffer; CMM: coordinate-measuring machine; R: robot; VC: video camera; MC: machining center.

182.1 is to transfer loads to remote locations following a guided path. For the long-distance handling in this FMS, a robot cannot provide the mobility of an AGV, and a conveyor does not offer the flexibility desired. The AGV sends the raw material from the AS/RS to the part buffer of each workstation and brings back the finished products from the part buffers to the AS/RS. An industrial robot is a reprogrammable, multifunctional manipulator designed to move materials, parts, tools, or special devices through variable programmed motions for the performance of a variety of tasks (Robotics Industries Association). In the system in Figure 182.1, the three robots load parts from part buffers to each CNC machine tool, transfer parts from the CNC machine tools to the CMMs, and unload parts from machines to the part buffers. The AS/RS is used to temporarily store the raw material and finished product. Although the AGV and the robots in the system in Figure 182.1 function separately, it is possible for them to work jointly to provide both mobility and flexibility. For example, an AGV can be interfaced with a robot to provide more flexible loading and unloading capability, and a robot can be mounted on an AGV to achieve mobility.

The control and management system includes the central control minicomputer, the microcomputer resided in each CNC machine and robot, and two industrial video cameras. The computer control system performs two fundamental functions: monitoring and control. For example, it stores process plans and NC programs; dispatches programs to the individual pieces of equipment; controls the production, traffic, tools, and quality; monitors the material handling system; and monitors and reports the system performance. The video camera (VC) monitors the critical machining processes. A VC may or may not have the capability to analyze and process the data collected. In the former case, it can process the image based on computer vision technology and inform the CNC system; in the latter case, a human expert monitors the image taken by the VC and then manually informs the corresponding CNC system. Other types of monitoring might be used in an FMS, for example, measuring the cutting force, torque, or power. In some types of monitoring, a measuring head may be placed in the tool magazine and used to measure the machining quality of certain operations as required. The use of the manufacturing automation protocol (MAP) in manufacturing is reaching a momentum. The equipment purchased from different vendors is linked through a shop local-area network (LAN), as the vendors tend to adopt the MAP standard. Tool management is one of the functions of the computer control system [Kusiak, 1990].

182.2 Flexible Assembly

Most of the observations regarding the flexible machining systems discussed in Kusiak [1990] apply to the flexible assembly systems (FASs) as well. Any differences that may arise are of terminology rather than concept. The earliest FASs were designed for assembling printed circuit boards. More recent FASs have been developed for mechanical assembly. The automated material-handling system — including

AGVs, conveyors, and robots — is more important in an FAS than an FMS. The design of a product is more closely related to the design and operations of an FAS than to that of a component with a flexible machining system. Boothroyd et al. [1982] discuss in-depth rules for designing products for automated assembly, including flexible assembly systems. Another widely used technique, the assembly evaluation method (AEM), was developed at Hitachi. The basic design for assembly (DFA) rules include:

1. Minimize the number of components in a product.
2. Ensure that a product has a suitable base (part) on which the assembly can be built.
3. Ensure that the product base has features that will enable it to be readily located in a suitable position in the horizontal plane.
4. Minimize the number of assembly directions; if possible, use only top-down, vertical assembly motions.
5. If possible, design the product so that it can be assembled in layers.
6. Provide chamfers or tapers to help the component be easily positioned.
7. Avoid expensive and time-consuming fastening operations and avoid using assembly tools (e.g., screwdrivers).
8. Design the product so that the assembly does not have to be lifted or rotated, since the lifting and rotating results in complicated fixtures and grippers, more degrees of freedom of the robot, and increased cycle time.
9. Design the product to simplify packaging. The more uniform and simple the product packaging is, the easier it will be to apply a robotic packaging station that uses standard carts and pallets.
10. Use symmetric features whenever possible; otherwise, exaggerate asymmetry to facilitate identification and orientation of components.
11. Design a component to avoid tangling when feeding.
12. Design product variations to allow common handling and assembly methods.

An example of mechanical product design for flexible assembly is presented in Elmaraghy and Knoll [1989]. The authors discuss design for flexible assembly of a family of DC motors and the design of the flexible assembly system.

The IBM Proprinter is a frequently cited example of an electronic product that was designed for flexible automated assembly. The goals for the printer design were relatively simple:

- Develop a modular design.
- Minimize the total number of parts.
- All parts are to be self-aligning for ease of assembly.

Other principles of design for assembly that were used in this example are as follows:

- No fasteners
- No springs
- No pulleys
- No excess modules
- No adjustment
- No labels
- No paint
- No extra parts
- No multidirectional assembly
- No alignment/location tools or fixtures
- No external tests
- No engineering change notices (ECNs)
- No custom builds or options
- No manual assembly

182.3 The Economic Justification of Flexibility

Flexibility is a critical objective in design, planning, and operating an FMS. An FMS is intended to accommodate a large number of types of products and allow for more changes of products and higher equipment utilization, whereas in lean and agile manufacturing, flexibility means not only more changes and more product types, but also quicker changes, plus a reasonable rather than ultimately high utilization. Although none of the definitions of manufacturing flexibility have been generally accepted, the following types of flexibility are frequently considered: machine flexibility, process flexibility, product flexibility, routing flexibility, volume flexibility, expansion flexibility, process sequence flexibility, operation flexibility, and production flexibility. How to price the product produced in an FMS causes difficulties and often creates conflicts between accounting and engineering departments. There is some evidence that the U.S. and Japan operate FMSs in radically different ways. Jaikumar [1986] shows that Japanese users had achieved at the time greater flexibility and yet shorter development time than users in the U.S.

183.3 Managing-for-Value Principles

Edward M. Knod, Jr.

Western Illinois University

As careers progress, engineers assume an increasingly diverse set of managerial responsibilities. Success in meeting those responsibilities demands — at the personal level — two things: First, the engineer-manager must possess an appropriate set of managerial skills and requisite implementation abilities. Such talents are broadly applicable. With periodic refresher training and situation-specific fine-tuning, they are useful in nearly any setting. Second, the individual must understand the road to achieving organizational success. Defining characteristics mark well-managed companies. These are not so much *outcome* characteristics as they are *process* characteristics; they describe the ways that managers and employees view things and get things done — the manner in which successful outcomes are achieved. In a nutshell, the focus is on *value*; specifically, the creation of value-adding operations in value-adding companies that create and deliver goods and services valued by society.

This chapter begins with an overview of contemporary management thought and practice, continues with a discussion of value as a core concept that underlies management actions in commercial ventures, presents and discusses a set of proven principles to guide managing-for-value activities, and concludes with suggested sources of additional information.

183.1 Management: Fundamental Concepts

Engineers often experience a sense of frustration with the imprecise or inexact nature of the “science” that they encounter during an initial foray into management studies. Indeed, *management* — in theory as well as in practice — has two “halves.” One is more objective, measurable, or tangible; often, its prescriptions have met the rigors of repeated field testing. The other is “softer,” more subjective, and less established, perhaps; it is less tangible and less measurable. Engineers must not (*cannot*) avoid the latter, but they might need to adopt a different perspective. On the one hand, they gain a deeper appreciation for the challenges faced by social scientists who must venture into the murky waters of research on human behavior; perhaps new cross-professional alliances emerge. On the other hand, the engineer must cling to a healthy skepticism until knowledge can be separated from conjecture.

An overview of management in contemporary competitive manufacturing and service organizations might first consider managers themselves. Managerial duties and activities, types and effects of management roles, requisite managerial skills and attributes, and leadership are key dimensions.

Duties and Activities

Briefly, the primary duty of management is to ensure organizational success in the creation and delivery of goods and services. Provide outputs that customers value and provide them in ways that keep customers coming back for more. Popular definitions of management often employ lists of activities that describe what managers do. Some activities — decision making, motivating, and communicating, for example — are quite generic; their importance is recognized by the widespread availability of training programs on those topics. One's ability to perform these activities is highly transferable from one job or company to another.

Other management activities tend to be more setting specific; analysis and description within the job or organizational context can be more revealing. These activities fall into one or more of three general, and overlapping, duties: creating, implementing, and improving.

- *Creating.* Activities such as planning, designing, staffing, budgeting, and organizing accomplish the creativity required to build and maintain customer-serving capacity. Product and process design, facility planning and layout, workforce acquisition and training, and materials and component sourcing are among the tasks that have a substantial creative component.
- *Implementing.* When managers authorize, allocate, assign, schedule, or direct, emphasis shifts from creating to implementing — putting a plan into action. A frequent observation is that the biggest obstacle to successful implementation is lack of commitment to the plan. Therefore, teaching, motivating, and mentoring are common activities exhibited by managers as plans are put into action. During implementation, managers also perform controlling activities — that is, they monitor performance and make necessary adjustments.
- *Improving.* Environmental changes (e.g., new or revised customer demands, challenges from competitors, and social and regulatory pressures) necessitate improvements in output goods and services. In response to — or better yet, in anticipation of — those changes, managers re-create; they start the cycle again with revised plans, better designs, new budgets, and so forth.

Outcomes, desirable or otherwise, stem from these activities. A goal-oriented manager might describe a broad aim as “faster product development,” or perhaps a more immediate and focused objective as “reduce routing mis-reads by 20%,” but he or she will try to attain that goal by employing various activities aimed at creating, implementing, and improving.

Management Roles

During the 20th century, theorists developed various models of management; their efforts usually driven by some perceived deficiencies with previous models. Quinn et al. [2003] summarize four of the more popular of those models (rational goal model, internal process model, human relations model, and open systems model) and argue that all have a place in contemporary management practice. They suggest movement away from an “either-or” mentality toward a more accommodating recognition that managers do face competing values and must employ the best of various approaches as they strive to attain what might appear to be conflicting objectives. In meeting those aims, managers may expect to assume the roles of mentor, facilitator, monitor, coordinator, director, producer, broker, and innovator; each role comes with its own set of required competencies.

A great many scholars cast managerial role expectations in a less generic fashion; they prefer to address roles within the context of the task at hand. Often they note potential negative as well as positive role expectations. For example, Nicholas [1998] gives specific attention to managerial roles in such activities as implementing cellular manufacturing, just-in-time (JIT), total preventive maintenance (TPM), and

total quality management (TQM). Other writers point out unhealthy effects — stress and burnout, for example — that might be tied to role-related aspects of managers' jobs. Role overload, role underload, role ambiguity, and role conflict have drawn attention [Aldag and Kuzuhara, 2002: chapter 9].

Requisite Skills and Attributes

Exact requirements are hard to pin down, but any skill or attribute that helps a manager make better decisions is desirable. When various lists of generic skills are compared, considerable (and not unexpected) similarities emerge. Some skills and traits (e.g., good time-management habits, effective communications skills, and pleasant personality) are obviously useful and serve managers in any job. Categorization of skills is helpful, but often reflects the background or discipline of the list maker. Aldag and Kuzuhara [2002], for example, categorize needed management skills as personal, interpersonal, or managerial. Bateman and Zeithaml [1993] propose a slightly more revealing classification; they suggest that managers need technical skills, interpersonal and communications skills, and conceptual and decision skills.

Extension of these broad categories into job-specific lists is perhaps unwarranted given the current emphasis on cross-functional career migration and assignments to interdisciplinary project teams or product groups. On the other hand, recent innovations, business trends, and newsworthy events have served to bring newer types of skills into play and to add renewed emphasis to a few “older” ones. Advancements in electronic business (e-business) or commerce (e-commerce) and the impact on integrated supply chain management (SCM) efforts, for instance, bump up the need for managers to possess greater computer and information system literacy [Chopra and Meindl, 2001: chapter 14]. In a similar fashion, increases in global business ventures place emphasis on foreign language skills and knowledge of foreign cultures. And, recent turmoil in stock markets and revelations of large-scale improprieties serve to focus attention on specific attributes that relate to personal and business ethics and on skills that suggest possession of sound business acumen.

The lasting power of the importance of these newly emphasized skills is unknown. The mandate for managers to possess and exhibit leadership skills, however, emerged early in the 20th century and has proven resilient.

Leadership

Leadership is one of the most heavily studied topics in management and organizational research. But noted leadership scholar Bernard M. Bass [1990] admits that, “There are almost as many different definitions of leadership as there are persons who have attempted to define the concept.” Such a statement cannot be expected to sit well with engineers who are accustomed to much closer agreement on definitions of key concepts. Bass goes on to argue, however, that sufficient similarity (among definitions) exists to permit a tentative classification scheme, and he proceeds to enumerate 11 separate conceptual foundation definitions of leadership along with numerous hybrids [Bass, 1990]. Clearly, much work remains before leadership moves very far from the realm of conjecture. (Leadership is one of those “soft” topics mentioned at the beginning of this section.)

We *do* know that effective leaders are both task oriented and people oriented; they take the mission seriously and they take care of their people. We also know that managers are expected to be leaders, and that successful managers are often described — by peers as well as by subordinates — as being good leaders. But, leadership researchers maintain that leadership and management are not the same things. Stephen R. Covey summarizes the distinction made by this camp by noting, “Leadership focuses on doing the right things; management focuses on doing things right” [Covey, 1996]. A fair critique might suggest that beyond the two traits noted at the outset of this paragraph, effective leadership skills are largely situation specific.

Engineers who wish to delve into the subject of leadership will find a rich assortment of materials. Wren [1995] provides insight into the history of leadership study; Kouzes and Posner [2003] offer a practical guide on leadership for everyday application; and Hesselbein, Goldsmith, and Beckhard [1996] offer a collection of essays on leadership composed by leading authorities.

183.2 Value: Evolution of a Concept

Value is not a new concept, nor is the recognition of value enhancement as a worthy goal. Value analysis and value engineering programs keep value as a primary focus; efforts to build world-class excellence also place a high premium on value; and value-chain analysis and the study of value migration also, as their names imply, revolve around the concept of value. These and related activities have resulted in a set of characteristics that serve to describe value-oriented organizations.

Value Analysis and Value Engineering

Value analysis (VA) programs originated in the late 1940s. Originally limited to purchased items, value analysis proved its merit and was subsequently applied to in-house designs under the title value engineering (VE). The buyer or customer assigns value to a good, a service, an activity or a process; value is the worth the customer imputes. Value, therefore, is a good indicator of what the customer is willing to pay, and as such, serves as a practical (market) limit on the provider's costs. VA/VE programs seek to increase value by increasing the performance-to-cost ratio.

Function statements lie at the heart of VA/VE. In standard verb–noun format, a vessel may be said to “contain fluid.” If pressure requirements exist, the provider may add the function “sustain pressure.” A customer might also want the vessel to “insulate fluid” and could be expected to pay more for the addition of that third performance function — recognition of value added. (Each performance function statement, of course, is clarified with operational performance specifics.) Formal VA/VE strives to ensure that the proposed vessel provides requested functions and can be delivered at a low price. As Nicholas [1998: chapter 2] notes, VA/VE often accompanies concurrent engineering and design for manufacture/assembly (DFMA) efforts. Two caveats close the VA/VE discussion:

- Customers hesitate to pay for unwanted functions; even marketing will not open some pocket-books.
- Customer desire for performance functions can be unstable; a current requirement may disappear tomorrow. In that case, the first caveat applies.

World-Class Management

Notions about value and about how companies ought to go about providing value changed substantially during the 1980s and 1990s. By the end of the 1970s, an eclectic set of factors had combined to force managers to critically assess old assumptions about the overall capacity required to provide continuous improvement in meeting evolving customer needs. Conference room briefings dealt with emerging markets, shifting patterns of global competitiveness and regional dominance in key industries, the spread of what might be called Japanese management and manufacturing technologies, and the philosophy and tools of the total quality movement. Leading industrial engineering and operations management experts released novel (at that time) prescriptions for how managers ought to establish and maintain world-class excellence in their organizations [Schonberger, 1982; Hall, 1983; Shingo, 1985; Suzuki, 1987]. The principles and implementation techniques first appeared in manufacturing and continue to have profound influence in that sector. At this writing, however, considerable inroads into the service sector exist as well.

The Malcolm Baldrige National Quality Award, first awarded in 1988, helped give widespread verification to some of the beneficial aspects of total quality management. It also served as an impetus for North American managers to examine other quality-oriented programs and awards — Japan's Deming Prize, The European Quality Model, The Shingo Prize, and ISO 9000/QS 9000 registration efforts, for example. Customer-centered, multidimensional definitions of quality became the rule; training programs addressed simple but effective quality-improvement tools; and vigorous attacks on variation proliferated as meaningful performance indicators (e.g., capability indexes) grew in popularity. Perhaps most noteworthy, improvement programs expanded to incorporate quality of *process* in addition to quality of *product*.

Improved quality was the first but not the sole objective of the world-class management movement. Blackburn, for instance, provided a reminder that *time*, in addition to quality, could be a formidable competitive weapon [Blackburn, 1991]. Just-in-time (JIT) performance has received considerable attention [Schonberger, 1982; Schneiderjans, 1993], but the pervasiveness of time-related factors in the development of value also extends into the reduction of such factors as throughput times (cycle or lead time in some settings), queue times, setup or changeover times, and transport times as well [Knod and Schonberger, 2001: chapter 11]. Time–quality interdependencies emerged; valued performance traits such as responsiveness and flexibility — frequently cited as quality dimensions — hinge on effective time management. Better *and* faster are not mutually exclusive.

Better quality and timing outcomes address the numerator of the performance-to-cost ratio. But world-class management has been equally focused on the denominator — costs. Simply stated, any cost incurred in performing an activity that was not valued by customers (immediate or subsequent) could be recovered by elimination of the activity. As world-class ideas began to spread, respected voices from the accounting profession called for revisions in managerial accounting so that more accurate statements of *true* costs for both value-adding and non-value adding activities might be obtained [Johnson and Kaplan, 1987].

Unquestionably, the world-class excellence movement has resulted in much improved identification and delivery of outcomes that customers value. Moreover, it has prompted scrutiny of the value-adding chain itself.

Value Chain Analysis

Competition drives value chain analysis. The technique is applicable at the firm and industry level, at the product or product-family level, and at the activity (or operation) and process level. Porter [1985] suggests that a company may add value through both primary and support activities. Primary activities include logistics (inbound and outbound), operations, marketing, sales, and service. Procurement, technology, human resources, and administration are notable supporting activities in Porter’s model. Value is reflected by total revenue, or what customers are willing to pay for the company’s goods and services. So long as the company’s overall business model remains viable, value exceeds costs, and profit results.

At the product or product group level, supply chain analysis is the popular term [Simchi-Levi et al., 2000; Chopra and Meindl, 2001]. In manufacturing, the role of suppliers as contributors to (or detractors from) value was quickly acknowledged as world-class ideas spread. Comparison of competing suppliers’ functional performance levels, of course, dictates the degree to which potential customers acknowledge product or service differentiation and are willing to pay for it. And, of course, the pressure to contain costs lurks at each stage of the supply chain.

Value-chain mapping as a technique for removing waste from activities and processes receives strong endorsement from the Lean Enterprises Institute (www.lean.org). The technique draws heavily from process flow-charting, but also mandates a critical assessment of the value-added — from the perspectives of the next-process customer as well as each downstream customer — at each step (activity, operation, workstation, etc.) of the value stream. The formula is simple: steps that add no value are waste; eliminate them. Streamline remaining steps by cutting as much waste as possible. The result is a leaner process.

To sum up, analyses of value chains at all levels have revealed common features

1. Value chain elements (operations, processes, products, suppliers, and so forth) that add no value are targets for elimination. Customers are unwilling to cover the costs required to maintain them.
2. Those elements that do add value are opportunities for competitors. The possibility for those competitors to encroach with superior performance-to-cost ratios demands a vigilant program of continuous improvement.
3. Elements that are unable to maintain some degree of distinction in the eyes of customers will not survive. A distinctive or core competency — superior value delivered on one or more dimensions — is a must.
4. Regardless of initial business plan or value-chain design, value will migrate.

Value Migration

At the broadest level, the concept of value migration applies to business design competitiveness [Slywotzky, 1996]. What a company is worth, its *market value*, is dependent on how well the company's business design is perceived to be capable of supplying what its customers want. Value flows into companies with superior designs, remains stable when the design roughly matches customers' expectations, and flows from the company if competitors (old or new) present customers with better options.

Value *can* migrate out of a company when customers change what they want (value), or when they change where they expect to find that value along the value chain. A company may lose (or voluntarily surrender) a product or component that costs too much to make, a process that becomes obsolete, or a function (e.g., design, manufacturing, or distribution) that can be performed better, faster, and cheaper elsewhere, for instance. If the change, the loss of a component in this case, does not result in a lower perception of the company's worth, outflow value migration has not occurred. In fact, deliberate handing off (outsourcing) can be a strategic plus when accomplished, say, under a broader program of honing distinctive competencies. Schonberger [2001: chapter 10] provides a thorough discussion and examples. However, when a company is stripped of value, perhaps due to its own complacency, someone needs to answer.

Prevention of *all* unwanted value migration *may* not be possible. However, a company (or plant, or office, etc.) must maintain a critical competency level. One solution is to attain success at value inflow to offset value outflow. New processing competencies, first-to-market products, engineering innovations leading to significant product and service improvements, and new strategic alliances are possible avenues for increased value inflow. To increase likelihood of successful inflow of value, value-focused management is a plus.

Value-Focused Management

In the 1970s North American managers allowed production scheduling and control systems to become too complicated, cumbersome, and costly. Costs skyrocketed as back-office and staff personnel served increasingly cumbersome systems, often paying allegiance to mandated reports and controls to the detriment of keeping an eye on what customers valued. "Lean" was clearly missing.

A more competitive approach lies in the simplification of the production environments themselves [Knod and Schonberger, 2001: chapter 16; Steudel and Desruelle, 1992: chapter 8; Schneiderjans, 1993: chapter 6]. Although simplicity has proven an elusive goal, there is merit in its continued pursuit. An array of publications, seminars, and other vehicles for disseminating "how and why" advice has bolstered the spread of contemporary world-class management theory and research. The information bounty can be reduced, tentatively, to a set of core items that might be said to define worthy aims for value-focused managers.

Table 183.1 presents those core items as a short list of six broad operating guidelines. They reflect dominant themes in world-class management, require leadership to implement, and help define what today's successful value-focused managers are all about.

183.3 Managing-for-Value Principles

Table 183.2 presents the final and most detailed component of this general-to-specific look at contemporary management. It is a set of action-oriented, prescriptive principles for managing for value. Originally crafted by Schonberger [1986] in a previous version aimed more specifically at manufacturing, the principles have evolved, stood the test of time, and apply to service settings as well. The principles apply to managers at any level and define ways for increasing competitiveness — by taking direct action to enhance value — in ongoing operations. Brief supporting rationale and techniques or procedures that exemplify each principle appear in the right column; Knod and Schonberger [2001: chapter 3] provide

TABLE 183.1 Characteristics of Value-Focused Management

Customers at center stage. The customer is the next person or process — the destination of one’s work. The provider–customer chain extends, process to process, on to final consumers. Whatever a firm produces, customers would like it to be better, faster, and cheaper; prudent managers therefore embrace procedures that provide *total quality*, *quick responses*, and *waste-free* (economical) *operations*. These three aims are mutually supportive and form the core rationale for many of the new principles that guide managers.

Focus on improvement. Managers have a duty to embrace improvement. A central theme of the total quality (TQ) movement is constant improvement in output goods and services and in the processes that provide them. Sweeping change over the short run, exemplified by business process reengineering [Hammer and Champy, 1993], anchors one end of the improvement continuum; the rationale is to discard unsalvageable processes and start over so as not to waste resources in fruitless repair efforts. The continuum’s other end is described as incremental continuous improvement and is employed to fine-tune already sound processes for even better results.

Revised “laws” of economics. Examples of contemporary logic include the following: Quality costs less, not more. Costs should be allocated to the activities that cause their occurrence. Prevention (of errors) is more cost-effective than discovery and rework. Training is an investment rather than an expense. Automation can be beneficial *after* process waste is removed and further reduction in variation is needed. Value counts more than price (e.g., in purchasing). Desired market price should define (target) manufacturing cost, not the reverse.

Elimination of waste. Waste is anything that doesn’t add value; it adds cost, however, and should be eliminated. Waste detection begins with two questions: “Are we doing the right things?” and “Are we doing those things in the right way?” Toyota identifies seven general categories of waste [Suzaki, 1987: chapter 1], each with several subcategories. Schonberger [1990: chapter 7] adds opportunities for further waste reduction by broadening the targets to include nonobvious waste. Simplification or elimination of indirect and support activities (e.g., production planning, scheduling, and control activities; inventory control; costing and reporting, etc.) is a prime arena for contemporary waste-reduction programs [Steudel and Desruelle, 1992: chapter 8].

Quick-response techniques. Just-in-time (JIT) management, queue limiters, reduced setups, better maintenance, operator-led problem solving, and other procedures increase the velocity of material flows, reduce throughput times, and eliminate the need for many interdepartmental control transactions. Less tracking and reporting (which add no value) reduces overhead. Collectively, quick-response programs directly support faster customer service [Blackburn, 1991: chapter 11].

Human resources management. Increased reliance on self-directed teams (e.g., in cells or product groups and/or on-line operators for assumption of a larger share of traditional management responsibilities) is a product of the management revolution of the 1980s that had noticeable impact in the 1990s. Generally, line or shop employees have favored those changes; they get more control over their workplaces. There is a flipside: As employee empowerment shifts decision-making authority, as JIT reduces the need for many reporting and control activities, and as certain supervisory and support-staff jobs are judged to be non-value-adding, many organizations downsize. Lower- and mid-level managers and support staff often bear the job-loss burden.

a more detailed discussion. Schonberger [2001] has compiled an extensive report of widespread successful applications of these principles in his international benchmarking study, *World Class by Principles*.

Whether an engineer is thrust into a new position with management responsibilities or simply desires to gain a greater understanding of what successful management is all about in today’s competitive arena, he or she will encounter the concept of value quite early in the process. Customers all along the value chain have new sources of information — data about performance levels, prices, options, and availability are much more available today. Value-based buying is, increasingly, not an option; it is a mandate.

Defining Terms

Management — Activities that have the goal of ensuring an organization’s competitiveness by creating, implementing, and improving capacity required to provide goods and services that customers want.

Process — A particular combination of resource elements and conditions that collectively cause a given outcome or set of results. Process performance depends on how the process components were designed, built or installed, operated, and maintained.

Value — Perceived worth; the amount that a buyer is willing to pay for a good or service.

Value analysis/value engineering (VA/VE) — Formal examination of existing design or method with the aim of increasing the performance-to-cost ratio.

TABLE 183.2 Managing-for-Value Principles

| Principle | Rationale and Examples |
|---|--|
| Get to know customers; team up to form partnerships and share process knowledge. | Providers are responsible for getting to know their customers' processes and operations. By so doing, they offer better and faster service, perhaps as a member of customers' teams. |
| Become dedicated to rapid and continual increases in quality, flexibility, and service; and decreases in costs, response or lead time, and variation from target. | The logic of continuous improvement, or <i>kaizen</i> [Imai, 1986], rejects the "if it ain't broke. . ." philosophy; seeks discovery and then prevention of current and potential problems; and anticipates new or next-level standards of excellence. |
| Achieve unified purpose through shared information and cross-functional teams for planning/design, implementation, and improvement efforts. | Information sharing keeps all parties informed. Early manufacturing/supplier involvement (EMI/ESI), and concurrent or simultaneous product and process design are components of the general cross-functional team design concept. |
| Get to know the competition and world-class leaders. | Benchmarking [Camp, 1989] elevates the older notion of "reverse engineering" to a more formal yet efficient means of keeping up with technology and anticipating what competitors might do. Search for best practices. |
| Cut the number of products (e.g., types or models), components, or operations; reduce supplier base to a few good ones and form strong relationships with them. | Product line trimming removes nonperformers; component reduction cuts lead times by promoting simplification and streamlining. Supplier certifications and registrations (e.g., ISO 9000) lend confidence, allow closer partnering with few suppliers (e.g., via EDI), and reduce overall buying costs. |
| Organize resources into multiple chains of customers, each focused on a family of products or services; create cells, flow lines, plants-in-a-plant. | Traditional functional organization by departments increases throughput times, inhibits information flow, and can lead to "turf battles." Flow lines and cells promote focus, aid scheduling, and employ cross-functional expertise. |
| Continually invest in human resources through cross-training for mastery of multiple skills, education, job and career path rotation, health and safety, and security. | Employee involvement programs, team-based activities, and decentralized decision responsibility depend on top-quality human resources. Cross-training and education are keys to competitiveness. Scheduling — indeed, all capacity management — is easier when the work force is flexible. |
| Maintain and improve present equipment and human work before acquiring new equipment; then automate incrementally when process variability cannot otherwise be reduced. | <i>TPM</i> , total productive maintenance [Nakajima, 1988], helps keep resources in a ready state and facilitates scheduling by decreasing unplanned downtime, thus increasing capacity. Also, process improvements must precede automation; get rid of wasteful steps or dubious processes first. |
| Look for simple, flexible, movable, and low-cost equipment that can be acquired in multiple copies — each assignable to a focused cell, flow line, or plant-in-a-plant. | Larger, faster, general-purpose equipment can detract from responsive customer service, especially over the longer run. A single fast process is not necessarily divisible across multiple customer needs. Simple, dedicated equipment is an economical solution; setup elimination is an added benefit. |
| Make it easier to make/provide goods and services without error or process variation. | The aim is to prevent problems or defects from occurring — the fail-safing (<i>pokayoke</i>) idea — rather than rely on elaborate control systems for error detection and the ensuing rework. Strive to do it right the first time, every time. |
| Cut cycle times, flow time, distance, and inventory all along the chain of customers. | Time compression provides competitive advantage [Blackburn, 1991]. Removal of excess distance and inventory aids quick response to customers. Less inventory also permits quicker detection and correction of process problems. |
| Cut setup, changeover, get-ready, and startup times. | Setup (or changeover) time had been the standard excuse for large-lot operations prior to directed attention at reduction of these time-consuming activities [Shingo, 1985]. Mixed-model processing demands quick changeovers. |
| Operate at the customer's rate of use (or a smoothed representation of it); decrease cycle interval and lot size. | Pull-mode operations put the customer in charge and help identify bottlenecks. Aim to synchronize production to meet period-by-period demand rather than rely on large lots and long cycle intervals. |

TABLE 183.2 Managing-for-Value Principles (*Continued*)

| Principle | Rationale and Examples |
|--|---|
| Record and <i>own</i> quality, process, and problem data at the workplace. Ensure that front-line associates get first chance at problem solving — before staff experts. | When employees are empowered to make decisions and solve problems, they need appropriate tools and process data. Transfer of point-of-problem data away from operators and to back-office staff inhibits responsive, operator-centered cures. |
| Cut transactions and reporting; control <i>causes</i> , not symptoms. | Transactions and reports often address problem symptoms (e.g., time or cost variances) and delay action. Quick-response teams, using data-driven logic, directly attack problem causes and eliminate the need for expensive reporting. |
| Market each improvement; share results with employees, suppliers, and customers. | Aside from the obvious benefits to company marketing, this principle fosters supply-chain development and nourishing. Also, company bulletins and displays allow employees — the ones responsible for the improvements — to keep abreast of progress and share in the credit. |

Value chain — Series of transformation processes that move a good or service from inception to final consumer. Ideally, each step adds worth (value) in the eyes of both next-stage and ensuing customers.

Value migration — Changes in either (1) priorities for what a customer requires, or deems worthy, from time to time, or (2) points along the supply chain at which the customer expects to find what is sought.

A. Terry Bahill

University of Arizona

[184.1 The System Design Process](#)

[184.2 Rapid Prototyping](#)

[184.3 When to Use Modeling and Prototyping](#)

To create a product and the processes that will be used to manufacture it, an engineer must follow a defined system design process. This process is an iterative one that requires refining the requirements, products, and processes of each successive design generation. These intermediate designs, before the final product is delivered, are called **models** or **prototypes**.

A model is an abstract representation of what the final system will be. As such, it can take on the form of a mathematical equation, such as $f = m \times a$. This is a deterministic model used to predict the expected force for a given mass and acceleration. This model only works for some systems and fails both at the atomic level, where quantum mechanics is used, and at the speed of light, where the theory of relativity is used. Models are developed and used within fixed boundaries.

Prototypes are physical implementations of the system design. They are not the final design, but are portions of the system built to validate a subset of the requirements. For example, the first version of a new car is created in a shop by technicians. This prototype can then be used to test for aerodynamic performance, fit, drivetrain performance, and so forth. Another example is airborne radar design. The prototype of the antenna, platform, and waveguide conforms closely to the final system; however, the prototype of the electronics needed to process the signal often comprises huge computers carried in the back of the test aircraft. Their packaging in no way reflects the final fit or form of the unit.

184.1 The System Design Process

The system design process consists of the following steps:

1. Specify the requirements provided by the customer and the producer.
 2. Create alternative system design concepts that might satisfy these requirements.
 3. Build, validate, and simulate a model of each system design concept.
 4. Select the best concept by doing a trade-off analysis.
 5. Update the customer requirements based on experience with the models.
 6. Build and test a prototype of the system.
 7. Update the customer requirements based on experience with the prototype.
 8. Build and test a preproduction version of the system and validate the manufacturing processes.
 9. Update the customer requirements based on experience with the preproduction analysis.
-

FIGURE 184.1 The system design process.

10. Build and test a production version of the system.
11. Deliver and support the product.

This can be depicted graphically on a spiral diagram as shown in Figure 184.1.

The process always begins with defining and documenting the customer's needs. A useful tool for doing this is quality function deployment (QFD). QFD has been used by many Japanese and American corporations to document the voice of the customer. It consists of a chart called the "house of quality." On the left is listed what the customer wants. Across the top is how the product will be developed. These are often referred to as *quality characteristics*. The "whats" on the left are then related to the "hows" across the top, providing a means of determining which quality characteristics are the most important to the customer [Akao, 1990; Bahill and Chapman, 1993].

After the customer's needs are determined the design goes through successive generations as the design cycle is repeated. The requirements are set and a model or prototype is created. Each validation of a model or test of a prototype provides key information for refining the requirements.

For example, when designing and producing a new airborne missile, the initial task is to develop a model of the expected performance. Using this model, the systems engineers make initial estimates for the partition and allocation of system requirements. The next step is to build a demonstration unit of the most critical functions. This unit does not conform to the form and fit requirements but is used to show that the system requirements are valid and that an actual missile can be produced. Requirements are again updated and modified, and the final partitioning is completed. The next version is called the *proof-of-design* missile. This is a fully functioning prototype. Its purpose is to demonstrate that the design is within specifications and meets all form, fit, and function requirements of the final product. This prototype is custom-made and costs much more than the final production unit will cost. This unit is often built partly in the production factory and partly in the laboratory. Manufacturing capability is an issue and needs to be addressed before the design is complete. More changes are made and the manufacturing processes for full production readied. The next version is the proof of manufacturing or the preproduction unit. This device will be a fully functioning missile. The goal is to prove the capability of the factory for full-rate production and to ensure that the manufacturing processes are optimum. If the factory cannot meet the quality or rate production requirements, more design changes are made before

the drawings are released for full-rate production. Not only the designers but the entire design and production team must take responsibility for the design of the product and processes so that the customer's requirements are optimized [Chapman et al., 1992]. Also see [Chapters 80, 180, and 181](#) of this book for additional information on design and production.

Most designs require a model upon which analysis can be done. The analysis should include a measure of all the characteristics the customer wants in the finished product. The concept selection will be based on the measurements done on the models. See [Chapter 209](#) for more information on selection of alternatives. The models are created by first partitioning each conceptual design into functions. This decomposition often occurs at the same time that major physical components are selected. For example, when designing a new car, we could select a mechanical or electronic ignition system. These are two separate concepts. The top-level function — firing the spark plugs — is the same, but when the physical components are considered the functions break down differently. The firing of the spark plugs is directed by a microprocessor in one design and a camshaft in the other. Both perform the same function, but with different devices. Determining which is superior will be based on the requirements given by the customer, such as cost, performance, and reliability. These characteristics are measured based on the test criteria.

When the model is of exceptional quality, a prototype can be skipped. Advances in computer-aided design (CAD) systems have made wire-wrapped prototype circuit boards obsolete. CAD models are so good at predicting the performance of the final device that no prototype is built. Simulation is repeated use of a model to predict the performance of a design. Any design can be modeled as a complex finite-state machine. This is exactly what the CAD model of the circuit does. To truly validate the model, each state must be exercised. Selecting a minimum number of test scenarios that will maximize the number of states entered is the key to successful simulation. If the simulation is inexpensive, then multiple runs of this model should be done. See [Chapters 13, 29, 95, 96, 97, and 159](#) for more information on simulations. The more iterations of the design process there are, the closer the final product will be to the customer's optimum requirements.

For other systems, modeling works poorly and prototypes are better. Three-dimensional solids modeling CAD systems are a new development. Their ability to display the model is good, but their ability to manipulate and predict the results of fit, force, thermal stresses, and so forth is still weak. The CAD system has difficulty simulating the fit of multiple parts (such as a fender and car frame) because the complex surfaces are almost impossible to model mathematically. Therefore, fit is still a question that prototypes, rather than models, are best able to answer. A casting is usually used to verify that mechanical system requirements are met.

Computer-aided manufacturing (CAM) systems use the CAD database to create the tools needed for the manufacture of the product. Numerical control (NC) machine instructions can be simulated using these systems. Before a prototype is built, the system can be used to simulate the layout of the parts, the movement of the cutting tool, and the cut of the bar stock on a milling machine. This saves costly material and machine expenses.

Virtual reality models are the ultimate in modeling. Here the human is put into the loop to guide the model's progress. Aircraft simulators are the most common type of this product. Another example was demonstrated when the astronauts had to use the space shuttle to fix the mirrors on the Hubble telescope. The designers created a model to ensure that the new parts would properly fit with the existing design. They then manipulated the model interactively to try various repair techniques. The designers were able to verify fit with this model and catch several design errors early in the process. After this, the entire system was built into a prototype and the repair rehearsed in a water tank [Hancock, 1993].

Computer systems have also proved to be poor simulators of chemical processes. Most factories rely on design-of-experiments (DOE) techniques, rather than a mathematical model, to optimize chemical processes. DOE provides a means of selecting the best combination of possible parameters to alter when building the prototypes. Various chemical processes are used to create the prototypes that are then tested. The mathematical techniques of DOE are used to select the best parameters based on measurements of the prototypes. Models are used to hypothesize possible parameter settings, but the prototypes are necessary to optimize the process [Taguchi, 1976].

FIGURE 184.2 Flight tests for the manned space program rockets.

The progressive push is to replace prototypes with models, because an accurate fully developed model is inexpensively simulated on a computer compared to the cost and time of developing a prototype. A classic example is the development of manned rockets. Figure 184.2 shows the number of test flights before manned use of the rockets.

The necessity for prototypes diminished rapidly as confidence in computer models developed. Initially, many of the rockets exploded in their first attempts at launch. As more was learned about rocketry, sophisticated models were developed that predicted performance of the rocket based on real-time measurements of valves, temperatures, fuel levels, and so forth. Using modern computers, the entire model could be evaluated in seconds and a launch decision made. This eliminated the need for many flight tests and reduced the cost of the entire Apollo moon-landing program.

184.2 Rapid Prototyping

Rapid prototyping is the key to reducing design time for parts and processes. Design is an iterative process. By creating prototypes quickly, the design can be completed faster. Japanese automobile manufacturers develop prototypes of their products in 6 months, whereas U.S. companies take 13 months [Womack et al., 1990]. This advantage allows the Japanese companies to get to the market faster, or if they choose they can iterate their design one more time to improve their design's conformance to the customer's requirements. Japanese automakers' ability to create the prototype quickly is due in part to better coordination with their suppliers, but also to the exacting use of design models to ensure that the design is producible.

As seen in Figure 184.3, the lead in prototype development accounts for 44% of the advantage that Japanese producers have in product development time. The rest of the advantage is from rapid creation of the huge dies needed to stamp out the metal forms of the automobiles. Design of these important manufacturing tools is given as much attention as the final product. By creating flexible designs and ensuring that the teams who will produce the dies are involved in the design process, the die development time is cut from 25 months in the U.S to 13.8 months in Japan. The rapid creation of the tooling is a key to fast market response.

Stereolithography is a new method of creating simple prototype castings. The stereolithography system creates a prototype by extracting the geometric coordinates from a CAD system and creating a plastic prototype. The solids model in the CAD system is extracted by "slicing" each layer in the z axis into a plane. Each layer is imaged by a laser into a bath of liquid photopolymer resin that polymerizes with the energy from the laser. Each plane is added, one on top of the other, to build up the prototype. The final part is cured and polished to give a plastic representation of the solids model. It illustrates the exact shape of the part in the CAD system. This technique will not, however, verify the function of the final product because the plastic material used will not meet strength or thermal requirements [Jacobs, 1992].

FIGURE 184.3 Comparison of Japanese, American, and European car producers. (Based on Womack, J. P., Jones, D. T., and Roos, D. 1990. *The Machine that Changed the World*. Rawson Associates, New York.)

Software developers also use rapid prototyping. This technique is used to get a fast, although barely functional, version of the product into the customer's hands early in the design cycle. The prototype is created using the easiest method to simulate functionality to the viewer. The customer comments on what is seen and the developers modify their design requirements. For example, when developing expert systems, models are almost never used. One of the driving rules is to show a prototype to the customer as soon as possible and afterward throw it away! The purpose of building the prototype was to find out what the knowledge that needs to be represented is like, so that the appropriate tool can be selected to build the product. If, as is usually the case, a nonoptimal tool was used for the prototype, then the prototype is thrown away and a new one is developed using better tools and based on better understanding of the customer's requirements. Beware, though — often a key function displayed in the prototype is forgotten when the prototype is abandoned. Be certain to get all the information from the prototype [Maude and Willis, 1991]. The fault with this technique is that the requirements are not written down in detail. They are incorporated into the code as the code is written, and they can be overlooked or omitted when transferred to a new system.

184.3 When to Use Modeling and Prototyping

When should modeling versus prototyping be used? The key difference is the value of the information obtained. Ultimately, the final product must be created. The prototype or model is used strictly to improve the final product. Costs associated with the prototype or model will be amortized over the number of units built. The major problem with models is lack of confidence in the results. Sophisticated models are too complex for any single engineer to analyze. In fact, most models are now sold as proprietary software packages. The actual algorithms, precision, and number of iterations are rarely provided. The only way to validate the algorithm (not the model) is by repeated use and comparison to actual prototypes. It is easier to have confidence in prototypes. Actual parts can be measured and tested repeatedly, and the components and processes can be examined. Prototypes are used more often than models once the complexity of the device exceeds the ability of the computer to accurately reflect the part or process. During the initial design phases, models must be used because a prototype is meaningless until a concept has been more firmly defined. At the other extreme, modeling is of limited benefit to the factory until the configuration of the part is well known. A general rule is to build a model, then a prototype, and then a production unit. Create even a simple mathematical model if possible so that the physics can be better understood. If the prototype is to be skipped, confidence in the model must be extremely high. If there is little confidence in the model, then a minimum of two or three prototype iterations will have to be done.

Defining Terms

Model — An abstract representation of what the final system will be. It is often a mathematical or simplified representation of a product.

Prototype — A physical representation of a product built to verify a subset of the system's requirements.

Stereolithography — A prototype-manufacturing technique used to rapidly produce three-dimensional polymer models of parts using a CAD database.

One of the most critical aspects of engineering applications involves the selection, shaping, and processing of raw materials obtained either directly from the Earth's crust or by special synthesis and purification methods. The history of successful cost competitive technologies and the development of modern societies is closely linked to one of two factors: (1) a new processing method for manufacturing a material with broad engineering utility, or (2) an altogether new discovery of a material with a composition that makes possible dramatically improved engineering properties. A good example of a processing method that can revolutionize engineering technologies is the now well-known discovery of zone refining and crystal growth of semiconductors, such as silicon and germanium, which are at the heart of the present-day microelectronic industries. Similarly, the discovery of new materials is best exemplified by the finding in the mid-1980s that certain ceramics (mixtures of yttrium-barium-copper oxides) — long known to be ferroelectric — can actually lose all resistance to electric current and become superconductors at a relatively warm temperature of about 90 K. This discovery of a new material is likely to have a major impact in many fields of technology.

Engineers and scientists continue the rich historical trend of seeking new materials or an unusual method for shaping/processing a material. Particularly striking evidence of this is found in many of the current worldwide activities in the fast-growing field of nanotechnology. Thus, spectacular engineering properties are attainable by making extremely small structures that are many times smaller than the

thickness of human hair. The principal goal is to synthesize nanometer-grained bulk materials or composite films in which at least one functional material has dimensions somewhere between 1 and 50 nm. Alternately, methods are being considered to carve out of bulk materials nanosize structures that promise to have a revolutionary impact on engineering and the physical and biological sciences. Examples of such materials and methods include the nanotechnology of making quantum wells and dots for laser optics, micromachined gears, ductile ceramics, and molecular motors. This chapter intends to provide a “road-runner’s” view of methods for shaping and processing materials both by the well-established techniques (e.g., casting, welding, powder sintering) and the more recent evolving methods. For a more detailed discussion of the topics in this chapter, refer to Groover (2002) and Kalpakjian and Schmid (2003).

185.1 Processing Metals and Alloys

The major methods for making engineering parts from metallic alloys consist of casting from the molten (liquid) state, followed by cold or hot working of the casting by processes such as rolling, forging, drawing, extrusion, and spinning. Powders of metals and alloys are also made into shapes by pressing and sintering or hot pressing (HP) and hot isostatic pressing (“hipping”). Grinding, polishing, and welding are some of the final steps in the production of an engineering component. There is a growing interest in encouraging near-net-shape manufacturing methods for engineering components to minimize the wastage in machining and grinding operations. Powder metallurgy methods provide an important advantage in this regard.

Casting Methods

Casting of liquid metals and alloys is one of the oldest and best-known processes for making ingots, or shapes in final form determined by the mold or die cavity in which the liquid is poured. The solidification of the liquid metal takes place after the melt is allowed to flow to all the areas of the mold. Shrinkage during solidification makes for a smaller casting size than the mold size, and this is accounted for in the design of the mold. Molds can vary from simple cavities to multipart molds clamped together and containing ceramic cores to create hollow spaces in some parts of the casting.

Sand casting is a metal casting process where sand is mixed with clay, the best-known traditional mold material, and is packed around a wooden pattern that is subsequently removed when the sand casting mold is ready for pouring of liquid metal. A small channel called a *gate* provides the liquid metal access to the mold cavity, while a riser column becomes the reservoir of liquid metal that feeds the shrinkage of the liquid metal during solidification. The sand-casting process is an inexpensive method for making a small number of parts; a range of ferrous and nonferrous alloys can be made by this method. The rough finish of sand-cast parts usually requires further machining and grinding.

Die casting is performed by pouring liquid alloys into preshaped metal molds machined to good accuracy, tolerances, and surface finish. Thus, the finished product is of good surface quality in die casting, and complex shapes can be made. Gravity die casting involves the flowing of the liquid metal under natural gravity conditions, whereas pressure die casting involves forcing the melt into the die under pressure. Centrifugal casting relies on a rotating mold to distribute the melt in the mold cavity by the action of centrifugal forces, a method especially suitable for making large-diameter metal pipes. Aluminum, zinc, copper, and magnesium alloys are often made by die-casting methods. Because machined molds are required, die casting is more expensive than sand castings, although molds are reused, and thus the process is good for large-scale production.

Investment casting or lost-wax casting is used particularly for alloys with high-melting temperatures and when high-dimensional accuracy and precision are needed. The high-melting metals attack the dies used in normal die casting, and thus patterns are produced from wax using a metal mold. The wax patterns are coated with a ceramic slurry and heated to melt the wax, whereupon a dense ceramic mold is created. Molten alloys are then forced into the ceramic mold cavity by use of pressure or by a centrifugal

TABLE 185.1 Summary of Metalworking Processes

| Process | Economic Quantity | Typical Materials | Optimum Size |
|------------------------|-------------------|------------------------|----------------------|
| Sand casting | Small–large | No limit | 1–100 kg |
| Die casting — gravity | Large | Al, Cu, Mg, Zn alloys | 1–50 kg |
| Die casting — pressure | Large | Al, Cu, Mg, Zn alloys | 50 g–5 kg |
| Centrifugal casting | Large | No limit | 30 min–1 m diam. |
| Investment casting | Small–large | No limit | 50 g–50 kg |
| Closed-die forging | Large | No limit | 3000 cm ³ |
| Hot extrusion | Large | No limit | 500 mm diam. |
| Hot rolling | Large | No limit | — |
| Cold rolling | Large | No limit | — |
| Drawing | Small–large | Al, Cu, Zn, mild steel | 3 mm–6 mm diam. |

process. Complicated shapes (e.g., aerospace turbine blades) or shapes in which fine detail is sought (e.g., figurines) are made by investment or lost-wax casting methods.

Metalworking Methods

Hot working of metal alloys is normally the next step in the shaping of the cast alloy into a component, and is also used to induce some refinement of the grain structure of the material to obtain the necessary ductility or strength. In hot working, the temperature is high enough that recrystallization occurs at a rate faster than work hardening due to deformation. Forging, rolling, and extrusion are some examples of hot-working processes.

Hot forging is a process of simply pressing the hot metal between two surfaces in open, closed, or flat-faced dies. This process is closest to the ancient art of the blacksmith, but modern manufacturing plants employ high-power hydraulic presses to deliver impact blows to achieve forging of large steel crankshafts, aerospace propellers, and so forth. Hot extrusion consists of taking a cylindrical billet from the cast ingot and placing the hot billet in a die of a slightly larger size. A piston or ram extrudes the hot metal through appropriately cut orifices or openings in the die. The process is akin to squeezing toothpaste out of a tube under pressure. Direct and inverted extrusion are the two most common variations of the extrusion process. Hot rolling is a popular method of reducing the cast ingots into billets, slabs, plates, or sheets by pressing the hot metal between rotating rollers. Four high-rolling mills consist of smaller-diameter work rolls backed by larger diameter backup rolls. Many other types of cluster mills also exist, including planetary mills and pendulum mills.

Cold working of metals and alloys has the advantage of producing a clean, smooth surface finish and a harder material. Cold rolling of aluminum foil or steel strips are some examples of products in daily use that have surfaces that can vary from a standard bright finish to matte and plated finishes, depending on the application. Drawing is another cold-working process in which cylindrical rods can be drawn through a die to make wires or sheets of metal can be shaped into cup-shaped objects by deep drawing the sheet into a die by pressure from the punch. By clamping the sheet around the edges, the pressing operation can produce domestic cookware, automobile bodies, and a variety of cup-like shapes. Circular cross sections can be made by spinning a metal blank in a lathe while applying pressure to the blank with a tool to shape it. Explosive forming is a special process used for shaping large-area sheets of metal into contoured panels such as those needed in communication reflectors. The wave generated by detonation of an explosive charge is used to convert a sheet blank into the shape of the die. Table 185.1 is a summary of the processes used with a listing of the advantages and limitations of each process.

TABLE 185.2 Typical Tolerance Limits, Based on Process Capability, for Various Processes

| Process | Typical Tolerance Limits | | Process | Typical Tolerance Limits | |
|---------------------------|--------------------------|------------------|---------------------------------|--------------------------|-----------|
| | mm | (inches) | | mm | (inches) |
| Sand casting | | | Abrasive | | |
| Cast iron | ±1.3 | (±0.050) | Grinding | ±0.008 | (±0.0003) |

Machining and Finishing

The cast, hot- or cold-worked metallic alloys are often subjected to some type of machining operation, which encompasses cutting, grinding, polishing, shearing, drilling, or other metal-removal methods. Chemical etching or polishing methods can also be used as finishing steps in the production of components from metals. Planing, turning, milling, and drilling are the main methods of removing chips from a metal part during machining.

Surface finish and dimensional accuracy of the component are the main goals of machining. Some recent studies in tolerance design were reviewed and reported in Feng and Kusiak (2000) and Feng et al. (2001). Table 185.2 illustrates the typical tolerances that can be achieved by common manufacturing processes. Figure 185.1 illustrates the typical process chains that a designer and a manufacturing engineer or technician should be aware of. Some recent turning surface roughness studies are reviewed in Feng and

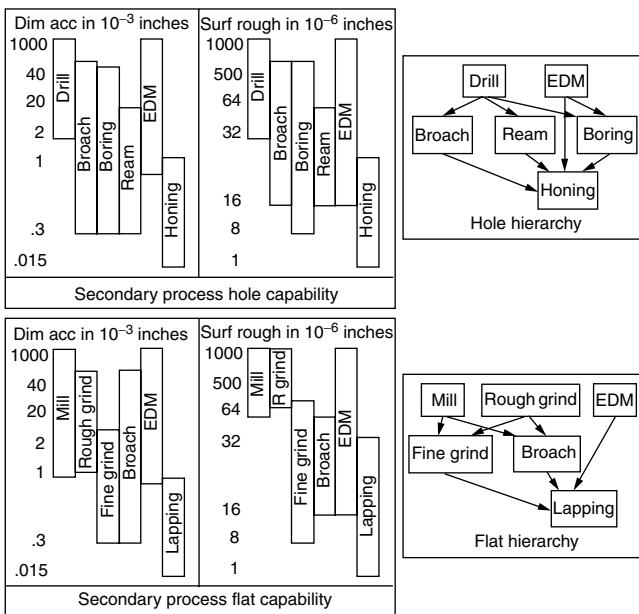

FIGURE 185.1 Process chains with tolerance levels. (Source: Wright, P. K. 2001. *21st Century Manufacturing*. Prentice Hall, Upper Saddle River, NJ. With permission.)

FIGURE 185.2 Relative machining cost with respect to surface roughness specifications. (Source: Kalpakjian, S. and Schmid, S. R. 2003. *Manufacturing Processes for Engineering Materials*, 4th ed. Prentice Hall, Upper Saddle River, NJ. With permission.)

Wang (2003) and honing surface roughness studies in Feng et al. (2002). Table 185.3 shows typical surface roughness values produced by the various manufacturing processes, and Figure 185.2 shows the relative costs caused by additional manufacturing operations with respect to surface roughness specifications.

Cutting and grinding tools required in machining are usually made from hard metal (carbide) or ceramic materials; a *machinability index* measures the ease with which a particular material can be machined with conventional methods. The higher the machinability index, the easier it is to machine the metal or alloy. In addition to these methods, metal removal can also be achieved by ultrasonic abrasion, laser or electron beam cutting and drilling, electrical discharge or spark machining, arc milling, and chemical milling. Honing has been and will remain to be the only process that will provide both the surface roughness and crosshatched lay directions for the internal surface of engine cylinder liners in

TABLE 185.3 Surface Roughness Values Produced by Various Manufacturing Processes

| Process | Typical Surface Finish | Range of Roughness | Process | Typical Surface Finish | Range of Roughness |
|----------------------|------------------------|--------------------|-----------------------|------------------------|--------------------|
| Casting | | | Abrasive | | |
| Die casting | Good | 1.2 (30–65) | Grinding | Very good | 0.1–2 (5–75) |
| Investment | Good | 1.5–3 (50–100) | Honing | Very good | 0.1–1 (4–30) |
| Sand casting | Poor | 12–25 (500–1000) | Lapping | Excellent | 0.05–0.5 (2–15) |
| Metal forming | | | Polishing | Excellent | 0.1–0.5 (5–15) |
| Cold rolling | Good | 1–3 (25–125) | Superfinishing | Excellent | 0.02–0.3 (1–10) |
| Sheet metal drawing | Good | 1–3 (25–125) | Nontraditional | | |
| Cold extrusion | Good | 1–4 (30–150) | Chemical milling | Medium | 1.5–5 (50–200) |
| Hot rolling | Poor | 12–25 (500–1000) | Electrochemical | Good | 0.2–2 (10–100) |
| Machining | | | Electric discharge | Medium | 1.5–1.5 (50–500) |
| Boring | Good | 0.5–6 (15–250) | Electric beam | Medium | 1.5–1.5 (50–500) |
| Drilling | Medium | 1.5–6 (20–250) | Laser beam | Medium | 1.5–1.5 (50–500) |
| Milling | Good | 1–6 (30–250) | Thermal | | |
| Planing | Medium | 1.5–12 (60–500) | Arc welding | Poor | 5–25 (250–1000) |
| Reaming | Good | 1–3 (30–125) | Flame cutting | Poor | 12–25 (500–1000) |
| Shaping | Medium | 1.5–12 (60–500) | Plasma arc cutting | Poor | 12–25 (500–1000) |
| Sawing | Poor | 3–25 (100–1000) | | | |
| Turning | Good | 0.5–6 (15–250) | | | |

order to help improve lubrication, and thus reduce wear, reduce emission, and increase oil efficiency when the new ISO13565 (ISO, 1996) surface roughness standard is implemented (Feng et al., 2002).

Numerically controlled (NC) machining of high-precision components and sophisticated robotically controlled fabrication methods continue to be investigated and applied in the manufacture of engineering materials and components. Refer to [Chapter 182](#) for more discussions on NC, robotics, and flexible manufacturing. Powder metallurgy methods are most suitable for directly converting powders of raw materials into finished shapes with little or no machining. This method, discussed later, has the greatest potential for near-net-shape manufacturing and is commonly used to consolidate metal, ceramic, and mixed composite powders.

185.2 Ceramics, Glasses, and Polymers

Nonmetallic materials such as ceramics, glasses, and polymeric organic materials require generally different methods for shaping and manufacturing than metals, although some common methods do exist for all of these materials. Inorganic silicate glasses and polymer melts are processed by methods that take into account their viscoelastic properties. Ceramics are normally refractory and high-melting materials and thus require powder sintering, hot pressing, or related methods for production.

Powder Processing and Sintering

Powder sintering of metal alloy powders and ceramics is a versatile method of producing near-final shapes of a component. Ceramic powders are typically blended with solid or liquid additives, binders, and so forth, and the batched system is treated by a series of mixing, chemical dissolution, washing, de-airing, or filtration to produce a slurry, paste, or suspension of solid particles in a liquid, often referred to as the *slip*. Depending on the consistency (viscosity of the syrup) of the suspension, forming a shape is achieved by tape casting onto plastic sheets or by pouring the slip into a plaster mold, followed by drying to remove the residual liquids in the batch. The shaped porous ceramic at this stage is called a *green ceramic body*. Green machining, surface grinding, or application of coatings or glazes is done at this stage. The final step in the process is consolidation to a nearly nonporous solid by firing or sintering at a high temperature. The sintered microstructure is usually a multiphase combination of grains, secondary phases, and some degree of remaining porosity.

Another common way of sintering ceramics, and particularly metal powders, is by direct pressing of the powders with some solid additives (called *sintering aids*). The component shape is determined by a die cavity and the powders are cold pressed at relatively high pressures, followed by heat treatment to create the sintered microstructure. In a combination of these steps, pressure and heat can be applied simultaneously in hot pressing or hot isostatic pressing (“hipping”). In these methods the powder fills in the die cavity, and, as the pressure is applied by hydraulic rams, the die is heated simultaneously to consolidate the powder to a solid. The evolution of a microstructure from powders to dense ceramics with grains and grain boundaries is now a well-developed science-based technology. Thus, deliberate process control is needed, including awareness of atmospheres used in firing, particle size distribution, chemistry of additives, control over grain boundary mobility, and elimination of exaggerated grain growth. The recent development of fast sintering methods includes the use of sparks, microwaves, and plasmas to activate the surfaces of very fine powders (micrometers to as small as a few nanometer particles) and cause consolidation to occur in just a few minutes. Microwave sintering and plasma-activated sintering are examples of promising new methods on the horizon for very fast sintering to achieve small grain sizes and high-purity materials in both metallic and ceramic systems. For an in-depth discussion of the above topics, refer to German (1994).

Glasses and Glass-Ceramics

The manufacture of glasses from mixtures of silicon-dioxide (silica) and a number of other oxides (e.g., sodium, calcium, aluminum oxides) is based on melting the mixtures in a tank-like furnace to create a

homogeneous bubble-free viscous melt. The composition of the glass is chosen such that, on cooling the melt during shaping, formation of the thermodynamically favored crystalline material does not occur. To make glass plates or sheets (e.g., car windshields), the molten liquid is allowed to float onto the surface of a liquid bath of low-melting metal that is immiscible with the glass (the lighter glass floats on the higher-density metal melt). This float glass process is but one of a variety of ways of converting molten silicate liquids to glassy shapes. Viscous glass streaming out of a furnace can be trimmed into “gobs” that drop into a preshaped die while blowing air under pressure to force the mushy viscous gob into the final shape (e.g., a beer bottle). Molten glass compositions can also flow through bushings containing small orifices to create fiberglass materials or optical fibers. Optical fibers of high purity are also processed in drawing towers using preforms of carefully engineered clad-and-core compositions. Thousands of glass compositions with specific chemical ingredients are known for generating color, inducing a refractive index gradient, permitting selective transparency, or resisting weathering. The common window glass composition is based on a mixture of the oxides of sodium, calcium, and silicon, and is popularly called soda-lime-silica glass.

Glass-ceramics are materials made by the heat treatment of a shaped piece of glass so as to allow the formation of copious amounts of small crystallites without changing the macroscopic dimensions of the object. The optical transparency of the glass changes to a translucent appearance typical of most glass-ceramics. It is best known in the form of domestic cookware sold under the trade name Corelle or Corningware, by Corning Glass Company. The glass-ceramic process is a useful method of obtaining fully dense ceramics from the glassy state and requires good control of the nucleating agents that are used to catalyze the crystallite formation in the glass-ceramic microstructure. The uniformity of the crystal grains in the structure and the small size are factors that give glass-ceramics higher strength and better mechanical properties compared to glasses. The number of glass-ceramics available for use in engineering practice has grown enormously in the last 25 years; applications of glass-ceramics in electrical, magnetic, structural, and optical fields are becoming more common. Machinable glass-ceramics based on a mica-like crystalline phase have made it easier to shape glass-ceramics by conventional machine shop tools.

Sol-Gel Methods

Sol-gel processes make it possible to use organic-polymeric synthesis methods to produce ceramics and glasses at relatively low temperatures. The major advantage of sol-gel techniques is that all the chemicals needed in a glass or ceramic can be blended into a solution to create a “sol” at close to room temperature. This avoids the high-temperature processing normally used in making a ceramic or a glass. The sol is then made to gel by appropriate hydrolysis reactions, and the gel is then fired into a monolithic body or made into coatings, powders, films, and so forth. The calcination and sintering steps remove water and vestiges of organic bonds to form an inorganic ceramic product. Not all ceramics can be made by sol-gel techniques — not because of any fundamental limitations, but due mainly to the lack of well-developed connections between a suitable starting precursor and the synthesis protocol to make the final ceramic or glass. For making bulk monoliths or coatings and films, the use of drying control agents in sol-gel processing is crucial to attain crack-free objects.

Polymer Processing

The forming of organic polymeric materials essentially consists of making powders or granules of the requisite blend of polymers with additives such as carbon, chalk, and paper pulp. In the next step, the granules are heated to soften the polymer mixture, and the soft material is viscoelastically shaped into the final component. The processing methods mainly involve extruding, injection molding, casting, and calendaring. The particular process used depends on the quantity, size, and form in which the polymer object is desired (e.g., sheets of plastic or bulk rods). Thermosetting polymers go through an irreversible chemical change upon heating and they are mostly made by molding or casting. Examples include thermosetting resins such as urea, melamine or phenol formaldehydes, and polyesters. Thermoplastic polymers are processible by repeated softening as long as the temperature is not too high to cause

TABLE 185.4 Comparison of Various Polymer-Processing Methods

| Process | Production Rate | Material Type | Optimum Size |
|---------------------|-----------------|------------------------|---|
| Extrusion | Fast | Th, plastic Th, set | Few mm–1.8 m |
| Blow molding | Fast | Th, plastic | 10^{-6} – 2m^3 |
| Injection molding | Fast | Th, set | 15 g–6 kg |
| Compression molding | Fast | Th, set | Few mm–0.4 m |
| Transfer molding | Fast | Th, set | |
| Layup techniques | Slow | Th, set and filler | Few mm–0.4 m, and 0.01–400 m ² |
| Relational molding | Medium | Th, plastic | 10^{-3} – 30 m^3 |
| Thermoforming | Fast | Th, plastic | 10^{-3} – 20 m^2 |

decomposition and charring. Ease of flow makes these attractive for processing by injection molding and extrusion methods. Examples include polycarbonate, polyethylene, polystyrene, polyamide (nylon), and polyvinyl chloride (PVC). Inclusion of gas gives rise to foamed plastics such as polystyrene foam (for thermal insulation), whereas polymers are reinforced by fibers (typically glass fibers) to form composites with better stiffness and strength.

The glass fiber polymer composites are shaped by injection molding and are useful in environments where moisture-resistant, high-fracture tough materials are needed. Continuous sheets of plastic are made from PVC or polyethylene polymers by calendering. This process consists of feeding the heated polymer granules or powder through a set of heated rollers. The first roller converts the granules to a sheet that is subsequently reduced to the appropriate thickness and surface finish. Laminates and coatings of polymers are formed by pressing, casting, and roll-coating technologies. Large polymer pieces such as boat hulls are put together manually by pasting several layers of gum-fiber-reinforced polyester. For a large number of parts (automobile bodies, etc.), vacuum forming of PVC or polypropylene-type polymers is the desired method. A comparison of some polymer-processing methods is shown in Tables 185.4 and 185.5.

185.3 Joining and Fastening Processes

Temporary joints between the shaped finished components made from several materials are easily achieved by mechanical means such as nuts, bolts, pins, and so forth. Some permanent joining of two materials requires physical or chemical changes at the joining surfaces.

Mechanical Fastening

Mechanical fastening may be preferred over other joining methods for its ease of manufacturing; ease of assembly and transportation; ease of parts replacement, maintenance, and repair; ease in creating designs that require movable points; and lower overall cost of manufacturing the product. Mechanical fastening

methods can be classified into two major groups: (1) those that allow for disassembly, and (2) those that create a permanent joint. Threaded fasteners including screws, bolts, and nuts are examples of the first group, and rivets and eyelets illustrate the second. Other methods include (1) interference fit, including press fitting, shrink and expansion fits, snap fits, and retaining rings; (2) stitching, stapling, sewing, and cotter pins; and (3) inserts in moldings and castings, integral fasteners (e.g., lanced tabs, embossed protrusions, beading, dimpling), and crimping. Refer to Groover (2002) and Kalpakjian and Schmid (2003) for more discussion.

Welding

For joining metals and alloys, welding, brazing, and soldering are the most common methods. Fusion welding consists of melting a part of the metal at the joint interface and allowing the joint to form by flow of the liquid metal, usually with another filler metal. When the same process is assisted by compressive forces applied by clamping the two pieces, the process is called *pressure welding*. Brazing and soldering use a lower-melting filler metal alloy to join the components. The parent pieces do not undergo melting and the liquid filler acts as the glue that makes the joint. The heat required to cause melting in the welding process classifies the process. Thus, in arc welding, heat is provided by creating an electric arc between electrodes often in the presence of a shielding atmosphere. Gas welding is performed using a gas mixture fuel to create a high-temperature flame that is targeted at the joining interface. The most popular gas-welding device is the oxyacetylene welding torch commonly seen in metalworking shops. Thermite welding is a well-known process for joining large sections in remote locations where gas or electric welding are difficult to perform. The thermite process relies on the exothermic heat generated by the reaction of iron oxide with aluminum. The molten product of the exothermic reaction is brought in contact with the joining interface and causes local melting of the parent pieces, followed by cooling, to form the weld. Electron and laser beam welding are some of the modern methods for joining metals and ceramics. Other methods include electroslag welding, friction welding, and explosive welding, which are made possible by a transient wave generated by detonating an explosive charge.

Brazing and Soldering

Brazing and soldering both use filler metals to join and bond two (or more) metal parts to provide a permanent joint. They are attractive compared to welding in the following conditions: (1) the metals have poor weldability, (2) dissimilar metals are to be joined, (3) the intense heat of welding may damage the components being joined, (4) the geometry of the joints does not lend itself to any of the welding methods, and/or (5) high strength is not a requirement (Groover, 2002). Brazing is a joining process in which a filler metal is melted and distributed by capillary action between the faying surfaces of the metal parts being joined. No melting of the base metals occurs in brazing; only the filler melts, as opposed to fusion welding. Brazing can be classified into torch brazing, furnace brazing, induction brazing, resistance brazing, dip brazing, infrared brazing, and braze welding. Soldering is similar to brazing and can be defined as a joining process in which a filler metal with a melting point not exceeding 4500°C (840°F) is melted and distributed by capillary action between the faying surfaces of the metals parts being joined. As in brazing, no melting of the base metals occurs, but the filler metal wets and combines with the base metal to form metallurgical bond. Common soldering methods include hand soldering, wave soldering, and reflow soldering.

Joining of Plastics, Ceramics, and Glasses

The joining of ceramics and glasses involves some methods common to metals and some that are specific to preparing glass-metal seals. Ceramic joining and bulk ceramic processing are closely related; the main joining methods consist of adhesive bonding, brazing with metals or silicates, diffusion bonding, fusion welding, and cementitious bonding. Brazing of metals to ceramics has attracted much recent attention because of its applications in heat engines, where high-temperature ceramic components (e.g., silicon

nitride based) are in use. Thus, metallic alloys based on Ti, Zr, and Fe-Ni-Co are used to braze silicon nitride parts designed for high-temperature service. Thermal expansion mismatch between joining materials is an important criterion in the choice of those materials. Studies of glass-metal, ceramic-metal, ceramic-ceramic, and ceramic-polymer interfaces have led to a sophisticated understanding of joints, coatings, and enamels used in ceramic, electronic, and thermal engineering applications.

185.4 Fabrication of Microelectronic and Micromechanical Devices

Electronics Assembly and Packaging

Integrated circuits (ICs) constitute the heart of an electronic system, but the complete system consists of much more than packaged ICs. These ICs and other components are mounted and interconnected on printed circuit boards (PCBs), which in turn are interconnected and contained in a chassis or cabinet. Chip packaging is only part of the total electronic package. The rest of electronics packaging is briefly introduced here. A well-designed electronic package serves the following functions: power distribution and signal interconnections, structure support, circuit protection from physical and chemical hazards in the environment, dissipation of treatment generated by the circuits, and minimum delays will signal transmission within the system (Groover, 2002). A complex electromechanical system is organized into levels, which are often called the packaging hierarchy: (1) Level 0, intraconnections on the chip; (2) Level I, chip to package interconnections to form IC package; (3) Level 2, IC package to circuit board interconnections; (4) Level 3, circuit board to rack, or card-to-board packaging; and (5) Level 4, wiring and cabling, connections to the cabinet.

Microfabrication and Nanofabrication

Miniaturization is an important trend in materials processing. Microelectromechanical systems (MEMS) illustrate this trend. These MEMS can potentially power microrobots to repair human cells, and produce microknives for surgery and camera shutters for precise photography. Some are now widely used in sensors, ink-jet printing mechanisms, and magnetic storage devices. The more recent trend is the development of nanoelectromechanical systems (NEMS), which operate on the same scale as biological molecules. [Figure 185.3](#) indicates the relative sizes and other factors usually associated with these and traditional manufacturing terms. MEMS products can be classified by type of device or by application. The first classification includes microsensors, microactuators, microstructures and microcomponents, and microsystems and microinstruments. The second classification includes ink-jet heads, thin-film magnetic heads, compact disks, automotive, medical, chemical and environmental, and other applications in scanning probe microscopes, biotechnology, and electronics.

Typical microfabrication technologies include silicon layer processes, LIGA processes, photochemical machining, electrodischarge machining, electron-beam machining, laser beam machining, ultrasonic machining, wire electrodischarge machining, ultra-high precision machining using single-crystal diamond cutting tools and control systems with resolutions as fine as 0.01 μm , electrochemical fabrication, microstereolithography, and photofabrication (Madou, 1997). Two good references on MEMS are Madou (1997) and Kovacs (1998).

Nanostructures consist of physical features whose dimensions are in the range of 1 to 100 nanometers (nm). Structures of this scale can almost be thought of as purposely arranged collections of individual atoms and molecules. Two alternative processing technologies may be used to fabricate these NEMS items: (1) additive molecular processes that build the nanostructure from individual atoms, and (2) nanofabrication technologies similar to microfabrication processes, only performed on a small scale. A good reference in NEMS is Goddard et al. (2003).

Two kinds of new nanomaterials have been widely covered in the media in terms of their science, discovery, and potential uses: fullerenes and carbon nanotubes. Fullerenes can be used for applications

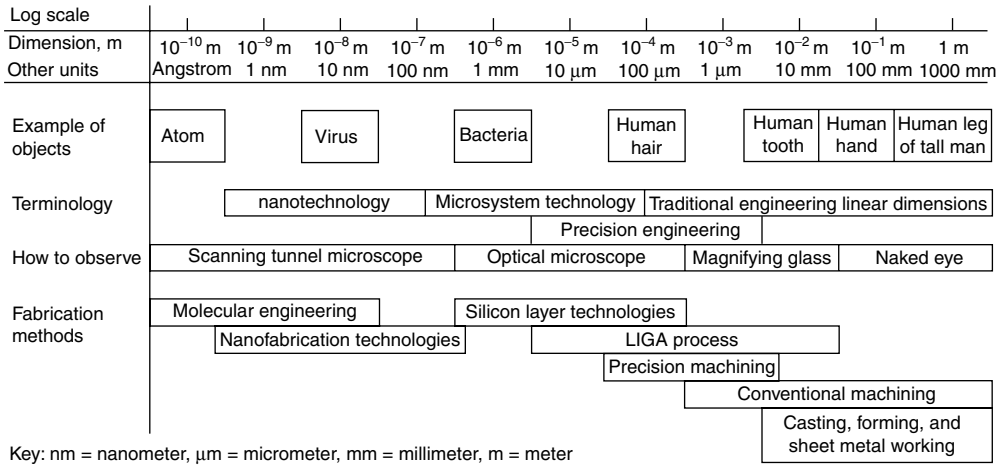

FIGURE 185.3 Terminology and relative sizes for microsystems and related technologies. (Source: Groover, M.P., *Fundamentals of Modern Manufacturing*, 2nd ed., p. 846, Wiley, New York. With permission.)

such as medical imaging and drug delivery. Carbon nanotubes look like cylinders of rolled-up chicken wire, but they are ten times stronger than steels, one-sixth the weight of steels, and more conductive than copper. Labs have been able to produce them for more than 10 years, but only with recent advances in equipment and instruments have the prices begun to drop to the point where commercial uses could be feasible. In 1999, the cost of buckyballs was around \$600 per gram, compared to only \$10 at the end of 2003.

Near-term commercial applications of nanomaterials will be largely found in nanoparticle-reinforced materials and nanoparticle-filled coatings. Nanoparticle-reinforced materials provide additional strength or some other desired property to polymers. Toyota, for example, uses layered silicates, in its cars on fan belt covers. It has also combined materials at the nanoscale to make bumpers as strong as traditional ones, but 60 times thinner. Nanoparticle-filled coatings can be used to create scratch resistant surfaces, antireflective coatings, and corrosion-resistant coatings for various metals.

185.5 Measurement and Inspection

A basic requirement in materials processing is to meet the design specifications in dimensions, tolerances, hardness, and surface finishes. Measurement is a procedure in which an unknown quantity is compared with a known standard. Inspection is a procedure in which a part or product characteristic, such as a dimension or hardness, is examined to determine whether it conforms to design specifications. Many inspection procedures rely on measurement techniques, while others using gaging methods. The inspection by measurement produces variables or quantitative data while inspection by gaging results in attributes or qualitative data. Gaging (also spelled as *gauging*) determines simply whether the part characteristic meets or does not meet the design specification. It is usually faster, but scant information is provided about the actual value of the characteristic of interest.

Some concepts and principles apply virtually to all measurements. The most important are accuracy and precision. Accuracy is the degree to which the measured value agrees with the true value of the quantity of interest. A measurement system is accurate when it is absent of systematic errors. Systematic errors are deviations from the true value that are consistent from one measurement to the next. Precision is the degree of repeatability in the measurement process. A measurement procedure is precise when the random errors in this procedure are minimized. Random errors are usually associated with human participation in the measurement process. They are assumed to obey a normal distribution whose mean is zero and estimated standard deviation is σ given by

$$\sigma = \sqrt{\sum (x_i - \bar{x})^2 / n}$$

where

n = the number of members in the population

x_i = the i th measurement of the quantity of interest

μ = population mean

The $\pm 3\sigma$ range is normally used as an indication of the precision of a measuring instrument. Since μ is usually unknown, the gage repeatability and reproducibility (gage R & R) study is sometimes used to estimate its value. A guideline often applied to determine the right level of precision is the “rule of 10,” which states that the measurement device must be ten times more precise than the specified tolerance. Coordinate measuring machines (CMMs) are among the best measuring devices for tight dimensional and geometrical tolerances. Some recent CMM measurement and digitization uncertainty studies are reviewed and reported in Feng and Wang (2002).

Acknowledgments

This revision is based on the same chapter contributed originally by Dr. Subhash H. Risbus of the University of California at Davis to the first edition of this book.

Defining Terms

Casting — The shaping of a metal alloy into a solid piece by pouring liquid metal into the cavity inside a sand mold.

Machining — Final steps in the manufacture of a component; may include cutting, polishing, and grinding operations.

Metalworking — Process steps to shape the cast material into components by cold or hot work. Examples of processes include rolling, forging, extrusion, and drawing.

Powder processing — The conversion of powdered material into a solid piece by cold pressing and heating (sintering) or simultaneous heating and pressure application (hot pressing).

Sol-gel process — The use of organic or organometallic solutions to make the component into a bulk piece or coating at lower temperatures than in conventional melting and casting. Used for oxide ceramics and glasses at present.

Machine Tools and Processes

Yung C. Shin
Purdue University

- 186.1 Economic Impact
- 186.2 Types of Machine Tools
- 186.3 Control of Machine Tools
 - Interpolation • Feedback Control
- 186.4 Machine Tool Accuracy

Machine tools are the machinery used to process various materials in order to get desired shapes and properties. Machine tools typically consist of a base structure that supports various components and provides overall rigidity; kinematic mechanisms and actuators, which generate necessary motions of the tools and tables; and various feedback sensors. Machine tools are often used in conjunction with jigs and fixtures, which would hold the part in position, and processing tools. An example of a machine tool used in material removal processing is shown in [Figure 186.1](#).

The first generation of modern machine tools was introduced during the industrial revolution in the 18th century with the invention of steam engines. Machine tools opened an era of automation by providing the means to replace human work with mechanical work. In the early days, automation with machine tools was performed using various kinematic mechanisms, but it evolved into programmable automation with the use of computer numerical control. Today, many machine tools are operated with electrical or hydraulic power and controlled by a computer.

The major application of automation using machine tools in the early years was in transfer lines. Many special-purpose machines were grouped together with a part-moving system, such as a conveyor, providing the transfer of parts from one machine to another. A specific operation was performed on each station, and the part was moved to the next station until the finished product was obtained. Recently, however, **flexible automation** has been actively pursued to cope with continuous and rapid change of product designs and cycles. In such systems, several numerically controlled machines are clustered together to perform a variety of jobs. Programs are used, instead of inflexible mechanisms, to control the machines, so that the system can easily adapt to different job requirements.

186.1 Economic Impact

In most industrialized countries, manufacturing contributes about 20 to 30% of the nation's GNP. Since most manufacturing processes are performed with machine tools, the production and consumption of machine tools play a significant role in the nation's economy. Machine tool companies in the U.S. directly employ about 350,000 people. If the surrounding ancillary industries are included — such as the tooling industry, material-handling industry, and sensors and controller manufacturers — the total

FIGURE 186.1 An example of machine tools.

employment would double that figure. More importantly, the machine tool industry affects a much larger user community.

186.2 Types of Machine Tools

Various manufacturing processes led to development of a variety of machine tools. Therefore, machine tools can be categorized by manufacturing processes. Manufacturing processes can be grouped into four main categories: casting, forming, material removing, and joining.

Casting machines are used to generate various unfinished or finished parts of defined shapes from shapeless materials. Casting is typically performed under high temperatures with molten material. The material in liquid state is poured into a mold or a die that has the shape of the final part, and is subsequently solidified. Examples of casting processes entail sand casting, centrifugal casting, die casting, and continuous casting. No processing tools are used on this type of machine, and high accuracy is not usually required. Casting is usually followed by forming or machining processes in order to attain a final shape or to improve the dimensional accuracy.

Forming machines are used to change the shape of materials in the solid state. During the process, no significant change of volume or weight in the material occurs, but the mechanical properties are altered due to the large amount of bulk deformation and high stresses. Forming processes are performed at either high or low temperature. The required force and power are usually large. Examples of forming machine tools include presses; forging machines; rolling mills; and stamping, drawing, extrusion, and bending machines.

Material removal processes are used to obtain an accurate shape of a part that has been obtained by casting or forming processes. During the material removal process, the volume as well as the shape is changed. Machine tools used for material removal processes often require the highest accuracy. Typical processes under this category include turning, drilling, milling, boring, grinding, and so forth. Material removal processes have been used mostly for metals but have recently found new applications in non-metallic materials such as ceramics and composites.

Machine tools for material removal processes are designed to provide multiaxis motions. They usually consist of a table used for mounting a workpiece, a spindle to hold tools, and a motor and gears to provide various speeds and feeds. In order to obtain a precision motion, axes are often controlled by microprocessor-based computer numerical controllers.

In addition to the processes already mentioned, many nontraditional machining processes are commonly used these days. Nontraditional machining processes include any that use another energy source with or without mechanical power. Typical nontraditional machining processes are electrodischarge

machining (EDM), electrochemical grinding, laser machining, and electron-beam machining. These processes utilize either electric or heat energy to remove the material.

Joining is an operation to assemble components. Examples are welding, soldering, adhesion, and riveting. These processes are usually performed at the final stage to fabricate a product from various finished components. The types of machine tools in this category are friction-welding, arc-welding, electron-beam-welding, and laser-welding machines. In addition, robots are commonly used for repetitive assembly operations.

186.3 Control of Machine Tools

In the early days, machine tools were controlled automatically by means of mechanical systems, such as cams, gears, and levers, which provided repetitive or sequential motions of machine tools. These mechanical devices shifted the operator's role from turning wheels or moving levers to supervising overall operation.

Later, hydraulic control replaced the mechanical control systems. Hydraulic systems provided more precise actions with higher power. The hydraulic control later combined with electronic switches were able to generate much more complex operations than mechanical control systems, but were eventually replaced by electronic controls.

Numerically controlled (NC) machines were developed to achieve automatic operation of machine tools with a program. The NC machine was first conceived by John Parson in 1948, and the first prototype was introduced by Massachusetts Institute of Technology (MIT) in 1952. In early NC machines, electric relays were grouped and hard-wired so that users could generate a complex sequence of operations. In NC machines, programs to generate commands for the sequences of operations were stored into punched tapes, which were subsequently read into a computer which interpreted the program and generated pulses to drive mechanisms.

In the beginning mainframes were used as computers to process the data. However, microprocessors and magnetic media replaced numerical control in the 1970s and opened the era of computer numerical controllers (CNCs). Instead of being connected to the mainframe computer and sequentially controlled, CNC machines were designed with individual microprocessor-based controllers. CNC machines are usually equipped with a tool magazine, which holds multiple tools. These machines can perform many different operations on a single machine with automatic tool change and hence are called *machining centers*.

Computer programs used to operate the CNC machines are called *part programs*, which contain a sequence of commands. The commands used in a part program include preparatory G codes and M codes defining miscellaneous functions, as well as specific codes such as S, F, T, or X codes. The G codes are universally used regardless of the type of CNC and are defined in both ISO (International Standards Organization) and EIA (Electronic Industry Association) standards (RS-273-A). Some examples of these codes are shown in Table 186.1. With NC or CNC machine tools, part programs can be generated at a remote site. The English-like languages, such as automatic programming tool (APT), are commonly used for the ease of generating part programs. Nowadays, various computer-aided manufacturing (CAM) packages provide means to graphically generate part programs from design drawings created by computer-aided design (CAD) software. The part programs generated with CAM software must be postpro-

cessed into the format of the specific CNC to be used and downloaded to the machine, where it can be edited if necessary.

Interpolation

Most CNC controllers have the capability of performing various types of interpolation. The simplest type is point-to-point interpolation. This scheme, in which beginning and final positions are of greatest importance, is usually used for rapid movement of tools or workpieces. The second type is the straight-line interpolation, which is used to generate a motion following a straight line with a specified speed. Accurate positioning and maintenance of a constant speed are required. The most complicated type of interpolation is contouring. Trajectory commands for contouring are typically generated using circular or cubic spline functions. Figure 186.2 shows the graphical illustration of these interpolations.

Feedback Control

The generated commands are sent to the actuators of each axis to provide the necessary motion of the pertinent component in either open-loop or closed-loop configuration. In early CNC machines, stepper motors were often used as actuators, but their usage is at present limited to inexpensive, small machine tools. Either DC (direct current) or AC (alternating current) servomotors are popularly used for modern machine tools with feedback control. Figure 186.3 shows the open-loop control system with a stepper motor, whereas Figure 186.4 depicts the closed-loop configuration.

FIGURE 186.3 Open-loop control system with stepper motors.

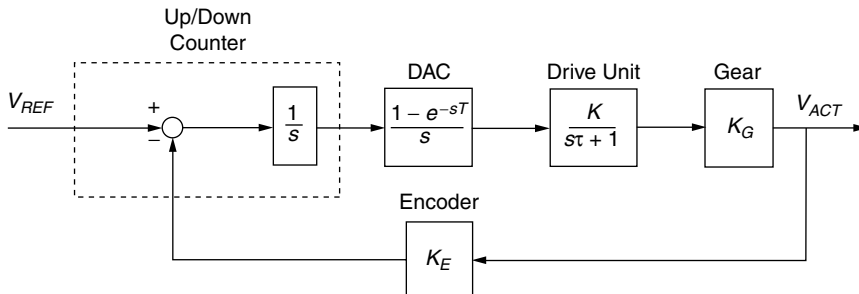

FIGURE 186.4 Closed-loop control system with stepper motors.

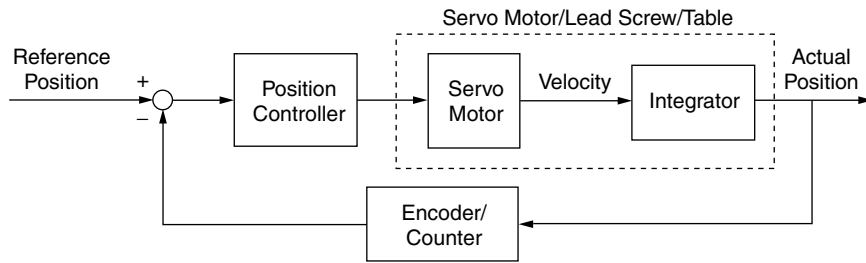

FIGURE 186.5 Digital position control system.

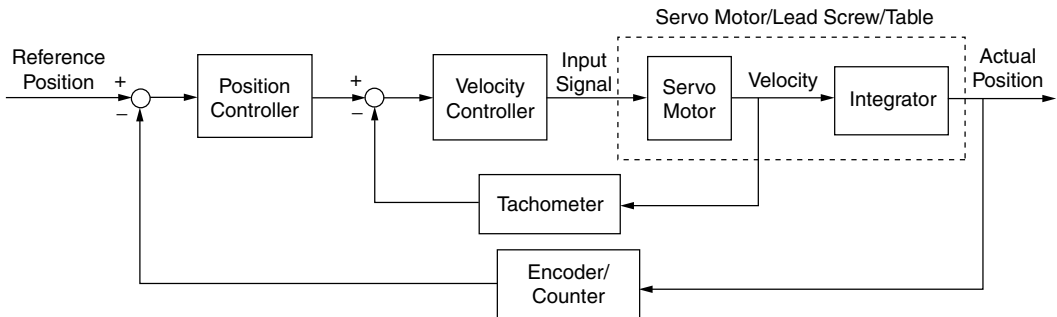

FIGURE 186.6 Digital control system with position and velocity feedback.

Early NC systems used a control scheme based on pulse reference and counting. In this scheme, positional reference commands are input to the system as a series of pulses, and the position feedback is obtained through an encoder. The command pulses are generated by the NC controller, with each pulse corresponding to a fixed **basic length unit** (BLU), which determines the system's accuracy. The frequency of the pulses determines the velocity of the axis, and positional accuracy is achieved by comparing the feedback pulses with the input pulse through the up-down counter.

In more recent CNC systems, command generation and control are performed digitally using a digital controller with servomotors. Proportional-integral-derivative (PID) controllers are most popularly used as feedback controllers with either single- or double-feedback loops. An example of a position control system with a proportional controller is shown in Figure 186.5. The more advanced system shown in Figure 186.6 has two feedback loops, which perform velocity control in the inner loop and position tracking in the outer loop. The most common method uses a proportional type for the position control and a PI controller for the velocity loop. These controllers are designed for the nominal operating condition of the machine.

Recently, adaptive control (AC) has opened a new era for machine tool control. Adaptive control provides the machine tool with the ability to adapt itself to the dynamic changes of the process condition to maintain optimum performance. Without adaptive control, operating conditions might have to be chosen too conservatively to avoid failure, thereby resulting in the loss of productivity. In addition, adaptive control can improve the accuracy of an existing machine, particularly in contouring. Adaptive control is particularly important for the realization of untended operation in the factory of the future.

186.4 Machine Tool Accuracy

The standard of accuracy has been increasing steadily over the last few decades. With the advent of high-precision machine tool technology and measurement techniques, manufacturers can presently attain accuracy that was almost impossible to achieve a few decades ago. For example, machining accuracy of 5 to 10 μm from regular machine tools and 0.1 μm from precision machine tools is routinely achieved. It is projected that the accuracy will improve about tenfold every 2 decades.

The accuracy of a part produced by a machine tool is influenced by many factors, such as

- Machine tool accuracy
- Deflection or distortion of the part due to load or temperature
- Process operating condition
- Tool wear
- Environmental disturbances

Among these causes, machine tool accuracy plays a very important role.

Machine tool error is defined as the deviation from the desired or planned path of the movement between the total and the workpiece. Machine tool errors are typically grouped into geometric and kinematic errors. *Geometric error* includes positional inaccuracies of the individual link and the errors in the shape of the machine tool components. *Kinematic errors* are those occurring in coordinated movement of multiple machine elements. Therefore, kinematic errors depend on the machine's kinematic configuration and functional movements.

Machine tool errors stem from many sources, including imperfect fabrication of elements, assembly errors, and friction, and errors associated with control, temperature variation, weight, and so forth. Depending on the source of error, various testing techniques must be adopted to evaluate the accuracy. Typical test methods include cutting tests, geometrical tests of moving elements, and master-part tract tests. Details of test procedures are described in [Hocken, 1980; NMTBA, 1972; ANSI/ASME, 1985]. In addition, machine tool accuracy varies over time depending on the environment, operating history, and maintenance and hence can deteriorate significantly [Shin et al., 1991]. Therefore, it is necessary to test the accuracy of the machine tools periodically and recalibrate the axes.

Machine tool error is divided into two categories: repeatable (deterministic) and nonrepeatable (random) errors. Typical measurements of positional errors are shown in Figure 186.7. Due to backlash and friction, errors often exhibit hysteresis if the measurements are performed in both directions. Generally, accuracy is defined as the worst possible error at a particular position, and is represented in terms of a deterministic value defined as the mean deviation from the target position and the probabilistic distribution of random variation. Mathematically, positional accuracy is defined as

$$\varepsilon(x, y, z) = \max(|\mu + 3\sigma|, |\mu - 3\sigma|)$$

where μ is the mean positional accuracy and σ is the variance of the random part. The nonrepeatable portion is used to specify the repeatability. Typically, three sigma (variation) values are used to determine the repeatability.

FIGURE 186.7 Presentation of errors of a machine tool axis moving in two directions.

Defining Terms

Basic length unit — Smallest resolution attainable in positioning.

Flexible automation — Automation used to produce a variety of parts without converting the hardware setup.

Waldemar Karwowski
University of Louisville

According to the International Ergonomics Association (IEA, 2000), ergonomics (or human factors) is the scientific discipline concerned with the understanding of interactions among humans and other elements of a system, and the profession that applies theory, principles, data, and methods to design in order to optimize human well-being and overall system performance. Ergonomists contribute to the design and evaluation of tasks, jobs, products, environments and systems in order to make them compatible with the needs, abilities, and limitations of people.

Ergonomics discipline promotes a holistic approach to work systems design and management that considers the physical, cognitive, social, organizational, environmental, and other relevant factors (Karwowski and Marras, 1999; Karwowski, 2001). *Physical ergonomics* is concerned with human anatomical, anthropometric, physiological, and biomechanical characteristics as they relate to physical activity. *Cognitive ergonomics* is concerned with mental processes, such as perception, memory, reasoning, and motor response, as they affect interactions among humans and other elements of a system. *Organizational ergonomics* (also known as macroergonomics) is concerned with the optimization of sociotechnical systems, including their organizational structures, policies, and processes. Relevant topics include communication, crew resource management, work design, design of working times, teamwork, participatory design, community ergonomics, cooperative work, new work paradigms, virtual organizations, telework, and quality management.

187.1 Origins of Ergonomics Discipline

The science of ergonomics originated in 1857 when Wojciech Jastrzebowski of Poland defined the term by combining two Greek words: *ergon* (work) + *nomos* (laws). This new science signified then the human work, play, thinking, and devotion as reflected in the manner of optimizing the use of four distinct human characteristics: motor (physical), sensory (aesthetic), mental (intellectual), and spiritual or moral (Karwowski, 1991). The term ergonomic was independently reinvented by K. E. H. Murrell in 1949. The contemporary *human factors* discipline the parallel term for this new scientific discipline adopted in the United States, discovers and applies information about human behavior, abilities, limitations, and other characteristics to the design of tools, machines, systems, tasks, jobs, and environments for productive, safe, comfortable, and effective human use (Sanders and McCormick, 1993). In this context, ergonomics deals with a broad scope of problems relevant to the design and evaluation of work systems, consumer products, and working environments, whereas human–machine interactions affect human performance and product usability. The wide scope of issues addressed by ergonomics is presented in [Table 187.1](#).

Human factors design and engineering aims to optimize the design and functioning of human–machine systems with respect to complex characteristics of people and the relationships between system users, machines, and outside environments. According to the Board of Certification in Professional Ergonomics (BCPE), a practitioner of ergonomics is a person who (1) has a mastery of a body of ergonomics knowledge, (2) has a command of the methodologies used by ergonomists in applying that knowledge to the design of a product, system, job, or environment, and (3) has applied his or her knowledge to the analysis, design testing, and evaluation of products, systems, and environments. The areas of current practice in the field can be best described by examining the focus of technical groups of the Human Factors and Ergonomics Society (2003), as illustrated in [Table 187.2](#).

187.2 Concept of Human–Machine Systems

A human–machine system can be broadly defined as an organization of people and the machines they operate and maintain in order to perform assigned jobs that implement the purpose for which the system was developed (Meister, 1987). The human functioning in such a system is described in terms of perception, information processing, decision making, memory, attention, feedback, and human response processes. Furthermore, the human work taxonomy can be used to describe five distinct levels of human functioning, ranging from primarily physical tasks to cognitive tasks (Karwowski and Rodrick, 2001). These basic, but universal, human activities are (1) tasks that produce force (primarily muscular work); (2) tasks of continuously coordinating sensory-monitor functions (e.g., assembling or tracking tasks); (3) tasks of converting information into motor actions (e.g., inspection tasks); (4) tasks of converting information into output information (e.g., required control tasks); and (5) tasks of producing information (primarily creative work). Any task in a human–machine system requires processing of information that is gathered based on perceived and interpreted relationships between system elements. The processed information may need to be stored by either a human or a machine for later use.

One of the important concepts in the design of human–machine systems is the stimulus–response compatibility paradigm (Wickens and Carswell, 1997). This paradigm relates to the physical relationship (compatibility) between a set of stimuli and a set of responses as this relationship affects the speed of human response. The spatial relations between arrangements of signals and response devices in human–machine systems with respect to direction of movement and adjustments are often ambiguous, with a high degree of uncertainty regarding the effects of intended control actions. It should be noted that the information displayed to the human operator can be arranged along a continuum that defines the degree to which that information is spatial-analog (i.e., information about relative locations, transformations, or continuous motion); or linguistic-symbolic/verbal (i.e., a set of instructions, alphanumeric codes, directions, or logical operations). The scope of ergonomics factors that need to be considered in design, testing, and evaluation of any human–machine system is shown in [Table 187.3](#) in the form of an exemplary ergonomic checklist.

187.3 Human–System Design: Compatibility Requirements

Ergonomics advocates systematic use of the knowledge concerning relevant human characteristics in order to achieve compatibility in the design of interactive systems of people, machines, environments, and devices of all kinds to ensure specific goals (HFES, 2003). Typically, such goals are improved (system) effectiveness, safety, ease of performance, and contribution to overall human well-being. Although a key to the above definition of HFES is “compatibility,” this term has been typically used in the past in relation to design of displays and controls, such as the classical spatial (location) compatibility, or the intention-response-stimulus compatibility related to movement of controls (Wickens and Carswell, 1997).

The use of compatibility in a greater context of ergonomics systems has been advocated by my colleagues and I (Karwowski et al., 1988; Karwowski, 1991). Recently, I introduced the term “human-compatible systems” (Karwowski, 1997) in order to focus on the need for comprehensive treatment of compatibility in the ergonomics discipline. The 1978 edition of the *American Heritage Dictionary* defines “compatible” as follows: “1. capable of living or performing in harmonious, agreeable, or congenial combination with another or others; and 2. capable of orderly, efficient integration and operation with other elements in a system.” Probing further, the word “congenial” is defined as suited to one’s needs, agreeable, while the “harmony” (from Greek *harmos*, meaning joint) is defined as “1. agreement in feeling, approach, action disposition, or the like, sympathy, accord; and 2. the pleasing interaction or appropriate combination of elements in a whole.”

Symvatology: The Science of Artifact–Human Compatibility

An *artifact system* is a set of all artifacts (meaning objects made by human work) as well as natural elements of the environment), and their interactions occurring in time and space afforded to us by nature. Due to its interactions, the artifact system is often a dynamic system with a high level of complexity that can exhibit a nonlinear behavior. A human system can be defined as the human (or humans) with all the characteristics (physical, perceptual, cognitive, emotional, etc.) that are relevant to an interaction with the artifact system. The notation of artifact–human system compatibility expresses the premise that it is the artifact system that should be compatible with the human system, and that such compatibility should primarily be ensured by design of the artifact system.

The science of the artifact–human (system) compatibility or “symvatology” (Karwowski, 2000) was proposed as the corroborative discipline to ergonomics in order to build solid foundations for the science

TABLE 187.2 Subject Interests of Technical Groups of Human Factors and Ergonomics Society

| Technical Group | Description/Areas of Concern |
|--|--|
| I. Aerospace systems | Applications of human factors to the development, design, operation, and maintenance of human-machine systems in aviation and space environments (both civilian and military). |
| II. Aging | Human factors applications appropriate to meeting the emerging needs of older people and special populations in a wide variety of life settings. |
| III. Communications | All aspects of human-to-human communication, with an emphasis on communication mediated by telecommunications technology, including multimedia and collaborative communications, information services, and interactive broadband applications. Design and evaluation of both enabling technologies and infrastructure technologies in education, medicine, business productivity, and personal quality of life. |
| IV. Computer systems | Human factors aspects of (1) interactive computer systems, especially user interface design issues; (2) the data-processing environment, including personnel selection, training, and procedures; and (3) software development. |
| V. Consumer products | Development of consumer products that are useful, usable, safe, and desirable. Application of the principles and methods of human factors, consumer research, and industrial design to ensure market success. |
| VI. Educators' professional | Education and training of human factors and ergonomics specialists in academia, industry, and government. Focus on both degree-oriented and continuing education needs of those seeking to increase their knowledge and/or skills in this area, accreditation of graduate human factors programs, and professional certification. |
| VII. Environmental design | Human factors aspects of the constructed physical environment, including architectural and interior design aspects of home, office, and industrial settings. Promotion of the use of human factors principles in environmental design. |
| VIII. Forensics professional | Application of human factors knowledge and technique to standards of care and accountability established within legislative, regulatory, and judicial systems. The emphasis on providing a scientific basis to issues being interpreted by legal theory. |
| IX. Industrial ergonomics | Application of ergonomics data and principles for improving safety, productivity, and quality of work in industry. Concentration on service and manufacturing process, operations, and environments. |
| X. Medical systems and functionally impaired populations | All aspects of the application of human factors principles and techniques toward the improvement of medical systems, medical devices, and the quality of life for functionally impaired user populations. |
| XI. Organizational design | Improving productivity and the quality of life by an integration of psychosocial, cultural, and technological factors and with user interface factors (performance, acceptance, needs, limitations) in design of jobs, workstations, and related management systems. |
| XII. Personality and individual differences in human performance | The range of personality and individual difference variables that are believed to mediate performance. |
| XIII. Safety | Research and applications concerning human factors in safety and injury control in all settings and attendant populations, including transportation, industry, military, office, public building, recreation, and home improvements. |
| XIV. System development | Concerned with research and exchange of information for integrating human factors into the development of systems. Integration of human factors activities into system development processes in order to provide systems that meet user requirements. |
| XV. Test and evaluation | A forum for test and evaluation practitioners and developers from all areas of human factors and ergonomics. Concerned with methodologies and techniques that have been developed in their respective areas. |
| XVI. Training | Fosters information and interchange among people interested in the fields of training and training research. |
| XVII. Visual performance | The relationship between vision and human performance, including (1) the nature, contents, and quantification of visual information and the context in which it is displayed; (2) the physics and psychophysics of information display; (3) perceptual and cognitive representation and interpretation of displayed information; (4) assessment of workload using visual tasks; and (5) actions and behaviors that are consequences of visually displayed information. |

TABLE 187.3 Examples of Factors to be Used in Ergonomics Checklists

I. Anthropometric, biochemical, and physiological factors

1. Are the differences in human body size accounted for by the design?
2. Have the right anthropometric tables been used for specific populations?
3. Are the body joints close to neutral positions?
4. Is the manual work performed close to the body?
5. Are there any forward-bending or twisted trunk postures involved?
6. Are sudden movements and force exertion present?
7. Is there a variation in worker postures and movements?
8. Is the duration of any continuous muscular effort limited?
9. Are the breaks of sufficient length and spread over the duration of the task?
10. Is the energy consumption for each manual task limited?

II. Factors related to posture (sitting and standing)

1. Is sitting/standing alternated with standing/sitting and walking?
2. Is the work height dependent on the task?
3. Is the height of the work table adjustable?
4. Are the height of the seat and backrest of the chair adjustable?
5. Is the number of chair adjustment possibilities limited?
6. Have good seating instructions been provided?
7. Is a footrest used where the work height is fixed?
8. Has the work above shoulder or with hands behind the body been avoided?
9. Are excessive reaches avoided?
10. Is there enough room for the legs and feet?
11. Is there a sloping work surface for reading tasks?
12. Have the combined sit-stand workplaces been introduced?
13. Are handles of tools bent to allow for working with the straight wrists?

III. Factors related to manual materials handling (lifting, carrying, pushing, and pulling loads)

1. Have tasks involving manual displacement of loads been limited?
2. Have optimum lifting conditions been achieved?
3. Is anybody required to lift more than 23 kg?
4. Have lifting tasks been assessed using the National Institute for Occupational Safety and Health (1991) method?
5. Are handgrips fitted to the loads to be lifted?
6. Is more than one person involved in lifting or carrying tasks?
7. Are there mechanical aids for lifting or carrying available and used?
8. Is the weight of the load carried limited according to the recognized guidelines?
9. Is the load held as close to the body as possible?
10. Are pulling and pushing forces limited?
11. Are trolleys fitted with appropriate handles and handgrips?

IV. Factors related to the design of tasks and jobs

1. Does the job consist of more than one task?
2. Has a decision been made about allocating tasks between people and machines?
3. Do workers performing the tasks contribute to problem solving?
4. Are the difficult and easy tasks performed interchangeably?
5. Can workers decide independently on how the tasks are carried out?
6. Are there sufficient possibilities for communication between workers?
7. Is sufficient information provided to control the assigned tasks?
8. Can the group take part in management decisions?
9. Are the shift workers given enough opportunities to recover?

V. Factors related to information and control tasks

Information

1. Has an appropriate method of displaying information been selected?
2. Is the information presentation as simple as possible?
3. Has the potential confusion between characters been avoided?
4. Has the correct character/letter size been chosen?
5. Have tests with capital letters only been avoided?
6. Have familiar typefaces been chosen?
7. Is the text/background contrast good?
8. Are the diagrams easy to understand?
9. Have the pictograms been properly used?
10. Are sound signals reserved for warning purposes?

TABLE 187.3 Examples of Factors to be Used in Ergonomics Checklists (*Continued*)

Controls

1. Is the sense of touch used for feedback from controls?
2. Are differences between controls distinguishable by touch?
3. Is the location of controls consistent and is sufficient spacing provided?
4. Have the requirements for the control–display compatibility been considered?
5. Is the type of cursor control suitable for the intended task?
6. Is the direction of control movements consistent with human expectations?
7. Are the control objectives clear from the position of the controls?
8. Are controls within easy reach of female workers?
9. Are labels or symbols identifying controls properly used?
10. Is the use of color in controls design limited?

Human–computer interaction

1. Is the human–computer dialog suitable for the intended task?
2. Is the dialog self-descriptive and easy to control by the user?
3. Does the dialog conform to the expectations on the part of the user?
4. Is the dialog error-tolerant and suitable for user learning?
5. Has command language been restricted to experienced users?
6. Have detailed menus been used for users with little knowledge and experience?
7. Is the type of help menu fitted to the level of user's ability?
8. Has the QWERTY layout been selected for the keyboard?
9. Has logical layout been chosen for the numerical keypad?
10. Is the number of function keys limited?
11. Have the limitations of speech in human–computer dialogue been considered?
12. Are touch screens used to facilitate operation by inexperienced users?

VI. Environmental factors

Noise and vibration

1. Is the noise level at work below 80 dBA?
2. Is there an adequate separation between workers and source of noise?
3. Is the ceiling used for noise absorption?
4. Are the acoustic screens used?
5. Are hearing conservation measures fitted to the user?
6. Is personal monitoring to noise/vibration used?
7. Are the sources of uncomfortable and damaging body vibration recognized?
8. Is the vibration problem being solved at the source?
9. Are machines regularly maintained?
10. Is the transmission of vibration prevented?

Illumination

1. Is the light intensity for normal activities in the range of 200 to 800 lux?
2. Are large brightness differences in the visual field avoided?
3. Are the brightness differences between task area, close surroundings, and wider surroundings limited?
4. Is the information easily legible?
5. Is ambient lighting combined with localized lighting?
6. Are light sources properly screened?
7. Can the light reflections, shadow, or flicker from the fluorescent tubes be prevented?

Climate

1. Are workers able to control the climate themselves?
2. Is the air temperature suited to the physical demands of the task?
3. Is the air prevented from becoming either too dry or too humid?
4. Are draughts prevented?
5. Are the materials/surfaces that have to be touched neither too cold nor too hot?
6. Are the physical demands of the task adjusted to the external climate?
7. Are undesirable hot and cold radiation prevented?
8. Is the time spent in hot or cold environments limited?
9. Is special clothing used when spending long periods in hot or cold environments?

Chemical substances

1. Is the concentration of recognized hazardous chemical substances in the air subject to continuous monitoring and limitation?
2. Is the exposure to carcinogenic substances avoided or limited?
3. Does the labeling on packages of chemicals provide information on the nature of any hazard due to their contents?

TABLE 187.3 Examples of Factors to be Used in Ergonomics Checklists (*Continued*)

-
4. Can the source of chemical hazards be removed, isolated, or their releases from the source reduced?
 5. Are there adequate exhaust and ventilation systems in use?
 6. Are protective equipment and clothing (including gas and dust masks for emergencies and gloves) available at any time if necessary?
-

Based on Dul, J. and Weerdmeester, B., 1993, *Ergonomics for Beginners: A Quick Reference Guide*, Taylor & Francis, London.

of ergonomics. To optimize both human and system well-being and their performance, the system–human compatibility should be considered at all levels, including the physical, perceptual, cognitive, emotional, social, organizational, environmental, and other relevant system characteristics. This requires a way to measure the inputs and outputs that characterize the set of system–human interactions (Karwowski, 1991), and the ability to identify, evaluate, and measure the artifact–human compatibility.

The Complexity-Incompatibility Principle

As discussed by Karwowski et al. (1988), the lack of compatibility (ergonomics incompatibility), defined as degradation (disintegration) of the artifact–human system, is reflected in the system’s measurable inefficiency and/or losses in human and system performance. In order to express the innate relationships between the system’s complexity and compatibility, Karwowski, Marek, and Noworol (1988, 1994) proposed the complexity-incompatibility principle, which can be stated as follows: “As the (artifact–human) system complexity increases, the incompatibility between the system elements, as expressed through their interactions at all system levels, also increases, leading to greater ergonomic (non-reducible) entropy of the system, and decreasing the potential for effective ergonomic intervention.”

The above principle was illustrated by Karwowski (1995), using as an example of design of the chair and the design of a computer display, two common problems in the area of human–computer interaction. In addition, Karwowski (1992) also discussed the complexity-compatibility paradigm in the context of organizational design. It should be noted here that the above principle reflects the natural phenomena that others in the field have described in terms of difficulties encountered in humans interacting with consumer products and technology in general. For example, according to Norman (1993), the paradox of technology is that functionality added to an artifact typically comes with the trade-off of increased complexity. These added complexities often lead to increased human difficulty and frustration when interacting with these artifacts. One of the possible reasons for the above is that a technology that has more features also has less feedback. Moreover, Norman argued that the added complexity cannot be avoided when functions are added, and can only be minimized with good design that follows natural mapping between the system elements (i.e., the control–display compatibility).

187.4 Human–Computer Interaction

HCI definition

The subfield of human–computer interaction (HCI) focuses on creating usable computer systems (Karwowski, Rizzo, and Rodrick, 2002). The Curriculum Development Group of the Association for Computer Machinery (ACM) Special Interest Group on Computer–Human Interaction (SIGCHI) defines HCI as a discipline concerned with the design, evaluation, and implementation of interactive computing systems for human use, and with the study of major phenomena surrounding them (Hewett et al., 1992). According to Dix et al. (1993), the “human–computer interaction (or HCI) is the study of the people, computer technology, and the way these influence each other.” We study HCI to determine how we can make this computer technology usable by people. Both definitions stress two main dimensions of HCI. The first one points out that in order to build usable and human-centered technologies, it is necessary to study the users, roles, needs, previous experiences, and the real context of use. The second one considers

HCI to be the discipline that focuses on human cognition and behavior, and applies relevant knowledge to the development of diverse cognitive artifacts.

User-Centered Design Paradigm

The main principles for the user-centered design approach in HCI formulated by Gould and Lewis (1983) follow:

- Understanding users. It is important to have an explicit representation about users' cognitive competences and attitudes and an explicit representation of the cognitive nature of the work that people have to perform.
- Interaction design. A consistent sample of the end users must be engaged in working with the design team.
- Evaluation. Since the beginning of the design process, the system has to be evaluated. It is important to evaluate together the human and machine components of the human-machine system (user evaluation).
- Iterative design. Design-evaluation-redesign until system performance attains the usability goal established for the system.

User involvement in system development can lead to better-designed products from the perspective of customers (Nielsen, 2000). Designers should work in conjunction with users, enrolling the users early in the developing process, when their contributions to the system design are thought to be fundamental. User involvement is often critical to ensure sufficient information about initial system requirements; assess whether the product meets end user requirements and needs, and to gather data for the next version of the design. The evaluation phase is fundamental in order to measure whether user requirements are being satisfied. The main evaluation methods suggested by the HCI field are cognitive walkthrough, usability tasting, and heuristic evaluation (Helander et al., 1997).

User interface adaptation has gained considerable recognition in recent years to ensure quality of use of interactive computer systems with respect to end-user abilities, requirements, preferences, and interests. Interactive computer systems can be classified into adaptable and adaptive systems (Akoumianakis and Stephanidis, 1997). A system is called adaptable if it provides tools that make it possible for the end user to change the system's characteristics (Opperman, 1994).

Usability Engineering

Usability engineering (Nielsen, 2000), a set of activities that take place throughout the life cycle of the product, focuses on the multidimensional properties of a user interface. The following five attributes constitute the concept of usability (Nielsen, 1997):

- Learnability
- Efficiency
- Memorability
- Errors]
- Satisfaction (Nielsen, 1997)

The usability engineering process (Good et al., 1986) includes the following basic steps:

1. Definition of measurable usability attributes.
2. Setting of the quantitative levels of desired usability for each attribute. Together, an attribute and a desired level constitute a usability goal.
3. Testing the product against the usability goals. If the goals are met, no further design is needed.
4. If further design work is needed, analysis of the problems that emerge.
5. Analysis of the impact of possible design solutions.

6. Incorporation of user-derived feedback in product design.
7. Return to Step 3 to repeat the test, analysis, and design cycle.

187.5 Ergonomics in Industry

The knowledge and expertise offered by ergonomics as applied to industrial environments can be used to provide engineering guidelines regarding redesign of tools, machines, and work layouts; evaluate the demands placed on the workers by current jobs; simulate alternative work methods and determine potential for reducing physical job demands if new methods are implemented; and provide a basis for employee selection and placement procedures. The basic foundations for ergonomics design are based on two components of industrial ergonomics: engineering anthropometry and biomechanics. Occupational biomechanics can be defined as the application of mechanics to the study of the human body in motion or at rest (Chaffin and Anderson, 1993). Occupational biomechanics provides the criteria for application of anthropometric data to the problems of workplace design.

Engineering anthropometry is an empirical science branching from physical anthropology that (1) deals with physical measurements for the human body (such as body size, form or shape, and body composition), including, for example, the location and distribution of center of mass, weights, body links, or range of joint motions; and (2) applies these measures to develop specific engineering design requirements. The recommendations for workplace design with respect to anthropometric criteria can be established by the principle of design for the extreme, also known as the method of limits (Pheasant, 1986). The basic idea behind this concept is to establish specific boundary conditions (percentile value of the relevant human characteristic), which, if satisfied, will also accommodate the rest of the expected user population. The main anthropometric criteria for workplace design are clearance, reach, and posture. Typically, clearance problems involve the design of space needed for the legs or safe passageways around and between equipment. If the clearance problems are disregarded, they may lead to poor working postures and hazardous work layouts. Consideration of clearance requires designing for the largest user, typically by adapting the 95th percentile values of the relevant characteristics for male workers. Typical reach problems in industry include consideration of the location of controls and accessibility of control panels in the workplace. The procedure for solving the reach problems is usually based upon the fifth percentile value of the relevant characteristic for female workers (smaller members of the population). When anthropometric requirements of the workplace are not met, biomechanical stresses that manifest themselves in postural discomfort, lower-back pain, and overexertion injury are likely to occur.

187.6 The Role of Ergonomics in Prevention of Occupational Musculoskeletal Injury

Lack of attention to ergonomic design principles at work and its consequences have been linked to occupational musculoskeletal injuries and disorders. Work-related musculoskeletal disorders (WRMDs), such as upper-extremity cumulative trauma and lower-back disorders (LBDs), affect several million workers each year, with total costs exceeding \$100 billion annually. For example, the upper-extremity cumulative trauma disorders account today for about 11% of all occupational injuries reported in the United States and has resulted in a prevalence of work-related disability in a wide range of occupations.

Work-related musculoskeletal disorders can be linked to several factors, including increased production rates leading to thousands of repetitive movements every day, widespread use of computer keyboards, higher percentage of women and older workers in the workforce, and better record keeping of employers due to better reporting requirements by the Occupational Safety and Health Administration (OSHA). Other factors include greater employee awareness of these disorders and their relation to working conditions, as well as a marked shift in the social policy regarding recognition of compensation for work-related disorders. Given the significance of the reported WRMDs, the federal government increases its efforts to reduce the frequency and severity of these disorders. For more information about these efforts,

see Waters et al. (1993); for NIOSH guidelines for manual lifting, see <http://www.cdc.gov/niosh/94-110.html>.

The current state of knowledge indicates that chronic muscle, tendon, and nerve disorders may have multiple work-related and non-work-related causes. Therefore, WRMDs are not classified as occupational diseases but rather as work-related disorders, where a number of factors may contribute significantly to the disorder, including work environment and human performance at work. Frequently cited risk factors of WRMDs are listed below (Karwowski and Rodrick, 2001):

- Repetitive exertions
- Posture
 - Shoulder (elbow above mid-torso reaching down and behind)
 - Forearm (inward or outward rotation with a bent wrist)
 - Wrist (palmar flexion or full extensions)
 - Hand (pinching)
- Mechanical stress concentrations over the base of palm, on the palmar surface of the fingers, and on the sides of the fingers
- Vibration
- Cold
- Use of gloves

A risk factor is defined as an attribute or exposure that increases the probability of disease or disorder. Work-related musculoskeletal disorders at work are typically associated with repetitive manual tasks that impose repeated stresses to the upper body, that is, the muscles, tendons, ligaments, nerves, tissues, and neurovascular structures. For example, the three main types of disorders to the arm are tendon disorders (e.g., tendonitis); nerve disorders (e.g., carpal tunnel syndrome); and neurovascular disorders (e.g., thoracic outlet syndrome or vibration, Raynaud's syndrome).

From the occupational safety and health perspective, the current state of ergonomics knowledge allows for management of WRMDs in order to minimize human suffering, potential for disability, and related worker's compensation costs. Ergonomics can help to identify working conditions under which WRMDs might occur, develop engineering design measures aimed at elimination or reduction of the known job risk factors, and identify the affected worker population and target it for early medical and work intervention efforts. The ergonomic intervention should allow management to perform a thorough job analysis to determine the nature of specific problems; evaluate and select the most appropriate intervention(s); develop and apply conservative treatment (implement the intervention); on a limited scale if possible; monitor progress; and adjust or refine the intervention as needed.

Most of the current guidelines for control of the WRMDs at work aim to (1) reduce the extent of movements at the joints, (2) reduce excessive force levels, and (3) reduce exposure to highly repetitive and stereotyped movements (Putz-Anderson, 1988). Workplace design to prevent the onset of WRMDs should be directed toward fulfilling the following recommendations:

- Permit several different working postures.
- Place controls, tools, and materials between waist and shoulder heights for ease of reach and operation.
- Use jigs and fixtures for holding purposes.
- Re-sequence jobs to reduce the repetition.
- Automate highly repetitive operations.
- Allow self-pacing of work whenever feasible.
- Allow frequent (voluntary and mandatory) rest breaks.

For example, some of the common methods to control the wrist posture are (1) altering the geometry of tool or controls (e.g., bending the tool or handle), (2) changing the location or positioning of the part, or (3) changing the position of the worker in relation to the work object. In order to control the extent

of force required to perform a task, one can (1) reduce the force required through tool and fixture redesign, (2) distribute the application of the force, or (3) increase the mechanical advantage of the (muscle) lever system.

187.7 Fitting the Work Environment to Workers

Ergonomics job redesign focuses on fitting jobs and tasks to workers' capabilities of workers — for example, designing out unnatural postures at work, reducing excessive strength requirements, improving work layout, introducing appropriate designs of hand tools, and addressing the problem of work rest requirements. As widely recognized, ergonomics must be seen as a vital component of the value-adding activities of the company. Even in strictly financial terms, the costs of an ergonomics management program will be far outweighed by the costs of not having one. A company must be prepared to accept a participative culture and to utilize participative techniques. Ergonomics-related problems and consequent intervention should go beyond engineering solutions and must include design for manufacturability, total quality management, and work organization alongside workplace redesign or worker training.

An important component of the management efforts to control musculoskeletal disorders in industry is the development of a well-structured and comprehensive ergonomics program. The basic components of such a program should include the following: (1) health and risk factor surveillance, (2) job analysis and improvement, (3) medical management, (4) training, and (5) program evaluation. Such a program must include participation of all levels of management; medical, safety, and health personnel; labor unions; engineering; facility planners; and workers.

The expected benefits of ergonomically designed jobs, equipment, products, and workplaces include the improved quality and productivity with error reduction, enhanced safety and health performance, heightened employee morale, and accommodation of people with disabilities to meet recommendations of the Americans with Disabilities Act and Affirmative Action programs. However, the recommendations offered by ergonomics can be successfully implemented in practice only with full understanding of the production processes, plant layouts, quality requirements, and total commitment from all management levels and workers in the company. Furthermore, these efforts can only be effective through participatory cooperation between management and labor through development of in-plant ergonomics committees and programs. Ergonomics must be treated at the same level of attention and significance as other business functions of the plant — for example, the quality management — and should be accepted as a cost of doing business, rather than an add-on activity calling for action only when the problems arise.

187.8 Human and Safety Aspects of Advanced Technologies

Advances in the global economy induce a need to implement adaptive organizational structures and utilize people-oriented, rather than technology-centered, approaches to the design and operation of advanced, information-based manufacturing systems. Information-based companies often apply organizational structures and procedures that enhance communication and cooperation between departments in order to increase market competitiveness, and ensure safe and comfortable working environments. Such structures should enable people to do what they can do best through an improvement of their technical qualifications, decision-making abilities, and utilization of advanced tools for information and knowledge processing, and feedback systems (Karwowski and Marras, 1999). Application of the science of ergonomics facilitates reaching these objectives.

System Integration Paradigm

The contemporary manufacturing paradigm stipulates the systems approach to integration of technology, people, and organization (Karwowski, Salvendy, Badham et al., 1994). Appropriate technology needs to be implemented with due consideration of requirements for selection and training of human resources, allocation of decision making, and control over technology by the people charged with its use. Organi-

zational structures allowing persons to manage available resources and adapt quickly to a changing marketplace also are needed. While many different concepts were developed in the recent past to realize this new manufacturing paradigm, they all attempt to capture critical requirements of the global economy and changing market conditions (i.e., cost, quality, flexibility, and time). Among others, these concepts include lean manufacturing, concurrent engineering, and agile manufacturing, as the more recent manufacturing philosophy and business approach.

The term *agile manufacturing* was first introduced with the publication of the *21st Century Manufacturing Enterprise Strategy* by the Iacocca Institute (1991), which argued that a new competitive environment is emerging, which is acting as a driving force for change in manufacturing, and that competitive advantage will accrue to those enterprises that develop the capability to rapidly respond to the demand for high-quality, highly customized products. In order to achieve the agility required to respond to these driving forces and to develop the required capability, it is necessary to integrate flexible technologies with a highly skilled, knowledgeable, motivated, and empowered workforce. This must be done within organization and management structures that stimulate cooperation both within and between firms.

According to the Iacocca Institute (1991), the agile manufacturing enterprise exhibits the following characteristics:

- Concurrency in all activities
- Continuing education for all employees
- Customer responsiveness
- Dynamic multiventuring capabilities
- Employees valued as intellectual assets
- Empowered individuals working in teams
- Environmental concern and proactive approach
- Accessible and usable knowledge
- Skilled and knowledgeable employees
- Open system architectures
- Right-first-time designs
- Total quality philosophy
- Short cycle times
- Technology awareness and leadership
- Enterprise integration
- Vision-based management.

Agile manufacturing can be viewed as the business concept that brings together many ideas in order to develop an appropriate response to global market opportunities. The agility comes from integration of organization, people and information-based technology into a coordinated and interdependent (often virtual) system.

Management Integration Framework for Quality, Ergonomics, and Occupational Safety Issues

Advanced technologies constitute complex systems that require a high level of integration from both the *design and management* perspectives. *Design integration* focuses on the interactions between hardware (computer-based technology), organization (organizational structure), information system, and people (human skills, training, and expertise). *Management integration* refers to the interactions between various system elements across the process and product quality, workplace and work system design, occupational safety and health programs, and corporate environmental protection polices. All design (integration) factors describing these subsystems must be considered at all levels of management system integration, that is, quality, occupational safety and health, and ergonomics. As illustrated in [Table 187.4](#), system integration is the complex function of design subsystems (design factors) and management subsystems (management factors). The above framework can be expressed as follows:

TABLE 187.4 Framework for Integration of Design and Management Subsystems

| System Integration Design Subsystems | Management (Integration) Subsystems | | | |
|---|-------------------------------------|------------|--------------------------|---------|
| | Safety and Health | Ergonomics | Environmental Protection | Quality |
| Organization | | | | |
| Technology | | | | |
| Information Systems | | | | |
| People | | | | |

$$\text{SYSTEM INTEGRATION} = f(\text{DESIGN INTEGRATION}, \text{MANAGEMENT INTEGRATION})$$

Many elements of quality, ergonomics, and safety and health issues directly or indirectly influence the integration efforts and the related corporate strategy with respect to planning for integration (Dzissah et al., 2001). In general, system performance can be improved by minimizing process deficiencies, accidents, environmental pollution, and increasing general well-being of all employees. For example, working conditions influence product quality, while productivity improvement is dependent on quality, macroergonomic and safety (occupational and health, natural environmental) management activities.

As discussed by Karwowski et al. (2002), due to inherent interrelationships between product quality defects, workplace design defects, and operational defects, both conceptual and operational models for the management system that integrates quality, ergonomics, and occupational safety and health are needed. The concepts of quality, ergonomics, and a broadly defined safety area reveal several interacting dimensions that need to be considered by the integration methods. The multidimensionality of factors involved in the integration calls for a methodology that is capable of establishing relationships between different dimensions to identify various directions for simultaneous system improvement.

Defining Terms

Ergonomics (or human factors) — The scientific discipline concerned with the understanding of interactions among humans and other elements of a system, and the profession that applies theory, principles, data, and methods to design in order to optimize human well-being and overall system performance. Ergonomists contribute to the design and evaluation of tasks, jobs, products, environments, and systems in order to make them compatible with the needs, abilities and limitations of people (International Ergonomics Association 2000; www.iea.cc).

Work-related musculoskeletal disorders (WRMDs) — These disorders are typically associated with repetitive manual tasks with forceful exertions, performed with fixed body postures that deviate from neutral, such as those at assembly lines and those using hand tools, computer keyboards, mice, and other devices. These tasks impose repeated stresses to the soft tissues of the arm, shoulder, and back, including the muscles, tendons, ligament, nerve tissues, and neurovascular structures, which may lead to tendon and/or joint inflammation, discomfort, pain, and potential work disability.

Occupational biomechanics — The application of mechanics to the study of the human body in motion or at rest, focusing on the physical interaction of workers with their tools, machines, and materials in order to optimize human performance and minimize the risk of musculoskeletal disorders.

Engineering anthropometry — An empirical science branching from physical anthropology that deals with physical measurements for the human body, such as body size, form (shape), and body composition, and application of such measures to the design problems.

188.1 Pressure

Pressure (P) can be defined as a force (F) acting on a given area (A); $P = F/A$. It is measured using metric (SI) units, pascals (Pa), or English units, pounds per square inch (psi). Pressure can also be indicated in absolute (abs) or gage (g) (as measured with a gage) units. Relationships between metric and English units of measure are as follows:

- 100 kPa = 1 bar = 14.7 psia \approx 1 atmosphere (atm).
- 100 kPa gage (or 100 kPa) = 14.7 psig (or 14.7 psi).
- 1 MPa abs = 147 psia.
- 1 MPa gage (or 1 MPa) = 147 psig (or 147 psi).

These units can be used when measuring seven kinds of pressure:

- *Absolute pressure*: sum of atmospheric and gage pressures.
 - *Atmospheric pressure*: ambient pressure at local elevations. The atmospheric pressure at sea level is approximately 100 kPa or 14.7 psia.
 - *Burst pressure*: theoretical or actual pressure at which a vessel/component will fail.
 - *Gage pressure*: pressure above atmospheric pressure as measured by a gage.
 - *Maximum allowable working pressure (MAWP)*: maximum pressure at which component is safe to operate. MAWP is the maximum permissible setting for relief devices. Service, rated, design, and working pressure (WP) are the same as MAWP.
 - *Maximum operating pressure (MOP)*: maximum pressure for continuous operation. MOP should be 10 to 20% below MAWP.
 - *Pressure test*: a test to ensure that a vessel or system will not fail or permanently deform and will operate reliably at a specified pressure.
-

TABLE 188.1 Comparison of Temperature Scales^{a,b}

| Criterion | Fahrenheit (°F) | Rankine abs (R) | Celsius or | |
|---------------|-----------------|-----------------|-----------------|----------------|
| | | | Centigrade (°C) | Kelvin abs (K) |
| Water boils | 212 | 672 | 100.0 | 373.0 |
| Water freezes | 32 | 492 | 0.0 | 273.0 |
| Zero °F | 0 | 460 | -17.7 | 255.3 |
| Absolute zero | -460 | 0 | -273.0 | 0.0 |

^a Conversion factors: °F = $\frac{9}{5}$ °C + 32; °C = $\frac{5}{9}$ (°F - 32); R = °F + 460; K = °C + 273.

^b Use absolute temperatures, either Rankine or Kelvin, in all calculations involving the ideal gas law, except when temperature is constant.

Source: This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under contract N. W-7405-Eng-48.

Temperature

Temperature (T) is the intensity of heat in a substance and may be measured on the graduated scale of a thermometer. It is usually measured in degrees Fahrenheit (°F) or degrees Celsius (°C). The two absolute scales are Rankine (R) and Kelvin (K) (see Table 188.1).

Volume

Volume (V) refers to a space occupied in three dimensions. It is generally measured in cubic meters (m³), cubic centimeters (cm³), cubic inches (in.³), or cubic feet (ft³). Volume may also be measured in units of liters (L) or gallons (gal).

Basic Pressure Equations

General Gas Law

The general (or ideal) gas law is the basic equation that relates pressure, volume, and temperature of a gas. It is expressed mathematically as

$$\frac{PV}{T} = \text{constant} \quad (188.1)$$

where

- P = pressure in kilopascals absolute (kPa abs) or pounds per square inch absolute (psia).
(Add atmospheric pressure of 100 kPa or 15 psia to gage pressure.)
- V = volume in any convenient cubic unit such as liters, cubic feet, etc.
- T = temperature in absolute units of Rankine or Kelvin.

When the conditions of a gas system change, they do so according to this general gas law, at least where moderate pressures are concerned. At higher pressures ($P > 200$ atm) gases do not obey the general gas law exactly; this problem is discussed later.

The following checklist will assist in solving general gas law problems:

1. Sketch the problem and mark all conditions.
2. List initial and final values of P , V , and T . Use absolute units for P and T .
3. Write the general gas law for initial and final conditions. Cross out conditions that remain constant.
4. Substitute known values and solve for unknowns.
5. Convert your answer if it is in units different from those given in the problem.

The general gas law expressed for initial (subscript 1) and final (subscript 2) conditions is

$$\frac{P_1 V_1}{T_1} = \frac{P_2 V_2}{T_2} \quad (188.2)$$

Any one of these quantities can be solved for by simply cross-multiplying. Following is an example to show how easily the general gas law can be applied and how much can be determined about the behavior of gases.

Example

A cylinder of dry nitrogen is received from a vendor. The temperature of the nitrogen is 70°F, and the pressure within the cylinder is 2250 psig. An employee inadvertently stores the cylinder too close to a radiator so that within 8 hours the nitrogen is heated to 180°F. What is the new pressure within the cylinder?

| Initial | Final |
|--|---|
| $P_1 = 2250 \text{ psig} = 2265 \text{ psia}$ | $P_2 = (\text{find})$ |
| $V_1 = V_2 = \text{constant}$ | $V_2 = V_1 = \text{constant}$ |
| $T_1 = 70^\circ\text{F} + 460^\circ = 530 \text{ R}$ | $T_2 = 180^\circ\text{F} + 460^\circ = 640 \text{ R}$ |

$$\frac{P_1 V_1}{T_1} = \frac{P_2 V_2}{T_2} \quad \text{cross-multiplying,} \quad P_2 = \frac{P_1 T_2}{T_1} \quad (188.3)$$

$$P_2 = \frac{2265 \times 640}{530} = 2735 \text{ psia} = 2720 \text{ psig}$$

Pascal's Law

According to Pascal's law, pressure exerted on a confined fluid will act in all directions with equal force.

$$\text{Pressure} = \frac{\text{Force}}{\text{Area}} \quad \text{or} \quad \text{Force} = \text{Pressure} \times \text{Area} \quad (188.4)$$

Example

Find the force on the end of a cylinder (see Figure 188.1).

$$F = AP \quad \text{or} \quad F = 450 \text{ in.}^2 \times 90 \text{ lb/in.}^2 = 40\,500 \text{ lb of force}$$

Safety Factor

The ratio of the calculated failure pressure (or actual failure pressure if known) to the MAWP is the safety factor.

FIGURE 188.1 Example problem: force on the end of a cylinder.

$$SF = \frac{\text{Burst pressure}}{\text{MAWP}} \quad (188.5)$$

A safety factor related to a value other than the failure pressure should be so identified with an appropriate subscript, such as SF_y for a safety factor based on the yield strength, or SF_u for a safety factor based on the ultimate strength of the material.

Stored Energy in a Pressurized Systems

Gas confined under high pressure is like a hungry tiger in a cage. If it should suddenly escape in a populated area, someone would probably be injured. When a gas-pressure vessel fails, it propels jagged vessel fragments in all directions. The energy of the gas, assuming isentropic expansion, is expressed as

$$U_{\text{gas}} = \frac{P_1 V}{k-1} \left[1 - \left(\frac{P_2}{P_1} \right)^{(k-1)/k} \right] \quad (188.6)$$

where

U_{gas} = stored energy

P_1 = container pressure

P_2 = atmospheric pressure

V = volume of the pressure vessel

$k = c_p/c_v = 1.41$ for N_2 , H_2 , O_2 , and air, and 1.66 for He (see Baumeister, 1958, chapter 4)

c_p = specific heat at constant pressure

c_v = specific heat at constant volume

This expression as written will yield an energy value in joules if pressure and volume units are in megapascals (MPa) and cubic centimeters (cc), respectively.

A liquid confined under high pressure is also a potential safety hazard. However, for systems of comparable volume and pressure, the amount of stored energy in the liquid case will be considerably less than that contained in the gas because liquids are essentially noncompressible. The energy involved in the sudden failure of a liquid-filled vessel may be conservatively determined from

$$U_{\text{liq}} = \frac{1}{2} \left(\frac{P_1^2 V}{B} \right) \quad (188.7)$$

where B is the liquid bulk modulus. Some typical bulk moduli (B) are 300,000 psi for water, 225,000 psi for oil, and 630,000 psi for glycerin.

An additional and significant potential source of released energy for confined gases is chemical reactions, such as hydrogen and oxygen. For these special situations, a separate analysis addressing any potential chemical energy release should also be made (see Baumeister, 1958, chapter 4).

Basic Design Equations (Internally Pressurized Vessels)

The following equations, when properly applied, give stresses that can be expected to exist in a design — longitudinal or axial stress (s_1), circumferential or hoop stress (s_2), and radial stress (s_3) (see [Figure 188.2](#)). These stresses must be compared to those permitted for the vessel material after application of the appropriate safety factor.

Thin Cylinders

A cylinder (or any vessel) is said to be “thin” when its thickness (t) and internal radius (r_i) satisfy the following relationship:

FIGURE 188.2 Stress in thin cylinders.

FIGURE 188.3 Stress in thin spheres.

FIGURE 188.4 Stress in thick cylinders.

$$\frac{t}{r_i} \leq 0.1 \quad (188.8)$$

The following stresses exist in a thin cylinder:

$$s_1 = \frac{P}{2} \times \frac{r_i}{t}, \quad s_2 = P \times \frac{r_i}{t}, \quad s_3 = -P \quad (188.9)$$

Given $P = 800$ psig, $r_i = 5$ in., and $t = 0.25$, then $s_1 = 8000$ psi, $s_2 = 16,000$ psi, and $s_3 = 800$ psi.

Thin Spheres

The following stresses exist in a thin sphere (see Figure 188.3):

$$s_1 = s_2, \quad s_2 = \frac{P}{2} \times \frac{r_i}{t}, \quad s_3 = -P \quad (188.10)$$

Given

$$\frac{t}{r_i} = 0.05 \quad (\leq 0.1), \quad \frac{r_i}{t} = 20, \quad s_1 = s_2 \quad (188.11)$$

then $s_1 = 800/2 \times 30 = 8000$ psi and $s_3 = 800$ psi. Note that the hoop stress of a thin sphere is half the hoop stress of a corresponding thin cylinder.

Thick Cylinders (Roark)

A cylinder or sphere is “thick” when its dimensions satisfy the following relationship [Roark, 1989]:

$$\frac{t}{r_i} > 0.1 \quad (188.12)$$

The following stresses exist in a thick cylinder (see Figure 188.4):

FIGURE 188.5 Stresses in thick spheres.

$$S_1 = P \frac{r_i^2}{(r_o^2 - r_i^2)}, \quad S_2 = P \frac{r_o^2 + r_i^2}{(r_o^2 - r_i^2)} \text{ (max. inner surface),} \quad (188.13)$$

$$S_3 = -P \text{ (max. inner surface)}$$

Thick Cylinders (Lamé)

Compare Roark's equation with that of Lamé [Baumeister, 1958, chap. 5]. Use the same vessel and conditions as above, with hoop stress maximum at the inner surface.

$$S_1 = P \frac{R^2 + 1}{R^2 - 1}, \quad R = \frac{r_o}{r_i} \quad (188.14)$$

Note that the Lamé equation agrees with Roark's. Actually, it is the same equation.

Thick Spheres

Figure 188.5 shows the stress relationship in thick spheres, where $t/r_i > 0.1$.

$$s_1 \text{ (max. inner surface)} = s_2,$$

$$s_2 = \frac{P(r_o^3 + 2r_i^3)}{2E(r_o^3 - r_i^3)} \text{ where } E \text{ is the joint efficiency} \quad (188.15)$$

$$s_3 \text{ (max. inner surface)} = -P$$

188.2 The Vacuum Environment

As a practical definition, any environment in which the pressure is lower than atmospheric may be referred to as a vacuum. It is useful to express this subatmospheric pressure condition in units which reference zero pressure. Atmospheric pressure is approximately equal to 760 torr, 101 300 Pa, or 14.7 psi. Table 188.2 provides conversion factors for some basic units.

TABLE 188.2 Conversion Factors for Selected Pressure Units Used in Vacuum Technology

| | Pa | torr | atm | mbar | psi |
|------|-------------------|--------|----------------------|-------|----------------------|
| Pa | 1 | 0.0075 | $9.78 \cdot 10^{-6}$ | 0.01 | $1.45 \cdot 10^{-4}$ |
| torr | 133 | 1 | $1.32 \cdot 10^{-3}$ | 1.333 | 0.0193 |
| atm | $1.01 \cdot 10^5$ | 760 | 1 | 1013 | 14.7 |
| mbar | 100 | 0.75 | $9.87 \cdot 10^{-4}$ | 1 | 0.0145 |
| psi | 6890 | 51.71 | $6.80 \cdot 10^{-2}$ | 68.9 | 1 |

The *ideal gas law* is generally valid when pressure is below atmospheric

$$PV = nRT \quad (188.16)$$

where

- P = pressure [atm]
- V = volume [liters]
- n = amount of material [moles]
- R = gas law constant [0.082 liter-atm/K-mole]
- T = temperature [K]

The rate at which molecules strike a surface of unit area per unit time is referred to as the *impingement rate* and is given by

$$I = 3.5 \times 10^{22} \left(\frac{P}{MW \times T} \right) \quad (188.17)$$

where

- P = pressure [torr]
- MW = molecular weight [g/mole]
- T = temperature [K]

The distance, on average, that a molecule can travel without colliding with another molecule is the *mean free path* and is given by

$$\lambda = \frac{1}{\sqrt{2}\pi d_o^2 n} \quad (188.18)$$

where

- λ = mean free path [m]
- d_o = molecular diameter [m]
- n = gas density (molecules per cubic meter) [m^{-3}]

The *average velocity* of molecules in the gas phase is a function of the molecular weight of the gaseous species and the average temperature:

$$\bar{V} = 145.5 \sqrt{\frac{T}{MW}} \quad (188.19)$$

where V = average velocity [m/s].

Methods for Measuring Subatmospheric Pressures

A wide variety of gages are used in vacuum applications. Gage selection is based upon the vacuum system operating pressure range, the presence of corrosive gases, the requirement for computer interface, and unit cost.

Subatmospheric pressure gages (Table 188.3), which infer pressure (gas density) from measurement of some physical property of the rarefied gas, have the unfortunate characteristic of being gas species-sensitive. Most commercial gages are calibrated for nitrogen; calibration curves for other gas species are available. Other factors which influence the readings of pressure gages used in vacuum technology include: location of the gage on the system, cleanliness of the gage elements, orientation of the gage, and environment of the gage (temperature, stray electric, and magnetic fields). Gage readings are typically accurate to $\pm 10\%$ of the reported value.

TABLE 188.3 Subatmospheric Pressure Gages

| Type | Principle of Operation | Range [torr] |
|-----------------------|------------------------------|-----------------------|
| U tube manometer | Liquid surface displacement | 1–760 |
| Bourdon tube | Solid surface displacement | 1–760 |
| McLeod gage | Liquid surface displacement | 10^{-4} – 10^{-1} |
| Diaphragm gage | Solid surface displacement | 10^{-1} –760 |
| Capacitance manometer | Solid surface displacement | 10^{-3} –760 |
| Thermocouple gage | Thermal conductivity of gas | 10^{-3} –1 |
| Piraini gage | Thermal conductivity of gas | 10^{-3} –760 |
| Spinning rotor gage | Viscosity of gas | 10^{-7} – 10^{-2} |
| Hot cathode ion gage | Gas ionization cross section | 10^{-2} – 10^{-4} |

TABLE 188.4 Vacuum Pumps

| Type | Principle of Operation | Range [torr] |
|---------------------|---------------------------|-----------------------|
| Rotary vane | Positive gas displacement | 10^{-2} –760 |
| Rotary piston | Positive gas displacement | 10^{-2} –760 |
| Cryo-sorption | Gas capture | 10^{-3} –760 |
| Oil vapor diffusion | Momentum transfer | 10^{-9} – 10^{-3} |
| Turbomolecular | Momentum transfer | 10^{-9} – 10^{-3} |
| Sputter-ion | Gas capture | 10^{-0} – 10^{-3} |
| He cryogenic | Gas capture | 10^{-0} – 10^{-3} |

Methods for Reducing Pressure in a Vacuum Vessel

Vacuum pumps (Table 188.4) generally fall into one of two categories: primary (roughing) pumps and secondary (high-vacuum) pumps. Primary pumps are used to evacuate a vacuum vessel from atmospheric pressure to a pressure of about 10 mtorr. Secondary pumps typically operate in the pressure range of from 10^{-10} to 10^{-3} torr.

Pump speed curves such as those presented in Figures 188.6 and 188.7 are generally supplied by the pump manufacturer and reflect optimal performance for pumping air.

Vacuum System Design

The following relationships provide a first-order method for calculating conductances, delivered pump speed, and time to achieve a specified pressure. These relationships assume that conductance elements are of circular cross-section and have smooth internal surfaces, and that the gas being pumped is air.

**FIGURE 188.6** Pump speed curve typical of a two-stage oil-sealed rotary vane pump.

FIGURE 188.7 Pump speed curve typical of a fractionating oil-vapor diffusion pump equipped with a liquid nitrogen cold trap.

FIGURE 188.8 Conductance as a function of pressure for a 1.0" I.D. tube 10 ft long.

The conductance of tubes and orifices is a function of the flow mode (see Figure 188.8), which in turn is determined by the average pressure and the conductance element inside diameter. Flow modes may be determined by the following method:

$$D\bar{P} > 0.18 \Rightarrow \text{turbulent flow} \tag{188.20}$$

$$D\bar{P} < 0.004 \Rightarrow \text{molecular flow}$$

where

D = tube inside diameter [in.]

P = average pressure [torr]

$$C = \frac{3000\bar{P}D^4 + 80D^3}{L} \tag{188.21}$$

where

C = conductance [L/s]

D = tube inside diameter [in.]

\bar{P} = average pressure [torr]

L = tube length [in.]

For conductance elements connected in series, the total conductance is given by

$$\frac{1}{C_{\text{tot}}} = \sum_{i=1}^n \frac{1}{C_i} \quad (188.22)$$

where

$$\begin{aligned} C_{\text{tot}} &= \text{total conductance [L/s]} \\ C_i &= \text{conductance of } i\text{th tube [L/s]} \end{aligned}$$

Manufacturers of vacuum components (valves, traps, etc.) generally publish the conductance of the unit in the molecular flow regime. If this information is unavailable, the maximum conductance of a valve or trap may be estimated using the formula for aperture conductance in molecular flow:

$$C_m^{\text{ap}} = 75A \quad (188.23)$$

where

$$\begin{aligned} C_m^{\text{ap}} &= \text{molecular flow conductance [L/s]} \\ A &= \text{area of aperture [in.}^2\text{]} \end{aligned}$$

The effect of conductance on the pump speed delivered to a vessel may be evaluated using the following relationship:

$$\frac{1}{S_t} = \frac{1}{C_{\text{tot}}} + \frac{1}{S_p} \quad (188.24)$$

where

$$\begin{aligned} S_t &= \text{delivered pump speed [L/s]} \\ S_p &= \text{speed measured at pump inlet [L/s]} \end{aligned}$$

The amount of time required to evacuate a vessel using a primary pump is given by:

$$t = \frac{V}{S_t} \ln \left(\frac{P_1}{P_2} \right) \quad (188.25)$$

where

$$\begin{aligned} t &= \text{time to pump from } P_1 \text{ to } P_2 \text{ [s]} \\ V &= \text{volume of vessel [L]} \\ S_t &= \text{delivered pump speed [L/s]} \\ P_1 &= \text{initial pressure [torr]} \\ P_2 &= \text{final pressure [torr]} \end{aligned}$$

The lowest pressure (ultimate pressure) that a vacuum system can attain is a function of the total gas load (which is the algebraic sum of gas loads due to leaks, outgassing [see [Table 188.5](#)], permeation, and process gas) and the pumping speed of the secondary pump.

$$Q_{\text{tot}} = S_t P_u \quad (188.26)$$

where

$$\begin{aligned} Q_{\text{tot}} &= \text{total gas load [torr-L/s]} \\ P_u &= \text{ultimate pressure [torr]} \end{aligned}$$

TABLE 188.5 Outgassing Data for Materials Used in Vacuum Vessels

| | Treatment | q [W/m ²] | q [T · l/s · cm ²] |
|----------------------|---------------------------------|-------------------------|----------------------------------|
| Metals | | | |
| Aluminum | 15 h at 250°C | $5.3 \cdot 10^{-10}$ | $3.98 \cdot 10^{-13}$ |
| Aluminum | 100 h at 100°C | $5.3 \cdot 10^{-11}$ | $3.98 \cdot 10^{-14}$ |
| 6061 aluminum | Glow discharge and 200°C bake | $1.3 \cdot 10^{-11}$ | $9.75 \cdot 10^{-15}$ |
| Copper | 20 h at 100°C | $1.46 \cdot 10^{-9}$ | $1.10 \cdot 10^{-12}$ |
| 304 stainless steel | 30 h at 250°C | $4.0 \cdot 10^{-9}$ | $3.00 \cdot 10^{-12}$ |
| 316L stainless steel | 2 h at 800°C | $4.6 \cdot 10^{-10}$ | $3.45 \cdot 10^{-13}$ |
| U15C stainless steel | 3 h at 1000°C and 25 h at 360°C | $2.1 \cdot 10^{-11}$ | $1.58 \cdot 10^{-14}$ |
| Glasses | | | |
| Pyrex glass | Fresh | $9.8 \cdot 10^{-7}$ | $7.35 \cdot 10^{-9}$ |
| Pyrex glass | 1 month in air | $1.55 \cdot 10^{-6}$ | $1.16 \cdot 10^{-9}$ |
| Elastomers | | | |
| Viton-A | Fresh | $1.52 \cdot 10^{-3}$ | $1.14 \cdot 10^{-6}$ |
| Neoprene | — | $4.0 \cdot 10^{-2}$ | $3.00 \cdot 10^{-5}$ |

Defining Terms

Atmosphere — The gaseous environment in a defined space.

Conductance — Mass throughput divided by the pressure drop across a tube.

Gas — The state of matter distinguished from the solid and liquid states by relatively low density and viscosity, relatively great expansion and contraction with changes in pressure and temperature, the ability to diffuse readily, and the spontaneous tendency to become distributed uniformly throughout any container.

Mole — Amount of material, $6.02E + 23$ particles; 1 mole of carbon weighs 12 grams.

Pressure — Force per unit area (expressed in units such as psi, Torr, and mBar).

Pressure gauge — An instrument for measuring pressure.

Outgassing — Evolution of gas from a solid or liquid in a vacuum environment.

Vacuum — An environment with pressure below atmospheric pressure (760 Torr).

Food Engineering

R. Paul Singh

University of California, Davis

189.1 Liquid Transport Systems

189.2 Heat Transfer

189.3 Mass Transfer

The food industry relies on a wide range of unit operations to manufacture a myriad of processed foods. In order to design food processes, a practitioner in the food industry uses fundamental principles of chemistry, microbiology, and engineering. During the last 30 years, the food engineering discipline has evolved to encompass several aspects of food processing. The diversity of processes typically employed in a food processing plant is illustrated in [Figure 189.1](#). Typical food processes may include sorting and size reduction, transport of liquid foods in pipes, heat transfer processes carried out using heat exchangers, separation processes using membranes, simultaneous heat and mass transfer processes important in drying, and processes that may involve a phase change such as freezing. A food engineer uses the concepts common to the fields of chemical, mechanical, civil, and electrical engineering in addition to food sciences to design engineering systems that interact with foods. When foods are used as raw materials they offer unique challenges. Perhaps the most important concern in food processing is the variability in the raw material. To achieve consistency in the final quality of a processed food, the processes must be carefully designed to minimize variations caused by processing. In this chapter, some of the unique engineering issues encountered in food processing will be presented. For more details on the engineering design of food processing systems, see Singh and Heldman [2001], Toledo [1991], Brennan et al. [1990], Heldman and Singh [1981], Loncin and Merson [1979], and Charm [1978].

189.1 Liquid Transport Systems

In a food processing plant, one of the common operations is the transport of liquid foods from one piece of processing equipment to the next. Characteristics of the liquid food must be known before a liquid transport system can be designed. As seen in [Figure 189.2](#), a linear relationship exists between the shear stress and shear rate for a Newtonian liquid, such as water, orange juice, milk, and honey. The viscosity of a Newtonian liquid is determined from the slope of the straight line. Viscosity is an important property needed in many flow-related calculations. For example, viscosity of a liquid must be known before the volumetric flow rate in a pipe, under laminar conditions, can be calculated from the following equation:

$$\dot{V} = \frac{\pi \Delta P R^4}{8\mu L} \quad (189.1)$$

For non-Newtonian liquids, the relationship between shear stress and shear rate is nonlinear. Non-Newtonian liquids are classified as shear thinning, shear thickening, Bingham, and plastic fluids. Both

Newtonian and non-Newtonian characteristics can be described by the Herschel–Bulkley model [Herschel and Bulkley, 1926].

$$\sigma = K \left[\frac{du}{dy} \right]^n + \sigma_0 \quad (189.2)$$

The values of the consistency coefficient, K , and the flow behavior index, n , in Equation (189.2) are used to differentiate between different types of non-Newtonian liquids (Table 189.1). A few measured value of K and n using capillary and rotational viscometers are shown in Table 189.2.

TABLE 189.2 Rheological Properties of Selected Liquid Foods

Adapted from Heldman, D. R. and Singh R. P. 1981. *Food Process Engineering*, 2nd ed. AVI, Westport, CT.

When designing transport systems for water and other Newtonian liquids, the flow regime is determined by calculating the Reynolds number. For example, a flow with Reynolds number smaller than 2,100 is considered to be laminar, whereas a Reynolds number greater than 10,000 indicates turbulent flow. In the case of non-Newtonian liquid foods, a generalized Reynolds number is calculated using both the consistency coefficient K and the flow behavior index n . The generalized Reynolds number (N_{Gre}) is defined as

$$N_{\text{Gre}} = \frac{\rho \bar{u}^{2-n} D^n}{2^{n-3} K \left[\frac{3n+1}{n} \right]^n} \quad (189.3)$$

It is well known that for Newtonian liquids flowing in a pipe, the ratio between the mean velocity, \bar{u} , and the maximum velocity, u_{max} , under laminar conditions is given by

$$\frac{\bar{u}}{u_{\text{max}}} = 0.5 \quad (189.4)$$

Similarly, in the case of turbulent flow, for a Newtonian liquid the velocity ratio is

$$\frac{\bar{u}}{u_{\text{max}}} = 0.82 \quad (189.5)$$

In the case of non-Newtonian liquids, the velocity ratio is influenced by the flow behavior index, n , and is determined as

$$\frac{\bar{u}}{u_{\text{max}}} = \frac{n+1}{3n+1} \quad (189.6)$$

The velocity ratio for non-Newtonian liquids plotted as a function of generalized Reynolds number is shown in [Figure 189.3](#) [Palmer and Jones, 1976]. Knowledge of such velocity profiles is important in the design of aseptic processing systems for liquid foods.

189.2 Heat Transfer

Heating and cooling processes are widely used in the food industry. The three common modes of heat transfer — conduction, convection, and radiation — play an important role in the processing of foods.

The governing equation for heat transfer in the conductive mode is

$$\frac{\partial T}{\partial t} = \frac{\partial}{\partial x} \left[\alpha \frac{\partial T}{\partial x} \right] \quad (189.7)$$

Under steady state conditions, Equation (189.7) reduces to the well-known Fourier law:

$$q_x = -kA \frac{dT}{dx} \quad (189.8)$$

The solution of both transient and steady-state equations (Equations (189.7) and (189.8)) requires a knowledge of the physical and thermal properties of foods. Considerable research has been done to measure food properties such as thermal conductivity, density, specific heat, and thermal diffusivity [Rao

FIGURE 189.3 Plot of velocity ratio versus generalized Reynolds numbers. (Source: Palmer, J. and Jones, V. 1976. Prediction of holding times for continuous thermal processing of power law fluids. *J. Food Sci.*, 41:1233.)

and Rizvi, 1995]. A computerized database developed by Singh [1993] contains over 2,500 food-property combinations, along with literature citations. Some selected food property values are shown in [Tables 189.3, 189.4, and 189.5](#). It is evident that for most high-moisture foods, the property values are greatly influenced by the presence of water. In fact, many of the empirical models used for predicting thermal properties are based on the amount of water present in a food material.

Thermal conductivity of foods can be estimated from an empirical equation developed by Sweat [1995] using 430 data points:

$$k = 0.25m_c + 0.155m_p + 0.16m_f + 0.135m_a + 0.58m_m \quad (189.9)$$

A more rigorous model of thermal conductivity has been suggested by Kopelman [1966] to account for the nonisotropic nature of foods. For example, for a food material containing fibers, when the fibers in a food are parallel to the applied heat transfer, the thermal conductivity may be calculated as

$$k_{\parallel} = k_L [1 - N^2(1 - k_s / k_L)] \quad (189.10)$$

If the food fibers are perpendicular to the direction of heat transfer,

$$k_{\perp} = k_L \frac{1 - Q''}{1 - Q''(1 - N)} \quad (189.11)$$

$$Q'' = \frac{N}{(1 - k_s / k_L)} \quad (189.12)$$

The specific heat of a food material is mainly influenced by the components of the food. Thus, specific heat may be estimated from the knowledge of food composition using the following equation:

TABLE 189.3 Thermal Diffusivity of Selected Foodstuffs

| Product | Water Content (% wt.) | Temperature ^a (°C) | Thermal Diffusivity ($\times 10^{-7}$ m ² /sec) |

$$c_p = 1.424m_c + 1.549m_p + 1.675m_f + 0.837m_a + 4.187m_m \quad (189.13)$$

Food composition values are available in a computerized database [Singh, 1993] and *Agricultural Handbook Number 8* [Watt and Merrill, 1975]. Composition of selected foods is given in [Table 189.6](#).

Newton's law of cooling is used when the mode of heat transfer is by convection. Thus,

$$q = h_c A (T_p - T_\infty) \quad (189.14)$$

The convective heat transfer coefficient is determined using the lumped heat capacity method, as illustrated by Singh and Heldman [2001]. One of the key pieces of processing equipment used in the heating and cooling of foods is a heat exchanger. In the case of Newtonian liquids, both plate- and tubular-type heat exchangers are commonly used. For example, milk pasteurization is done using plate-type heat exchangers. When working with non-Newtonian liquids such as fruit purees and pastes, or liquid foods that contain food particulates such as beef chunks in a gravy, the scraped-surface heat exchangers are used. To calculate the rate of heat transfer in Equation (189.14), a value for the convective heat transfer coefficient must be known. For a scraped-surface heat exchanger, the following relationship is recommended:

$$h = 1.2 \left(\frac{k}{D} \right) N_{Re}^{0.5} N_{Pr}^{0.33} N_m^{0.26} \quad (189.15)$$

A more complete and rigorous analysis of non-Newtonian heat transfer in scraped-surface heat exchangers is given by Harrod [1987].

Unsteady-state heat transfer is important in many food processing applications. Reactions occurring in the initial stages of a heating or cooling process can significantly affect the quality attributes of foods. For example, in the food canning process, knowledge of temperature and time inside the can during the heating and cooling processes is important when designing thermal processes that ensure required

TABLE 189.6 Composition of Selected Foods

| Food | Water (%) | Protein (%) | Fat (%) | Carbohydrate (%) | Ash (%) |
|----------------------|-----------|-------------|---------|------------------|---------|
| Apples, fresh | 84.4 | 0.2 | 0.6 | 14.5 | 0.3 |
| Applesauce | 88.5 | 0.2 | 0.2 | 10.8 | 0.6 |
| Asparagus | 91.7 | 2.5 | 0.2 | 5.0 | 0.6 |
| Beans, lima | 67.5 | 8.4 | 0.5 | 22.1 | 1.5 |
| Beef, hamburger, raw | 68.3 | 20.7 | 10.0 | 0.0 | 1.0 |
| Bread, white | 35.8 | 8.7 | 3.2 | 50.4 | 1.9 |
| Butter | 15.5 | 0.6 | 81.0 | 0.4 | 2.5 |
| Cod | 81.2 | 17.6 | 0.3 | 0.0 | 1.2 |
| Corn, sweet, raw | 72.7 | 3.5 | 1.0 | 22.1 | 0.7 |
| Cream, half-and-half | 79.7 | 3.2 | 11.7 | 4.6 | 0.6 |
| Eggs | 73.7 | 12.9 | 11.5 | 0.9 | 1.0 |
| Garlic | 61.3 | 6.2 | 0.2 | 30.8 | 1.5 |
| Lettuce, iceberg | 95.5 | 0.9 | 0.1 | 2.9 | 0.6 |
| Milk, whole | 87.4 | 3.5 | 3.5 | 4.9 | 0.7 |
| Orange juice | 88.3 | 0.7 | 0.2 | 10.4 | 0.4 |
| Peaches | 89.1 | 0.6 | 0.1 | 9.7 | 0.5 |
| Peanuts, raw | 5.6 | 26.0 | 47.5 | 18.6 | 2.3 |
| Peas, raw | 78.0 | 6.3 | 0.4 | 14.4 | 0.9 |
| Pineapple, raw | 85.3 | 0.4 | 0.2 | 13.7 | 0.4 |
| Potatoes, raw | 79.8 | 2.1 | 0.1 | 17.1 | 0.9 |
| Rice, white | 12.0 | 6.7 | 0.4 | 80.4 | 0.5 |
| Spinach | 90.7 | 3.2 | 0.3 | 4.3 | 1.5 |
| Tomatoes | 93.5 | 1.1 | 0.2 | 4.7 | 0.5 |
| Turkey | 64.2 | 20.1 | 14.7 | 0.0 | 1.0 |
| Turnips | 91.5 | 1.0 | 0.2 | 6.6 | 0.7 |
| Yogurt, whole milk | 88.0 | 3.0 | 3.4 | 4.9 | 0.7 |

microbial sterilization. Standard methods involving Heisler charts may be used to determine the temperature history of conduction heating of foods [Holman, 1990]. Due to the low thermal diffusivities of foods, obtaining values of Fourier number and temperature ratios from the Heisler charts is cumbersome. Numerical methods are often employed to solve the governing heat-transfer equation [Heldman and Singh, 1981].

For heating or cooling processes without phase change, the thermal diffusivity is usually a weak function of temperature. However, when a phase change occurs during a process, such as in freezing or boiling, the properties of the food material change, often dramatically.

$$\alpha(T) = \frac{k(T)}{\rho(T)c_{pa}(T)} \quad (189.16)$$

Due to the nonlinearities introduced by the variable properties, more rigorous approaches are used to calculate heat transfer. In the case of freezing, food properties are influenced by the state of water. For example, a dramatic change in the specific heat of sweet cherries as a function of temperature in the freezing zone is shown in Figure 189.4. The freezing time, t_F , may be estimated using the following equation:

$$t_F = \frac{\rho H_L}{T_F - T_\infty} \left(\frac{P'a}{h_c} + \frac{R'a^2}{k} \right) \quad (189.17)$$

In the freezing of foods, there is a phase change of water into ice. Other processes where such complexities are encountered include thawing, dehydration, and evaporation. Design considerations of such processes are elaborated in Heldman and Lund [1992] and Singh and Mannapperuma [1990].

Microwave heating of foods has become popular in domestic cooking. However, industrial applications have been limited largely due to nonuniformity of raw materials that causes difficulties in obtaining consistent heating rates. Nevertheless, manufacturing of microwaveable foods for cooking in domestic ovens has increased dramatically during the last few decades. In preparing foods for microwave applications, the dielectric properties of foods are required. Table 189.7 gives the relative dielectric constant, ϵ' , and relative dielectric loss constant, ϵ'' , for selected foods at 2.45 GHz, the frequency employed in domestic ovens. The conversion of the microwave energy to heat can be approximated by the following equation (given by Copson [1975]):

$$P_D = 55.61 \times 10^{-14} E^2 f \epsilon' \tan \delta \quad (189.18)$$

and the penetration of microwave energy into a food may be obtained by using an equation developed by von Hippel [1954]. Accordingly, the depth Z , below the surface of the food material at which the electrical strength is $1/e$ of the electrical field in the free space, is given by the following expression:

$$Z = \frac{\lambda}{2\pi} \left[\frac{2}{\epsilon'(\sqrt{1 + \tan^2 \delta} - 1)} \right]^{1/2} \quad (189.19)$$

189.3 Mass Transfer

Analogous to heat transfer, mass transfer in a food is described by equations similar to Equation 189.7, as follows:

$$\frac{\partial c}{\partial t} = D_e \left(\frac{\partial^2 c}{\partial x^2} \right) \quad (189.20)$$

Solution of the preceding equation provides information on the rate of change in concentration of a substance in a food material, such as how moisture may be distributed in a food, or how during salting operation, the salt concentration may appear in a food. The unsteady-state mass transfer equation is widely used in a variety of food processing applications such as for determining drying rates, diffusion of solutes, and design of packaging materials for foods. A steady-state solution of Equation (189.20) is used to determine transport of a gas through a polymeric material used in food packaging:

$$\dot{m}_B = \frac{P_B A (p_{B1} - p_{B2})}{(x_2 - x_1)} \quad (189.21)$$

The preceding discussion provides ample evidence that food processing offers complex situations that require the use of advanced mathematical skills to develop appropriate solutions. The data on food properties presented in this chapter show the diversity of input conditions prevalent in the design and analysis of food processing operations.

Defining Terms

Newtonian liquids — Newtonian liquids exhibit a linear relationship between shear stress and rate of shear. The slope of the straight line passing through the origin of the axis is used to calculate viscosity of the liquid. Examples of Newtonian liquids include water, milk, and orange juice.

Non-Newtonian liquids — Non-Newtonian liquids exhibit a nonlinear relationship between shear stress and rate of shear. Furthermore, these liquids may be classified as time-independent or time-dependent non-Newtonian liquids. The rheological properties that describe non-Newtonian liquids are consistency coefficient, flow behavior index, and yield stress. Examples of non-Newtonian liquids are minced fish paste, apple sauce, banana puree, and tomato paste.

Physical and thermal properties — Physical and thermal properties of foods include thermal diffusivity, thermal conductivity, specific heat, density, and viscosity. A knowledge of these properties is essential in designing food processes and equipment.

Nomenclature

| Symbol | Quantity | Unit |
|--------|--|-------------------|
| A | Area (normal to x direction) through which heat flows | (m ²) |
| a | Product thickness for an infinite slab, diameter for an infinite cylinder, and diameter for a sphere | |

| Symbol | Quantity | Unit |
|-----------------|---|-----------------------|
| α | Thermal diffusivity | (m ² /s) |
| c | Concentration | (kg/m ³) |
| c_p | Specific heat capacity | (kJ/kg°C) |
| c_{pa} | Apparent specific heat capacity | (kJ/kg°C) |
| D | Pipe diameter | (m) |
| D_e | Diffusivity | (m ² /s) |
| E | Electrical field strength | (V/m) |
| $\frac{du}{dy}$ | Strain | s ⁻¹ |
| ϵ' | Relative dielectric constant | |
| ϵ'' | Relative dielectric loss constant | |
| f' | Frequency | (Hz) |
| h_c | Convective heat-transfer coefficient | (W/m ² °C) |
| H_L | Latent heat of fusion | (kJ/kg) |
| K | Consistency coefficient | (Pa·s ⁿ) |
| k | Thermal conductivity | (W/m·°C) |
| k_L | Thermal conductivity of liquid component | (W/m°C) |
| k_S | Thermal conductivity of solid component | (W/m°C) |
| L | Length of pipe | (m) |
| μ | Viscosity of liquid | (Pa·s) |
| \dot{m}_B | Mass flow rate | (kg/s) |
| m_a | Mass fraction of ash | |
| m_c | Mass fraction of carbohydrate | |
| m_f | Mass fraction of fat | |
| m_m | Mass fraction of water | |
| m_p | Mass fraction of protein | |
| N^2 | Volume fraction of solids or discontinuous phase in the fibrous product | |
| N_m | Number of blades on the mutator | |
| N_{Nu} | Nusselt number | |
| N_{Pr} | Prandtl number | |
| N_{GRe} | Generalized Reynolds number | |
| n | Flow behavior index (dimensionless) | |
| ΔP | Pressure drop | (Pa) |
| P | Power at the penetration depth | (W) |
| P_B | Permeability coefficient of component B | |
| P_D | Power dissipation | (W/cm ³) |
| P' | Coefficient in Equation (189.17) | |
| p_B | Partial pressure of gas | Pa |
| Q'' | Coefficient defined in Equation (189.12) | |
| R | Radius of pipe | (m) |
| R' | Coefficient in Equation (189.17) | |
| q | Rate of heat transfer | (W) |
| q_x | Rate of heat flow in x direction by conduction | (W) |
| R | Radius of pipe | (m) |
| ρ | Density | (kg/m ³) |
| s | Shear stress | (Pa) |
| σ_0 | Yield stress | (Pa) |
| $\tan\delta$ | Loss tangent, ϵ''/ϵ' | |
| T | Temperature | (°C) |
| T | Surrounding temperature | (°C) |
| T_F | Freezing point | (°C) |
| T_p | Surface temperature | (°C) |
| t_F | Freezing time | (s) |
| t | Time | (s) |
| \bar{u} | Mean velocity | (m/s) |
| \dot{V} | Volumetric flow rate | (m ³ /s) |
| x | Length | (m) |
| y | Length | (m) |
| Z | Penetration depth | (m) |

Agricultural Engineering

David J. Hills
University of California, Davis

190.1 Equipment Sizing Criteria

Field Capacity • Power Requirements

190.2 Equipment Selection

Soil Tillage • Crop Planting • Crop Harvest

Agricultural engineering is the application of engineering principles and animal/plant biology to the production, handling, processing, packaging, and use of agricultural materials. Although agricultural engineering encompasses a broad area, this chapter focuses only on crop production and specifically on equipment associated with cultural practices. The three paramount operations in crop production are soil tillage, planting, and harvesting. Additionally, judicious attention paid to water, nutriment, and plant protection can maximize crop yields.

Selection of agricultural equipment requires the consideration of three parameters that can lead to high performance: machine, power, and operation. Measures of machine performance are the rate and quality at which the operations are accomplished. Rate is an important measure because agriculture is sensitive to changeable weather and crop ripeness. Most biological materials are fragile and many are perishable, so the amount of product damage or reduction in product quality caused by a machine's operation is important. The second performance parameter that must be considered is the effectiveness with which power is applied to accomplish an agricultural operation. Selecting the proper implement for a certain task and matching the implement to the engine power are critical for obtaining high power efficiency. The final performance parameter refers to the machine operator. Knowledge of the machine's mechanisms and of the overall agricultural enterprise is needed by the operator. Sensors and automatic controls are incorporated in modern equipment for additionally improving operator efficiency.

190.1 Equipment Sizing Criteria

Field Capacity

Field capacity refers to the amount of processing that a machine can accomplish per hour on either an area or a material basis. These two capacities are expressed as follows:

$$C_f = \frac{SWE}{10} \quad (190.1)$$

$$C_m = \frac{SWYE}{10} \quad (190.2)$$

where

- C_f = field capacity on an area basis (ha/h)
- C_m = field capacity on a material basis (t/h)
- S = travel speed (km/h)
- W = machine working width (m)
- Y = crop yield (t/ha)
- E = field efficiency (decimal)

Theoretical field capacity is used to describe a machine's capacity when the field efficiency term is equal to 1.0. This capacity implies that the machine is utilizing its full width and assumes no interruption for turns or other idle time. For cultivators and many harvesters, which work in rows, the machine working width is equal to the row spacing times the number of rows processed in each pass. Operator performance is not perfect, however, so less than the full width of such machines is used in order to ensure coverage of the entire land area; that is, there is some overlapping on each pass. A range of efficiency values for various field operations is provided in [Table 190.1](#). The actual values depend on operator skill, equipment condition, and field, crop, and environmental conditions.

Typical operating speeds for various machines are listed in [Table 190.1](#). Travel speeds for harvesters and other machines that process a product are limited by their materials-handling capacity. For machines that do not process a product, such as tillage machines, the speed is limited by other factors, such as available power, quality of the work, and safety.

Power Requirements

The power required for an agricultural machine is determined by its intended use. Tractors, for example, typically provide power to implements in three forms: drawbar, rotary, and hydraulic. Pulled or towed implements are powered through the traction of drive wheels and the pull, or **draft**, from the drawbar. Rotary power is obtained from the power takeoff (PTO) shaft. Either linear or rotary power can be produced by a tractor's hydraulic system. These three power terms are defined in Equations (190.3), (190.4), (190.5), respectively:

$$P_{db} = \frac{D_u WS}{3.6} \quad (190.3)$$

where

- P_{db} = **drawbar power** (kW)
- D_u = unit draft of the implement (kN)
- W = machine working width (m)
- S = travel speed (km/h)

$$P_{pto} = \frac{TN}{9.5} \quad (190.4)$$

where

- P_{pto} = **PTO power** (kW)
- T = torque (N-m)
- N = revolutions per minute (rpm)

TABLE 190.1 Typical Field Equipment Efficiencies and Operating Speeds

| Machine | Field Efficiency (%) | | Speed (km/h) | |
|-----------------------|----------------------|---------|--------------|---------|
| | Range | Typical | Range | Typical |
| Tillage | | | | |
| Cultivator (field) | 70–90 | 85 | 5.0–13.0 | 9.0 |
| Cultivator (row crop) | 70–90 | 80 | 4.0–8.0 | 5.5 |
| Harrow (disk) | 70–90 | 80 | 5.0–9.9 | 6.5 |
| Harrow (spiketooth) | 70–90 | 85 | 5.0–9.5 | 8.0 |
| Harrow (springtooth) | 70–90 | 85 | 5.0–9.5 | 8.0 |
| Landplane | 70–90 | 85 | 3.0–8.0 | 6.5 |
| Plow (chisel) | 70–90 | 85 | 6.5–10.5 | 10.5 |
| Plow (disk) | 70–90 | 85 | 3.5–9.5 | 7.0 |
| Plow (moldboard) | 70–90 | 80 | 5.0–9.5 | 7.0 |
| Rotary hoe | 70–85 | 80 | 8.0–15.5 | 11.0 |
| Rotary tiller | 70–90 | 85 | 1.5–7.0 | 5.0 |
| Subsoiler/ripper | 70–85 | 80 | 3.0–5.0 | 4.0 |
| Planters | | | | |
| Grain drill | 65–80 | 70 | 4.9–9.0 | 6.5 |
| Row crop planter | 50–75 | 60 | 3.0–6.5 | 4.0 |
| Harvesters | | | | |
| Combine | 65–80 | 70 | 3.0–11.0 | 5.0 |
| Corn picker | 60–75 | 65 | 3.0–6.5 | 4.0 |
| Harvester — cotton | 60–75 | 70 | 3.0–6.5 | 5.0 |
| Harvester — potato | 55–70 | 60 | 2.5–6.5 | 3.0 |
| Harvester — tomato | 55–70 | 60 | 2.5–6.5 | 4.0 |
| Hay baler | 60–85 | 75 | 4.0–8.0 | 5.5 |
| Mower | 75–85 | 80 | 6.5–11.0 | 8.0 |
| Miscellaneous | | | | |
| Mower — flail | 75–90 | 85 | 5.0–7.0 | 5.5 |
| Sprayer — boom type | 50–80 | 65 | 5.0–11.0 | 10.5 |
| Spreader — fertilizer | 70–70 | 70 | 5.0–8.0 | 7.0 |

$$P_{\text{hyd}} = \frac{pQ}{1000} \quad (190.5)$$

where

- P_{hyd} = hydraulic power (kW)
- P = pressure of pumped oil (kPa)
- Q = oil flow rate (L/s)

The total power requirement for operating implements is the sum of implement power components converted to equivalent PTO power.

$$P_T = 1.15 \left[\frac{P_{db}}{K_t} + P_{pto} + P_{hyd} \right] \quad (190.6)$$

where

P_T = total implement power requirement (kW)

1.15 = factor that adds 15% to total power for acceleration, slope, and so on

K_t = tractive and transmission efficiency (decimal)

Values for the equation variables can be obtained directly from the implement manufacturer or can be estimated from typical values as listed in [Table 190.2](#). The major factors influencing draft on tillage tools are soil characteristics, forward speed, and crop resistance. The draft for most pull-type, nontillage implements is in the form of rolling resistance.

Approximate values for tractive and transmission efficiency for two- and four-wheel-drive tractors and crawler tractors are provided in [Table 190.3](#). As shown, tractive efficiencies for four-wheel-drive tractors are somewhat higher than those for two-wheel-drive tractors, especially for soft soils. Crawler-type tractors seldom have more than 5% slip, even on soft soils.

Fuel requirements for tractors can be estimated from [Table 190.4](#), provided that the maximum PTO power rating and the actual PTO power requirement (as calculated by Equation (190.6)) are known. The drawbar power is always less than PTO power because of drive-wheel slippage, tractor rolling resistance, and friction losses in the drive between the engine and the wheels. The sum of these losses forms the basis of the tractive and transmission coefficients listed in [Table 190.3](#). These coefficients are essentially the ratios of drawbar power to PTO power.

190.2 Equipment Selection

Soil Tillage

Tillage is used for seedbed preparation, weed control, incorporation of crop residues and fertilizer materials, breaking soil crusts and hardpans to improve water penetration and aeration, and shaping the soil for irrigation and erosion control. The tillage requirement is determined by the type of crop, soil type, and field conditions. A tillage implement consists of a single tool or a group of tools, together with the associated frame, wheels, hitch, control and protection devices, and power transmission components.

Tillage operations for seedbed preparation are often classified as primary or secondary. A primary tillage operation constitutes the initial, major soil-working operation after harvest of the previous crop. It is normally designed to reduce soil strength, cover plant materials, and rearrange soil aggregates. The main objective of secondary tillage is to break down large clods and to prepare a seedbed ideal for planting. An ideal seedbed provides for good seed-to-soil contact, conserves moisture needed for germination, and allows for vigorous and uninhibited root and shoot growth.

Implements used for primary tillage are moldboard plows, disk plows and tillers, heavy disk harrows, chisel plows, subsoilers, rotary plows, listers, and bedders. Moldboard plows and heavy disk harrows are the most commonly used primary tillage tools. Implements used for secondary tillage are disk harrows, cultivators, spike and spring tooth harrows, and rotary hoes and cultivators. The most common implement used for secondary cultivation is the disk harrow. Generally, several tillage operations are performed before the field is ready for planting. In dry climates, culti-packers are also used as the final tillage operation before planting. Increasing the soil density in the top few centimeters helps retain soil moisture.

Example 190.1

What is the engine power requirement for a four-wheel drive tractor pulling a three-bottom, 400-mm moldboard plow to a depth of 18 cm and at a speed of 6.0 km/h on medium textured soil?

TABLE 190.2 Draft and Energy Requirements for Selected Field Equipment Operated at 5 km/h

| Machine | Unit Draft (kN/m) | Energy or Work (kW-h/ha) |
|-------------------------------------|-------------------|--------------------------|
| Tillage | | |
| Cultivator (field) | 0.9–4.4 | 2.4–12.0 |
| Cultivator (row crop) | 0.6–1.2 | 1.6–3.3 |
| Harrow (disk) | 0.7–1.5 | 2.0–4.0 |
| Harrow (spiketooth) | 0.3–0.9 | 0.7–2.4 |
| Harrow (springtooth) | 1.0–4.4 | 2.1–12.2 |
| Landplane | 4.4–11.7 | 12.2–31.3 |
| Plow (chisel — 18 to 23 cm) | 2.9–13.1 | 8.1–36.9 |
| Plow (moldboard or disk) | | |
| Light soils — 18-cm depth | 3.2–6.3 | 8.7–17.5 |
| Medium soils — 18-cm depth | 5.3–9.5 | 14.6–25.8 |
| Heavy soils — 18-cm depth | 8.5–16.6 | 22.1–46.1 |
| Rotary hoe | 0.4–0.9 | 1.3–2.4 |
| Rotary tiller — 10-cm forward slice | 12.2–24.5 | 25.8–51.6 |
| Subsoiler/ripper 2-m spacing | | |
| Light soils — 40-cm depth | 16.0–26.3/unit | 7.2–12.0 |
| Medium soils — 40-cm depth | 23.3–36.5/unit | 10.1–15.7 |
| Planters | | |
| Grain drill | 0.4–1.5 | 1.1–3.9 |
| Row crop planter — 1-m spacing | 0.5–0.8/row | 1.1–2.4 |
| PTO Power (kW/m or kW/row) | | |
| Harvesters | | |
| Combine — small grain | 3.6–11.0 | 7.2–22 |
| Corn picker | 1.5–3.7/row | 4.4–8.8 |
| Harvester — cotton (spindle) | 7.5–11.2/row | 12.9–18.4 |
| Harvester — potato | 0.7–1.5/row | |
| Hay baler | | 8.3–13.8 |
| Rotary mower (grass, legumes) | 7.3–19.6 | 1.2–2.0 |
| | | 9.2–24 |
| Miscellaneous | | |
| Mower — flail | | 0.9–2.0 |
| Sprayer — boom type | 0.2 kW | 0.02–0.4 |
| Spreader — fertilizer | 0.3–1.2 | 0.9–3.1 |

Solution. Data from [Tables 190.2](#) and [190.3](#) are incorporated into Equations (190.3) and (190.6), respectively.

$$P_{db} = \frac{(7.4)(3 \cdot 400 / 1000)(6)}{3.6} = 14.8 \text{ kW}$$

$$P_T = 1.15 \frac{14.8}{0.75} = 22.7 \text{ kW}$$

Crop Planting

Agricultural plants usually begin from either seeds or seedling transplants. Important factors affecting seed germination and emergence include seed viability, soil temperature, availability of moisture and air to the seeds, and soil strength and resistance to seedling emergence. The planter can exert a strong influence on the rate of germination and emergence of seeds through control of planting depth and firming of soil around the seeds or roots of seedlings. In addition, the planter must meter seeds at the proper rate and, in some cases, must control the horizontal down-the-row placement of seeds in a desired pattern.

Equipment is available for three seeding practices: broadcasting, drilling, and precision planting. Broadcasting refers to random placement of seeds on the soil surface. Seed is metered from a hopper through a variable orifice onto a spinning disk, which accelerates the seed and distributes it. Drilling is the random down-the-row or horizontal placement of seeds in furrows that are then covered. In a seed drill, seeds are metered from a series of hoppers, typically by fluted wheels, into small furrows that are subsequently covered and pressed. High-density plantings, high costs of hand thinning, and erratic performance of mechanical thinners have resulted in the development of precision seeding techniques. In precision planting, the seeds are planted in rows at uniform spacing. Precision planters are similar in operation to press drills; however, the metering hardware is more complex, allowing for seed placement at precise depths and locations.

[Table 190.5](#) provides data on typical seeding rates and practices for selected crops. The wide ranges of seed spacing reflect the dependence on climate, season, and type of market. For agronomic crops, the lower seeding rates and wider spacings are more typical for nonirrigated conditions. For vegetable crops, spacing is determined by type of market (fresh versus processor), desired fruit size, harvesting equipment dimensions, and time of year. Depth of seeding is determined by antecedent soil moisture, soil type, and soil temperature. These data can be used to establish general criteria for planting and cultural equipment.

Example 190.2

A 3.4-m wide grain drill is used to plant a 50-ha field in wheat. Approximately how many hours are required for this planting operation?

TABLE 190.5 Traditional Seed Depth and Rate for Selected Crops

| Crop | Depth to Plant Seed (cm) | Spacing between Plants in Row (cm) | Spacing between Rows (cm) | No. Seeds per Gram | Seeding Rate (kg/ha) |
|-----------------|--------------------------|------------------------------------|---------------------------|--------------------|----------------------|
| Alfalfa | 0.6–1.3 | Drilled | Drilled | 480 | 9–22 |
| Barley | 1.3–2.5 | Drilled | Drilled | 28 | 81–108 |
| Bean, snap | 2.5–3.8 | 10–30 | 46–107 | 4–5 | 75–100 |
| Broccoli | 0.6 | 36–91 | 61–91 | 320 | 0.5–1.5 |
| Cabbage | 0.6 | 36–91 | 61–91 | 320 | 0.5–1.5 |
| Carrot | 0.6 | 3–8 | 38–61 | 820 | 2–4 |
| Cauliflower | 0.6 | 36–61 | 61–122 | 320 | 0.5–1.5 |
| Celery | 0.6 | 15–30 | 46–91 | 2500 | 1–2 |
| Corn, field | 2.5–5.0 | 13–30 | 61–91 | 4–6 | 12–18 |
| Corn, sweet | 2.5–5.0 | 15–25 | 61–91 | 4–6 | 10–17 |
| Cotton | 2.5–5.0 | 3–8 | 61–97 | 2–4 | 18–25 |
| Cucumber | 2.5 | 30–91 | 91–122 | 40 | 3–6 |
| Lettuce, head | 0.6–1.3 | 15–25 | 46–91 | 900 | 1–3 |
| Oat | 1.3–2.5 | Drilled | Drilled | 28 | 54–143 |
| Onion | 1.3 | 8–10 | 38–91 | 305 | 3–5 |
| Pea, English | 5.0 | 3–5 | 46–91 | 3–6 | 100–250 |
| Potato (tubers) | 10.0 | 23–38 | 76–107 | — | 1000–2000 |
| Rice | 0.6–1.9 | Drilled | Drilled | 25 | 75–179 |
| Sorghum | 1.3–5.0 | Drilled | Drilled | 62 | 17–50 |
| Soybean | 2.5–3.8 | 3–15 | 30–91 | 6–12 | 20–50 |
| Squash, bush | 2.5 | 46–122 | 91–152 | 4–14 | 2–7 |
| Sugar beet | 0.7–1.5 | 10–15 | 60–91 | 120 | 0.5–1.5 |
| Tomato | 1.3 | 30–91 | 61–152 | 250–430 | 0.5–1.5 |
| Watermelon | 2.5 | 61–244 | 183–244 | 1–3 | 1–3 |
| Wheat | 1.5–2.5 | Drilled | Drilled | 26 | 67–101 |

J. 1996. *Knott's Handbook for Vegetable Growers*, 4th ed. John Wiley & Sons, New York; and Treadgill, E. D. 1988. Plant growth data. In: *Handbook of Engineering in Agriculture*, R. H. Brown, Ed. CRC Press, Boca Raton, FL, pp. 129–131.

Solution. Data for [Table 190.1](#) are used in Equation (190.1) for determining the field capacity, and then the operation time is calculated.

$$C_f = \frac{(6.5)(3.4)(0.7)}{10} = 1.55 \text{ ha/h}$$

$$\text{Time} = \frac{50 \text{ ha}}{1.55 \text{ ha/h}} = 32 \text{ h or four 8 h days}$$

Crop Harvest

The final crop production operation is the harvesting of the plant parts that have economic value to the grower. In some cases, more than one plant part may have economic value. Many crops are highly perishable products that must be harvested within a very narrow time range, handled carefully, and either processed, properly stored, or consumed fresh soon after harvesting. Mechanical harvesters are available for a number of crops. The general groups are hay and forage harvesters, grain harvesters, and fruit, nut, and vegetable harvesters.

Hay and forage harvesters are used in producing animal feed as ensilage or hay. Ensilage involves cutting the forage at 70 to 80% moisture, allowing it to field dry to 50 to 60% moisture, chopping it into short lengths to obtain adequate packing, and preserving it by fermentation in an airtight chamber. Equipment for the following steps are required: cut/condition, windrow, wilt, chop, transport, and store. For hay production, the forage is cut and allowed to dry to a moisture content of 15 to 23% before

storage. Hay production requires equipment for the following steps: cut/condition/swath, rake into windrows, dry, bale or chop, transport, and store.

The harvesting of cereal grains, grasses, and legumes is accomplished almost entirely with the combine. A combine has five general mechanical functions: cutting, feeding, threshing, separating, and cleaning. The cutting operation is accomplished with a cutter bar and reel. The feeding mechanism distributes and delivers the crop material to the threshing cylinder in a steady uniform flow. The threshing operation is accomplished with a cylinder working against iron bar concaves. The separating mechanism extracts the straw. Cleaning of the grain, the final step, is accomplished with screening devices and blowers.

Harvesters for fruits, nuts, and vegetables are usually crop specific and may be equipped with special sensors for product selection according to maturity and size. Although these harvesters are designed for a broad range of specialty crops, they may be broadly classified according to the physical location in which the harvestable portion of the crop is located. These four crop zones are root (e.g., for sugar beets, potatoes); surface (e.g., for beans, tomatoes); bush and trellis (e.g., for boysenberries, grapes); and tree (e.g., for olives, almonds). Successful harvest mechanization requires a total systems approach, which includes varietal breeding, cultural practices, materials handling, grading and sorting, and ultimate processing. Harvester selection is therefore based on these factors, as well as such factors as economics and available labor.

Example 190.3

A tomato harvester is observed to travel at 4.0 km/h with a design width of 1.5 m. The average yield for the field is 80 t/ha. What is the material capacity of the machine?

Solution. Data from [Table 190.1](#) are used in Equation (190.2) for determining the material handling capacity.

$$C_m = \frac{(4.0)(1.5)(80)(0.60)}{10} = 28.8 \text{ t/h}$$

Defining Terms

Draft — The horizontal force required to propel an implement in the direction of travel.

Drawbar power — The power to pull or move an implement at a uniform speed. It is chiefly a function of implement draft and forward speed.

Field capacity — The amount of processing that a machine can accomplish per hour, expressed on either an area or a material basis.

PTO power — The power to operate an implement from the power-takeoff shaft. It is chiefly a function of torque and rotational speed.

Application of system reliability evaluation techniques is gaining importance because of its effectiveness in the detection, prevention, and correction of failures in the design, manufacturing, and operational phases of a product. Increasing emphasis on the reliability and quality of products and systems, coupled with pressures to minimize cost, further emphasize the need to study and quantify reliability and arrive at innovative designs.

Reliability engineering has grown significantly during the past 5 decades (since World War II) to encompass many subareas, such as reliability analysis, failure theory and modeling, reliability allocation and optimization, reliability growth and modeling, reliability testing (including accelerated testing), data analysis and plotting, quality control and acceptance sampling, maintenance engineering, software reliability, system safety analysis, Bayesian analysis, reliability management, simulation, Monte Carlo techniques, and economic aspects of reliability.

The objectives of this chapter are to introduce the reader to the fundamentals and applications of classical reliability concepts and bring out the importance and benefits of reliability considerations.

191.1 Catastrophic Failure Models

Catastrophic failure refers to the case in which repair of the component is not possible, not available, or of no value to the successful completion of the mission originally planned. Modeling such failures is typically based on life test results. We can consider the “lifetime” or “time to failure” T as a continuous random variable. Then,

$$P(\text{survival up to time } t) = P(T > t) \equiv R(t) \quad (191.1)$$

where $R(t)$ is the *reliability* function. Obviously, as $t \rightarrow \infty$, $R(t) \rightarrow 0$ because the probability of failure increases with time of operation. Moreover,

$$P(\text{failure at } t) = P(T \leq t) \equiv Q(t) \quad (191.2)$$

where $Q(t)$ is the unreliability function. From the definition of the distribution function of a continuous random variable, it is clear that $Q(t)$ is indeed the distribution function for T . Therefore, the failure density function $f(t)$ can be obtained as

$$f(t) = \frac{d}{dt} Q(t) \quad (191.3)$$

The *hazard rate function* $\lambda(t)$ is defined as

$$\lambda(t) \equiv \lim_{\Delta t \rightarrow 0} \frac{1}{\Delta t} \left[\begin{array}{l} \text{probability of failure in } (t, t + \Delta t), \\ \text{given survival up to } t \end{array} \right] \quad (191.4)$$

It can be shown that

$$\lambda(t) = \frac{f(t)}{R(t)} \quad (191.5)$$

The four functions $f(t)$, $Q(t)$, $R(t)$, and $\lambda(t)$ constitute the set of functions used in basic reliability analysis. The relationships between these functions are given in Table 191.1.

TABLE 191.1 Relationships between Different Reliability Functions

| $f(t)$ | $\lambda(t)$ | $Q(t)$ | $R(t)$ |
|--|---|--|----------------------------|
| $f(t) = f(t)$ | $\lambda(t) \exp \left[- \int_0^t \lambda(\xi) d\xi \right]$ | $\frac{d}{dt} Q(t)$ | $-\frac{d}{dt} R(t)$ |
| $\lambda(t) = \frac{f(t)}{1 - \int_0^t f(\xi) d\xi}$ | $\lambda(t)$ | $\frac{1}{1 - Q(t)} \frac{d}{dt} (Q(t))$ | $-\frac{d}{dt} [\ln R(t)]$ |
| $Q(t) = \int_0^t f(\xi) d\xi$ | $1 - \exp \left[- \int_0^t \lambda(\xi) d\xi \right]$ | $Q(t)$ | $1 - R(t)$ |
| $R(t) = 1 - \int_0^t f(\xi) d\xi$ | $\exp \left[- \int_0^t \lambda(\xi) d\xi \right]$ | $1 - Q(t)$ | $R(t)$ |

FIGURE 191.1 Bathtub-shaped hazard function. (Source: Ramakumar, R. 1993. *Engineering Reliability: Fundamentals and Applications*. Prentice Hall, Englewood Cliffs, NJ. With permission.)

191.2 The Bathtub Curve

Of the four functions discussed, the hazard rate function $\lambda(t)$ displays the different stages during the lifetime of a component most clearly. In fact, typical $\lambda(t)$ plots have the general shape of a bathtub curve as shown in Figure 191.1. The first region corresponds to *wear-in* (infant mortality) or early failures during debugging. The hazard rate goes down as debugging continues. The second region corresponds to an essentially constant and low failure rate — failures can be considered to be nearly random. This is the useful lifetime of the component. The third region corresponds to the *wear-out* or fatigue phase with a sharply increased hazard rate.

Burn-in refers to the practice of subjecting components to an initial operating period of t_1 (see Figure 191.1) before delivering them to the customer. This eliminates all the initial failures from occurring after delivery to customers requiring high-reliability components. Moreover, it is prudent to replace a component as it approaches the wear-out region (i.e., after an operating period of $[t_2 - t_1]$). Electronic components tend to have a long useful life (constant hazard) period. The wear-out region tends to dominate in the case of mechanical components.

191.3 Mean Time to Failure

The mean or expected value of the continuous random variable *time to failure* is the *mean time to failure* (MTTF). This is a very useful parameter that is often used to assess the suitability of components. It can be obtained using either the failure density function $f(t)$ or the reliability function $R(t)$ as follows:

$$\text{MTTF} = \int_0^{\infty} tf(t)dt \quad \text{or} \quad \int_0^{\infty} R(t)dt \quad (191.6)$$

In the case of repairable components, the repair time can also be considered as a continuous random variable with an expected value of MTTR. The mean time between failures, MTBF, is the sum of MTTF and MTTR. For well-designed components, $\text{MTTR} \ll \text{MTTF}$. Thus, MTBF and MTTF are often used interchangeably.

TABLE 191.2 Relationships between Different Failure Rate Units

| λ (#/hr) | %/K | PPM/K (FIT) |
|------------------------------|-----------------|-------------------|
| $\lambda = \lambda$ | 10^{-5} (%/K) | 10^{-9} (PPM/K) |
| %/K = $10^5 \lambda$ | %/K | 10^{-4} (PPM/K) |
| PPM/K (FIT) = $10^9 \lambda$ | 10^4 (%/K) | PPM/K |

Source: Ramakumar, R. 1993. *Engineering Reliability: Fundamentals and Applications*. Prentice Hall, Englewood Cliffs, NJ. With permission.

191.4 Average Failure Rate

The average failure rate over the time interval 0 to T is defined as

$$\text{AFR}(0, T) \equiv \text{AFR}(T) = -\frac{\ln R(T)}{T} \quad (191.7)$$

191.5 A Posteriori Failure Probability

When components are subjected to a burn-in (or wear-in) period of duration T , and if the component survives during $(0, T)$, the probability of failure during $(T, T + t)$ is called the *a posteriori failure probability* $Q_c(t)$. It can be found using

$$Q_c(t) = \frac{\int_T^{T+t} f(\xi) d\xi}{\int_T^{\infty} f(\xi) d\xi} \quad (191.8)$$

The probability of survival during $(T, T + t)$ is

$$\begin{aligned} R(t|T) &= 1 - Q_c(t) = \frac{\int_{T+t}^{\infty} f(\xi) d\xi}{\int_T^{\infty} f(\xi) d\xi} \\ &= \frac{R(T+t)}{R(T)} = \exp\left[-\int_T^{T+t} \lambda(\xi) d\xi\right] \end{aligned} \quad (191.9)$$

191.6 Units for Failure Rates

Several units are used to express failure rates. In addition to $\lambda(t)$, which is usually in number per hour, %/K is used to denote failure rates in percent per thousand hours, and PPM/K is used to express failure rate in parts per million per thousand hours. The last unit is also known as FIT for “fails in time.” The relationships between these units are given in Table 191.2.

191.7 Application of the Binomial Distribution

In an experiment consisting of n identical independent trials, with each trial resulting in success or failure with probabilities of p and q , the probability P_r or r successes and $(n - r)$ failures is

$$P_r = {}_n C_r p^r (1-p)^{n-r} \quad (191.10)$$

If X denotes the number of successes in n trials, then it is a discrete random variable with a mean value of (np) and variance of (npq) .

In a system consisting of a collection of n identical components with a probability p that a component is defective, the probability of finding r defects out of n is given by the P_r in Equation (191.10). If p is the probability of success of one component and if at least r of them must be good for system success, then the system reliability (probability of system success) is given by

$$R = \sum_{k=r}^n {}_n C_k p^k (1-p)^{n-k} \quad (191.11)$$

For a system with redundancy, $r < n$.

191.8 Application of Poisson Distribution

For events that occur *in time* at an average rate of λ occurrences per unit of time, the probability $P_x(t)$ of exactly x occurrences during the time interval $(0, t)$ is given by

$$P_x(t) = \frac{(\lambda t)^x e^{-\lambda t}}{x!} \quad (191.12)$$

The number of occurrences X in $(0, t)$ is a discrete random variable with a mean value of μ of (λt) , and a standard deviation σ of $\sqrt{\lambda t}$. By setting $X = 0$ in Equation (191.12), we obtain the probability of no occurrence in $(0, t)$ as $e^{-\lambda t}$. If the event is failure, then no occurrence means success and $e^{-\lambda t}$ is the probability of success or system reliability. This is the well-known and often used exponential distribution, also known as the constant hazard model.

191.9 Exponential Distribution

A constant hazard rate (constant λ) corresponding to the useful lifetime of components leads to the single parameter exponential distribution. The functions of interest associated with a constant λ are

$$f(t) = \lambda e^{-\lambda t}, \quad t > 0 \quad (191.13)$$

$$R(t) = e^{-\lambda t} \quad (191.14)$$

$$Q(t) = Q_c(t) = 1 - e^{-\lambda t} \quad (191.15)$$

The a posteriori failure probability $Q_c(t)$ is independent of the prior operating time T , indicating that the component does not degrade no matter how long it operates. Obviously, such a scenario is valid only during the useful lifetime (horizontal portion of the bathtub curve) of the component.

The mean and standard deviation of the random variable *lifetime* are

$$\mu \equiv \text{MTFF} = \frac{1}{\lambda} \quad \text{and} \quad \sigma = \frac{1}{\lambda} \quad (191.16)$$

191.10 Weibull Distribution

The Weibull distribution has two parameters — a scale parameter α and a shape parameter β . By adjusting these two parameters, a wide range of experimental data can be modeled in system reliability studies. The associated functions are

$$\lambda(t) = \frac{\beta t^{\beta-1}}{\alpha^\beta}; \quad \alpha > 0, \beta > 0, t \geq 0 \quad (191.17)$$

$$f(t) = \frac{\beta t^{\beta-1}}{\alpha^\beta} \exp\left[-\left(\frac{t}{\alpha}\right)^\beta\right] \quad (191.18)$$

$$R(t) = \exp\left[-\left(\frac{t}{\alpha}\right)^\beta\right] \quad (191.19)$$

With $\beta = 1$, the Weibull distribution reduces to the constant hazard model with $\lambda = (1/\alpha)$. With $\beta = 2$, the Weibull distribution reduces to the Rayleigh distribution.

The associated MTTF is

$$\text{MTFF} = \mu = \alpha \Gamma\left(1 + \frac{1}{\beta}\right) \quad (191.20)$$

where Γ denotes the gamma function.

191.11 Combinatorial Aspects

Analysis of complex systems is facilitated by decomposition into functional entities consisting of subsystems or units and by the application of combinatorial considerations and network modeling techniques.

A *series structure* (or chain structure) consisting of n units is shown in [Figure 191.2](#). From the reliability point of view, the system will succeed only if all the units succeed. The units may or may not be physically in series. If R_i is the probability of success of the i th unit, then the series system reliability R_s is given as

$$R_s = \prod_{i=1}^n R_i \quad (191.21)$$

if the units do not interact with each other. If they do, then the conditional probabilities must be carefully evaluated.

If each of the units has a constant hazard, then

$$R_s(t) = \prod_{i=1}^n \exp(-\lambda_i t) \quad (191.22)$$

where λ_i is the constant failure rate for the i th unit or component. This enables us to replace the n components in series by an equivalent component with a constant hazard λ_s where

$$\lambda_s = \sum_{i=1}^n \lambda_i \quad (191.23)$$

FIGURE 191.2 Series or chain structure. (Source: Ramakumar, R. 1993. *Engineering Reliability: Fundamentals and Applications*. Prentice Hall, Englewood Cliffs, NJ. With permission.)

If the components are identical, the $\lambda_s = n\lambda$ and the MTTF for the equivalent component is $(1/n)$ of the MTTF of one component.

A *parallel structure* consisting of n units is shown in Figure 191.3. From the reliability point of view, the system will succeed if any one of the n units succeeds. Once again, the units may or may not be physically or topologically in parallel. If Q_i is the probability of failure of the i th unit, then the parallel system reliability R_p is given as

$$R_p = 1 - \prod_{i=1}^n Q_i \quad (191.24)$$

if the units do not interact with each other (i.e., are independent).

If each of the units has a constant hazard, then

$$R_p(t) = 1 - \prod_{i=1}^n [1 - \exp(-\lambda_i t)] \quad (191.25)$$

and we do not have the luxury of being able to replace the parallel system by an equivalent component with a constant hazard. The parallel system does not exhibit constant hazard even though each of the units has constant hazard.

The MTTF of the parallel system can be obtained by using Equation (191.25) in Equation (191.6). The results for the case of components with identical hazards λ are: $(1.5/\lambda)$, $(1.833/\lambda)$, and $(2.083/\lambda)$ for $n = 2, 3$, and 4 , respectively. The largest gain in MTTF is obtained by going from one component to two components in parallel. It is uncommon to have more than two or three components in a truly parallel configuration because of the cost involved. For two nonidentical components in parallel with hazard rates λ_1 and λ_2 , the MTTF is given as

$$\text{MTTF} = \frac{1}{\lambda_1} + \frac{1}{\lambda_2} - \frac{1}{\lambda_1 + \lambda_2} \quad (191.26)$$

FIGURE 191.3 Parallel structure. (Source: Ramakumar, R. 1993. *Engineering Reliability: Fundamentals and Applications*. Prentice Hall, Englewood Cliffs, NJ. With permission.)

An r -out-of- n structure, also known as a partially redundant system, can be evaluated using Equation (191.11). If all the components are identical, independent, and have a constant hazard λ , then the system reliability can be expressed as

$$R(t) = \sum_{k=r}^n C_k e^{-k\lambda t} (1 - e^{-\lambda t})^{n-k} \quad (191.27)$$

For $r = 1$, the structure becomes a parallel system. For $r = n$, it becomes a series system.

Series-parallel systems are evaluated by repeated application of the expressions derived for series and parallel configurations by employing well-known network reduction techniques.

Several general techniques are available for evaluating the reliability of complex structures that do not come under purely series or parallel or series-parallel. They range from inspection to cut-set and tie-set methods and connection matrix techniques that are amenable to computer programming.

191.12 Modeling Maintenance

Maintenance of a component could be a scheduled (preventive) one or a forced (corrective) one. The latter follows in-service failure and can be handled using Markov models discussed later. Scheduled maintenance is conducted at fixed intervals of time, irrespective of the system continuing to operate satisfactorily.

Scheduled maintenance, under ideal conditions, takes very little time (compared to the time between scheduled maintenance events) and the component is restored to an “as new” condition. Even if the component is irreparable, scheduled maintenance postpones failure and prolongs the life of the component. Scheduled maintenance makes sense only for those components with increasing hazard rates. Most mechanical systems come under this category. It can be shown that the density function $f_T^*(t)$, with scheduled maintenance included, can be expressed as

$$f_T^*(t) = \sum_{k=0}^{\infty} f_1(t - kT_M) R^k(T_M) \quad (191.28)$$

where

$$f_1 = \begin{cases} f_T(t) & \text{for } 0 < t \leq T_M \\ 0 & \text{otherwise} \end{cases} \quad (191.29)$$

and

$$\begin{aligned} R(t) &= \text{component reliability function} \\ T_M &= \text{time between maintenance (constant)} \\ f_T(t) &= \text{original failure density function} \end{aligned}$$

In Equation (191.28), $k = 0$ is used only between $t = 0$ and $t = T_M$, and $k = 1$ is used only between $t = T_M$ and $t = 2T_M$ and so on.

A typical $f_T^*(t)$ is shown in Figure 191.4. The time scale is divided into equal intervals of T_M each. The function in each segment is a scaled-down version of the one in the previous segment, the scaling factor being equal to $R(T_M)$. Irrespective of the nature of the original failure density function, scheduled maintenance gives it an exponential tendency. This is another justification for the widespread use of exponential distribution in system reliability evaluations.

FIGURE 191.5 State-space diagram for a single repairable component. (Source: Ramakumar, R. 1993. *Engineering Reliability: Fundamentals and Applications*. Prentice Hall, Englewood Cliffs, NJ. With permission.)

191.13 Markov Models

Of the various Markov models available, the discrete-state, continuous-time Markov process has found many applications in system reliability evaluation, including the modeling of repairable systems. The model consists of a set of discrete states (called the state space) in which the system can reside and a set of transition rates between appropriate states. Using these, a set of first-order differential equations is derived in the standard vector-matrix form for the time-dependent probabilities of the various states. Solution of these equations incorporating proper initial conditions gives the probabilities of the system residing in different states as functions of time. Several useful results can be gleaned from these functions.

191.14 Binary Model for Repairable Component

The binary model for a repairable component assumes that the component can exist in one of two states — the *up* state or the *down* state. The transition rates between these two states, S_0 and S_1 , are assumed to be constant and equal to λ and μ . These transition rates are the constant failure and repair rates implied in the modeling process and their reciprocals are the MTTF and MTTR, respectively. Figure 191.5 illustrates the binary model.

The associated Markov differential equations are

$$\begin{bmatrix} P_0'(t) \\ P_1'(t) \end{bmatrix} = \begin{bmatrix} -\lambda & \mu \\ \lambda & -\mu \end{bmatrix} \begin{bmatrix} P_0(t) \\ P_1(t) \end{bmatrix} \quad (191.30)$$

with the initial conditions

$$\begin{bmatrix} P_0(0) \\ P_1(0) \end{bmatrix} = \begin{bmatrix} 1 \\ 0 \end{bmatrix} \quad (191.31)$$

The coefficient matrix of Markov differential equations, namely

$$\begin{bmatrix} -\lambda & \mu \\ \lambda & -\mu \end{bmatrix}$$

is obtained by transposing the matrix of rates of departures

$$\begin{bmatrix} 0 & \lambda \\ \mu & 0 \end{bmatrix}$$

and replacing the diagonal entries by the negative of the sum of all the other entries in their respective columns. The solution of Equation (191.30) with initial conditions as given by Equation (191.31) yields

$$P_0(t) = \frac{\mu}{\lambda + \mu} + \frac{\lambda}{\lambda + \mu} e^{-(\lambda + \mu)t} \quad (191.32)$$

$$P_1(t) = \frac{\lambda}{\lambda + \mu} [1 - e^{-(\lambda + \mu)t}] \quad (191.33)$$

The limiting, or steady-state, probabilities are found by letting $t \rightarrow \infty$. They are also known as limiting availability A and limiting unavailability U and they are

$$P_0 = \frac{\mu}{\lambda + \mu} \equiv A \quad \text{and} \quad P_1 = \frac{\lambda}{\lambda + \mu} \equiv U \quad (191.34)$$

The time-dependent $A(t)$ and $U(t)$ are simply $P_0(t)$ and $P_1(t)$, respectively.

Referring back to Equation (191.14) for a constant hazard component and comparing it with Equation (191.32) which incorporates repair, the difference between $R(t)$ and $A(t)$ becomes obvious. Availability $A(t)$ is the probability that the component is up at time t , and reliability $R(t)$ is the probability that the system has continuously operated from 0 to t . Thus, $R(t)$ is much more stringent than $A(t)$. While both $R(0)$ and $A(0)$ are unity, $R(t)$ drops off rapidly as compared to $A(t)$ as time progresses. With a small value of MTTR (or large value of μ), it is possible to realize a very high availability for a repairable component.

191.15 Two Dissimilar Repairable Components

Irrespective of whether the two components are in series or in parallel, the state space consists of four possible states: S_1 (1 up, 2 up), S_2 (1 down, 2 up), S_3 (1 up, 2 down), and S_4 (1 down, 2 down). The actual system configuration will determine which of these four states correspond to system success and failure. The associated state-space diagram is shown in [Figure 191.6](#). Analysis of this system results in the following steady-state probabilities:

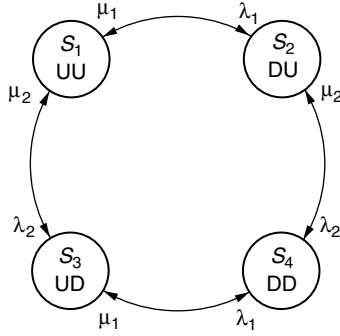

FIGURE 191.6 State-space diagram for two dissimilar repairable components. (Source: Ramakumar, R. 1993. *Engineering Reliability: Fundamentals and Applications*. Prentice Hall, Englewood Cliffs, NJ. With permission.)

$$P_1 = \frac{\mu_1 \mu_2}{\text{Denom}}; \quad P_2 = \frac{\lambda_1 \mu_2}{\text{Denom}}; \quad P_3 = \frac{\lambda_2 \mu_1}{\text{Denom}}; \quad P_4 = \frac{\lambda_1 \lambda_2}{\text{Denom}} \quad (191.35)$$

where

$$\text{Denom} \equiv (\lambda_1 + \mu_1)(\lambda_2 + \mu_2) \quad (191.36)$$

For components in series, $A = P_1$, $U = (P_2 + P_3 + P_4)$, and the two components can be replaced by an equivalent component with a failure rate of $\lambda_s = (\lambda_1 + \lambda_2)$ and a mean repair duration of r_s , where

$$r_s \equiv \frac{\lambda_1 r_1 + \lambda_2 r_2}{\lambda_s} \quad (191.37)$$

Extending this to n components in series, the equivalent system will have

$$\lambda_s = \sum_{i=1}^n \lambda_i \quad \text{and} \quad r_s \equiv \frac{1}{\lambda_s} \sum_{i=1}^n \lambda_i r_i \quad (191.38)$$

$$\text{and system unavailability} = U_s \equiv \lambda_s r_s = \sum_{i=1}^n \lambda_i r_i \quad (191.39)$$

For components in parallel, $A = (P_1 + P_2 + P_3)$, $U = P_4$, and the two components can be replaced by an equivalent component with

$$\lambda_p \equiv \lambda_1(\lambda_2 r_1) + \lambda_2(\lambda_1 r_2) \quad \text{and} \quad \mu_p = \mu_1 + \mu_2 \quad (191.40)$$

$$\text{and system unavailability} = U_p = \lambda_p (1/\mu_p) \quad (191.41)$$

Extension to more than two components in parallel follows similar lines. For three components in parallel,

$$\mu_p = (\mu_1 + \mu_2 + \mu_3) \quad \text{and} \quad U_p = \lambda_1 \lambda_2 \lambda_3 r_1 r_2 r_3 \quad (191.42)$$

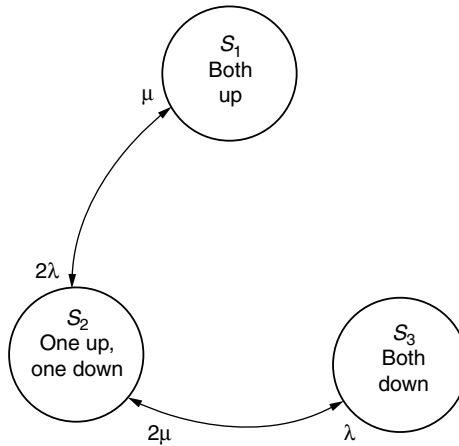

FIGURE 191.7 State-space diagram for two identical repairable components. (Source: Ramakumar, R. 1993. *Engineering Reliability: Fundamentals and Applications*. Prentice Hall, Englewood Cliffs, NJ. With permission.)

191.16 Two Identical Repairable Components

In this case, only three states are needed to complete the state space: S_1 (both up), S_2 (one up and one down), and S_3 (both down). The corresponding state-space diagram is shown in Figure 191.7. Analysis of this system results in the following steady-state probabilities:

$$P_1 = \left(\frac{\mu}{\lambda + \mu} \right)^2; \quad P_2 = \frac{2\lambda}{\mu} \left(\frac{\mu}{\lambda + \mu} \right)^2; \quad P_3 = \left(\frac{\lambda}{\lambda + \mu} \right)^2 \quad (191.43)$$

191.17 Frequency and Duration Techniques

The expected residence time in a state is the mean value of the passage time from the state in question to any other state. Cycle time is the time required to complete an *in* and *not in* cycle for that state. Frequency of occurrence (or encounter) for a state is the reciprocal of its cycle time. It can be shown that the frequency of occurrence of a state is equal to the steady-state probability of being in that state multiplied by the total rate of departure from it. Also, the expected value of the residence time is equal to the reciprocal of the total rate of departure from that state.

Under steady-state conditions, the expected frequency of entering a state must be equal to the expected frequency of leaving that state (this assumes that the system is *ergodic*, which will not be elaborated for lack of space). Using this principle, frequency balance equations can be easily written (one for each state) and solved in conjunction with the fact that the sum of the steady-state probabilities of all the states must be equal to unity to obtain the steady-state probabilities. This procedure is much simpler than solving the Markov differential equations and letting $t \rightarrow \infty$.

191.18 Applications of Markov Process

Once the different states are identified and a state-space diagram is developed, Markov analysis can proceed systematically (probably with the help of a computer in the case of large systems) to yield a wealth of results used in system reliability evaluation. Inclusion of installation time after repair, maintenance, spare, and stand-by systems, and limitations imposed by restricted repair facilities are some of the many problems that can be studied.

191.19 Some Useful Approximations

For an r -out-of- n structure with failure and repair rates of λ and μ for each, the equivalent MTTR and MTTF can be approximated as

$$\text{MTTR}_{\text{eq}} = \frac{\text{MTTR of one component}}{n-r+1} \quad (191.44)$$

$$\text{MTTR}_{\text{eq}} = \left(\frac{\text{MTTF}}{\text{of one component}} \right) \left(\frac{\text{MTTF}}{\text{MTTR}} \right)^{n-r} \left[\frac{(n-r)!(r-1)!}{n!} \right] \quad (191.45)$$

The influence of weather must be considered for components operating in an outdoor environment. If λ and λ' are the normal weather and stormy weather failures rates, λ' will be much greater than λ , and the average failure rate λ_f can be approximated as

$$\lambda_f \cong \left(\frac{N}{N+S} \right) \lambda + \left(\frac{S}{N+S} \right) \lambda' \quad (191.46)$$

where N and S are the expected durations of normal and stormy weather. For well-designed, high-reliability components, the failure rate λ will be very small and $\lambda t \ll 1$. Then, for a single component,

$$R(t) \cong 1 - \lambda t \quad \text{and} \quad Q(t) \cong \lambda t \quad (191.47)$$

and for n dissimilar components in series,

$$R(t) \cong 1 - \sum_{i=1}^n \lambda_i t \quad \text{and} \quad Q(t) \cong \sum_{i=1}^n \lambda_i t \quad (191.48)$$

For the case of n identical components in parallel,

$$R(t) \cong 1 - (\lambda t)^n \quad \text{and} \quad Q(t) \cong (\lambda t)^n \quad (191.49)$$

For the case of an r -out-of- n configuration,

$$Q(t) \cong {}_n C_{(n-r+1)} (\lambda t)^{n-r+1} \quad (191.50)$$

Equations (191.47) through (191.50) are called rare-event approximations.

191.20 Reliability and Economics

There are two fundamental facts involved in the interaction of reliability and economics. First of all, it is impossible to realize 100% reliability, and second, the closer we want to approach this ideal value, the more expensive the system will become. Then, how much should be spent on an item (or system) and what should be the design reliability? These are very difficult questions since the answers are highly case specific, and often depend on how nonmonetary items are quantified in monetary terms. No matter how this is done, it will evoke controversy. To add to the complexity, resources spent on improving reliability are certain and near term, while the cost of failure is uncertain and far removed in the time frame.

There are three basic categories of options for improving reliability:

- Provide additional redundancy
- Design with environmental capability
- Conduct environmental testing and redesign based on results

Ultimately, an integrated cost-benefit tradeoff will have to be used, keeping in mind the less precise and more subjective nature of the world we live in.

Recognizing the vast scope of this topic, only one aspect, namely the economics of redundancy, will be considered here. There are two basic redundancy configurations:

- System redundancy (parallel-series configuration)
- Unit redundancy (series-parallel configuration)

System Redundancy

Figure 191.8 illustrates these two redundancy configurations. In system redundancy, the basic or original system consisting of a number of units in series is completely replicated one or more times and are operated in parallel. In unit redundancy, each of the units in the basic system is replicated and connected in parallel. These parallel units are operated in series to form the redundant system. All the units in series

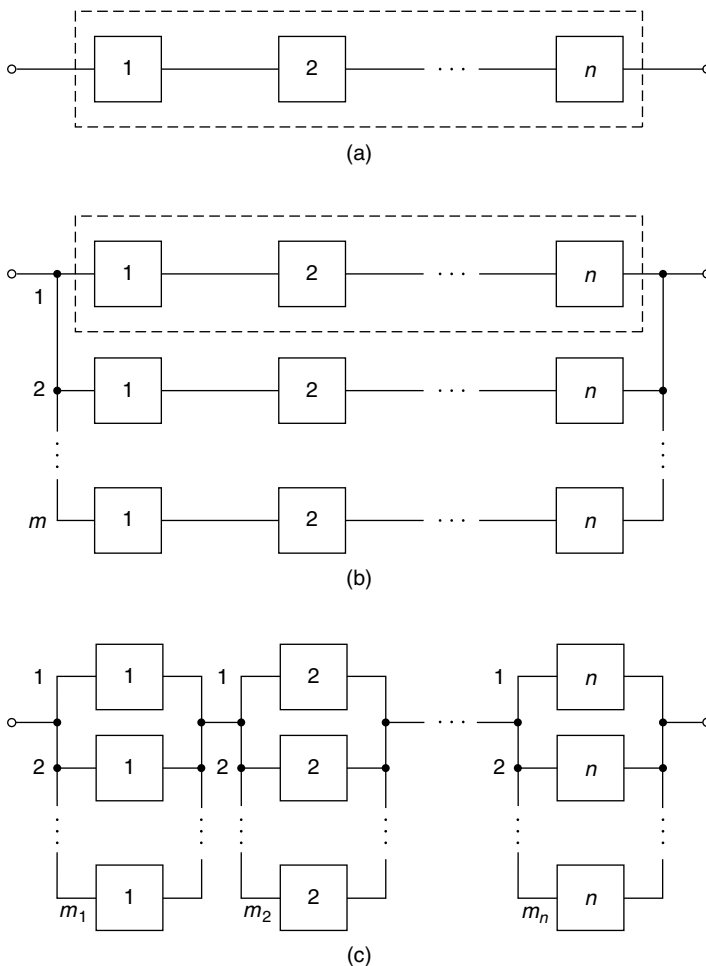

FIGURE 191.8 Redundancy configurations. (a) Basic (original) system. (b) System redundancy; parallel-series configuration. (c) Unit redundancy; series-parallel configuration. (Source: Ramakumar, R. 1993. *Engineering Reliability: Fundamentals and Applications*. Prentice Hall, Englewood Cliffs, NJ. With permission.)

in the original system may or may not be identical. However, replication of any one unit always involves identical units. The number of units in parallel with each basic unit in unit redundancy may or may not be equal. A simple economic analysis is considered next.

For the basic system,

$$\text{Total Cost} = C_0 = \sum_{i=1}^n c_i \quad (191.51)$$

$$\text{Reliability} = R_0 = \prod_{i=1}^n p_i \quad (191.52)$$

where c_i and p_i are the unit cost and reliability of the i th unit and n is the number of units in series in the basic system.

For the system redundancy configuration,

$$\text{Total Cost} = C_s = mC_0 \quad (191.53)$$

$$\text{Reliability} = R_s = 1 - (1 - R_0)^m \quad (191.54)$$

where m is the number of replicated systems operating in parallel.

For the unit redundancy configuration,

$$\text{Total Cost} = C_u = \sum_{i=1}^m c_i m_i \quad (191.55)$$

$$\text{Reliability} = R_u = \prod_{i=1}^n [1 - (1 - p_i)^{m_i}] \quad (191.56)$$

where m_i is the number of replicated units for the i th basic unit.

In general, system redundancy configuration is costly and wasteful as compared to the unit redundancy configuration.

Unit Redundancy

Starting with a basic system as shown in [Figure 191.8\(a\)](#) with a total cost C_0 and reliability R_0 , we seek to improve the reliability to R by employing unit redundancy at minimum cost. By applying simple optimization techniques, we can derive the values of m_i , $i = 1, 2, \dots, n$, that will minimize the total cost and achieve the desired system reliability value of R . The results are summarized in the following equations.

$$m_i = \frac{\ln(1 - R^{\alpha_i})}{\ln(1 - p_i)} \quad (191.57)$$

in which

$$\alpha_i = \frac{\left[\frac{c_i}{\ln(1 - p_i)} \right]}{\left[\sum_{j=1}^n \frac{c_j}{\ln(1 - p_j)} \right]} \quad \text{for } i = 1, 2, \dots, n \quad (191.58)$$

The m_i values calculated using Equation (191.58) should be rounded up to the nearest integer for obvious reasons. Once the m_i values are known, the minimum cost figure can be easily calculated using Equation (191.55).

Defining Terms

Availability — Availability $A(t)$ is the probability that a system is performing its required function successfully at time t . The steady-state availability A is the fraction of time that an item, system, or component is able to perform its specified or required function.

Bathtub curve — For most physical components and living entities, the plot of failure (or hazard) rate versus time has the shape of the longitudinal cross section of a bathtub.

Hazard rate function — The plot of instantaneous failure rate versus time is called the hazard function. It clearly and distinctly exhibits the various life cycles of components.

Mean time to failure (MTTF) — Mean time to failure is the mean or expected value of time to failure.

Parallel structure — Also known as a completely redundant system, it describes a system that can succeed when at least one of two or more components succeeds.

Redundancy — Refers to the existence of more than one means, identical or otherwise, for accomplishing a task or mission.

Reliability — Reliability $R(t)$ of an item or system is the probability that it has performed successfully over the time interval from 0 to t . In the case of irreparable systems, $R(t) = A(t)$. With repair, $R(t) \leq A(t)$.

Series structure — Also known as a chain structure or nonredundant system, it describes a system whose success depends on the success of all its components.

- 192.4 Conclusion

To remain competitive a company has to respond to market changes. For a company to quickly react to these changes, integration of manufacturing activities becomes a necessity. Integration implies that necessary information can be accessed at any time and location, which in turn means that a robust and up-to-date information system containing all information necessary for any stage of the manufacturing process is necessary. Having the information stored in a database is not sufficient; rather the information should be transformed into knowledge. This chapter identifies areas of potential applications of data mining in computer-integrated manufacturing. An attempt will be made to answer the following questions:

1. How can data mining technology be employed beyond prediction and modeling?
2. How can several quality, process-planning, and maintenance problems in manufacturing environment be overcome?
3. How can data mining results be used among different applications?

192.1 Computer Integrated Manufacturing

Definition and Rationale

Computer integrated manufacturing (CIM) involves integration of manufacturing activities by a computer system. This integration makes it possible for various functional areas (e.g., planning, manufacturing, design, and control) to exchange information.

According to Kalpakjian and Schmid [7], advances in automating manufacturing processes have been driven by several competitive forces, such as the need to continuously improve productivity and product

quality and to reduce manufacturing costs. In this way, automation has become a key factor. Automating manufacturing facilities, agile manufacturing, and integration into a single system has led to CIM.

The goals for CIM are to improve productivity, increase product quality and uniformity, minimize cycle time, and reduce labor costs [7]. CIM leads to:

- Timely response to rapid changes in market demands and product changes
- Better use of materials, machinery, personnel, and reduction of inventory
- Better production control and management of manufacturing operations
- Manufacture of high-quality products at low cost

Computer simulation of manufacturing processes and systems considers process variability and process optimization.

CIM Requirements

To fully realize the benefits of integration, CIM has to be a global system that allows all users to share the same up-to-date information. CIM calls a large database that should be shared by the entire organization. The database must contain up-to-date, detailed, and accurate data. The data relate to products, designs, machines, processes, materials, production, marketing, inventory, and so on. Ideally the data should be collected in real time using automated data acquisition systems.

The data acquisition system should collect and transfer information to the database as needed by different users. The database information should be easily accessible by users, such as designers, manufacturing engineers, process planners, financial officers, and managers. Moreover, different users may require different access modes and tools.

Due to a variety of access modes, the database should be protected against failure or unauthorized use. Management of such a database is critical.

For real-time management and online data analysis, many sensors that provide information about the system are necessary. The data acquisition system populates the database with the following types of data:

- Products and processes
 - Product data: part shapes, dimensions, specifications
 - Data management attributes: owner, revision level, part number
 - Production data: manufacturing process involved
 - Operational data: scheduling, lot size, assembly requirements
 - Resources data: capital, machines, equipment tooling, personnel and their capabilities
- Current manufacturing
 - Number of parts being produced per unit of time
 - Part dimensional accuracy
 - Part surface finish
 - Part weight

The database should make it possible to observe the state of the production system, including the number of parts that have been produced, stock levels, requirements, production rates, and so on. This will help in the decision making and control of the production system. Communication and exchange of data, information, and knowledge among different systems calls for use of standards, such as STEP (Standard for the Exchange of Product Model Data) [6]. STEP facilitates the transfer of information from the design stage to planning, and manufacture without reentering product-related data.

192.2 Data Mining

The volume and scope of manufacturing data are growing at an unprecedented rate, making data analysis and decision making based on the data increasingly difficult for engineers and managers. Numerous tools, including statistics, are used for data analysis. Statistics makes it possible for engineers and managers

to plan products and evaluate processes. They provide population-based answers using various models (e.g., regression) and parameters (e.g., mean, confidence interval).

Data mining offers algorithms and tools for discovery of nontrivial, implicit, previously unknown, and potentially useful and understandable patterns from large data sets [1]. It concentrates on discovery of models applicable to an individual or group of individuals (subpopulation) rather than entire populations of objects (e.g., parts).

Data Mining Tasks

Data mining realizes two kinds of tasks: *prediction* produces a model that can be used for classification or estimation; and *description* produces understandable and useful patterns and relationships that permit users to understand a complex database. Westphal and Blaxton [14] described data mining tasks as follows:

- Classification involves assigning labels to data records. The labels come from a small predefined set (good/bad or red/white/yellow). The job of the data miner is to build a model that will successfully classify the records.
- Estimation is the task of filling in a missing value in a particular field of an incoming record as a function of other fields in the record. The usual statistical regression techniques are most often employed for estimation. Estimation is also a popular application of neural networks.
- Segmentation or clustering breaks the population into smaller subpopulations having similar behavior. Clustering methods achieve maximum homogeneity with groups and maximum heterogeneity between groups. Clustering is an unsupervised learning tool aiming at finding natural groupings (clusters). Cluster detection, affinity grouping, and link analysis are mostly used for clustering.
- The description task focuses on explaining the relationships among the data. Among others, link analysis and visualization techniques can be used. Link analysis determines associations between the variables, and visualization techniques are used to simplify data comprehension with adapted representations.

Data Mining Algorithms

An algorithm determines a function (model) linking an output with inputs. Various classes of algorithms are used to mine data [2]. Two general model types are available:

- If the output variable is discrete valued, classification modeling is employed.
- If the output variable is continuous valued, prediction modeling is employed.

Common *predictive modeling* (also called classification or supervised learning) techniques include neural networks, decision trees, and decision rules algorithms.

In *clustering modeling* (called segmentation or unsupervised learning), an algorithm identifies sets of similar examples in some optimal fashion. To obtain these sets, various methods are used, such as k-means algorithm, hierarchical algorithms, pattern recognition, Bayesian statistics, and neural networks.

In *frequent pattern extraction models* (called association rule mining), algorithms extract combinations of variables that exist in the data with some predefined level of regularity. For instance, an association $A \Rightarrow B$ can be provided with two statistical measures: support and confidence. *Support* measures the number of times that A exists as a fraction of the total data. *Confidence* measures the fraction of times that B exists in the data when A is present. An association with high confidence and support is provided to the user.

General Methodology

Figure 192.1 illustrates the data mining process. According to Fayyad et al. [5], this process includes the following steps:

1. Develop an understanding of the application domain, relevant prior knowledge, and goals of the end user.

FIGURE 192.1 The data mining process. (Source: Fayyad U. M., Piatetsky-Shapiro G., Smyth P. et al., *Advances in Knowledge Discovery and Data Mining*, MIT Press, Cambridge, MA, 1996.)

2. Create a target data set.
3. Clean and preprocess data.
4. Reduce and project data, that is, reduce the effective number of variables under consideration.
5. Select data mining task (classification, regression, clustering).
6. Select data mining algorithm(s), that is, determine which models and parameters are appropriate.
7. Mine data — search for patterns of interest in a particular representational form or a set of such representations, including classification rules, decision trees, regression, clustering, and so on.
8. Interpret mined patterns. Return to any of Steps 1 through 7 for further iteration as necessary.
9. Consolidate discovered knowledge.

192.3 CIM and Data Mining

The information system of an integrated enterprise disposes the information in the areas depicted in Figure 192.2. With the growing number of applications of enterprise requirement planning (ERP) and material and manufacturing requirement planning (MRP and MRP II) in companies of various sizes, more information about products, production capacity, and means of production is becoming available. Along the product life cycle, plenty of information is generated by product data management (PDM) systems that define products, data from marketing studies to define market shares, design form information, and so on.

The data reflect the experience of the designer and manufacturing process planner. All this information has not been sufficiently used. The latter leads to high expectations for applications of data mining in a CIM environment. These data can be mined to meet numerous goals, including understanding the manufacturing system — specific studies of a machine, a set of machines, a product, or a set of products; focus on a time interval, process, or any other subset of the database. Data mining in a CIM environment can help managers to understand complex systems by:

- Presenting high-probability rules for a better understanding of the system
- Presenting complete information to enhance decision making
- Providing information to predict performance or response to disturbances

FIGURE 192.2 Sources of information in an integrated enterprise. (Source: Kusiak A., *Computational Intelligence in Design and Manufacturing*, Wiley-Interscience, New York, 2000.)

- Estimation of production costs
- Providing information for fast detection of defects in a production or in supply chain

Benefits of data mining follow:

- Accelerate development of a new product/process by analogy to existing designs.
- Recommending manufacturing processes to accelerate process definition or to assist inexperienced engineers.
- Identification of the best set of process parameters from the experience of historical projects.
- Data mining can be used for group technology applications. Classification can set a group to a new part and extract all relevant processes, times, and costs from the database.
- Group technology with data mining makes possible standardization of part design and minimization of design duplication, taking advantage of the design and processing similarities (clustering).
- Process plans can be standardized and developed more efficiently.
- Parts can be managed as families. Data mining can suggest the use of a similar part, product, process, and design stored in the database.
- The best sets of manufacturing parameters can be extracted.

In the following, we discuss how to extract useful information for product manufacturing from databases created independently at different points in the product life cycle.

Data Mining Process in Engineering

Büchner et al. [4] proposed a data mining process in a manufacturing environment (Figure 192.3). The process begins with the identification of a problem by management. The application of data mining techniques focuses on resolution of a specified problem. Steps discussed by Büchner et al. [4] are summarized below.

1. *Human resource identification.* To resolve an identified manufacturing problem, the following three experts are recommended:
 - A. Domain expert. This expert could belong to an engineering unit. S/he will join the study to provide information on the manufacturing process, and is able to analyze the results.
 - B. Data expert. This individual comes from the company's informatics technologies department. The data expert is necessary to locate in the database the data of interest to the problem at hand.
 - C. Data mining expert. This person, typically an outsider, is in charge of the processing of the data. S/he will select the best algorithm and parameters to perform the analysis.

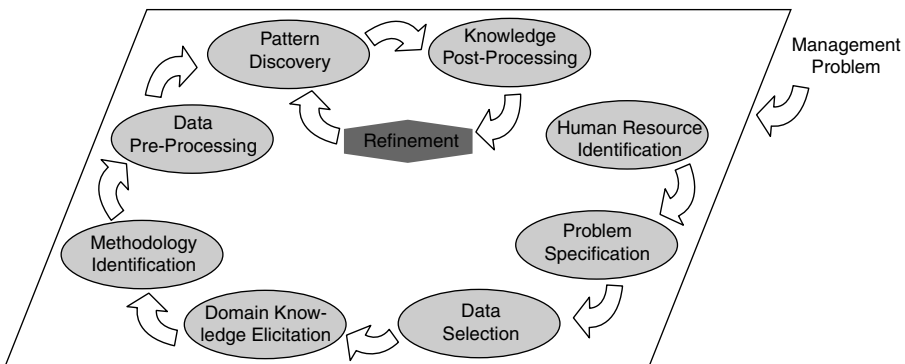

FIGURE 192.3 Data mining process in manufacturing environment. (Source: Büchner A. G., Anand S. S., and Hugues J. G., *Stud. Informatics Control*, 6, 319–328, 1997.)

2. *Problem specification.* After initial analysis and discussion, the experts develop a better comprehension of the problem. The problem is decomposed into subproblems that are easier to understand and manage. The subproblems that can be resolved with data mining techniques are identified, and the most suitable data mining approach is selected (association rules, classification, estimation, cluster analysis, frequent pattern extraction, regression, deviation detection, or visualization techniques; Fayyad et al. [5]).
3. *Data selection.* This step involves analyzing the state of the data required to solve the problem at hand. Four main characteristics are considered:
 - A. Identification of relevant attributes
 - B. Accessibility of data
 - C. Population of required data attributes
 - D. Distribution and heterogeneity of data
4. *Domain knowledge elicitation.* During this stage, the data mining expert attempts to elicit any domain knowledge of interest that could be incorporated in the discovery process:
 - A. Specific constraints on the search space
 - B. Hierarchical generalization
5. *Methodology identification.* The best data mining methodology for solving the specified problem is selected.
6. *Data preprocessing.* This step is comprised of the following components:
 - A. Adaptation of the database to a format that the data mining algorithm can understand.
 - B. Predict/fill in the missing data in the database as needed by the data mining algorithm.
 - C. Reduction in problem size.
7. *Pattern discovery.* This step involves using algorithms that automatically discover patterns in the preprocessed data. Selection of the algorithm depends on the data mining goal. Pattern discovery is an iterative process that calls for several refinements. When the volume of data is too large for computation in a reasonable time, decomposition of the data set could be considered. Kusiak [9] proposed two forms:
 - A. Feature set decomposition: partitioning a data set on features (e.g., columns of a spreadsheet)
 - B. Object set decomposition: partitioning a data set on objects (e.g., rows of the spreadsheet)
8. *Knowledge post-processing.* Trivial and obsolete information must be filtered out and discovered knowledge must be presented in a user-readable way. Visualization techniques may help to facilitate the comprehension of extracted knowledge. The new knowledge must be validated; the domain and data mining experts should work together at this stage. Often the knowledge post-processing provides supplemental knowledge to refine pattern discovery, and may necessitate a return to data preprocessing as well.

Data Mining in Engineering Design

Analysis of a product and its environment is key to improving the product. In order to better match customers' requirements, marketing analysis provides information about customer expectations. Data mining techniques are able to assist marketing personnel to better learn the market; results are then communicated to departments responsible for product design and maintenance.

Marketing

Marketing can use data mining to discover knowledge about customers. The data to be mined could include the number of products sold; description of product contents (options, variants); how the customer paid (cash, check, credit card); whether credit has been arranged and with which bank; services obtained (warranties, delivery dates, delivery at home, installation at home); whether instructions for using the product were requested; customer's age, employment, hobbies, marital status; whether s/he has children; and whether product was purchased for self or as gift.

Informal data could be provided by salespeople, such as the time needed by a customer to make a decision, and whether s/he considered competing products.

From these types of data, the following knowledge can be extracted:

1. Customer requirements can be separated into product clusters. This will allow producing customized products for each cluster instead of a generic product for all consumers. The type and number of products needed can be determined.
2. Predict customers who are likely to buy a particular product/service. With this information we are able to size the production ranges that will help in design (select materials and processes).
3. Anticipate future requirements and wishes for new functionality, so as to work on new products or adapt existing products.
4. Discovery of links between options, as in product/customer, customer/service, and product/service that could be useful to create new products/services or to improve existing designs.
5. Improve the services offered around a product. Propose different ways of buying products — for example, with a customer-specific credit. An agreement with a bank or a credit organization could be necessary. Other services could be organized around delivery (with a transportation company), installation (with hotlines or specialists), teaching (courses or web pages), and so on.

These results, combined with national or local statistics, could be helpful in determining whether a new product/service has to be created, when, for how many customers, at what price, with what parameters and options, and so on. With this knowledge, the design team will be able to develop the new product/service. Berry and Linoff [3] present many examples and applications of data mining in marketing, sales, and customer support.

Yeo et al. [15] used data mining for the prediction of claim costs for automobile insurance industry. Insurance companies are confronted with a dilemma. When claim costs are high, there is a high profit from each consumer but a small number of consumers. On the other hand, if claim costs are low, the profit per consumer is small but there is a large number of consumers. In this situation, policyholders have been classified according to their perceived risk, and claim costs within each risk group have been modeled.

Engineering Design

The product development process generates a large volume of information. The information comes from PDM systems, computer-aided design (CAD) systems, simulations, computation, tests, and so on. In this section we discuss how data mining techniques can extract information from product and design process databases.

The goal of data mining in product development is to learn from past designs in order to assist in decision making of new designs. For instance, Leu et al. [11] applied data mining for prediction of tunnel support stability. In this case study, a company had to design a tunnel through rock for a railroad. Designing such a project requires a large amount of surveying and experience. A crucial task is to estimate the causes of instability of tunnel support that depend on many parameters such as rock characteristics and construction characteristics. Tunnel project engineers had incomplete understanding of rock mechanisms and the impact of construction methods and procedures.

To solve this complex problem, traditional tools, discriminant analysis, and multiple nonlinear regression methods did not prove to be successful. The company had a large database of previous tunnel descriptions and decided to apply data mining techniques. After classification of the historical projects according to rock mass, neural networks were trained and tested on filtered data. The study demonstrated the ability of data mining to deliver new project insights in areas where traditional techniques had not been successful.

To conduct a design project, several meetings are necessary. Reports from these meetings contain all ideas that emerged, which ideas were developed, which decisions have been taken, and which solutions were discontinued and why, as well as the set of tasks that must be done before the next meeting. At the

same time, e-mails are exchanged between the members of the team, some tasks are accomplished, others are cancelled, decisions are made, and so on.

In an integrated company, all this information is stored in a database. PDM systems are designed to collect such information. In an ISO-9001 certified company, the PDM system is a central information system for quality data. When a project is finished, members of the team can find in the database how and why a decision was made. However, PDM systems are often used for storage when they could be used for knowledge extraction. Mining such data could provide knowledge about product design development, how decisions are made, and how ideas and concepts are used and developed. In a repetitive design environment, data mining can be used for learning from previous designs. The data mining results can be used to provide the right information to the right person at the right time.

For example, in a product design team, some tasks are always done in the same order. For each task, the person who has to perform it needs a certain amount of data. All data are shared in the database. Data mining would save time by providing the necessary knowledge. Moreover, data mining will lead to understanding repetitive design activities and design reuse. The discovered knowledge will accomplish the following:

- Identify valid, novel, useful, and understandable patterns in design (about methods and processes). This knowledge is useful for repetitive designs or repetitive elements of designs.
- Provide adequate information when needed.
- Learning relations between customer needs and design specifications.
- Enabling extraction of relations between design requirements and manufacturing specifications.
- Understanding how requirements are translated into product specifications.
- Project evaluation is facilitated by comparisons with previous projects.
- Understanding of team's decisions and better team coordination.

Simoff and Maher [13] used text analysis to analyze different aspects of participation in a collaborative design project (in an educational design context). Their goal was to understand the style of collaboration and the potential of different environments in a computer-supported collaborative design. The authors learned that different environments facilitate different types of collaboration. After extraction of related and unrelated activities, they reconstructed and ordered task-related activities to understand how the tasks evolved and evaluated individual contributions.

After Sales

After-sales service follows the relationship that was initiated in sales services. It is an important source of information for developing a market overview, and for improving the product or service provided to the consumer. For instance, at the time of product/service delivery and/or after delivery, the consumer may be asked questions about use and preferences, among many other possibilities.

Sforma [12] analyzed the relations between a power company and its consumers. Each consumer was considered as a unique individual rather than as one of many similar consumers. The goal was to discover changes in their habits and then quickly respond with suggestions and appropriate services. The customer database was analyzed according to the following process:

1. Extraction of only the data that was considered useful for the analysis.
2. Application of simple statistics to aggregate values and calculation of new meaningful variables.
3. Organization of the data in a format suitable for the application of a classification technique.

Data mining allowed the company to contact each consumer individually when a change was observed in the energy consumption pattern. A better knowledge of the consumer by the company implies a stronger relationship and loyalty.

Berry and Linnof [3] studied a company manufacturing diesel engines. During the warranty period, the manufacturer received complaints from independent distributors that maintained engines covered by the manufacturer's warranty. Each complaint was studied by an expert to determine if the manpower and the parts used looked acceptable. A set of existing rules was used to analyze the problems without

great success. Data mining was applied to a large set of complaints and new rules were discovered. The new rules were linked to an automatic routing of claims implied that faster service would save the company millions of dollars per year.

The knowledge extracted from after-sales services must be transmitted to different departments and be integrated with the product and service improvement process. To accomplish this integration, the following are needed:

- Time to fix a maintenance problem should be provided to the ERP system.
- Delivery delays should be automatically transmitted to sales services.
- Recurrent breakdowns should be identified and a corrective task should be automatically suggested to the design department and be integrated as a future design task.
- Recurrent breakdowns should be signaled to the maintenance department in order to develop a specific answer suitable to each of these specific breakdowns.
- Recurrent requirements (about products and services) should be transmitted to the marketing and project department to evaluate market evolution and possibilities for improvement.

Data Mining for Quality Management

Data mining can increase product quality by optimizing product quality and by isolating and deleting quality detractors. Two options can be considered in optimizing product quality: increasing average product quality or reduction of the product variability (variance reduction).

In the following example, a particular product characteristic is measured and represented as shown in Figure 192.4. Three levels of quality have been defined: low, medium, and high. The objective is to identify and understand the conditions that contribute to varying quality.

1. Discrimination techniques are applied to discriminate between different classes of objects. These discrimination techniques can be levels, limits, a set of rules, or an application of clustering methods to find models that are able to separate different quality levels.
2. Once the groups have been identified, the products are grouped into low-, medium-, and high-quality clusters.
3. For each quality class, select the objects.
4. For each group of objects selected, extract the conditions that have led to these different states.

After these steps have been completed, we know which conditions led to each level of quality, and then we will be able to select the best set of parameters that lead to a particular quality.

The second way to improve the quality of the manufacturing system is to isolate quality detractors and/or underline reasons why a product may not pass a quality test. The data mining process is based on discrimination of good and bad results and provides the conditions that lead to each quality level. Kusiak [10] performed a fault analysis using the data mining approach to identify the causes of solder defects in a circuit board.

FIGURE 192.4 Product quality.

Data Mining in Manufacturing

Data mining can be used to obtain various types of information aimed at the following objectives:

- Capturing the best manufacturing practices
- Reducing operations expenses
- Predict and prevent failure of components
- Identifying conditions leading to critical situations in order to correct the problem and prevent future failures

Sensitivity Analysis

Sensitivity analysis can be applied to determine which parameters (of the manufacturing system or the process) impact a particular characteristic (productivity, quality, efficiency). Once this knowledge is obtained, it will be possible to optimize the parameters.

A guided data mining analysis can be performed. The parameters that lead to different values of output can be extracted from the database. For instance, if there is an acceptable value of the output, we will have the parameters that lead to it from the model. Next, if the output has to be in a particular range, we can select a range for the inputs or optimize the value of each input in order to reduce manufacturing cost. For example, a parameter that has a low influence on output and a high cost could be modified.

What-If Analysis

A what-if analysis determines what the output (e.g., productivity, quality, efficiency) will be according to new entries or parameters (e.g., time, hardness, temperature). This type of predictive analysis is easy to realize and can be beneficial. The hypothesis is that the new parameters will have the same impact on the output as the former parameters. The steps of a what-if analysis follow:

1. Generate a predictive model from the database (regression analysis or neural networks).
2. Provide a new parameters to the model.
3. Evaluate the new output.
4. Accept the output, and go to Step 2.

This type of analysis determines parameter sensitivity to the output. One can predict the output for a certain combination of input parameters, and then select the set of parameters that optimizes a goal, such as minimizing costs and risks.

Preventive Maintenance

Maintenance is another possible area for the application of data mining, such as in troubleshooting and maintenance planning. The probability of a certain fault or malfunction to occur can be predicted in advance from the maintenance database. The period of time between a certain malfunction or problem can be evaluated and maintenance activities could be scheduled.

Once a fault occurs, it has to be identified and a relevant decision must be made. Using data mining techniques, unexpected faults can be transformed from repairs to preventive maintenance.

Data Mining in Process and Resource Planning

Process planning is concerned with selecting and sequencing resources in order to manufacture a component or a product. Data mining can help in comparing the evolution of process planning activities across different generations of components and products. Knowledge can be extracted from the production database in defining a set of rules (heuristics) for process and resource planning. Data mining can also be useful in predicting customer demands and in optimizing inventory.

192.4 Conclusion

An integrated company generates a large volume of data stored in transactional databases and data warehouses. This chapter discussed possible applications of data mining techniques in an integrated company. Data mining allows to profit from the data collected across many departments. Moreover, data mining provides different forms of knowledge that can be used to meet different goals. Marketing, engineering design, after-market sales service, quality management, manufacturing, and planning activities can all benefit from data mining tools.

193.1 Background

193.2 Flow about a Body
Lift • Drag

193.3 Two-Dimensional Airfoils

193.4 Finite Wing Effects

193.5 Effects of Compressibility

Aerodynamics is a subset of fluid dynamics that deals with the flow of air about objects, typically aircraft, missiles, or their components. Much of the work in aerodynamics focuses on the generation of forces and moments on a body due to the air flowing over and through the body. Aerodynamics deals with theoretical and numerical predictions of performance characteristics, experimental determination of performance characteristics, and the design of new and improved geometries using this information. This chapter provides the basic understanding and equations to enable the engineer to calculate the performance of many aerodynamic configurations and interpret aerodynamic data.

193.1 Background

Understanding aerodynamics requires a knowledge of the basic principles of fluid mechanics. These principles are covered in Section 6. However, several key points required for the understanding of aerodynamics are provided in this section.

To understand how lift is generated, it is important to know the relationship between velocity and pressure in a fluid flow. For flows where the effects of viscosity are negligible, the density is constant, and gravity does not play a role, *Bernoulli's equation* describes this relationship:

$$p + \rho \frac{V^2}{2} = p_0 = \text{constant along a streamline} \quad (193.1)$$

where p is the static pressure, ρ is the density of the fluid medium, and V is the fluid velocity. The constant in Equation (193.1) is the total pressure, denoted p_0 , and is the sum of the static pressure, p , and the dynamic pressure, $\rho V^2/2$. A *streamline* is the path that a fluid particle makes in the flow, assuming the flow is steady, and Equation (193.1) indicates that the total pressure is constant along this line. If the velocity and pressure are known at one point on the streamline, the flow quantities can be computed at another point on the streamline by rewriting Equation (193.1) as

$$p_2 + \rho \frac{V_2^2}{2} = p_1 + \rho \frac{V_1^2}{2} \quad (193.2)$$

FIGURE 193.1 Velocity profile in a boundary layer.

where the subscripts refer to two points along the streamline. The total pressure is a measure of the energy in the flow and Equation (193.1) indicates that this energy is shared between the static pressure and the dynamic pressure (kinetic energy). If the velocity goes to zero at a point in the flowfield, this point is referred to as a *stagnation point* and the pressure there is the stagnation pressure, which is equal to the total pressure.

The effects of *viscosity* and the *no-slip* condition are also important concepts for understanding aerodynamics. When a fluid moves over the surface of a body, it actually “sticks” to the surface of the body so that there is no relative velocity between the fluid and the surface. This is called the no-slip condition and is caused by intermolecular forces and molecular-scale surface roughness. Due to the effects of viscosity, a *boundary layer* is formed near the surface where the velocity increases from zero at the surface to the freestream value, U_∞ , far away (see Figure 193.1). Viscous effects are important only in the boundary layer for most streamlined bodies. Since viscous effects are important in the boundary layer, Bernoulli’s equation cannot be applied there. In fact, in the absence of strong curvature, the pressure at the wall where the velocity is zero is equal to the static pressure in the outer flow and not the total pressure as predicted by Bernoulli’s equation.

Reynolds number is a measure of the importance of viscous effects and is defined as the ratio of momentum forces to viscous forces:

$$\text{Re} = \frac{U_\infty \rho l}{\mu} \quad (193.3)$$

where l is a length scale of the flowfield and μ is the viscosity of the fluid. As the Reynolds number is increased, the effects of viscosity become less important.

193.2 Flow about a Body

This section describes the forces developed in a constant-density flow about general bodies. Figure 193.2 illustrates the flow about an arbitrary two-dimensional body. The body is traveling through still air at a

FIGURE 193.2 Flow about an arbitrary two-dimensional body illustrating the aerodynamic forces and moment exerted by the flowfield. The reference frame is fixed to the body.

velocity of U_∞ and the figure is drawn in the reference frame of the body so the fluid appears to move past the body. Two forces are generated — *lift*, L , and *drag*, D . Lift is the force perpendicular to the incoming velocity and drag is the force parallel to the incoming velocity. A *moment*, M , is also exerted on the body. As the freestream velocity changes, the forces on the body change even if the flowfield remains approximately similar. It is therefore useful to define nondimensional force coefficients, which vary much less with flow speed than the forces themselves. The forces are nondimensionalized by the dynamic pressure times an area associated with the body, S (in the case of a wing, it is usually the wing area). The lift and drag coefficients are defined as

$$C_L \equiv \frac{L}{\frac{1}{2}\rho U_\infty^2 S} \quad (193.4)$$

$$C_D \equiv \frac{D}{\frac{1}{2}\rho U_\infty^2 S} \quad (193.5)$$

The moment coefficient is defined using an additional parameter, l , a length scale of the body (in the case of a wing, it is usually the streamwise length of the wing), as

$$C_M \equiv \frac{M}{\frac{1}{2}\rho U_\infty^2 S l} \quad (193.6)$$

The particular choice of the reference area and length is not critical, but when using published data it is important to know which reference quantities the coefficients are based upon.

Two types of forces act on the surface of a body due to the motion of the fluid — *pressure forces* and *viscous forces*. Pressure forces are simply due to the pressure, p , and act perpendicular to the surface. Viscous forces, or friction forces, are caused by the flow “rubbing” against the surface as it passes over the body. This force acting on a unit area of the surface is termed the *wall shear stress*, τ_w , and acts tangentially to the surface. It is proportional to the velocity gradient normal to the wall at the wall, and is defined as

$$\tau_w = \mu \left. \frac{\partial U}{\partial y} \right|_w \quad (193.7)$$

where μ is the viscosity and the subscript w denotes that the derivative is evaluated at the wall. No matter how complex the surface geometric or the flowfield, the only way that aerodynamic forces are transmitted to a body is through these two mechanisms.

Lift

A lift force is generated on a body by pressure differences between the top and bottom of the body. If the average pressure over the bottom of the body is higher than the average pressure over the top of the body, the lift force points upward. If we consider the flow over a two-dimensional cylinder without viscosity, the streamline pattern is symmetric, as shown in [Figure 193.3\(a\)](#). The presence of the cylinder in the flow requires the same amount of fluid to pass in a smaller area. Thus, the fluid must speed up in some regions of the flowfield. A fluid element moving along the centerline slows down to zero velocity at the stagnation point A , where the pressure is equal to the total pressure. As the fluid moves away from the center of the cylinder, it speeds up, and a minimum pressure occurs in the two regions marked B . This reduction in pressure can be seen using Bernoulli’s equation (Equation (193.1)) because, as the flow speeds up, the static pressure drops in order for the total pressure to remain constant. The fluid slows

FIGURE 193.3 Flow about a cylinder without spin (a) and with spin (b).

down again toward the rear of the cylinder as the streamlines come together and another stagnation point is formed at C. The total lift force is the integral of the pressure over the entire surface in a direction perpendicular to the freestream flow:

$$L = \int p dA_y \quad (193.8)$$

where A_y is the component of the area perpendicular to the freestream flow. Thus, on the upper surface of the cylinder, there is an upward force, but there is an equal and opposite downward force on the lower surface because the flow is symmetric, and the net lift is zero.

If the cylinder is spun about its axis, as shown in Figure 193.3(b), the flow pattern becomes asymmetric. The stagnation points at A and C have moved below the centerline and the minimum pressure occurs only on the upper surface. In this case, it can be seen that the average pressure over the lower half of the cylinder will be higher than that over the top because the stagnation points are both on the bottom. In this case, there is a net lift force pointing up. The same effect is used in the aerodynamics of sport balls. For example, in tennis, a top spin on the ball causes it to drop much more quickly than a ball without top spin because of the downward-pointing lift vector.

By spinning the cylinder, a *circulation* has been introduced about the body. Circulation, Γ , is related to the average velocity tending to move fluid elements around the body. This average is made up of velocities on a path encircling the body. However, a nonzero value of circulation does not indicate that the fluid elements are actually moving around the cylinder. As the cylinder is spun faster, and Γ is thus increased, the lift force increases.

The relationship between lift and circulation is termed the *Kutta-Joukowski theorem* after the two people who independently discovered it, and is expressed as

$$L' = \rho U_\infty \Gamma \quad (193.9)$$

where L' is the lift per unit span of the cylinder. This theorem applies to any two-dimensional body about which a circulation exists, not just a cylinder. Circulation about a body can be represented as a **vortex**. A vortex is a circular flowfield in which the fluid rotates about a common axis, and the farther the fluid element is from the axis, the slower it moves around the axis. In the case of lift generation, the vortex is not attached to the same fluid elements, but is “bound” to the body and is often called a *bound vortex*.

FIGURE 193.4 Diagram illustrating boundary layer separation.

Drag

For a general body, the total drag force results from two sources — *pressure drag* and *viscous drag*. Pressure drag is simply the component of the total pressure force on the body that is in the streamwise direction (parallel to the direction of the freestream). In many flows, *boundary layer separation* causes significant pressure drag. Boundary layer separation can occur when a boundary layer flows into a region of increasing pressure. For fluid elements outside the boundary layer, this increase in pressure is traded off as a decrease in velocity, as can be seen by Bernoulli's equation. Because the pressure is approximately constant across the boundary layer, the fluid near the wall must also undergo an increase in pressure. The fluid near the wall has less energy than the flow at the edge of the boundary layer because it is moving slower. If the pressure increases too rapidly in the downstream direction, the velocity near the wall can reverse. If this happens, the boundary layer is said to have separated, as shown in Figure 193.4. The boundary layer leaves the surface and a recirculating region is developed between the airfoil surface and the boundary layer fluid that left the surface. As the flow is not attached to the surface, it does not continue on a path which leads to a higher pressure in that region as it would if the flow had not separated. The result is a lower pressure acting over the surface. This surface usually has a component of area facing downstream and the low pressure acting on this area is seen as drag (pressure drag). Pressure drag, D_p , is calculated as

$$D_p = \int p dA_x \quad (193.10)$$

where A_x is the streamwise component of the area. For this reason, boundary layer separation is usually considered to have a negative effect on a flow.

Viscous drag, D_v , is present in all vehicles that move through a fluid. It is caused by the wall shear stress, which was discussed earlier in this section. Wall shear stress acts tangentially to the surface, so the total viscous drag is determined by integrating the streamwise component of τ_w over the surface:

$$D_v = \int \tau_w dA_x \quad (193.11)$$

193.3 Two-Dimensional Airfoils

Typically, wings have been analyzed by splitting the problem into two parts: (1) analysis of a wing section (*airfoil*), and (2) modification of the airfoil properties to account for the effects of the complete, finite wing. An airfoil is the cross section of a wing in a plane parallel to the freestream velocity and perpendicular to the wing, as shown in Figure 193.5.

Airfoils are usually described using the nomenclature indicated in Figure 193.6. The longest dimension of the airfoil section is termed the *chord*, and the line connecting the *leading edge* to the *trailing edge* is the *chord line*. Airfoil *thickness* is the maximum distance between the upper and lower surfaces along a

FIGURE 193.5 Diagram illustrating the relationship between an aircraft wing and an airfoil.

FIGURE 193.6 Airfoil terminology.

line perpendicular to the chord line. Thickness is usually expressed as a percentage of the chord (e.g., a 12% thick airfoil has a maximum thickness of 12% of the chord). The *mean camber line* is the locus of points halfway between the upper and lower surfaces. The variation of the thickness along the mean camber line is termed the *thickness distribution*. *Camber* of the airfoil is defined as the maximum distance between the mean camber line and the chord line in a direction perpendicular to the chord line. When a fluid is moving past the airfoil, the angle of attack is defined as the angle between the freestream velocity and the chord line, denoted as α in Figure 193.6.

Airfoil designs that cover a wide range of thickness, thickness distributions, and camber have been designed and tested by the National Advisory Committee for Aeronautics (NACA) (the predecessor of the current NASA). These include the *four-digit* series (e.g., the NACA 2412); the *five-digit* series (e.g., the NACA 23012); and the *six-digit* series (e.g., the NACA 65-218). The numbers indicate various characteristics of the airfoils. A complete description of the numbering system can be found in Abbott and von Doenhoff [1959]. These and other airfoil designs and their performance characteristics can be found in the books in the Further Information section.

In selecting an airfoil for a particular application, the variation of lift, drag, and moment with angle of attack is necessary. A typical variation of lift coefficient with angle of attack is shown in Figure 193.7. Recall from the earlier discussion that this data represents the performance of a two-dimensional airfoil and is sometimes referred to as *infinite wing data*. The value of α when the lift is zero is termed $\alpha_{L=0}$, the zero-lift angle of attack. As the angle of attack is increased from $\alpha_{L=0}$, the lift increases linearly over a wide range of α . The slope of this line is the *lift slope*. As α becomes large, the pressure gradients on the upper surface of the airfoil also become large, and separation of the boundary layer occurs. Separation causes a large reduction in lift and the airfoil is said to be stalled. The maximum lift generated by the airfoil is indicated by $C_{L,max}$. Before the decrease in lift occurs, the curve becomes nonlinear because of viscous effects.

In the linear region of the curve where viscous effects have a small impact on the lift, *thin airfoil theory* can be used to predict the airfoil behavior. If the airfoil thickness is small in comparison to its chord,

FIGURE 193.7 Lift and moment coefficients as a function of angle of attack for the NACA 2412 airfoil.

the flowfield about the airfoil can be represented by distributing vortices along the mean camber line. An infinite number of solutions are possible for the distribution of the strengths of the vortices as a function of chord. All but one of these solutions is eliminated by applying the *Kutta condition*. The Kutta condition essentially requires that the flow be physically realistic in that the fluid cannot flow around a sharp trailing edge. More specifically, it states that the following be true: (1) the value of the circulation, Γ , is such that the flow leaves the trailing edge smoothly; (2) if the included angle at the trailing edge is finite, then the trailing edge is a stagnation point; and (3) if the trailing edge is cusped (zero included angle), then the velocities from the upper and lower surfaces are equal in magnitude and direction at the trailing edge. Thin airfoil theory then yields a lift slope of 2π , so in the case of symmetric airfoil $C_L = 2\pi\alpha$. For relatively thin airfoils, less than about 12%, this prediction is accurate to within several percent of experimentally determined values.

Camber controls the amount of lift generated at zero angle of attack. A symmetric airfoil (zero camber) generates no lift at $\alpha = 0$. An airfoil with positive camber generates lift at $\alpha = 0$, and zero lift occurs at a negative angle of attack, as shown in Figure 193.7.

Figure 193.7 also shows the variation of moment coefficient with angle of attack for a typical cambered airfoil. The moment is usually taken about a point one quarter of the way along the chord line from the leading edge. This point is known as the *quarter-chord point*. Note that the value of the moment is negative, indicating that the moment acting on the airfoil tends to rotate it in the counterclockwise direction for the airfoil depicted in Figure 193.6. Camber also affects the moment; a symmetric airfoil produces no moment and an increase in the camber causes an increase in the magnitude of moment.

In Figure 193.7, the moment coefficient is approximately constant over a wide range of angle of attack. The quarter-chord point was chosen as the point about which to determine moments for specifically this reason — it is the *center of pressure* for an airfoil. The center of pressure is defined as the point about which the moment is constant, independent of angle of attack. Another useful point in aerodynamics is the *aerodynamic center*, which is the point about which the moment is zero. For a symmetric airfoil, this point happens to be also at the quarter-chord point. In general, the aerodynamic center may or may not lie on the body itself. As viscous effects become important, the moment varies from its ideal behavior, as did the lift behavior. Near stall, the magnitude of the moment increases because of boundary layer separation altering the static pressure distribution.

Drag data are usually presented as a function of lift coefficient, instead of angle of attack, in what is termed a *drag polar*. An example of a drag polar is shown in Figure 193.8 for a cambered airfoil. This

FIGURE 193.8 Drag polar for the NACA 2412 airfoil.

drag coefficient includes both the viscous and pressure drags. The penalty in drag for generating high lift coefficients is clear from Figure 193.8. In addition, when the airfoil approaches stall, and the upper surface boundary layer separates, the drag increases dramatically. This increase is caused by the large pressure drag associated with separation, as indicated in Section 193.2. In many applications, the ratio of lift to drag, L/D , is an important performance parameter. The L/D s of different airfoils can easily be compared using a drag polar simply by looking at the slope of a line drawn between a point on the polar and the origin of the plot.

193.4 Finite Wing Effects

Two-dimensional, or infinite wing, performance was discussed in the previous section. Of course, all real aircraft have finite wings. In this section, the modification of infinite wing performance due to the finite nature of real wings is presented. The primary difference between the two cases is that, in the finite wing, the flow can be three-dimensional (i.e., flow can occur into and out of the paper in Figure 193.4 as well as in the plane of the paper). If a wing is generating lift, then the average pressure on the lower surface must be higher than that on the upper surface. Near the wing tips, this pressure difference causes flow from the lower surface to the upper surface, as shown in Figure 193.9. This leakage around the wing tips causes the flow to rotate about a streamwise axis as it leaves the wing tip, forming *wing tip vortices*, as shown in Figure 193.10. Inboard of the wing tips, the flow has a spanwise component due to the leakage around the wing tips. As shown in Figure 193.9, the flow over the lower surface tends to move out toward the wing tip, and the flow over the upper surface tends to move inboard. Clearly, the flow is not two-dimensional, as was assumed in the previous section.

Wing tip vortices induce flow about their axes. In the region of the wing, it can be seen from Figure 193.9 that the resulting induced flow will be downward. This induced downward flow is termed *downwash* and locally rotates the incoming velocity vector, as shown in Figure 193.11. Locally, the angle of attack is reduced by α_i . Thus, the effective angle of attack is $\alpha_{\text{eff}} = \alpha - \alpha_i$. Lift is generated perpendicular to the local freestream velocity, and as it has been rotated by α_i , then the lift vector is also rotated by α_i . The lift vector now has a component parallel to the freestream that is far from the wing, D_i — the *induced drag*. In summary, the downwash induced in the region of the wing by the wing tip vortices reduces the effective angle of attack of the airfoil section. This tilts the lift vector downstream, resulting in a component of lift acting in the drag direction. Typical airfoil sections might have a L/D ratio of about 100. Thus, only a small rotation of the large lift vector can cause a significant increase in drag, which appears as pressure drag.

FIGURE 193.9 Finite wing effects.

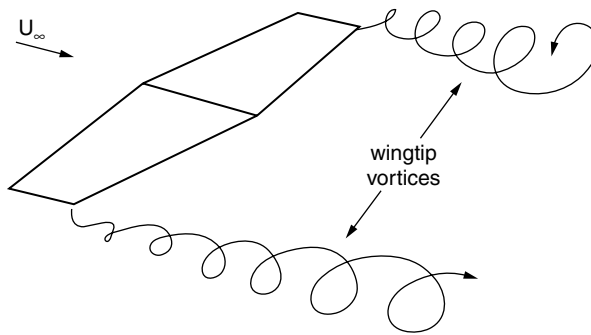

FIGURE 193.10 Wing tip vortices formed by a finite wing.

FIGURE 193.11 Diagram illustrating the tilting of the lift vector due to the downwash.

The induced drag of a wing depends on the downwash distribution along its span. It can be shown that the downwash distribution depends on the lift distribution across the wing span. Lift per unit span can vary for several reasons: (1) changes in chord, (2) changes in angle of attack, and (3) variations in airfoil shape. An elliptical distribution of lift across the span, as shown in Figure 193.12, provides a minimum induced drag. Lifting-line theory can be used to predict the downwash for an elliptical lift

FIGURE 193.12 Elliptical lift distribution over a finite wing.

distribution and a detailed discussion of this technique can be found in Kuethé and Chow [1986]. In this case, the drag coefficient for the induced drag is

$$C_{D,i} = \frac{C_L^2}{\pi AR} \quad (193.12)$$

where AR is the *aspect ratio* of the wing defined as $AR \equiv b^2/S$. It can be seen from Equation (193.12) that, as the aspect ratio increases (i.e., the wing becomes longer and more slender), the induced drag is reduced. This equation also indicates the dependence of induced drag on lift. As the lift increases, the strength of the tip vortices increases, and therefore the downwash increases, which causes the lift vector to tilt more in the downstream direction.

In practice, it is difficult to obtain an elliptical lift distribution. Thus, the induced drag is higher than that for an elliptical distribution. In general,

$$C_{D,i} = \frac{C_L^2}{\pi e AR} \quad (193.13)$$

where e is the *span efficiency factor*. For elliptical wings, $e = 1$, but for typical subsonic aircraft, $0.85 < e < 0.95$. Thus, the total drag for a finite wing is the sum of the induced drag and the infinite wing drag:

$$C_{D,tot} = C_{D,2-D} + \frac{C_L^2}{\pi e AR} \quad (193.14)$$

In addition to affecting the drag of two-dimensional airfoil data, the finite nature of a wing also reduces the lift slope. The downwash reduces the effective angle of attack, and therefore reduces the lift generated. For a general wing, the effective angle of attack is

$$\alpha_{\text{eff}} = \alpha - \frac{57.3 C_L}{\pi e' AR} \quad (193.15)$$

where e' is another span effectiveness factor, which, in practice, is approximately equal to e . The reduced lift for a given angle of attack indicates a reduction in the lift slope, a , which becomes

$$a = \frac{a_0}{1 + 57.3 a_0 / (\pi e' AR)} \quad (193.16)$$

where a_0 is the two-dimensional lift slope and a is the lift slope including finite wing effects.

FIGURE 193.13 Drag as a function of Mach number (a), and airfoil flowfields associated with the three Mach number ranges (b–d).

193.5 Effects of Compressibility

It has been assumed to this point that the flow speed has been low enough that the effects of compressibility of the fluid have been negligible. (Section 6 describes compressibility in more detail and should be reviewed at this time if the reader is unfamiliar with this topic). However, as the freestream speed and thus the freestream Mach number (M_∞) are increased, compressibility effects are seen. Only a brief discussion of some of these effects is presented here.

If the local Mach number increases above 1.0, the possibility exists for the formation of shock waves. This effect is one of the major differences between compressible and incompressible flows and is depicted in Figure 193.13. Over the upper surface of an airfoil, the flow moves faster than the freestream. Thus, the Mach number in a region above the upper surface can be supersonic even if the freestream Mach number is less than one (Figure 193.13(c)). The freestream Mach number at which the flow over the upper surface reaches Mach 1.0 is termed the *critical Mach number*, M_{crit} . As the freestream Mach number increases, a shock wave forms on the upper surface, causing boundary layer separation because of the strong adverse pressure gradient (Figure 193.13(d)). In this case, the drag of the airfoil increases dramatically, as shown in Figure 193.13(a). The Mach number where the drag begins to rise is the *drag divergence Mach number*, $M_{\text{drag rise}}$.

High-speed subsonic aircraft often have swept wings. The purpose of wing sweep is to increase $M_{\text{drag rise}}$ so the aircraft can fly faster. By sweeping the wing back, the airfoil “sees” only the component of the freestream Mach number normal to the leading edge, which is lower than the total freestream Mach number, as shown in Figure 193.14. Thus, the critical Mach number with sweep should be $M_{\text{cr,sweep}} = M_{\text{cr}}/\cos \theta$. In practice, because of the complex flowfield induced by wing sweep, the benefit of sweep is less than this. A more complete discussion of compressibility effects in aerodynamics can be found in Anderson [1984].

FIGURE 193.14 The effect of wing sweep on the normal Mach number.

Defining Terms

Drag — The net aerodynamic force on a body in a direction parallel to the freestream.

Lift — The net aerodynamic force on a body in a direction perpendicular to the freestream direction and to the wing platform.

Vortex — A flowfield in which fluid elements rotate about a common axis. In a vortex where viscous effects are not important, the velocity at which a fluid element circles the axis is inversely proportional to its distance from the axis.

Wake — The region of a flowfield downstream of a body where the momentum is less than that of the freestream.

- 194.2 Turbulence and Aircraft Dynamics
 - Fourier Integral Representation • Aerodynamic Force/Moment Prediction • Extension to More Complex Fields • Computer Simulation

The aerodynamic forces that allow the flight of heavier-than-air vehicles are created by the relative motion between the aircraft and the air mass through which it moves. In the case of a nonquiescent atmosphere, that is, one that is moving relative to the Earth, the motion of the air mass itself contributes to this relative motion. Since the atmosphere is rarely quiescent, the subject of aircraft stability and control in a moving atmosphere is of considerable importance to aerospace engineers from the standpoint of performance, passenger comfort, and safety.

194.1 Descriptions of Atmospheric Motion

The fundamental approach that physicists and engineers adopt in describing the motion of a continuum like the atmosphere is a *field description*. In a field description, the velocity of the atmosphere (relative to the Earth) is considered to be a continuous function of location and time. Consider [Figure 194.1](#) showing an orthogonal axis system fixed relative to the Earth. At some point, x_0 , y_0 , and z_0 , and at some time instant t_0 , the three components of the velocity of the atmosphere are $u_a(x_0, y_0, z_0, t_0)$, $v_a(x_0, y_0, z_0, t_0)$, and $w_a(x_0, y_0, z_0, t_0)$. The field description allows a convenient means of categorizing atmospheric motion.

Mean Wind

If, for example, $u_a = U$, $v_a = V$, and $w_a = W$, where U , V , and W are constants, one has defined a mean wind. Obviously, this is an idealized description, but nonetheless, a useful one. For example, airliner flight in the jet stream can often be adequately described by such a mean wind condition.

Wind Shear

If, for example, $u_a = u_a(x)$, $v_a = V$, and $w_a = W$, one has defined a simplified wind shear, in which the velocity field varies with position in the x direction, but not with time. In applications to aircraft stability

FIGURE 194.1 Axis systems for description of atmospheric turbulence.

and control, changes in $x(\Delta x)$ over which significant changes in u_a occur are typically assumed to be such that $\Delta x \gg l_f$ where l_f represents the fuselage length.

More complex wind shears are possible. If, for example, $u_a = u_a(x)$, $v_a = 0$, and $w_a = w_a(x)$, and

$$u_a(x) = -U \left[\sin\left(\frac{2\pi(x-x_0)}{X_h}\right) \right] \quad \text{for } x_0 \leq x \leq X_h + x_0 \quad (194.1)$$

$$u_a(x) = 0 \quad \text{for } x < x_0 \text{ and } x > X_h + x_0 \quad (194.2)$$

$$w_a(x) = \frac{W}{2} \left[1 - \cos\left(\frac{2\pi[x-x_0 - \frac{(X_h - X_v)}{2}]}{X_v}\right) \right] \quad (194.3)$$

$$\text{for } x_0 + \frac{(X_h - X_v)}{2} \leq x \leq x_0 + \frac{(X_h + X_v)}{2}$$

$$w_a(x) = 0 \quad \text{for } x < x_0 + \frac{(X_h - X_v)}{2} \text{ and } x > x_0 + \frac{(X_h + X_v)}{2} \quad (194.4)$$

one has defined a simplified version of a meteorological phenomenon called a *microburst*. A microburst is a downburst that is confined to a relatively small area, and is characterized by a massive downward air mass movement that disperses radially near the ground. An intense microburst can be extremely hazardous to aircraft when landing or taking off [Wingrove and Bach, 1989]. Figure 194.2 represents a vertical

FIGURE 194.2 Vertical section through a microburst.

FIGURE 194.3 A wake vortex from aircraft wing tip; aircraft viewed from behind.

cross-section through the center of a microburst velocity field with the arrows representing wind direction. Equations 194.1 and 194.2 represent the “headwind and tailwind” air velocities as the microburst is traversed. Equations 194.3 and 194.4 represent the “down-draft” air velocities during the same encounter. The parameters X_h and X_v represent the distances over which the particular microburst velocity fields extend. The x_0 is the Earth-fixed coordinate x at which the head and tailwind components of the downburst become important. These are obviously a function of altitude. The following parameter values model a particular microburst that occurred at Philadelphia International Airport in 1976 and resulted in the loss of an aircraft [Psiaki and Stengel, 1985]:

$$X_h = 10,000 \text{ ft } U = 35 \text{ ft/sec } X_v = 3,000 \text{ ft } W = 20 \text{ ft/sec} \quad (194.5)$$

Wake Vortices

If, for example, $u_a = 0$, and we consider a tangential velocity,

$$V_t = \sqrt{V^2(y,z) + W^2(y,z)} = \Gamma_\infty / 2\pi \left[\frac{R}{R_c^2 + R^2} \right] \quad (194.6)$$

one has a simple model for a wake vortex. In Equation 194.6, Γ_∞ is referred to as the circulation (ft^2/sec), R_c is the radius of the core of the vortex (ft), and R is the distance from the axis of the vortex (ft). Wake vortices are created when a wing generates lift. As the name implies, they are characterized by a swirling or vortical flow, emanating from each wingtip of an aircraft as shown in Figure 194.3. For large commercial aircraft, the wake vortices can be quite severe and can persist for some distance behind the aircraft generating the vortices. They can also pose serious dangers for other aircraft encountering them. The following parameter values describe the wake vortex created by a Boeing 747. This vortex was implicated in an aviation accident involving another aircraft that encountered it after takeoff [Fiorino, 2002]:

$$\Gamma_\infty = 5,328 \text{ ft}^2/\text{sec } R_c = 14.8 \text{ ft} \quad (194.7)$$

Thus, if an aircraft were following the Boeing aircraft with $R = 20$ ft, tangential air velocities on the order of 30 ft/sec would be experienced at that radial location.

Turbulence

If, for example, $u_a = U$, $V_a = V$ and $w_a = w_a(x,t)$, and if the changes Δx over which significant changes in w_a occur are such that Δx is the same order of magnitude as l_f , one has defined a simplified atmospheric turbulence field or gust field. If, as in Figure 194.1, the direction of the w_a axis is vertical, the field is referred to as a vertical turbulence field or a one-dimensional “upwash” field [Etkin, 1972].

As opposed to the velocity fields that have been introduced thus far, turbulence cannot be adequately described in deterministic fashion. That is, the air velocity at any point (x,y,z) and time (t) is a random variable. Given this fact, the intensity of turbulence is typically quantified by the root mean square (RMS)

FIGURE 194.4 Aircraft in a one-dimensional, frozen upwash field.

value of each of the velocity components. Thus, for example, at some point x_0 in the one-dimensional upwash field just described,

$$\sigma_{w_a} = \text{RMS value of } w_a(x_0, t) = \sqrt{\lim_{T \rightarrow \infty} \frac{1}{2T} \int_{-T}^T w_a^2(x_0, t) dt} \quad (194.8)$$

Simplified Description

In aircraft stability and control analyses, it is often assumed that the statistical description of the turbulence velocity field, such as the RMS velocity at a point, is not a function of time or the origin or orientation of the axis system used to describe the field. These assumptions are referred to as stationarity, homogeneity, and isotropy, respectively. A final simplifying assumption is employed if, as is often the case, the aircraft is moving through the turbulence field with a velocity that is significantly larger in magnitude than the RMS value of the turbulence. In this case, the spatial and temporal variation of the turbulence field may be replaced by the spatial variation alone. Thus, $w_a(x, t) = w_a(x)$. This simplification is referred to as the frozen turbulence field hypothesis or Taylor's Hypothesis, after the British researcher G. I. Taylor [Houbolt, 1973].

194.2 Turbulence and Aircraft Dynamics

Figure 194.4 is a representation of an aircraft flying through the one-dimensional, frozen upwash field described in the preceding section. The velocity profile of the field is represented in the figure, with the vertical arrows indicating the magnitude and direction of the air velocity at each point on the idealized linear flight path. The problem now becomes one of determining the aerodynamic forces and moments that are created on the aircraft by the indicated turbulence velocities. To accomplish this, a mathematical description of the frozen turbulence field, $w_a(x)$, is needed.

Fourier Integral Representation

The spatially dependent $w_a(x)$ can be represented as a sample function from an ergodic random process [Bendat and Piersol, 1966]. One measure associated with such sample functions is the autocorrelation function defined as

$$\phi_{w_a w_a}(\xi) = \lim_{X \rightarrow \infty} \frac{1}{2X} \int_{-X}^X w_a(x) w_a(x - \xi) dx \quad (194.9)$$

The autocorrelation function has a Fourier integral or Fourier transform representation

$$\phi_{w_a w_a}(\xi) = \frac{1}{2\pi} \int_{-\infty}^{\infty} \phi_{w_a w_a}(\omega) e^{j\omega\xi} d\omega \quad (194.10)$$

and

$$\phi_{w_a w_a}(\omega) = \int_{-\infty}^{\infty} \phi_{w_a w_a}(\xi) e^{-j\omega\xi} d\xi$$

Here ω represents spatial frequency with units of radians per foot. $\phi_{w_a w_a}(\omega)$ is referred to as the *power spectral density* of $w_a(x)$. Power spectral density representation constitutes one of the primary ways in which the characteristics of atmospheric turbulence have been measured and reported [Houbolt, 1973].

Two power spectral forms widely used in turbulence analyses are the von Karman and Dryden spectra [Etkin, 1972]. For example, the von Karman spectrum can be given by

$$\phi_{w_a w_a}(\omega) = \sigma_{w_a}^2 L \frac{1 + \frac{8}{3}(1.339L\omega)^2}{[1 + (1.339L\omega)^2]^{\frac{11}{6}}} \quad (194.11)$$

with the Dryden form given by

$$\phi_{w_a w_a}(\omega) = \sigma_{w_a}^2 L \frac{1 + 3(L\omega)^2}{[1 + (L\omega)^2]^2} \quad (194.12)$$

where L is referred to as the *turbulence scale length*. Depending on altitude and turbulence intensity, scale lengths from 200 to 5000 ft have been measured [Houbolt, 1973]. Often in flight control system analysis, a simpler spectrum than that given by Equations 194.11 and 194.12 is used. For example,

$$\phi_{w_a w_a}(\omega) = 2\sigma_{w_a}^2 L \frac{1}{1 + (L\omega)^2} \quad (194.13)$$

The simplicity of the spectrum of Equation 194.13, its ability to closely approximate the spectra of Equations 194.11 and 194.12 and the preservation of the parameters σ_w and L , suggest its use.

If one limits the spatial “duration” of $w_a(x)$ to a large but finite value, $X = X_M$, such that for $X > X_M$, $w_a(x) = 0$, then $w_a(x)$, itself, is amenable to representation by a Fourier integral or Fourier transform as

$$w_a(x) = \frac{1}{2\pi} \int_{-\infty}^{\infty} W_a(j\omega) e^{j\omega x} d\omega \quad (194.14)$$

and

$$W_a(j\omega) = \int_{-\infty}^{\infty} w_a(x) e^{-j\omega x} dx$$

The first of Equations 194.14 can be used to demonstrate that $w_a(x)$ may be envisioned as the sum of an infinite number of sinusoids, each of infinitesimal amplitude, with the frequency of each constituent sinusoid differing only infinitesimally from that of its neighbor [McRuer et al., 1973].

Aerodynamic Force/Moment Prediction

The problem of determining the aerodynamic forces and moments exerted on an aircraft as it moves through an upwash field can be further simplified as follows: Consider the case where $w_a(x)$ (envisioned as the infinite sum of infinitesimal sinusoids just described) has the majority of its power below a frequency ω_0 . If the fuselage length l_f is such that

$$l_f \leq \frac{1}{8} \left(\frac{2\pi}{\omega_0} \right) \quad (194.15)$$

where $(2\pi/\omega_0)$ is the spatial wavelength (ft) of the constituent sinusoid with frequency ω_0 , then the variation in $w_a(x)$ over the length of the aircraft can be considered to be approximately linear. The inequality in Equation (194.15) is derived from the fact that a straight line (of appropriate slope) can be considered an adequate approximation to a sinusoid if the length of the line is less than one-eighth of the period (wavelength) of the sinusoid.

Figure 194.4 suggests that, at the instant shown, the relative motion of the aircraft and upwash field is aerodynamically equivalent to that which would be in evidence if the aircraft were moving through quiescent air but with (1) an instantaneous vertical velocity component given by

$$w(t) = -w_a(x_{cg}) \quad (194.16)$$

and (2) an instantaneous angular pitch rate of

$$q(t) = \frac{dw_a(x_{cg})}{dx} = \frac{1}{U_0} \left. \frac{dw_a(x_{cg})}{dt} \right|_{x_{cg}=U_0 t} \quad (194.17)$$

As Figure 194.1 indicates, $w(t)$ is the z_b body-axis component of the velocity of the aircraft center of gravity (cg) in a quiescent atmosphere, and x_{cg} is the x -coordinate of the aircraft center of gravity in the Earth-fixed axis system used to describe the upwash field. U_0 is the x_b body-axis component of the aircraft velocity in steady flight in a quiescent atmosphere.

The manner in which turbulence effects are included in the aircraft equations of motion can now be described. The force equations can be written in the familiar form:

$$\bar{F} = m \frac{d\bar{v}}{dt} \quad (194.18)$$

where \bar{F} represents the vector sum of the aerodynamic and propulsive forces acting on the aircraft with mass m , and \bar{v} represents the velocity of the aircraft center of gravity. For aircraft applications, Equation 194.18 is typically linearized about a condition of steady, wings-level flight [Etkin, 1972; McRuer et al., 1973]. The components of \bar{F} in this equation are expressed as linear functions of the aircraft's linear and angular velocity perturbations and their derivatives. Thus, for example, referring to Figure 194.1, the x_b and z_b body-axis components of \bar{F} can often be simplified to

$$F_x = m[-g\theta + X_u u + X_w w + X_\delta \delta] \quad (194.19)$$

$$F_z = m[Z_u u + Z_w \dot{w} + Z_w w + Z_q q + Z_\delta \delta]$$

where θ , u , w , and δ represent, respectively, perturbations in the aircraft pitch attitude, perturbations in the x_b and z_b body-axis components of the velocity of the aircraft center of gravity, and perturbations in control/propulsive inputs. X and Z represent the components of the aerodynamic and propulsive forces

in the x_b and z_b body-axis directions. The quantities X_w, Z_w , and so on are referred to as mass-normalized stability derivatives [McRuer et al., 1973]. Equation 194.19 can now be modified to include the effects of the one-dimensional upwash field by simply replacing w by $(w - w_a)$, and q by $\left(q + \frac{\dot{w}_a}{U_0}\right)$ on the right sides of these equations. Note that since the left sides of the equations are describing inertial as opposed to aerodynamic terms in the equations, they are not included in these substitutions. The result of these substitutions will be the addition of “disturbance” terms to each of Equations 194.19.

Extension to More Complex Fields

The preceding treatment describing modification to the X and Z -force equations to account for a one-dimensional upwash field can be extended to more complex turbulence fields, such as those involving consideration of u_a and v_a terms in the gust field. In such treatments, it is typical to consider the entire aircraft submersed in the u_a component existing at the aircraft center of gravity (equivalent to considering the aircraft as a point). The v_a terms in the lateral-directional equations are handled in a manner similar to that for the w_a terms in the longitudinal equations, that is, treating the variation in $v_a(x)$ over the length of the aircraft as approximately linear. The equations of motion so derived can also be used to study aircraft response to the deterministic velocity fields discussed earlier, such as the microburst and wake vortex descriptions.

Computer Simulation

Computer simulation of aircraft encountering moving air masses such as turbulent upwash fields requires that one create the desired time history of the disturbance inputs as a function of time rather than position. This can be accomplished through spectrum factorization of the power spectral density of the upwash field. For example, converting the spectrum of Equation 194.13 from spatial frequency ϖ (rad/ft) to temporal frequency ω (rad/sec) can be accomplished as follows:

$$\Phi_{w_a w_a}(\omega) = \frac{1}{U_0} \Phi_{w_a w_a}(\varpi) \Big|_{\varpi = \frac{\omega}{U_0}} \quad (194.20)$$

Assume that the spatial spectrum had parameters $\sigma = 5$ ft/sec and $L = 1,000$ ft, and that the aircraft was flying at a speed of 500 ft/sec. The temporal spectrum corresponding to Equation 194.13 would take the form:

$$\Phi_{w_a w_a}(\omega) = \frac{100}{[1 + (2\omega)^2]} \quad (\text{ft}^2/\text{sec}^2)/\text{rad} \quad (194.21)$$

The spectrum of Equation 194.21 can be spectrum factorized as

$$\Phi_{w_a w_a}(\omega) = \frac{10}{[1 + (2j\omega)]} \cdot \frac{10}{[1 + (-2j\omega)]} \quad (194.22)$$

Finally, a random function of time (sample function from an ergodic random process) with the power spectral density of Equation 194.21 can be obtained by passing white noise with unity covariance through a linear transfer function given by

$$G(s) = \frac{10}{1 + 2(j\omega)} \Big|_{j\omega = s} \quad (194.23)$$

In this manner, $w_a(t)$ can be created for use in computer simulation.

FIGURE 194.5 Pitch-rate and pitch-attitude time histories for light aircraft traversing wake vortex at 90° .

Examples

Two computer simulation examples of aircraft encountering moving air masses are discussed. The first involves a light aircraft encountering the tip vortex described by Equations 194.6 and 194.7. The flight condition is an altitude of 5,000 ft with an aircraft velocity (U_0) of 219 ft/sec. The aircraft crosses the tip vortex emanating from the left wing of the generating aircraft at an angle of 90° . A simulated pilot controlling pitch attitude is included. Only the effect of the vertical velocity component of the vortex is considered. It should be noted that the length of the aircraft (approximately 24 ft) will not invalidate the linear approximation to the upwash field used in creating the vehicle equations of motion.

The second example involves a small executive jet aircraft encountering an upwash field with a spatial power spectral density given by Equation 194.13 with $\sigma = 10$ ft/sec and $L = 1,000$ ft. The flight condition is an altitude of 40,000 ft and an aircraft velocity (U_0) of 677 ft/sec. Again a simulated pilot controlling pitch attitude is included. The approximate length of the aircraft in question is 46 ft.

The spatial “bandwidth” $\bar{\omega}_0$ of the turbulence spectrum, defined here as the value of $\bar{\omega}_0$ where the spectrum $\varphi_{w_a w_a}(\bar{\omega}_0)$ has dropped to 5% of its zero frequency value, is 0.00437 rad/ft. These values mean that the constraint of the inequality in Equation 194.15 is clearly satisfied.

Figure 194.5 shows the pitch rate and scaled pitch attitude for the light aircraft. Note the very large pitch rates that occur as the aircraft crosses the tip vortex center. Figure 194.6 shows the pitch rate and scaled pitch attitude for the executive jet for a 10-sec period.

Defining Terms

Field description — A representation of a scalar or vector quantity as a continuous function of position and time.

Frozen turbulence field (Taylor’s hypothesis) — Considering the time and spatial variation of turbulent velocity field as a spatial variation only.

Mean wind — A constant air velocity, independent of location and time.

Microburst — An atmospheric phenomenon that is confined to a relatively small area, characterized by a massive downward air mass movement that typically disperses radially near the ground.

Power spectral density — A means of describing the distribution of the power in a signal with frequency.

FIGURE 194.6 Pitch-rate and pitch-attitude time histories for executive jet traversing one-dimensional upwash field.

Root mean square (RMS) value — The square root of the integral of a squared function, divided by the integration interval.

Turbulence (gust) field — A field representation of the rapid, random variations of air velocity components at a point in space.

Turbulence scale length — A parameter appearing in the power spectral density representation of a frozen turbulence field. It is related inversely to the break frequency of the power spectral density, that is, the larger the characteristic length, the smaller the spatial or temporal break frequency.

Wake vortex — The swirling air flow emanating from the tip of any wing that generates lift.

Wind shear — The variation in air velocity as a function of position, often associated with microbursts.

In the past 2 decades, enormous progress has been made in computational methods for the study of fluid flow phenomena in a broad variety of scientific and engineering disciplines. Examples include aircraft, ship, and automobile design; oceanography; meteorology; and astrophysics. The focus of this chapter is, however, on computational aerodynamics, which is rapidly emerging as a crucial enabling technology for the analysis and design of flight vehicles. Computational simulations, coupled with targeted experimental testing, have proven to be a cost-effective way of developing flight vehicles. Such combined evaluations are performed to ensure that the final product will efficiently meet target performance characteristics, using few design cycles. On the other hand, for some flight regimes, such as hypersonic flows at high altitude, experimental testing may not be feasible, and in such cases even greater reliance is placed on computational simulations.

In aeronautical applications, the computational analysis of the aerodynamic performance of a flight vehicle — be it an aircraft, a helicopter, or a launch vehicle — is a multistep process. First, a geometric description of the configuration is obtained in discretized form. Second, a grid is generated around the object to provide a finite set of points over which the flow field solution is calculated. The flow is then solved, and enormous quantities of data for pressure, temperature, and velocity variables are processed to obtain the aerodynamic quantities of interest — namely, the lift, drag, moment coefficients, and other parameters required to assess the flight vehicle performance.

In this respect, recent developments in computational fluid dynamics primarily fall into two broad categories: (1) computational prediction of the flow field about increasingly complex configurations, and (2) the simulation of flow physics leading to a better understanding of such flow phenomena as transition and turbulence. This chapter covers only the first category: the computational tools employed in aerodynamic analysis and their application in analyzing the aerodynamic performance of complex configurations.

195.1 Geometry Modeling and Grid Generation

In the aerospace industry, the geometric description of the configuration in discretized form is routinely created using computer-aided design (CAD) systems. However, the generation of a suitable three-dimen-

sional grid about complete aircraft configurations remains a formidable task. In this respect, there have been significant developments in the past decade, with both the algebraic and partial differential equations-based techniques fairly well developed for the generation of structured global grids about complex three-dimensional shapes. The recent thrust has been toward zonal grids and unstructured grid technologies since they are thought to be more effective for treating flows over complex three-dimensional objects. In addition, there have been major advances in adaptive grid and grid embedding techniques, for optimal distribution of grid points around an object in order to resolve sharp gradients and discontinuities, at the least cost possible. A review article by Steinbrenner and Anderson [1990] appropriately describes these developments.

195.2 Flow Simulation Algorithms

For flow field solutions, mathematical models vary in complexity from the simple Laplace equation to the unsteady compressible Navier–Stokes equations. Figure 195.1 describes the equations of fluid dynamics for mathematical models of varying complexity.

During the late 1960s, panel methods were developed for calculating inviscid subsonic flow about complex aerodynamic shapes by solving the Laplace equation. Also, boundary-layer solution techniques were developed to allow for viscous effects, primarily for attached flows. During the early 1970s, a major breakthrough was achieved by Murman and Cole [1971], who solved the mixed elliptic-hyperbolic transonic, small-disturbance equation. Later, Jameson [1974] extended the Murman–Cole technique to the solution of the transonic full-potential equation. Such codes are routinely used in transport aircraft design and have proven to be an effective tool, when combined with boundary-layer corrections, for predicting the aerodynamic performance of a variety of flight vehicles in the transonic range.

Most of the recent progress in the development of numerical algorithms has been for the solution of the Euler and Navier–Stokes equations, especially the development of efficient and accurate shock-capturing algorithms. Central-difference algorithms with artificial viscosity (dissipation), characteristics-based upwind schemes, and total-variation-diminishing schemes have been developed for hyperbolic conservation laws. Strong discontinuities (shocks) are captured by these schemes with little oscillation and minimal dispersive and dissipative errors. It is beyond the scope of this chapter to provide details of these techniques, and the reader is referred, for example, to a survey paper by Jameson [1990].

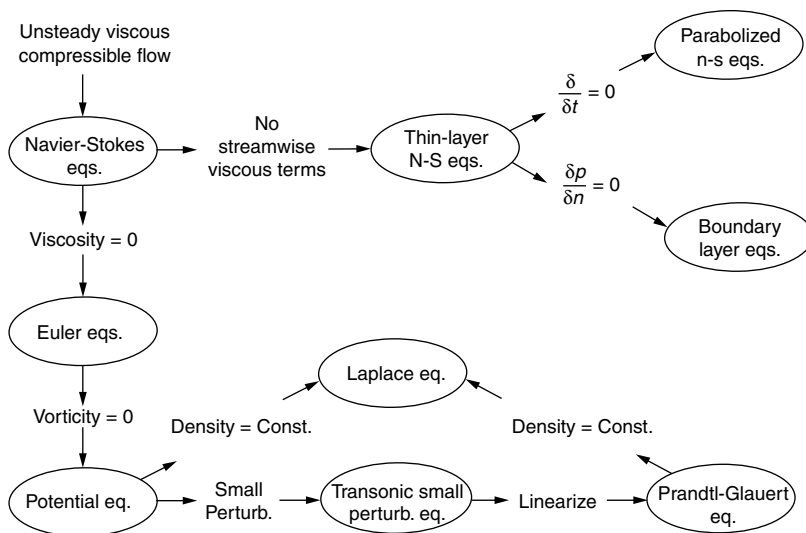

FIGURE 195.1 Equations of fluid dynamics for mathematical models of varying complexity.

195.3 Turbulence Modeling

The currently intractable problem of accurately and practically modeling turbulence effects must be addressed before computational aerodynamics becomes a reliable routine prediction tool for flow situations where viscous effects are dominant. Examples of such situations include separated flows over control surfaces at high angles of attack and aerodynamic heating on high-speed vehicles. The computation of the effect of turbulence from first principles remains an elusive goal at the present time, even for simple two-dimensional shapes such as airfoils, and using maximum available computing power.

In current aerodynamic analyses, turbulence effects are accounted for by phenomenological models. The time-averaged form of the Navier–Stokes equations (known as the Reynolds-averaged Navier–Stokes equations) are solved. Time-averaging introduces the turbulent Reynolds stresses in the Navier–Stokes equations, and these are calculated by multiplying an eddy-viscosity coefficient with the strain-rate tensor. The phenomenological description of eddy viscosity is known as “turbulence modeling.” At present, there is no universal turbulence model that works for all flow situations. Generally, turbulence models are developed by validating them against experimental data for simple flow situations, and are then used for calculation of complex flow fields. This approach introduces an element of uncertainty into the prediction of complex flows.

A variety of turbulence models of varying complexity have been developed over the last half-century. The underlying theoretical framework behind these models and their range of applicability are not given here, but an interested reader can find a comprehensive discussion in a review paper by Rubesin [1987].

195.4 Flow Simulation Examples

The selected flow simulation examples given here basically draw upon the author’s own work and that of co-workers at the McDonnell Douglas Research Laboratories. The purpose of these examples is to illustrate the current state in computational aerodynamics for the prediction of aircraft, launch vehicle, and helicopter flow fields, from a manufacturer’s point of view.

Figure 195.2 shows the surface grid on a complete twin-jet transport aircraft. Figure 195.3 shows the pressure distribution on the aircraft at a cruise Mach number of 0.76 and angle of attack of 2° obtained with the Euler code described by Deese and Agarwal [1988]. Figure 195.4 shows the comparison of the computed pressure distribution, at various spanwise locations of the wing, with experimental data. The inviscid Euler solution tends to predict shocks that are too strong and too far downstream on the wing upper surface. Addition of the viscous terms moves the shock location and strength toward

FIGURE 195.2 Surface grid over a complete twin-jet aircraft.

FIGURE 195.3 Euler solution predictions of surface pressure on a generic twin-jet transport aircraft; $M_\infty = 0.76$, $\alpha = 2.0^\circ$.

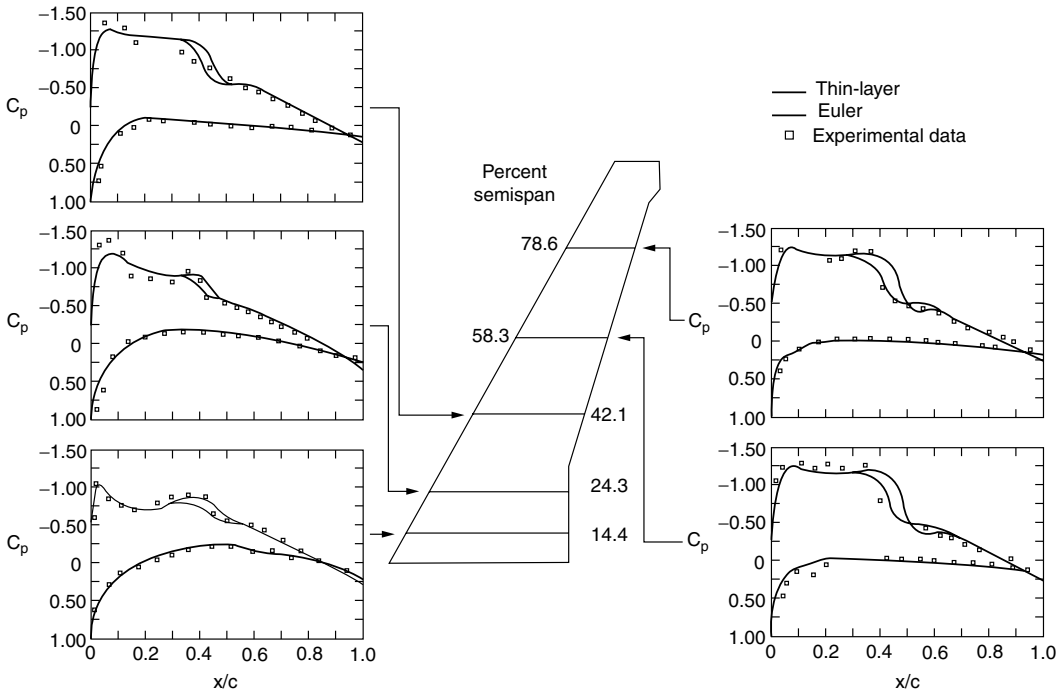

FIGURE 195.4 Comparison of Euler and thin-layer Navier–Stokes pressure distribution with experimental data for typical transport wing body at $M_\infty = 0.76$, $Re = 6.39 \times 10^6$, $\alpha = 2.0^\circ$, $160 \times 34 \times 42$ mesh.

better agreement with the experimental data, except in the region near the suction peak, where better grid resolution is needed to capture the high-flow field gradients. Figure 195.5 shows the surface grid on a complete fighter aircraft with faired inlets. Figure 195.6 shows the pressure distribution on the aircraft at a Mach number of 0.90 and an angle of attack of 4.84° , obtained with an Euler code described in Deese and Agarwal [1988]. Figure 195.7 shows the comparison of the computed and experimental pressure distributions at various spanwise locations of the fighter wing. The Euler solution tends to predict a suction peak higher than that observed experimentally. Better resolution of the relatively small-radius fighter wing should improve the agreement with data. The shocks on the wing upper surface are predicted to be stronger and slightly downstream of the measured shocks, as is typical of inviscid solutions.

FIGURE 195.5 Surface grid on a generic fighter with faired inlets.

comparison with experimental data. These calculations were performed with the Navier–Stokes code described by Marcum and Agarwal [1990].

Many examples of a similar kind exist in the aerospace literature, showing the power of computational aerodynamics in simulating flows about complex configurations.

195.5 Future Directions and Challenges

We can look back on the progress in computational aerodynamics during the last 3 decades with great satisfaction. At present, we can generate three-dimensional grids about complete vehicle configurations and employ efficient and accurate numerical algorithms for the solution of the Euler and Navier–Stokes equations. Inviscid flow can be computed quite accurately over the entire Mach number range.

However, confidence in the predictive capability of computational codes for viscous-dominated flows remains low because of turbulence model limitations and insufficient computing power. Furthermore, although significant advances have taken place in the analysis of flow fields, their impact on the development of direct design methods has been limited. The development of inverse design techniques has lagged far behind that of analysis tools. In the future, a strong emphasis is needed on the development of such design methods.

The next computational challenge will be in developing methods and techniques for multidisciplinary design optimization, that is, to include several disciplines simultaneously in the design optimization process, rather than in a sequential manner. A configuration could be optimized taking into account aerodynamic, structural, and signature constraints simultaneously.

Finally, two of the emerging computer-related technologies, artificial intelligence and massively parallel technology, are likely to have major impacts on flight vehicle design. Expert system technology will have a substantial impact on automating the design process, thus reducing the cost and time of a design cycle.

Massively parallel technology will make real-time interactive analysis possible, opening up great opportunities for real-time design modifications and improvements in product quality, at a substantially reduced cost.

196.1 System and Material Requirements

Aeronautical and space engineering materials requirements are much different than other engineering disciplines due to the exposure of flight vehicles to complex dynamic loading conditions during missions. This environment, which influences material selection, will be somewhat different depending on the operating altitude of the vehicle, as depicted in [Figure 196.1](#). Flight systems are classified in terms of whether the system will operate only within the atmosphere (“aeronautical”), in space (“space”), or within the atmosphere as well as in space (“aerospace”). Structural failures in-flight can often result in loss of life and vehicles; hence, the engineer faces a major design requirement of a high degree of structural integrity against failure and a low weight requirement to achieve stringent performance goals. A flight vehicle structure must be designed to meet a number of conflicting requirements that include adequate strength to meet maximum expected loads with a suitable factor of safety, adequate stiffness so that deformations are kept within acceptable levels, good in-service properties such as fatigue and corrosion resistance, and good tolerance to atmospheric or space environment conditions.

Flight vehicle engineers have a wide range of materials to choose from for their systems including the commonly used ones described below. In aeronautical and space applications, materials must have both high strength-to-weight and high stiffness-to-weight ratios. Considering the degradation of mechanical properties of materials at elevated temperatures, care must be used in selecting materials for thermal environment applications. Additional properties and parameters to be considered are the strength of the material throughout the entire temperature range, fatigue, stiffness, thermal stress, toughness, stability, cost, availability, producibility, formability, and corrosion. This chapter is intended to direct readers to proper materials groups for their application and to provide typical approximate values of properties for representative materials; readers must refer to material data from the provided sources list at the end of this chapter or from material data sheets to obtain exact numerical properties to be used for their specific application.

In general, materials can be grouped as nonferrous metals, ferrous metals, plastics, ceramics, and composite materials. Although there have been new advances in materials, aluminum is still the most commonly used material for flight systems owing to its ease in forming, ready availability, and low

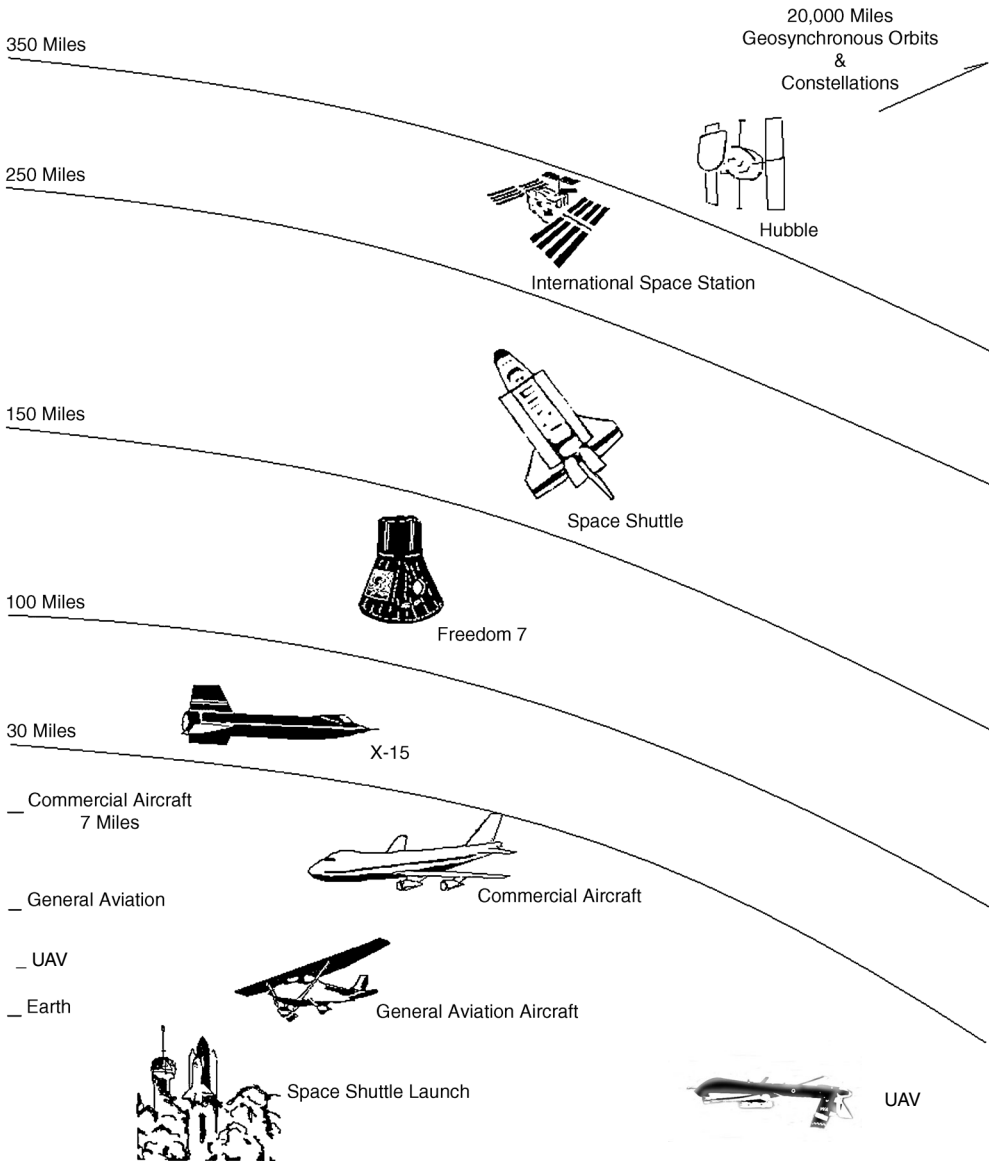

FIGURE 196.1 Aeronautical and space vehicles and their design environment within the atmosphere and beyond.

recycling cost. On the other hand, composites are preferred for their easy tailorability. Metal matrix composites and ceramic matrix composites are expected to be the next-generation advanced composite materials if their low toughness can be improved. Steel, which is a ferrous metal, is used for strength-critical applications. Titanium is used for higher-temperature applications and has good corrosion resistance. As temperature requirements increase beyond 1,500°F (815°C), nickel is used, and beyond 2,000°F (1,093°C), carbon-carbon composites and refractory metals such as beryllium and zirconium in the form of thermal coating are used. Three of the most commonly used flight system material groups are described below: light alloys, used in low-temperature applications; titanium alloys, used in high-temperature applications; and carbon fiber composites, used in higher-temperature applications.

Light alloys are usually based on aluminum and are used in the majority of aeronautical and space applications. Their primary advantages are high strength- and stiffness-to-weight ratios, relatively low cost, and a range of available fabrication processes. They depend on relatively low-temperature heat-

treatment processes in obtaining desired material properties, which implies poor strength and stiffness at elevated temperatures and relatively poor fatigue properties. Heat-treatable aluminum alloys are designated as 2xxx, 6xxx, and 7xxx series based on the primary alloying elements. Heat treatment in general can greatly increase the strength of these alloys. For stiffness-critical applications, 6061-T6 is used owing to its weldability and low cost. The most common 2xxx-series alloy used in aerospace is the 2219. Retrogression, a relatively new type of heat treatment is applied to the 7xxx series to improve the combination of strength and stress-cracking resistance. Identified as the T77xx, these alloys are used in primary structures, such as the Boeing 777 upper-wing skin plate, as spar and stringers materials of 7055-T77 and 7150-T77. The higher-strength alloys in general are poorer in fatigue, and their use is restricted to compression-sensitive areas. Tensile loads tend to produce more fatigue problems. The maximum temperature at which light alloys can be used for continuous operations is about 266°F (130°C). This temperature value is what occurs when a flight vehicle is traveling at twice the speed of sound due to kinetic heating when allowance is made for heat dissipation by the structure. Aluminum alloys are often thought of as corrosion resistant, but aluminum is a reactive metal and is susceptible to various forms of corrosion. In order to improve resistance to corrosion, aluminum alloys need to be coated or anodized. Despite some of the abovementioned limitations, aeronautical and space systems that do not use light alloys are rare.

A more recent light alloy that offers a lower-density, higher modulus of elasticity and higher strength than the 2xxx, 6xxx, and 7xxx aluminum alloy series is aluminum-lithium. Alcoa develops the most mature form, and properties are available in sources given at the end of this chapter. The disadvantages of these newer alloys are welding difficulty and directional dependence in modulus. Known applications of aluminum-lithium alloys include the Centour upper stage and payload adaptors for the Titan-IV launch vehicle.

Magnesium alloys, on the other hand, are about two-thirds as dense as aluminum alloys and have similar strength-to-weight ratios. They have poor resistance to corrosion and low wear resistance. The biggest disadvantage is that magnesium is not formable at room temperature.

Beryllium is highly attractive for stiffness-critical structures owing to its very high specific stiffness, which is the ratio of elastic modulus to density, with a value on the order of six times greater than most metals. In addition, it has very low coefficient of thermal expansion and high thermal conductivity. Beryllium in powder form becomes toxic, and it has low fracture toughness. It is commonly used in space structures.

Titanium alloys have greater density than light alloys, but they have higher strength-to-weight and stiffness-to-weight ratios and they maintain these values even at elevated temperatures. Despite their inherently high cost and difficulty to manufacture, the use of titanium alloys has become common especially when weight reduction is required, or strength is required at temperatures higher than that can be sustained by aluminum alloys or polymer composites. The wide-chord fan blade, full moving stabilizer surfaces, and internal structure of combat aircraft provide good examples of titanium alloy applications. Their biggest use is in engine structures for discs, blades, shafts, high-pressure compressors, and nozzle assemblies. Titanium alloy comprises almost 10% of the Boeing 777 aircraft's weight. Ti-6Al-4V is the most general-purpose, high-strength alloy used in aerospace applications.

Carbon fiber composites have high specific stiffness, specific strength, and excellent resistance to fatigue when compared with metallic alloys. Due to their high cost, composites are not replacing metals on commercial aircraft, and the focus on technical developments is changing to find cheaper methods of manufacture with less emphasis on improving properties. Carbon fiber composites have excellent fatigue properties, although these vary depending on the fiber lay-up, matrix type, and loading pattern. Composite matrices include polymers (epoxies), metals, carbon, and ceramics. In advanced composites, the fibers provides the strength and stiffness, and the matrix (resin) holds the fibers together as well as transferring loads to allow the composite to act as a whole. Advanced composites can be categorized with respect to their matrix types as polymer matrix composites (PMCs), metal matrix composites (MMCs), intermetallic matrix composites (IMCs), and ceramic matrix composites (CMCs). The PMCs are further grouped according to their polymer matrices as thermosets (epoxy) or thermoplastics (*polyethylene*).

TABLE 196.1 Specific Modulus and Strength of Typical Fiber Composites and Bulk Metals

| Material | Specific Modulus Msi-in ³ /lb (GPa-m ³ /kg) | Specific Strength Ksi-in ³ /lb (MPa-m ³ /kg) |
|-------------------------------|--|---|
| Graphite | 513 (0.13) | 4610 (1.15) |
| Glass | 137 (0.034) | 2489 (0.62) |
| Unidirectional graphite/epoxy | 454 (0.113) | 3764 (0.94) |
| Unidirectional glass/epoxy | 86 (0.021) | 2368 (0.59) |
| Cross-ply graphite/epoxy | 240 (0.06) | 936 (0.233) |
| Cross-ply glass/epoxy | 53 (0.013) | 197 (0.04) |
| Steel | 107 (0.026) | 334 (0.083) |
| Aluminum | 107 (0.026) | 426 (0.11) |

TABLE 196.2 Density, Elastic Modulus, and Poisson's Ratio Rough Values of Common Aerospace Materials (Room Temperature)

| Material | Density lb/ft ³ (kg/m ³) | Elastic Modulus lb/in ² (MPa) | Poisson's Ratio |
|--|--|---|-----------------|
| Aluminum alloy | 173 (2771) | 10×10^6 (69×10^3) | 0.33 |
| Titanium alloy | 276 (4422) | 16×10^6 (110×10^3) | 0.34 |
| Copper | 556 (8907) | 15×10^6 (103×10^3) | 0.34 |
| Nickel | 556 (8907) | 29×10^6 (204×10^3) | 0.31 |
| Steel | 480 (7689) | 30×10^6 (207×10^3) | 0.30 |
| Pyrex | 144 (2307) | 6.2 lb/ft ³ | 0.24 |
| Quartz | 160 (2563) | 7.9 lb/ft ³ | 0.33 |
| Rubber | 1100–950 lb/ft ³ | 0.23–0.0005 lb/ft ³ | 0.4–0.5 |
| Cork | 240 (3845) | — | — |
| Wood | 38 (609) | Grain direction: 1.5×10^6 (11×10^3) Orthogonal to grain direction: 0.1×10^6 (0.6×10^3) | — |
| Carbon fiber — epoxy matrix (60% volume fraction carbon fiber) | 105 (1682) | Longitudinal: 32×10^6 (220×10^3) Transverse: 1×10^6 (6.9×10^3) | 0.25 |

The strength- and stiffness-to-weight ratios of composite materials can best be illustrated by “specific” properties. These are simply the result of dividing the mechanical properties of a material by its density. Generally, there is a spread of specific properties and it must be taken into account in analysis. The specific tensile strength and specific tensile modulus values allow the engineer to compare materials on the basis of mechanical properties per unit density. The higher the number, the better the material is for the structural efficiency and the lower the weight. Specific modulus and strength values of the most common aerospace composite and metal materials are presented in Table 196.1. For ready comparison, Table 196.2 lists a wider range of materials with their density, elastic modulus, and Poisson's ratio at room temperature.

196.2 Material Selection by Subsystems and Loads

The driving force behind the advancement of aviation has always been the desire to fly higher and faster. Within the atmosphere, the motion of vehicles takes place under the influence of gravity, aerodynamic forces, and possibly some type of air-breathing propulsion force. In space, however, the mode of propulsion must be entirely independent of air for its thrust. Therefore, system loading conditions must be predicted correctly. In general, loads acting on the flight systems are complex and include static, dynamic,

FIGURE 196.2 Lightweight aerospace primary structural members. (a) Web forms with beads and cutouts. (b) Skin shells integrated, built-up and honeycomb forms. *Continued on facing page.*

and repeated (cyclic) types, and may act under a wide range of temperatures. Therefore, the engineer needs to understand the behavior of materials under complex loading. For space transportation vehicles, the loads could even get more complicated, which introduces new constraints to the design. For example, for space transportation vehicles, additional loading requirements are imposed to avoid coupling of characteristic launch vehicle frequencies to critical spacecraft control system frequencies.

The load-carrying structural elements of flight vehicles are the “primary structure.” The other structures such as control surfaces are called the “secondary structure.” Flight vehicle structural forms are evolved from the need for minimum-weight design to achieve stringent performance goals. As new materials are introduced, structural forms change to take full advantage of the materials’ load-carrying characteristics, thereby reducing weight. Lightweight structural forms are depicted in Figure 196.2 for both metal and composite materials. Figure 196.2(a) shows two lightweight web forms, and Figure 196.2(b) details various lightweight shells, including an internally stiffened shell to reduce part count, a built-up, a honeycomb-resin-integrated molded structure, and a sandwich construction for high dynamic-pressure applications. An all-metal, lifting-surface structural form partially skinned to show cutouts on the webs and a carbon fiber/epoxy matrix composite, skinned foam-core wing, lightweight lifting-surface structural form are depicted in Figure 196.3. In a weight-reduction effort at the Scaled Model Aerospace Research and Testing Laboratory (SMARTLAB) at the University of California-Davis, kevlar, carbon, and kevlar/carbon fibers and epoxy matrix materials are used to manufacture various fuselages for an uninhabited aerospace vehicle (UAV) (Figure 196.4). This UAV was flight tested and successfully carried 5.5 times its empty weight as payload. The lightweight structure was achieved using aeroelastic tailoring and manufacturing techniques for advanced composites in design.

The flight vehicle design process starts with an overall configuration that meets the defined vehicle-fairing geometry constraints. Using the acceleration load factors and safety factors applied to the estimated limit loads, the structure is sized using the structural properties for a given material. It is then necessary to estimate the stiffness characteristics of the structure and compare these with minimum requirements. If the stiffness is inadequate, the structure is resized to increase cross-section thickness or inertia, or stiffer materials are applied, and the analysis is repeated. Advanced methods such as aeroelastic tailoring

TABLE 196.3 Spacecraft Subsystem Temperature Requirements

| Subsystem | Temperatures (°F) | Temperatures (°C) |
|------------------|----------------------|----------------------|
| Solar panels | -200 to +170 | -129 to 76 |
| Batteries | 30 to 50 | -1 to 10 |
| Electronics | Zero to 140 | -17 to 60 |
| Propulsion tanks | 40 to 120 | 4 to 48 |
| Optical systems | 70 | 21 |

to take into account the effects of stiffness together with strength in the preliminary design phase are new methods used for lightweight designs. Limit loads to be expected during each critical period are based on rational predictions with allowance for statistical variation when possible. The factor of safety is an arbitrary number on type and use of structure to account for variations in materials properties from batch to batch, manufacturing quality, load redistribution, and possible strength degradation due to service treatment. Factor of safety values vary between 1.1 to 1.5, depending on whether the vehicle system is going to carry humans or not and whether it is for commercial or military usage.

In addition to mechanical loads, the structure should resist vibration and thermal effects without excessive deformations. As an example, the typical temperature environment for spacecraft by subcomponent is listed in Table 196.3. Stiffness requirements for launch vehicles include fundamental frequencies required being above minimum values to avoid excessive acceleration during launch and ascent. In addition, the deployed frequencies in space must be acceptable for spacecraft control system requirements.

In the process of the optimum material selection, parameters that must be considered are payload type, atmospheric or space environment, speed, and life cycle, measured in terms of flight hours or years. Once the constraints are determined, then the designers must consider the tradeoff between strength and toughness when selecting alloys and their heat treatments. For minimum weight, high specific strength is desired. For damage tolerance, high toughness is needed; however, as strength increases, usually toughness decreases. The best engineering material is strong enough and tough enough, and provides the minimum weight design at lowest cost. Depending on the operating environment and the system and design requirements, one property or another may be critical, and the material choice is made accordingly. Tables 196.3 and 196.4 provide typical properties of metals and composites commonly used in aeronautical and space applications.

Propulsion Subsystem Materials

All flight vehicle systems except gliders and balloons require a propulsion system for sustaining flight. Propulsion systems have different material requirements depending on whether air breathing, combined cycle, or rocket propulsion types exist. Among propulsion subsystem elements, material selection for blades will be focused for propeller blade and compressor blade cases.

A propeller blade of a piston-engine aircraft experiences vibratory excitations. As a result of vibratory excitation, the blade has to be designed in such a way as to ensure that no natural frequencies are excited in the propeller operating range. The first generation of propeller-driven aircraft used blades made by the natural composites (wood). However, the propeller blade is in many ways a very suitable application for carbon fiber composites. Composites are a good choice as blade materials owing to their tailorability in lay-up and fiber orientations to avoid harmful resonance conditions without significantly impacting the strength or weight of the blades. In addition to the structural requirements of the blades, there are environmental requirements to resist erosion from foreign objects such as stones during ground operations.

Aluminum alloy blades have to be repaired frequently to remove notches, which can significantly reduce fatigue life. Composite blades, however, when suitably treated, require little maintenance, are easy to repair, and last significantly longer than metal blades. For example, aluminum blades are worn after only 10,000 flight hours, while composite blades can last more than three times longer. The cost

of ownership of composite blades is therefore lower and the life-cycle cost of running turbo pumps can be significantly reduced.

Advanced high-temperature propulsion materials applications include PMCs for fans; MMCs, IMCs, and superalloys for compressor and turbine materials; and CMCs for turbine applications.

Spacecraft Materials

Prior to selection of materials for spacecraft applications, their strength, corrosion resistance, electrochemical interaction, toxicity, flammability and outgassing must be considered. The latter four properties of toxicity, odor flammability, and outgassing properties are specific to human flight missions and relate to safety aspects. Outgassing is one of the major problems associated with using materials in a vacuum. One example criteria is that its outgassing shall not exceed 1% of its total mass.

All materials, whether structural or not, are flight qualified through extreme tests before commitment to production. For example, interior materials for commercial aircraft must satisfy federal requirements for low smoke and toxic emissions in a fire. In addition, these materials must be durable and cleanable. Cockpit canopies or windshields must meet standards for bird strikes, and compliance is demonstrated by analysis and testing. Wiring and electronic components must meet standards for reliability in the service environment. Paints must be environmentally friendly and strippable to enable vehicle refurbishment without damage to the basic structure. Sealants must have good in-service properties for application, and must perform in the service environment for the design life of the system.

196.3 Flight Speed/Altitude/Temperature Effects on Material Selection

The speed of aerospace vehicles has increased over time. The speed of sound in gases depends on the nature of the particular gas and its temperature. For air at standard sea level under standard temperatures, the speed of sound is 340 m/sec or 1,115 ft/sec or 1,224 km/h or 761 mph. In the stratosphere, where the airliners cruise, the speed of sound is 1,060 km/h (659 mph). Current transport aircraft, with the exception of the Concorde, cruise at a speed below the speed of sound in stratosphere. The flight vehicle speed divided by the speed of sound is defined as the Mach number, M . Most airliners then cruise at speeds of $M < 1$. A typical flight vehicle traveling twice the speed of sound would see an equilibrium upper-surface skin temperature of 130°C and a nose temperature of 160°C , as sketched in Figure 196.5. The material choice is greatly affected by dynamic pressure, which is one-half the air density, ρ times the flight speed, U , squared:

$$q = \frac{1}{2}(\rho U^2)$$

(Upper surface temperatures in $^{\circ}\text{C}$ at $M = 2.2$)

FIGURE 196.5 Representative high-speed aerospace structure's equilibrium skin temperatures at supersonic flight.

FIGURE 196.6 Flight total temperature and dynamic pressure material limit as a function of mach number and altitude. (Source: Sarigul-Klijn, N. 2002. *Material Corridors and Empty Weight Fractions for Atmospheric and Orbital Vehicles*, Technical Report 021001. Scaled Model Aerospace Research and Testing Laboratory, University of California-Davis, Davis, CA. With permission.)

As the flight Mach number and altitude change, the values of total temperature and dynamic pressure change and will limit the types of materials available for that application. Figure 196.6 shows material limits for aerospace systems. In this figure, the total temperature, and dynamic pressure limits are plotted as a function of Mach number and altitude. As seen in Figure 196.6, heating at high Mach numbers and altitudes can generate extreme skin temperatures. Unfortunately, materials able to withstand high temperatures and flight loads for extended periods of time are not presently available, especially at low densities. Therefore, a commercial hypersonic vehicle to carry passengers has not yet been developed.

Aerodynamically heated structures are one of the very recent challenges to the field of engineering design and materials research and development. There are many materials that have application to the design of aerodynamically heated structures. Titanium and high-strength steel are the first two candidate materials. The third high-strength material for consideration in primary structures subject to aerodynamic heating is aluminum. The fourth is beryllium and it has poor ductility and high cost, followed by molybdenum, and columbium materials combined with proper coating. They must be coated to be satisfactory in service. Heat-sink materials should have higher thermal conductivity, high specific heat and melting, and for aerospace applications they must have low specific gravity. Metals can resist temperatures higher than their melting points by convection cooling, which is heat exchange with a coolant. Metal alloys suitable for elevated temperatures are usually nickel and cobalt based, as they exhibit high strength and modulus and maintain their properties at high temperatures. Densities are similar to steel values. The most commonly used elevated-temperature alloys are A-286, Inconel 718, and Invar.

In extreme heat conditions such as during the reentry phase, ablative materials are used. The heat is carried off with material removal. The less material is lost, the more efficient the ablative material. Ablative materials must have a low thermal conductivity so that the heat may remain concentrated in the thin surface layer.

FIGURE 196.7 Empty weight fractions for various aerospace vehicles. (Source: Sarigul-Klijn, N. 2002. *Material Corridors and Empty Weight Fractions for Atmospheric and Orbital Vehicles*, Technical Report 021001. 196.4 Effects of Materials on Empty-Weight Mass Fractions and the Future

Tremendous progress in aeronautics, space, and aerospace has been made in the 100 years since the first flight of the Wright Flyer in 1903. The aerospace systems of the future must be affordable and even lighter in weight in order to go beyond Planet Earth.

Potential materials and process contributions to affordability include lower costs for raw materials, fabrication, assembly, and maintenance. Innovative design concepts and materials and process improvements will help achieve the goal of more affordable systems.

The empty-weight to maximum gross-weight ratios of aeronautical and space vehicles are critical parameters in their performance and material selection plays a big role in this value. The empty-weight fraction for a flight system is defined as the empty weight, W_e , divided by the take-off gross weight, W_o . It differs from the dry mass fraction in that it does not include payload since payloads are on the order of 5% to 35% of take-off gross weight. The take-off gross weight (or the maximum gross weight) includes the aircraft's empty weight, aircraft fuel, and payload.

$$\text{Empty weight fraction} = \text{Empty weight} / \text{Maximum gross weight}$$

The empty-weight fractions versus maximum take-off gross weight for various current aeronautical and space vehicles are plotted in Figure 196.7. Compared to the wide variation in the maximum gross-weight values of the current fleet of aeronautical and space vehicles, their empty-weight fractions are much less variable. The maximum gross weight of a Boeing 747 is about 850,000 lbs; the same value for the space shuttle system is 4.5 million lbs, of which 80% is fuel and oxidizer. The X-15, on the other hand, carried propellant equal to 55% of its launch mass. This value is similar to other supersonic aircraft, such as the Concorde.

Increased concern for the environment has had a significant influence on how materials are produced, processed, and disposed of. More environment-friendly materials that meet all performance requirements are replacing some materials. The downward trend of toxic chemical release into the environment is expected to continue. The American Society for Testing and Materials (ASTM) has developed standard test-specimen geometries, and the test techniques for materials and material data provided in this chapter

Note: Density depends on volume fraction and density of constituents. Design strengths and modulus depend on constituent property values, fiber volume fraction, and fiber orientation.

largely used their published values. Underlying principles of materials testing include assurances that test techniques do not influence test results, that test data are reproducible, and that the tests are in fact providing reliable information that can be used in making sound engineering design decisions.

In addition, technological availability of a material for a specific mission is important. A good example is the materials factors that have been influencing the pace of developing human space vehicles. Space launch vehicles have empty weight fractions of 5 to 20% of their maximum gross weight. Such low fractions are achieved by eliminating wings, landing gear, and aerodynamic control surfaces. Designers should be cautioned on assuming that future materials will show significant improvements in empty weight fractions.

Historical data on structural material weight percentages for aeronautical vehicles show that the empty-weight fraction values achieved varied from 60 to 40%, covering the last 100 years of flight vehicle design improvements and material-related developments. There has been significant progress in the understanding of fundamental materials behavior, enabling improved prediction of materials performance in service. Research must continue to ensure higher standards of excellence in aerospace materials together with improved specific properties.

Defining Terms

Ablative material — Materials used for dissipation of heat by mass removal.

Advanced composite material — Structural material made by combining high-performance reinforcements in a matrix material such as epoxy or metal.

Aeroelastic tailoring — Use of stiffness constraints together with strength constraints in early stages of a design to achieve minimum-weight components.

Brittleness — Property of breaking without noticeable warning or deformation.

Creep — Slow deformation of a material under stress that results in permanent change in geometry.

Damping — Dissipation of energy during oscillations.

Elastic limit — Maximum stress level that a material can withstand without deforming permanently.

Factor of safety — Ratio of ultimate strength to the maximum design stress.

Fatigue strength — Load-carrying ability without failure of a material subjected to a loading that is repeated a definite number of times.

Material allowable — Statistically derived material-mechanical property from coupon tests that is used in developing design allowable. An A-basis material allowable is a value that is equaled or exceeded by 99% of the population of values with a confidence of 95%. A B-basis material

allowable is a value that is equaled or exceeded by 90% of the population of values with a confidence of 95%.

Natural frequency — Frequency in cycles per second (Hz) at which a system will oscillate when excited by a time-varying load and then the load is removed.

Stiffness — Measure of load that is required to cause a unit deformation.

Strength — Amount of load that a structure can carry without collapse or extreme deformation.

Toughness — Relative degree of resistance to impact loads without fracture.

Ultimate strength — Stress level that causes fracture of material that is calculated based on maximum value of the force and the undeformed cross-section area.

*National Aeronautics and Space
Administration*

Rocket propulsion is an application of Newton's first, second, and third laws of motion. Newton's first law of motion states that a particle not subjected to external forces remains at rest or moves with constant velocity in a straight line. A rocket lifting off the launch pad goes from a state of rest to a state of motion. Newton's second law of motion states that force equals mass times acceleration. Force in the equation is the rocket thrust, where mass is the amount of rocket fuel being burned and converted into gas, which expands and then escapes from the rocket. As the gas exits the combustion chamber through a nozzle, it picks up speed. Newton's third law of motion states that for every action, there is an equal and opposite reaction. With rockets, the action is the expelling of gas out of the engine; the reaction is the force or thrust of the rocket in the opposite direction.

197.1 Performance Characteristics

In the process of producing thrust, rocket engines generate more power per unit weight than any other engine. To enable a rocket to climb into low-Earth orbit, it is necessary to achieve velocities in excess of 28,000 kph. Escape velocity is a speed of about 40,250 kph. To achieve these velocities, the rocket engine must burn a large amount of fuel and push the resulting gas out of the engine as rapidly as possible. Containing and controlling this power is the basic challenge in the development of these devices. For example, the power density produced by liquid hydrogen (LH₂) turbomachinery utilized by the space shuttle main engine (SSME) is approximately 83 horsepower per pound of turbopump weight.

Rocket propulsion system design solutions are quite varied: thrust levels from ounces to millions of pounds force; liquid and solid *propellants*; and liquid systems with pressures that are maintained by turbopumps or pressurized tanks. Liquid system applications vary from small pressure-fed, storable monopropellant thrusters for keeping satellites stationary, to large turbopump-fed, cryogenic bipropellant engines for boost propulsion. *Combustion chamber* pressures vary from a few pounds per square inch (psi) to several thousand psi. Generally, liquid propulsion systems consist of a propellant feed system, and *injector*, a combustion chamber, and a nozzle. The propellant feed system includes ducting and valves for controlling flows and, in the case of pump-fed systems, turbomachinery that draws propellants from lightweight propellant tanks and increases the pressure to the level necessary to support the desired combustion chamber pressure.

The ideal rocket propulsion equation is

$$\Delta V_{\text{ideal}} = g_0 I_{\text{sp}} \ln \frac{M_0}{M_1} \quad (197.1)$$

where ΔV_{ideal} is the ideal delta velocity imparted on a vehicle, g_0 is the gravitational constant, I_{sp} is the propulsion system's specific impulse, M_0 is the initial mass of the vehicle, and M_1 is the final or burnout mass of the vehicle. This equation provides two important performance parameters: specific impulse, which is a measure of propulsion system efficiency expressed in seconds, and vehicle burnout mass, which includes all structures (tankage, thrust structure, etc.), residual propellants, engine systems, feed systems, pressurization systems, auxiliary systems, electronic systems, upper stages, payload supporting structures, and the payload itself.

One of the more important internal rocket engine parameters is characteristic exhaust velocity, commonly referred to as C-star (C^*), which relates combustion chamber pressure, chamber throat area, and propellant flow rate. Theoretical characteristic exhaust velocity C^* is computed as follows:

$$C^* = \frac{P_{ns} A_t g_0}{\dot{w}_{tc}} \quad (197.2)$$

where P_{ns} is *nozzle* stagnation pressure in psi, A_t is throat area in square inches, and \dot{w}_{tc} is chamber propellant mass flow rate in pounds-mass per second. A number of losses will reduce the actual C^* realized. These losses are generally a function of injector design and are related to mixture ratio maldistribution, mixing, and so on. The actual C^* realized by a given design is

$$C_{\text{act}}^* = \eta_{c^*} C^* \quad (197.3)$$

where η_{c^*} is C^* efficiency, typically between 0.80 and 0.99.

Another useful parameter is thrust coefficient, which relates thrust F , chamber pressure, and throat area as follows:

$$F = C_F P_{ns} A_t \quad (197.4)$$

where C_F is the thrust coefficient, P_{ns} is nozzle stagnation pressure, and A_t is throat area. Once again, additional parameters must be added to reflect actual values. This yields the following:

$$F = \eta_{CF} C_F P_{ns} A_t - P_a A_e \quad (197.5)$$

where η_{CF} is thrust coefficient efficiency, typically between 0.90 and 0.97, P_a is local atmospheric pressure in psi, and A_e is exit area in square inches. This equation yields thrust at any point between *sea level* and *vacuum* conditions.

Specific impulse I_{sp} is an overall efficiency term and is defined as

$$I_{\text{sp}} = \frac{F}{\dot{w}_t} \quad (197.6)$$

where F is thrust level in pounds-force and \dot{w}_t is the total mass flow rate in pounds-mass per second. Specific impulse can be computed for the engine or thrust chamber by utilizing either engine thrust and flow rate or thrust chamber thrust and flow rate, as appropriate. Specific impulse can also be computed if C^* and the thrust coefficient are known. This relationship is expressed as

$$I_{sp} = \frac{C^* C_F}{g_0} \quad (197.7)$$

Again, one must maintain consistency between theoretical values and actual values.

Thrust and specific impulse are commonly calculated at either sea level or vacuum conditions for reference or comparative purposes. Later discussions will refer to sea level thrust (F_{sl}), vacuum thrust (F_{vac}), sea-level-specific impulse ($I_{sp_{sl}}$), and vacuum-specific impulse ($I_{sp_{vac}}$).

Mixture ratio is the ratio between the oxidizer and fuel flow rates, and is expressed in equation form as

$$MR = \frac{\dot{w}_o}{\dot{w}_F} \quad (197.8)$$

where \dot{w}_o is oxidizer flow rate in pounds per second and \dot{w}_F is fuel flow rate in pounds per second. Mixture ratio can be computed for the engine or thrust chamber by utilizing either engine flow rates or thrust chamber flow rates, as appropriate.

Expansion ratio ϵ is a ratio of the thrust chamber nozzle exit area, A_e , and the thrust chamber throat area, A_t :

$$\epsilon = \frac{A_e}{A_t} \quad (197.9)$$

A more complete definition of these and other rocket engine equations, including solid propellant systems, can be found in *Rocket Propulsion Elements* [Sutton, 1992].

197.2 Liquid Rocket Engine Cycles

A number of power cycles are available for liquid propellant systems. These include pressure-fed, expander, gas generator, and staged combustion cycles. Each cycle has advantages and disadvantages; the one selected for a given application is determined after a series of system trade studies. A description of a number of engine systems is given in [Table 197.1](#). A brief description of each of these power cycles follows.

Pressure Fed

This system consists of a *thrust chamber assembly*, associated ducting and valves necessary for control, pressurized tankage, and the pressurization system for the tankage. This system is widely utilized for satellite attitude control, orbital transfer, and as auxiliary propulsion for most major launch vehicles. Pressure-fed systems are perhaps the simplest of all propulsion systems, but are performance limited because of the weight penalty associated with increasing chamber pressures. As pressures increase, tank wall thickness and the mass of the gases needed to maintain tank pressures increase. Tank pressures are set by chamber pressure plus pressure losses in the cooling circuit (if any), injector, valves, and ducting. In most pressure-fed applications, combustion chambers are passively cooled (i.e., film cooled or radiative/ablative). The space shuttle utilizes pressure-fed systems for the orbital maneuvering system and the reaction control system. A schematic of a simple pressure-fed system is given in [Figure 197.1](#).

Expander

This is the simplest of the turbopump-fed systems primarily because the power source for the turbines is the thrust chamber cooling circuit. Only the thrust chamber requires an ignition system. Pump discharge pressures are set by chamber pressure plus pressure losses in the cooling circuit, turbine, injector, valves, and ducting. The combustion chamber is *regeneratively cooled*. In some applications, extensible

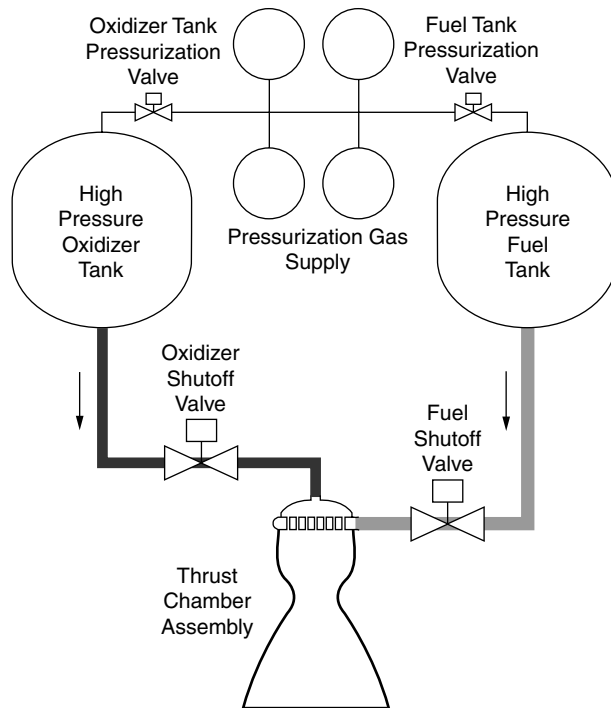

FIGURE 197.1 Pressure-fed propulsion system schematic.

radiation-cooled nozzle extensions are used to increase area ratio while maintaining a short stowed length. Expander cycles are limited in the combustion chamber pressure that can be attained because the energy available to drive the turbine(s) is obtained from the combustion chamber cooling circuit. For applications that require operation at sea level, this reduces the area ratio that can be achieved without *side loads*. Nozzle flow separation is discussed later. The RL10 engine is utilized by the Centaur upper stage for the Atlas-Centaur and Titan-Centaur launch vehicles. A schematic of a simple expander system is given in [Figure 197.2](#).

Gas Generator

This is the most common engine cycle in use today. Turbine power is derived from a separate combustor or gas generator (GG) that utilizes the same propellants as the main system. This hot gas is routed through the turbopump turbines and is dumped overboard. Pump discharge pressures are set by chamber pressure plus pressure losses in the cooling circuit, injector, valves, and ducting. Because the gas generator is parallel to the main chamber, turbine pressure losses do not impact pump discharge pressure in most designs. This highlights one of the disadvantages of this cycle. The gas generator propellants are not used in the main chamber to produce thrust. Some concepts use GG gases for cooling nozzle extensions, but the thrust added is minimal. Gas generators are operated at relatively low mixture ratios because turbine temperatures must be maintained in the 1,000 to 2,000° Rankine range. The main combustor mixture ratio is biased higher to offset this parasitic flow. The combination of poor thrust efficiency of the GG gases and main chamber mixture ratio bias results in a specific impulse penalty. The gas generator cycle was utilized on the F-1 and J-2 engines of the Saturn V launch vehicle and is currently in use on the Delta, Atlas, and Titan launch vehicles. A schematic of a simple gas generator system is given in [Figure 197.3](#).

FIGURE 197.2 Expander engine system schematic.

FIGURE 197.3 Gas generator engine system schematic.

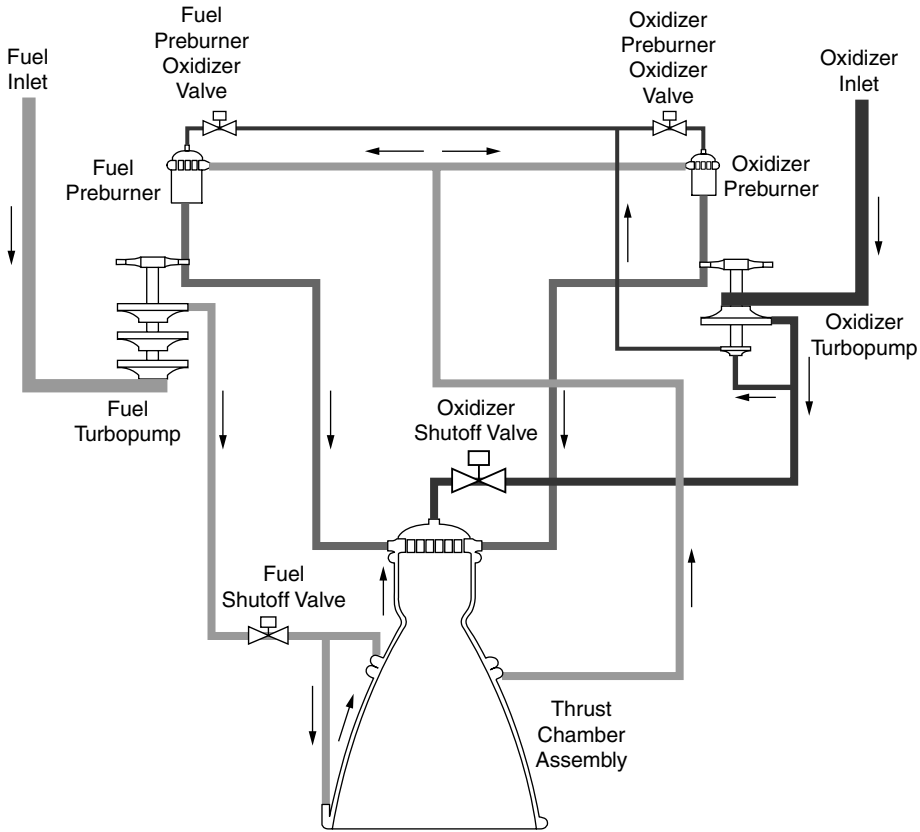

FIGURE 197.4 Staged combustion cycle engine system schematic.

Staged Combustion

The staged combustion cycle provides the highest performance of conventional chemical rocket engines. Turbine power is derived from a separate combustor or preburner which also utilizes the same propellants as the main system. In bipropellant systems, the hot gas is routed through the turbopump turbines to the main injector where it is mixed with the other propellant and is combusted in the main chamber. Pump discharge pressures are set by chamber pressure plus pressure losses in the cooling circuit, turbine, injector, valves, and ducting. Thrust chambers are regeneratively cooled. Staged combustion cycle engines developed in the U.S. have utilized a fuel-rich preburner. Several rocket engine systems developed in Russia have utilized an oxidizer-rich preburner. In the former case, the fuel-rich hot gases are mixed with oxidizer in the main chamber. In the latter, oxidizer-rich hot gases are mixed with fuel in the main chamber. The staged combustion cycle utilizes all propellants in the main combustion chamber, which provides maximum performance. A schematic of a simple staged combustion system is given in Figure 197.4.

A variant of the staged combustion cycle is the full-flow cycle, in which the oxidizer pump turbine is driven with an oxidizer-rich preburner and the fuel pump is driven with a fuel-rich preburner. This cycle offers some simplification in turbomachinery design because of the simplified seal design between the pump end and the turbine end, and a significant reduction in turbine temperatures because all the propellants can be utilized in the turbine drive circuits. This concept is currently under study as a candidate engine system for the next generation launch vehicle. A schematic of a simple full flow staged combustion system is given in Figure 197.5.

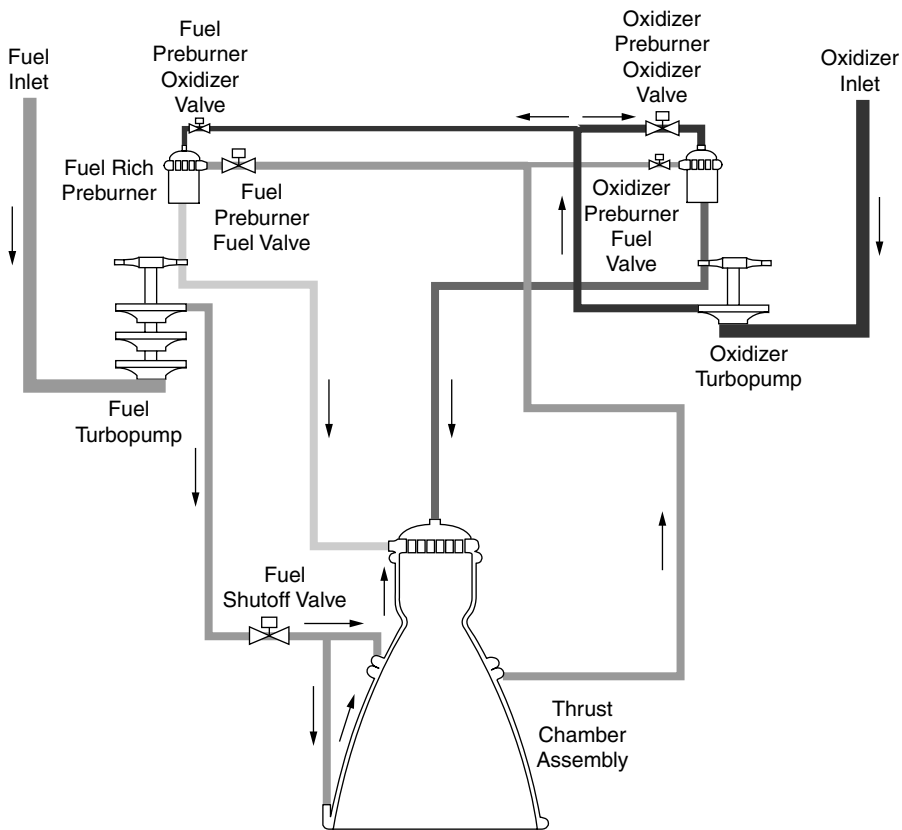

FIGURE 197.5 Schematic of full-flow, staged combustion-cycle engine system.

197.3 Major Components

Main Injector

The purpose of the injector is to introduce propellants into the combustion chamber in a controlled manner, to atomize the propellants, and to mix the propellants at the proper mixture ratio in a homogeneous manner. Mixture ratio variations across the injector face are one of the most common problems that the designer will encounter, and these maldistributions lead to combustion efficiency losses. In some cases, maldistributions are deliberately introduced. To enhance the durability of combustion chambers, a film of fuel is injected at the outer circumference of the injector. In order to produce a stable combustion process, baffle elements which are cooled with fuel are commonly used. The most common injector concepts are coaxial, showerhead, and impinging. These are illustrated in [Figure 197.6](#).

The coaxial injector consists of a series of concentric tubes into which the oxidizer is introduced through a center tube and the fuel introduced through the annular area formed by a second tube. This type of injector is commonly used in oxygen-hydrogen engines. Impinging and showerhead injectors, which are commonly used in oxygen-kerosene and storable propellant engines, consist of a series of two sets of orifices. One injects the oxidizer, and the other the fuel. The number of orifices, injection velocities, and injection angles are selected to provide consistent atomization and mixing of propellants. Impinging injectors slant the orifices to impinge the two propellant streams against each, enhancing mixing. The design utilized by the conventional impinging injector consists of a series of concentric copper rings containing the injection orifices. The rings alternate between oxidizer and fuel. The outer ring is generally

FIGURE 197.6 Injector concepts.

a fuel ring and contains a set of smaller orifices that control film coolant for the combustion chamber. Separate manifolding routes propellants to each set of orifices.

Thrust Chamber

A number of design solutions have been utilized in thrust chambers, varying from passively cooled ablatives to a number of regeneratively cooled concepts. In some applications, the thrust chamber is composed of two separate components. The upper portion — including the throat region and a portion of the expansion region — is commonly called a combustion chamber. The lower portion — consisting of the remainder of the expansion region — is called a nozzle. Regeneratively cooled thrust chamber designs include brazed tube bundles, copper with milled channels, and steel with milled channels. The bundled tube concept utilizes: steel tubes, pressed to vary the shape necessary for formation of the overall

thrust chamber shape; a structural shell in the combustion chamber region with a number of straps spaced along the thrust chamber length for additional strength; and necessary manifolding for inlet and discharge coolant flow. For higher-pressure applications (greater than approximately 1800 psia), the heat load produced by the combustion process exceeds the capability of brazed tube designs. For these applications, a copper liner is required in the high heat flux region. This configuration consists of a slotted copper liner, structural jacket, and manifolding. [Figure 197.7](#) illustrates these two thrust chamber concepts.

Turbomachinery

The turbomachinery design process of liquid rocket engines is very similar to a normal pump/turbine design, except for two critical areas. The first is the critical need to minimize weight. This is perhaps the greatest difference. As stated earlier, the power density of the space shuttle main engine turbopump is 83 horsepower per pound of turbopump weight. The second difference is the dynamic and steady state environments that rocket engines require. Although a number of turbojet engines operate at turbine temperatures significantly higher than most rocket engines, they attain the steady state operating point in a matter of minutes, not in 1 to 4 seconds as do rocket engine turbines. This produces severe thermal strains that tax the ability of materials to sustain. Other environments that provide problems in some materials are oxygen and hydrogen. Particle impact, fretting, and rubbing in an oxygen environment can lead to disastrous fires. Susceptibility of materials to hydrogen embrittlement reduces the variety of materials available for the designer or requires platings to protect materials. Another environment to which rocket engine turbomachinery is susceptible is rotor dynamics, which is considerably more critical than in conventional rotating machinery because of the reduced weight of rocket turbopumps. Structural design considerations, including explanation of the processes utilized in the SSME, can be found in *Structural Design/Margin Assessment* [Ryan, 1993].

197.4 System Preliminary Design Process

A number of theoretical thrust chamber performance computer models are readily available that provide the basic performance parameters needed to support a conceptual design. The most common is the Finite Area Combustor Theoretical Rocket Performance Program, commonly referred to as the One-Dimensional Equilibrium (ODE) Program referenced in *Computer Program for Calculation of Complex Chemical Equilibrium Compositions and Applications, Supplement I — Transport Properties* [Gordon et al., 1984]. This model generates performance data for various propellant combinations as a function of mixture ratios, combustion chamber pressures, and nozzle expansion ratios. A sample set of data for liquid oxygen (LO₂)/liquid hydrogen propellants is given in [Table 197.2](#).

The following process outlines a methodology of determining the initial set of overall system requirements for a liquid rocket engine. A preliminary set of top-level engine requirements must be established by the vehicle systems designer for a booster engine. For this exercise, they are as follows:

Propellants: Liquid oxygen/liquid hydrogen
Sea-level thrust: 400,000 pounds force
Mixture ratio: 6.0:1.0

In some instances, a minimum specific impulse value is specified. However, in most cases, the design value should be selected as the result of vehicle-engine trade studies, along with engine weight, recurring costs, and nonrecurring costs.

One of the first choices to be made by the engine designer is the value of combustion chamber pressure. This choice is also the result of a series of trades. For this exercise, 2,000 psia has been chosen and is a good first approximation for the optimum value when recurring costs are one of the more important parameters. This value will provide good performance, while simplifying turbomachinery to two pump stages with moderate turbine temperatures. An initial assumption needs to be made as to engine cycle. For a booster application, either a gas generator cycle or a staged combustion cycle usually provides

FIGURE 197.7 Two thrust chamber concepts.

optimum performance. For this exercise, the staged combustion cycle is selected. This simplifies the initial set of calculations in that the engine flow rate and thrust chamber flow rate are approximately identical. Table 197.3 provides a typical ODE output for a thrust chamber operating at a chamber pressure of 2,000 psia and a mixture ratio of 6.0. The first parameter to select is area ratio. From previous vehicle trade studies, the optimum nozzle exit pressure (P_e) for a first stage or booster vehicle is approximately 6.5 psia, the optimum for a single-stage-to-orbit vehicle is approximately 4.0 psia, and the optimum for a parallel burn core stage (booster and core stages ignite at sea level) is 2.5 psia. Standard atmospheric conditions for sea level and various altitudes can be found in *Terrestrial Environment (Climatic) Criteria Guidelines for Use in Aerospace Vehicle Development, 1993 Revision* [Johnson, 1993].

Another consideration is side loads on the nozzle. For an overexpanded nozzle ($P_e < P_a$), unsymmetrical flow separation results if significant dynamic loads are applied to the nozzle (pressure times surface area forces). These side loads can ultimately destroy a nozzle and, at a minimum, result in significant weight increases. Side loads are computed using both empirical techniques and detailed nozzle fluid flow with computational fluid dynamics techniques. Calculating the locations within the nozzle where flow separation will occur is very difficult and side loads can usually be quantified accurately with test data.

As the application for this exercise is a booster, an exit pressure of approximately 6.5 psia is desired. Using Table 197.3, an expansion ratio of 30 yields an exit pressure of 6.2 psia, which is close enough for a first approximation of the engine characteristics. Using the initial vehicle thrust and mixture ratio requirements, theoretical values of C^* and C_F obtained from Table 197.3, and assumed values of C^* efficiency of 0.99 (readily obtainable with oxygen/hydrogen coaxial tube injectors) and C_F efficiency of 0.97, various engine parameters can be computed using Equations (197.3), (197.5), (197.6), (197.8), and (197.9) and are shown below in order of computation:

197.5 Conclusion

The science of rocketry has enabled some of humankind's greatest achievements, ranging from instantaneous global communications and accurate weather forecasting via geostationary satellites to trips to the moon. The National Aeronautics and Space Administration's (NASA) space shuttle is one of the most complex flying machines ever built and is the only partially reusable launch vehicle. While several countries have rockets capable of carrying a variety of payloads, the U.S. and Russia are the only countries with spacecraft that can transport a crew to and from orbit. France and China have expendable launch vehicles now in use, and Japan is developing another.

The U.S. is on the threshold of a next-generation launch system. NASA aerospace engineers and industry experts are exploring new concepts, including the first fully reusable launch vehicle. Developing rockets for 21st-century missions promotes enhanced technologies to meet new challenges, including balancing design requirements between operability, performance, weight, and cost. The next generation of spaceships will open new doors to the space frontier.

Defining Terms

Ablation — A passive cooling technique in which heat is carried away from a vital part by absorption into a nonvital part, which may melt or vaporize and then fall away, taking the heat with it.

Combustion chamber — A device — which includes a throat region — to mix, burn, and control propellants.

Injector — A device to distribute and inject propellants into the combustion chamber.

Nozzle — A device used to accelerate the combusted gases.

Propellant — Fuel [the chemical(s) the rocket burns] and an oxidizer (oxygen compounds) to ignite the fuel.

Sea level — Standard atmospheric conditions at an altitude of zero feet.

Side loads — Unsymmetrical loads put on a nozzle because of internal flow separation of overexpanded gases.

Regeneratively cooled — A cooling technique in which propellants, usually fuel, are utilized to remove heat from the inner wall of a combustor in a heat exchange process.

Thrust chamber assembly — An assembly consisting of the main injector, combustion chamber, and nozzle. Depending upon fabrication techniques, the combustion chamber and nozzle can be separate components or combined into a single component.

Vacuum — Conditions where atmospheric pressure can be considered to be 0.0 psia.

Weight Fractions

198.2 Level Flight

198.3 Climbing Flight

198.4 Turning Flight

Francis Joseph Hale

North Carolina State University

Two major considerations in the performance and design of an aircraft are its range and maneuverability. *Range* deals with how far the aircraft can fly with a given fuel load and given payload under specified flight conditions. *Maneuverability* treats turning rates, rates of climb, and acceleration. A performance analysis starts with knowledge of the physical characteristics of an aircraft, either actual or hypothetical, and determines how the aircraft will fly under various flight conditions. The converse of the performance analysis is the design of an aircraft to meet a set of operational requirements and constraints. Design, however, is an iterative process, and the first few tries, which yield major aircraft characteristics, may be referred to as *conceptual* or *feasibility* designs. The performance analysis and preliminary design processes are often intertwined in a series of iterations and it may be difficult to distinguish between the two.

The flight path and behavior of an aircraft are determined by the interaction between its characteristics and those of the environment in which it is operating — namely, the atmosphere. The aircraft characteristics can be categorized as its physical characteristics, such as shape, mass, volume, and surface area; the characteristics of the propulsion, guidance, and control subsystems; and the structural characteristics, such as loading and temperature limitations and the stiffness (rigidity) of the structure. The environment affects the flight of an aircraft through the field forces, surface forces, and inertia forces. The only field force that needs to be considered is gravity, which appears as the *weight* and is a function of the mass of the aircraft. The surface forces are the aerodynamic forces (lift, drag, and side forces), which are strongly dependent on the shape and surface area of the aircraft, especially of the wings, and the properties of the atmosphere. The inertia forces result from non-equilibrium processes and are very important in dynamic and stress analyses of aircraft.

Aircraft operational units are still principally English and will be given preference over SI units in this article with distance in nautical miles (nmi), airspeed in knots (kt) and feet per second (ft/sec), force and weight in pounds (lb), and pressure in lb/ft², where 1 nmi = 1.15 mi = 1.84 km; 1 kt = 1 nmi/h = 1.15 mi/h = 1.84 km/h = 0.51 m/sec; 1 ft/sec = 0.59 kt; 1 lb = 4.448 N = 0.4535 kg; and 1 lb/ft² = 47.87 Pa.

TABLE 198.1 Standard Atmosphere Ratios

| Altitude (1000 ft) | 0 | 10 | 20 | 30 | 36 | 40 | 50 | 60 |
|------------------------|-------|-------|-------|-------|-------|-------|-------|-------|
| Density ratio σ | 1.000 | 0.738 | 0.533 | 0.374 | 0.297 | 0.246 | 0.152 | 0.094 |
| Sonic ratio a^* | 1.000 | 0.965 | 0.929 | 0.821 | 0.867 | 0.867 | 0.867 | 0.867 |

Note: $\rho_o = 23.769 \cdot 10^{-4}$ lb-s/ft²; $a_o = 1116$ ft/sec.

198.1 Aircraft Forces and Subsystems

Atmosphere

Although the standard atmosphere comprises a number of concentric layers surrounding the Earth, only the first two layers of the lower atmosphere are of interest. The *troposphere* starts at sea level and is characterized by a decreasing ambient temperature. At 36,089 ft (11,000 m) above sea level (the *tropopause*), the temperature becomes and remains essentially constant in the *stratosphere* until reaching an altitude of 82,021 ft (25,000 m). In the troposphere, as the atmospheric temperature decreases so does the local speed of sound a , thus affecting the Mach number M ; in the isothermal stratosphere the sonic velocity remains constant. Table 198.1 is an abbreviated listing, as a function of the altitude h , of the two atmospheric ratios of most interest — namely, the *density ratio* σ (ρ/ρ_o), where ρ is the atmospheric density at altitude h and ρ_p is the sea level density ($\rho = \rho_o\sigma$), and the *sonic ratio* a^* (a/a_o). The standard-day sea level values of ρ_o and a_o are given below Table 198.1.

A commonly used exponential approximation for the density ratio σ is

$$\sigma = \rho / \rho_o \cong \exp(-h / \beta) \tag{198.1}$$

where β is an empirical factor with a generally accepted value of 23,800 ft (7254 m). Because the atmosphere is assumed to be an ideal gas, variations in the actual temperature and pressure will produce appropriate changes in the actual density. Consequently, on a hot day or with a below-standard barometric pressure, the density will be lower than the standard value for that altitude and the aircraft and propulsion system will perform as though at a higher altitude.

Aerodynamic Forces

In coordinated flight, the two principal aerodynamic forces are the *lift* L and the *drag* D . The lift is perpendicular to the velocity (*airspeed*) of the aircraft and has the primary function of compensating for the weight of the aircraft. The drag is parallel to the airspeed and resists the motion of the aircraft. The wing is the major source of lift and drag, and is designed to maximize the lift while minimizing the drag.

Wing parameters of importance with respect to performance are (1) the wing span b , the distance from wing tip to wing tip; (2) the average chord c_w , the distance from the front (leading edge) of the wing to the back (trailing edge); and (3) the wing area S , the area of one side of the wing to include the area included by the fuselage. The ratio of the wing span to the average wind chord is the aspect ratio AR of the wing, a measure of the narrowness of the wing. The following relationships are useful:

$$S = bc_w; \quad AR = b / c_w = b^2 / S \tag{198.2}$$

The lift and drag forces can be obtained from the following expressions:

$$L = \frac{1}{2} \rho_o \sigma V^2 SC_L = q SC_L; \quad D = \frac{1}{2} \rho_o \sigma V^2 SC_D = q SC_D \tag{198.3}$$

where q is the dynamic pressure and C_L and C_D are the dimensionless lift and drag coefficients.

FIGURE 198.1 Typical variation of L/D with C_L for a specified drag polar.

The drag polar is an expression for C_D as a function of C_L and is an important performance and design parameter. The *parabolic drag polar* is an approximation that can be used with many subsonic (and thin-winged supersonic) aircraft configurations and can be written as

$$C_D = C_{D0} + KC_L^2 \quad \text{where } K = 1/(\pi eAR) \quad (198.4)$$

C_{D0} is the *zero-lift drag coefficient* of the aircraft, KC_L^2 represents the *drag-due-to-lift coefficient*, and e is the *Oswald span efficiency* (on the order of unity and less). The lift-to-drag ratio (L/D) or (C_L/C_D) represents the *aerodynamic efficiency* of an aircraft. It has a maximum value that is a design characteristic of the aircraft. This maximum value $(L/D)_m$ cannot be exceeded, although the aircraft may, and usually does, fly at lower values. The expression for the maximum (L/D) of a parabolic drag polar is

$$(L/D)_m = 1/[2(KC_{D0})^{1/2}] \quad (198.5)$$

A large $(L/D)_m$ calls for low values of K (high AR and large e) and C_{D0} . Figure 198.1, a typical plot of the (L/D) ratio for a specific aircraft and specific parabolic drag polar shows the variation in (L/D) as C_L varies. Typical values of $(L/D)_m$ for several classes of aircraft are: 35 for sailplanes, 18 for Mach 0.8 transports, 7 for supersonic aircraft, and 3 for helicopters.

Propulsion Subsystems

Current aircraft engines are air breathers that produce thrust or power, or a combination thereof. The *turbojet* engine represents a thrust producer, whereas an internal combustion engine in combination with a propeller (a *piston-prop*) represents a power producer. Turbofans, unducted fans, turboprops, and propfans combine the characteristics of both to varying degrees. Turbofans and unducted fans are usually described in turbojet terms and turboprops and propfans in piston-prop terms.

The actual performance and functional relationships of an aircraft engine should be obtained from power plant charts. However, to a first approximation, the *thrust* T (lb) produced by a turbojet can be considered to be independent of the airspeed and, for a given throttle (percent rpm) setting, to be directly proportional to the atmospheric density, so that

$$T(h) \cong T_0 \sigma \quad (198.6)$$

where T_0 is the thrust at sea level. Furthermore, the *fuel consumption rate* (lb/h) is proportional to the thrust, so that

$$dW_f / dt = cT \quad (198.7)$$

where c , the *thrust specific fuel consumption* (tsfc), has the units of lb/h/lb or h^{-1} . Although c varies somewhat with airspeed and altitude, it may, again to a first approximation, be assumed constant for all altitudes and airspeeds. For current turbine engines, the maximum *thrust-to-engine weight ratio* (T/W_e) $\cong 6-8$. Piston-prop engines can be *aspirated* or *turbocharged*, and produce *shaft power* (HP), measured in units of horsepower (hp), which is assumed to be independent of the airspeed but to vary with altitude and power setting. The decrease with altitude of the HP of an aspirated engine is similar to that for the turbojet, but the HP of a turbocharged engine with a constant power setting remains constant until the *critical altitude* (15,000 to 20,000 ft) is reached and then decreases with altitude. The approximations for the density relationships are

$$HP \cong (HP)_0 \sigma (\text{aspirated}) \quad \text{and} \quad HP \cong (HP)_0 (\sigma / \sigma_{cr}) (\text{turbocharged}) \quad (198.8)$$

where σ_{cr} is the density ratio at the critical altitude. Figure 198.2 shows the qualitative relationship of the HP with altitude of the two types of engines. (The variation of turbojet thrust is similar to that shown for the aspirated engine.) The propeller converts the shaft horsepower into the *thrust power* P , which is equal to the product of the thrust and airspeed TV . The shaft power, thrust power, and thrust are related by the expressions:

$$P = TV = k\eta_p(HP); \quad T = k\eta_p(HP)/V \quad (198.9)$$

where η_p is the propeller efficiency (on the order of 80 to 85% for a well-designed, constant speed propeller) and k is a conversion factor with a value of 326 when V is in knots. Note that for a given horsepower, the thrust power of a piston-prop is independent of the airspeed. However, the available thrust is inversely proportional to V , decreasing as the airspeed increases, whereas the thrust of a turbojet

FIGURE 198.2 Variation of piston-prop HP with altitude, both aspirated and turbocharged.

is constant and the thrust power (TV) increases with V . Because of these differences, propeller and jet aircraft fly differently for best performance. The fuel consumption rate (lb/h) of a piston-prop is proportional to the HP being delivered, so that

$$dW_f / dt = c^*(HP) = c^* TV / (k\eta_p) \quad (198.10)$$

where c^* , the *horsepower specific fuel consumption* (hpsfc) with units of lb/h/hp, has the same variations as the tsfc and will also be assumed to be constant. Current piston-prop engines are relatively small (less than 1000 hp) because they are the heaviest of all the engines with $(HP)_m / W_e \cong 0.5$ hp/lb of engine weight. The specific fuel consumption is an extremely important performance parameter. Some typical values, all expressed as an equivalent tsfc (lb/h/lb), are listed below.

| | |
|------------------------------|---------|
| Rocket engines | 10 |
| Ramjets | 3 |
| Turbojets (with afterburner) | 2.5 |
| Turbojets | 0.9–1.0 |
| High-bypass turbofans | 0.6–0.8 |
| Turboprops | 0.5–0.6 |
| Piston-props | 0.4–0.5 |

The order of this list also indicates the relative airspeed regime of the flight vehicles in which these engines are used. Piston-props are used in aircraft with airspeeds on the order of 220 kt or less; turboprops have higher speeds up to Mach 0.7 or so; turbofan engines for airspeeds up to M 0.85; and so on up the speed ladder with turbojets (and very low-bypass turbofans) in supersonic aircraft, ramjets for M 3.0 and higher, and rocket engines in missiles and space boosters. Furthermore, the piston-prop engine is the least expensive and the heaviest of the engines, and the cost increases and weight decreases as the list is ascended.

Weight Fractions

Weight may well be the most important consideration in the design and performance of an aircraft. Every extra pound of weight is accompanied by an increase in the wing area and in the thrust and fuel required, all leading to a further increase in aircraft weight and thus adversely affecting performance and costs (both initial and operating) of the aircraft. Weight fractions are useful in performance and design analyses and are obtained by expressing the gross (total) weight of the aircraft W_o as the sum of the weights of the major components and then dividing each weight by the gross weight. Using a simple weight breakdown made up of the *structural weight* W_s , the *engine weight* W_e , the *fuel weight* W_f , and the *payload weight* W_{PL} , the *gross weight* W_o of the aircraft is the sum of these component weights. The weight fractions are obtained by dividing through by W_o to obtain

$$1 = W_s / W_o + W_e / W_o + W_f / W_o + W_{PL} / W_o \quad (198.11)$$

With this breakdown, W_s includes not only the weight of the structure, but also the weight of everything not included in the other categories. It includes the weight of all the equipment and landing gear, for example, and even the weight of the flight and cabin crews when appropriate. Aircraft manufacturers often lump W_s and W_e together into the *operational empty weight* and combine W_f and W_{PL} into the *useful load*. In Equation (198.11), the sum of the individual fractions must always be unity. For a turbojet, $W_e / W_o = (T_m / W_o) / (T_m / W_e)$, and, for a piston-prop, $W_e / W_o = (HP_m / W_o) / (HP_m / W_e)$. Values of T_m / W_o are on the order of 0.25 to 0.35 for large high-subsonic transports and on the order of 0.1 hp/lb of aircraft weight for the HP / W_o of the typical piston-prop.

Although the determination of W_s is quite complex, order of magnitude values for W_s / W_o can be used to give a feel for its size and significance. As W_o increases, W_s / W_o decreases because, for example, minimum volume requirements for cabin and cargo space and fixed equipment weights have a higher impact on

the structural weight fractions of the smaller aircraft. For large subsonic transports, W_s/W_o values are on the order of 0.45, but smaller aircraft, such as fighters and general aviation aircraft, can have values in excess of 0.55. Note that in this article the structural weight does not include engine weight.

The payload ratio (the payload weight fraction) is of major interest inasmuch as it relates the payload weight to the gross weight of the aircraft. For example, $W_{pl}/W_o = 0.1$ means that 10 pounds of aircraft weight is required for each pound of payload (or excess weight). As W_{pl}/W_o is equal to unity minus the sum of the other weight fractions, any increase in any of these three either decreases the payload weight fraction, thus increasing W_o or decreasing the payload, or decreases W_f/W_o , thus decreasing the range. For example, the increase of T_m/W_o to convert a CTOL aircraft to a V/STOL aircraft can either dramatically reduce the range and payload or increase the gross weight.

198.2 Level Flight

For any aircraft in unaccelerated level flight,

$$L = W; \quad T = D; \quad dX/dt = V \quad (198.12)$$

The weight, however, does not remain constant during flight. As fuel is used, the weight decreases at a rate that is the negative of the fuel consumption rate (Equation (198.7)), so that for a *turbojet* $dW/dt = -cT$. The *instantaneous range* (mileage), the nautical miles per pound of fuel, is equal to dX/dt divided by dW/dt and, with the relationship from Equation (198.13) that the required thrust $T = W/(L/D)$, can be expressed as

$$dX/dW_f = V/cT = V(L/D)/cW \quad (198.13)$$

The last expression of Equation (198.13) shows that the best mileage (maximum range per pound of fuel) of an aircraft is obtained when the product of V and (L/D) , which are coupled, is maximized, and c and W are individually minimized. Because W decreases along the flight path, the mileage improves with time and distance.

Although the mileage at a particular point or instant of time is of interest, the range for a given amount of fuel and set of flight conditions and the amount of fuel required to fly a specified range (from point 1 to point 2) are of greater interest. With c assumed constant, integrating the mileage over the cruise flight path while holding V and C_L (and thus L/D) constant, yields the *Breguet range equation* in the form:

$$X = [V(L/D)/c] \ln MR = [V(L/D)/c] \ln[1/(1-\zeta)] \quad (198.14)$$

where the mass ratio $MR = W_1/W_2$ and the *cruise-fuel weight fraction* $\zeta = \Delta W_f/W_1 = (MR-1)/MR$. In order to keep both V and L/D (i.e., C_L) constant along the flight path as fuel is used, the altitude must increase so as to keep W/σ constant (see Equation (198.15)). The required flight path angle, however, is sufficiently small ($<1^\circ$) so that the level flight approximation is still valid. Such flight is known as *cruise-climb*. It gives the maximum range for a given fuel load and, for long flights in a controlled area, can be approximated by a series of constant altitude legs with appropriate altitude increases (*stepped altitude flight*). Note that the larger the product of V and L/D is, the longer the range.

The airspeed V and the lift coefficient C_L (and thus L/D) are related by expressions from Equation (198.12) and Equation (198.3) — namely,

$$V = \sqrt{\frac{2(W/S)}{\rho_o \sigma C_L}}; \quad C_L = \frac{2(W/S)}{\rho_o \sigma V^2} = \frac{(W/S)}{q} \quad (198.15)$$

Equation (198.15) shows that for a give C_L , a high airspeed V calls for a high *wing loading* (W/S) and a small σ (a high altitude) for good range performance. Consequently, turbojet aircraft *must* fly high and fast to achieve their best range performance; reduced flight times and flight above weather are accompanying bonuses. The *best-range* airspeed (and maximum range) of a particular turbojet is 60% greater at 30,000 ft than at sea level, and 80% greater at 35,000 ft. For long-range subsonic transports, design W/S values are on the order of 120 to 135 lb/ft². Shorter-range and fighter aircraft have lower values to meet requirements for shorter runway lengths or for greater maneuverability.

For a *piston-prop*, the relationships of Equation (198.13) still apply, but now the *thrust power* TV is of primary interest and equilibrium requires that the thrust power be equal to the drag power ($TV = DV$). The required thrust power $P \equiv TV = WV/(L/D)$. With $dW/dt = -dW_f/dt = -c^*TV/(k\eta_p)$, the mileage (nmi/lb) of a piston-prop is

$$dX/dW_f = k\eta_p V / (cTV) = k\eta_p (L/D) / (c^*W) \quad (198.16)$$

Note that the mileage of a piston-prop is explicitly independent of the airspeed, which must, however, be that required to achieve the desired L/D . Good mileage still calls for a high L/D and low values of c^* and W as for the turbojet. Holding C_L (and thus L/D) constant yields the piston-prop version of the *Breguet range equation*:

$$X = [326\eta_p (L/D) / c^*] \ln MR = [326\eta_p (L/D) / c^*] [\ln 1 / (1 - \zeta)] \quad (198.17)$$

with V in kt. Although the range is explicitly independent of V , V must have the value appropriate to the cruise (L/D). Increasing V by increasing the altitude or W/S will not increase the range but will decrease the flight time (and increase the power required). Although the maximum range occurs when (L/D) is at its maximum value, the associated airspeed, especially with an aspirated engine, is usually much lower than the maximum airspeed of the aircraft and the required power for cruise is below the best operating point for the engine. Consequently, the cruise of a piston-prop is customarily at 75% of the maximum power available to reduce flight time and favor the engine. With respect to other power plants, whereas a turbojet is a single-flow engine that produces only jet thrust, a *turbofan* is a multiblow engine that uses a turbine to drive a multibladed ducted fan that produces thrust power in addition to jet thrust. It has characteristics of both turbojet and propeller aircraft, and its performance (and specific fuel consumption) lies in the region between the two but closer to the turbojet. The turbojet range equation is normally used.

A *turboprop*, on the other hand, is primarily a power producer, with little or no jet thrust, that uses the piston-prop equations and is replacing the piston-prop because it is lighter and capable of higher speeds. It has a lower C_{D0} but a higher sfc, than the piston-prop. (*Derating* a turboprop results in an altitude variation of the power which resembles that of a turbocharged piston-prop.) The maximum airspeed of a turboprop with a conventional propeller is limited by the drop in η_p at the higher airspeeds. The *propfan* uses a double row of multibladed, variable camber propellers to increase the operating airspeed. The *unducted fan* (UDF) with an ultrahigh bypass ratio is still driven directly from the turbine, but resembles the propfan in appearance and approaches its performance. The *absolute ceiling* of an aircraft occurs when the maximum available thrust of a turbojet is equal to the required thrust, $T_m = W/(L/D)_m$, or when the maximum available power of a piston-prop is equal to the required power, $(HP)_m = WV/[k\eta_p(L/D)_m]$. At the ceiling, the rate of climb is zero and the aircraft cannot turn without losing altitude.

198.3 Climbing Flight

The steady-state climbing flight equations are

$$T - D - W \sin \gamma = 0; \quad L - W \cos \gamma = 0; \quad R/C = dh/dt = V \sin \gamma \quad (198.18)$$

where γ , the *climb (flight path) angle*, is the angle between the horizon and the airspeed vector. The two climb equations of interest are

$$\sin \gamma = (T - D) / W = (T / W) - [\cos \gamma / (L / D)]; \quad R / C = V \sin \gamma = (TV - DV) / W \quad (198.19)$$

The first expression in Equation (198.19) shows that γ is determined by the *excess thrust* (the thrust not needed to overcome the drag) per unit weight, whereas the *R/C* is determined by the amount of *excess power* per unit weight. The two climb programs of special interest are *steepest climb*, γ_m , and *fastest climb*, $(R/C)_m$. Both have their largest values at sea level, where the excess thrust and excess power are at a maximum, and both decrease with altitude until γ and *R/C* both go to zero at the absolute ceiling. Using the expressions of Equation (198.19), the climb performance can be obtained either graphically (as sketched in Figure 198.3 for a turbojet) for various altitudes, weights, power settings, and velocities, or by analytic methods.

(a)

(b)

FIGURE 198.3 Climb relationships for a typical turbojet: (a) climb angle γ ; (b) rate of climb *R/C*.

Climb angles for conventional aircraft are not large, as can be seen by dropping the drag term in Equation (198.20) to obtain the inequality that $\sin \gamma_m < (T_m/W)$, which shows that the maximum climb angle for a high-performance turbojet transport, with $T_m/W = 0.33$, will be less than 19° . Obviously, γ for $(R/C)_m$ will be less. As expected, the higher the available thrust for a turbojet and the higher the available power for a piston-prop, the better the climb performance is. In general, the turbojet outclimbs the piston-prop and the climb airspeeds are higher.

198.4 Turning Flight

One aspect of maneuverability is the ability to turn. The equations governing steady-state turns in the horizontal plane are

$$T = D; \quad L = W / \cos \phi; \quad \dot{\chi} = \frac{g \tan \phi}{V} \quad (198.20)$$

where ϕ is the *bank angle* (deg), $\dot{\chi}$ is the *turning rate* (rad/sec), V is the airspeed (ft/sec), and g is the acceleration of gravity (32.2 ft/sec^2). The *load factor* is defined as $n = L/W$ (g's). From Equation (198.20) and Equation (198.3),

$$n = \frac{L}{W} = \frac{1}{\cos \phi} = \left(\frac{T}{W} \right) (L/D); \quad V = \sqrt{\frac{2n(W/S)}{\rho_o \sigma C_L}} = \sqrt{\frac{2(W/S)}{\rho_o \sigma C_L \cos \phi}} \quad (198.21)$$

When $n > 1$ g, as in a turn, the airspeed is less than that for wings at level flight with the same power setting, and the stall speed also decreases. It can be shown that the best turning performance (tightest turn and fastest turn) for both types of aircraft occurs at low speeds (on the edge of a stall) and at low altitude while using maximum thrust or power.

Defining Terms

Air breathers — Engines that obtain oxygen from the atmosphere.

Aspect ratio — Wingspan divided by the average chord length.

CTOL — Conventional (horizontal) takeoff and landing aircraft.

Drag polar — Drag coefficient–lift coefficient relationship.

Lift-to-drag ratio (L/D) — Aerodynamic efficiency of an aircraft.

Mach number — Air speed divided by local sonic velocity.

Mass ratio (MR) — Aircraft weight at start of cruise divided by aircraft weight at end of cruise.

Payload ratio — Payload weight divided by gross weight of an aircraft.

V/STOL — Aircraft capable of both vertical and short takeoffs and landings.

Weight fraction — Component weight divided by aircraft weight.

Wing loading (W/S) — Aircraft weight divided by wing area (lb/ft^2).

199.5 Spacecraft/Mission Design Process

Wallace T. Fowler

University of Texas, Austin

The design of a spacecraft and the design of its mission are closely related parts of the same iterative process. The mission concept usually comes first, but new missions for existing spacecraft designs have also been developed. The key to any successful design is the development of a good set of requirements. In any case, the mission concept is often changed by design factors, and the spacecraft design is driven by mission requirements. Effort spent in defining and refining requirements is crucial to good design.

The design process starts with either a mission concept or spacecraft and arrives at a complete design. However, every design process is unique, and no design is optimal. Factors will always arise that do not seem to fit. When this happens, the mission requirements or the design process should be modified to accommodate or eliminate the unique factors.

The match between spacecraft and mission is determined by a number of factors. The two most important preliminary design factors are the mass of the mission payload and the amount of velocity change, ΔV , that must be provided to the payload to carry out the mission. These two factors dictate much of the mission and spacecraft design, as they are the primary drivers for the mass of the booster assembly. Other primary design factors are mission duration and destination to which the payload is being sent. A 2-day mission on which the spacecraft stays near the Earth will require a very different hardware/mission plan combination than will a multiyear mission to an outer planet. If a spacecraft is manned, its design and mission planning are greatly complicated. Safety factors that are acceptable for unmanned flight are unacceptable for manned flight. Life support and safety equipment, as well as backups for such systems, dominate the design. One factor that should not be ignored during the design

of a spacecraft/mission combination is operations. A detailed operations plan is as important to a successful space mission as is good hardware and a good mission plan. Inclusion of operations planning in the initial spacecraft and mission design process, including planning for contingencies, has the potential for lowering mission costs, increasing the chances of mission success, and lowering the potential for problems caused by unforeseen operator/hardware interactions.

199.1 Spacecraft Environments

Every spacecraft must be able to survive in several environments. All those built on earth must be able to survive the earth's atmosphere or be protected from it. The Earth's standard atmosphere is described in [Chapter 198](#), and atmosphere models for other planets are available in NASA literature. The launch environment, characterized by vibration, noise, g -loads, aerodynamic loads, transition from air to vacuum, and so on, constitutes a major test for spacecraft. The space environment presents another set of problems for the designer. Hard vacuum, radiation, and temperature extremes are common to all missions. Spacecraft that fly through or beyond the Van Allen radiation belts experience more severe radiation hazards than those spacecraft that stay inside the Van Allen belts. For manned spacecraft, extended flight beyond the protection of the Van Allen belts implies special crew radiation shielding. Orbital debris is also a hazard that must be considered.

Vehicles that reenter the Earth's atmosphere or enter the atmosphere of another planet must contend with entry aerodynamics and accompanying loads and heating. For landers, abrasive dust can be a problem. Finally, if a spacecraft has a crew, its internal environment must support life while its structure protects the habitable volume. Good discussions of the role of environment in spacecraft design can be found in Fortescue and Stark [2003] and Griffin and French [1991].

199.2 Fundamental Principles

The primary factor linking the spacecraft and the mission scenario is linear momentum change, and this is the key driver in overall sizing of the spacecraft and its booster system. Except for missions dominated by attitude-control requirements, the mission scenario that requires the lowest total linear momentum change will be the most efficient in terms of propellant. Thus, in designing mission and spacecraft, it is important to (1) explore many mission scenarios to ensure that the total momentum change required is as low as possible; (2) use staging to discard unneeded mass and reduce the propellant required during each mission phase; (3) employ engine/propellant combinations that produce large momentum changes with relatively small amounts of propellant (i.e., propellants with high exhaust velocities relative to the vehicle); (4) keep all spacecraft component masses as small as possible; and (5) use unmanned spacecraft whenever possible to keep vehicle masses small. It is also important to use space-qualified hardware when available (and appropriate) to reduce cost and risk.

The ability of a propulsion system to impart momentum changes to a spacecraft is the velocity of the exhaust with respect to the spacecraft. The key equation is

$$c = I_{sp}g \tag{199.1}$$

where c is exhaust velocity relative to the vehicle, I_{sp} is specific impulse, and g is the acceleration of gravity at the surface of the Earth. c is in m/sec (ft/sec), g is in m/sec² (ft/sec²), and I_{sp} is in units of seconds.

Note: The value used for g in Equation (199.1) does not change when the spacecraft is in a non-Earth gravity field.

Propellant combinations (fuel and oxidizer) are often listed in propulsion references with a corresponding I_{sp} value. These values imply an appropriate engine in which to combine the propellants efficiently. In spacecraft design studies, trade-offs between propellant storability and I_{sp} are common. I_{sp}

values for most large solid rockets are just under 300 seconds. The I_{sp} value for the space shuttle main engines (liquid oxygen–liquid hydrogen) is more than 400 seconds.

A second basic equation, which relates the mass of the spacecraft assembly at the i th stage in the mission (the total mass to be propelled at that point in the mission) to propellant mass that produces the velocity change, is

$$\Delta V_i = c_i \ln(m_{oi} / m_{fi}) \quad (199.2)$$

where ΔV_i is the velocity increment provided to the spacecraft assembly by the propellant in the i th stage, c_i is the exhaust velocity of the propulsion system in the i th stage relative to the spacecraft assembly, m_{oi} is the mass of the spacecraft assembly prior to burning the propellant in the i th stage, and m_{fi} is the mass of the spacecraft assembly after the i th stage propellant is expended. The mass of the propellant burned in the i th stage is the difference between m_{oi} and m_{fi} .

Sequential staging is a very important concept. Mass that is no longer needed should be discarded as soon as is practical in order to avoid using propellant to change the momentum of useless mass. The following equation shows the total ΔV for a two-stage vehicle.

$$\Delta V = c_1 \ln(m_{o1} / m_{f1}) + c_2 \ln(m_{o2} / m_{f2}) \quad (199.3)$$

When staging occurs, excess hardware (tanks, engines, pumps, structure) is dropped after a stage burns out and before the next stage begins its burn. Thus, m_{f1} will be larger than m_{o2} . This difference is one of the most important factors in space vehicle design and performance. A good discussion of staging can be found in Wertz and Larson [1998].

Equation (199.2) does not apply directly when the two different types of engines with different I_{sp} values are being used simultaneously. The space shuttle first stage (with solid rocket boosters and main engines burning simultaneously) and the Delta booster (with strap-on solid rockets around a liquid rocket core vehicle) are examples of this. A simple modification of Equation (199.2) applies, however. This equation looks like Equation (199.2) but has a significant difference in the definition of the exhaust velocity. For such vehicle mission stages,

$$\Delta V = c^* \ln(m_o / m_f) \quad (199.4)$$

where c^* is a weighted combination of the exhaust velocities of the two types of engines being used. Specifically,

$$c^* = f_1^* c_1 + f_2^* c_2 \quad (199.5)$$

where c_1 and c_2 are the exhaust velocities for the two engine types being used, and f_1^* and f_2^* are the respective mass flow rate fractions for the two engine types (note that $f_1^* + f_2^* = 1$). Equations (199.4) and (199.5) allow characteristic ΔV values to be calculated for vehicle stages involving parallel burning of dissimilar engine types.

199.3 Spacecraft/Mission Categories

Launch Vehicles

Launch vehicles and launches are a common element/system for almost all spacecraft. The choice of launch vehicle is determined by the mission, the mass to be boosted to orbit, the required ΔV , the compatibility between launcher and payload, and the overall cost of the launch (launcher plus launch services). The *International Reference Guide to Space Launch Systems* [Isakowitz, 1999] is an excellent source of informa-

tion on launchers. A good rule of thumb to keep in mind is that for eastward launches into low Earth orbit (LEO) from a latitude of about 30°, between 9300 m/sec (30,500 ft/sec) and 9,450 m/sec (31,000 ft/sec) total ΔV must be supplied by the booster. (This accounts for gravity and drag losses as well as increasing the potential and kinetic energy of the spacecraft.) The time from launch to orbit insertion will depend on the booster acceleration capabilities and constraints, but will generally be less than 8 min.

Sounding Rockets

Sounding rockets are usually small, and their missions are characterized by short mission duration and short times out of the atmosphere of the Earth (or another planet). Their objectives are usually scientific, their equipment is powered by batteries, and they usually possess a recovery system for the instrumentation package (or perhaps the entire vehicle). Sounding rocket payloads usually consist of structure, instrumentation, a control system, a power system, communications, and a recovery system. The mass and ΔV requirement for a sounding rocket depend primarily on the mass to be boosted, the propellant combination to be used, and the altitude to which the payload is to be sent.

Earth-Orbiting Spacecraft

There are many varieties of Earth-orbiting spacecraft. Examples include the original Sputnik and Explorer spacecraft, the space shuttle, and communications satellites such as Intelsat. There are resource mappers, weather satellites, military satellites, and scientific satellites. There are many active satellites in orbit around the Earth today. Useful satellite lifetimes range from a few hours to years. It is likely that the Lageos satellite, a passive laser reflector, will be providing useful data for at least 100 years. Typical Earth-orbiting spacecraft systems are the structure, power system, thermal management system, communications, sensors, computation/data storage, propulsion, and possibly a deorbit/entry system. Launch dates, orbits, and missions of a wide variety of Earth-orbiting spacecraft have been summarized in compact form in the *TRW Space Log* [Thompson, 1987]. Especially useful are the summary documents in this series.

Lunar Spacecraft

A special category of Earth-orbiting spacecraft meriting separate mention is lunar spacecraft. Such spacecraft must climb out of the Earth's gravity well, requiring a ΔV of more than 3100 m/sec (10,200 ft/sec) to reach the moon starting in LEO. Spacecraft that orbit the moon require about 1070 m/sec (3500 ft/sec) to enter an orbit about the moon and 2070 m/sec (6800 ft/sec) to land. Special thermal considerations are necessary for vehicles designed to rest on the lunar surface because of the slow rotation rate of the moon (the lunar day and night are 14 Earth days each). Lunar spacecraft have the systems typical of Earth-orbiting spacecraft, with the possible exception of the deorbit/entry system.

Interplanetary Spacecraft

Interplanetary spacecraft have much in common with lunar vehicles, but they also have many unique characteristics. Spacecraft targeted to the outer planets have longer mission times and different power supplies than those that remain in the inner solar system. The inner planets (Venus and Mercury) present particular problems for the designer of landers. The atmosphere of Venus is hot, dense, and corrosive. The surface of Mercury, except near the poles, sees wide swings in temperature. A point on the equator of Mercury sees 88 Earth days of sunlight followed by 88 Earth days of darkness. Obviously, structure, materials, and thermal systems are important for such spacecraft. Injection onto a minimum-energy transfer to Mars requires 3600 m/sec (11,800 ft/sec). Orbiting Mars will require another 2100 m/sec (7000 ft/sec).

Entry Vehicles

Entry vehicles are spacecraft (or spacecraft segments) designed to use aerodynamic lift and drag to slow or turn the spacecraft, leading to an orbital plane change, lowering of an orbit, or a descent into the

planetary atmosphere. Aerothermodynamic considerations (both stagnation point temperature and integrated heat load) and deceleration loading dominate the design of such vehicles. Aerodynamic control surfaces are the primary means of trajectory shaping, which in turn controls the heating and deceleration. Survivability is a primary design consideration. An entry vehicle is a special type of hypervelocity vehicle, usually a glider (see [Chapter 198](#) for additional information).

Landers

Landers are a special class of spacecraft. Some landers are also entry vehicles and some are not, depending on whether the body on which the landing is to take place has an atmosphere. Landings on targets with atmospheres can involve parachutes, cushions, shock absorbers, and so on. Landings on airless bodies usually involve either rocket braking or braking via penetration of the surface of the target body.

Returning Spacecraft

Spacecraft that return to the planet of origin are a very special case. Vehicles that fly to Earth orbit and then deorbit and land on Earth, although complex, are much simpler than vehicles that fly from the Earth to a target, land operate, launch, return to Earth, enter the atmosphere, and are recovered. For such vehicles, mass is by far the most important driver for all design decisions, and repeated staging is the primary feature of the overall design. Often the redesign of the staging process can greatly simplify an otherwise complex vehicle and mission (the lunar orbit rendezvous used in the Apollo program is an excellent example).

199.4 Spacecraft Subsystems

Once the overall mission and spacecraft requirements have been defined, the process of defining requirements for various spacecraft subsystems can begin. The integration of the various subsystems into a harmoniously functioning spacecraft can be very difficult. One way to reduce the difficulties in spacecraft integration is to spend sufficient time and effort *early* in carefully and completely defining the interfaces between the subsystems of the spacecraft. Time spent in defining interfaces will repay itself many times as the design progresses. The following is a brief discussion of the major design considerations of the principal spacecraft subsystems. Chetty [1991], Fortescue and Stark [2003], and Griffin and French [1991] provide excellent discussions of various spacecraft subsystems.

Structure Subsystem

The structure of the spacecraft holds the components together, provides load paths for launch forces, maneuver loads, and so on, and is usually an integral part of the thermal control system and/or the electrical system for the spacecraft. Design constraints that the structural subsystem must usually meet include stiffness requirements, placing principal inertia axes in preferred directions, sustaining mission loads, and serving as a ground for all spacecraft electrical equipment. Spacecraft structures can be metallic, composite, or ceramic. Structural mass is generally 5 to 20% of the overall spacecraft launch mass.

Power Subsystem

The type of power system chosen for a spacecraft is strongly dependent on the mission of the spacecraft and the power demands of the equipment to be carried. Short-duration missions often use batteries. Longer-duration missions that go no farther from the sun than Mars can use photoelectric power (solar cells). Long-duration, low-power missions on which the spacecraft go very far from the sun (e.g., Voyager) use radioisotope thermoelectric generators (RTGs). Other potential power sources are solar thermionic systems, chemical dynamic systems, and nuclear power systems. Limitations on power often place constraints on spacecraft designs and mission operations.

Attitude Control Subsystem

Most spacecraft require attitude stabilization to point antennas, properly orient solar arrays, point sensors, and orient thrusters. Attitude control consists of sensing the current attitude of the spacecraft and applying torques to reorient the spacecraft to a desired attitude.

Three-Axis Stabilization

The most complex and precise spacecraft attitude control is three-axis stabilization accomplished using momentum wheels or reaction wheels. Attitude thrusters are also used for three-axis stabilization, either as the primary attitude control mechanism or to desaturate the momentum wheels. Three-axis stabilization systems can be fast and accurate. For example, the attitude control system on the Hubble Space Telescope, which uses reaction wheels, can point the optical axis of the telescope to within 0.007 arc seconds of the desired direction.

Spin Stabilization

Spin stabilization is much simpler and less precise than three-axis stabilization. Spin-stabilized spacecraft must be rigid and spinning about the principal axis with the largest mass moment of inertia. The first U.S. orbiting satellite, Explorer 1 (launched 31 January 1958), provided an early demonstration of the need for spinning spacecraft to be rigid. Explorer 1 was a long, slender cylinder spinning about its long axis. It possessed flexible whip antennas that dissipated energy and caused the spacecraft to tumble within a day of orbit insertion.

Dual-Spin Spacecraft

Some spacecraft have a spinning section and a despun section. Such spacecraft must have systems to maintain the attitude of the despun section and to control the direction of the spin vector. Reactions between the spinning and despun sections are major design and operational considerations.

Gravity Gradient Stabilization

Spacecraft can use the gradient of the gravitational field of a planet to provide restoring torques and maintain the spacecraft in an orientation with the spacecraft's long axis pointing along the local vertical. Spacecraft designed to employ gravity gradient stabilization usually feature mass concentrations at the ends of a long boom that lies along the local vertical. Gravity gradient stabilization works best with near-circular orbits and would not work on even moderately elliptic orbits. A pointing accuracy of about 1° with some wobble is achievable with gravity gradient stabilization of Earth satellites.

Magnetic Stabilization

Spacecraft attitudes can be stabilized or changed using torques developed by running currents through coils (torque rods) mounted in the spacecraft if the spacecraft is orbiting a body with a significant magnetic field. The primary difficulty with this type of attitude stabilization system is keeping track of the relative orientations of the spacecraft axes and the magnetic field lines as the spacecraft moves along in its orbit. Magnetic stabilization is slow and coarse.

Solar Radiation Stabilization

The pressure of solar radiation falling on a spacecraft can be used to create torques. Spacecraft that employ solar radiation stabilization are large and lightweight.

Telecommunications Subsystem

The primary function of the telecommunications subsystem is to receive, process, and transmit electronic information. Some satellites (communications, intelligence, and weather satellites) are designed to meet one or more telecommunications mission objectives. The telecommunications subsystem often demands a significant amount of electrical power, and this demand often drives the design of the power system. The spacecraft computer/sequencer can be considered part of the telecommunications system or a separate system. Chetty [1991], Fortescue and Stark [2003], and Griffin and French [1991] provide excellent discussions of spacecraft telecommunications.

The telecommunications system often drives the attitude and pointing requirements for the spacecraft. Furthermore, the capabilities of the spacecraft telecommunications antenna(s), coupled with limited power available for signal transmission, often require the use of large and expensive receiving antennas on Earth. This can greatly increase operational costs. Finally, deployable spacecraft antennas carry additional risks. The very successful Galileo mission was severely impacted by the failure of the onboard high-gain antenna to deploy properly.

Propulsion Subsystem

The spacecraft propulsion subsystem will be considered separately from the launch vehicle and upper stages. The propulsion subsystem is responsible for orbit maintenance, small orbit changes, attitude control system desaturation, and so on. Spacecraft onboard propulsion systems use chemically reacting fuels and oxidizers, monopropellants and catalysts, cold gas, and ion thrusters. Chetty [1991], Fortescue and Stark [1992], and Griffin and French [1991] provide excellent discussions of propulsion systems.

Thermal Control Subsystem

Spacecraft thermal control is of utmost importance. Maintaining appropriate thermal environments for the various spacecraft is essential to proper component function and longevity. The primary problem with thermal management of spacecraft is that all excess heat must ultimately be radiated by the spacecraft. For many unmanned spacecraft, passive thermal control involving coatings, insulators, and radiators is ideal. For other spacecraft, active thermal control is necessary. Active systems can employ heaters, radiators, heat pipes, thermal louvers, and flash evaporators. Significant spacecraft mass reductions can sometimes be made if the excess heat from one component is conducted to another component that would otherwise require active heating.

Spacecraft Mechanisms

Some spacecraft are mechanically passive and have no mechanisms in their designs. However, even these spacecraft require mechanisms to deploy them from their boosters. Mechanically active spacecraft can feature a wide variety of mechanisms. There are deployment systems for booms and antennas, docking mechanisms, robot arms, spin/despin systems, sensor pan and tilt mechanisms, gyroscopes, reaction wheels (also considered as part of the attitude control system), landing legs, and airlocks. The types of mechanisms depend on the mission of the spacecraft.

Launch Vehicles

The launch vehicle, or booster, is an integral part of most spacecraft systems. The *International Reference Guide to Space Launch Systems* [Isakowitz, 1999] covers the capabilities of most currently available launch vehicles in detail. The rotation of the Earth has a major effect on launch vehicle performance. The eastward motion of the launch site must be considered when computing the payload that a launch vehicle can place in orbit. The launch azimuth and the latitude-dependent eastward velocity of the launch site can be combined to determine how much velocity assist is provided by Earth's rotation. For westward

launches (to retrograde orbits), the rotation of the Earth extracts a penalty, requiring additional velocity to be provided by the booster to make up for the eastward velocity of the launch site.

Upper Stages

Launch vehicles are often combined with upper stages to form a more capable launch vehicle. Commonly used upper stages include the IUS, the Centaur, and several types of PAM (payload assist modules). Upper stages are also carried aloft in the payload bay of the space shuttle to boost spacecraft to higher orbits. Designers should always consider the option of using an available upper stage if the mission requires more ΔV than can be provided by the basic launch vehicle.

Entry/Landing Subsystems

Entry subsystems can be considered either as a separate set of devices or as parts of other subsystems. The heat shield can be reusable or ablative, and could be considered to be part of the thermal control subsystem. The retrorockets, if any, might be considered to be part of the propulsion system. Parachutes, landing legs, cushions, wings, aerosurfaces, a streamlined shape, and landing gear, when needed, belong solely to the category of entry and landing subsystems.

Subsystem Integration and Redundancy

The interplay among spacecraft subsystems is great, and their integration into an efficient, smoothly operating, and reliable spacecraft is an immense challenge. Redundant system elements can provide added reliability if the risk of failure must be lowered. However, redundancy increases initial costs and usually increases overall mass. It is often good to avoid physically redundant elements, choosing physically different but functionally redundant elements instead. System elements that are to be functionally duplicated should be identified as early in the design process as possible.

199.5 Spacecraft/Mission Design Process

The spacecraft/mission design process can be outlined as follows:

1. Beginning with a set of mission goals, develop a set of mission and spacecraft requirements that must be met in order to achieve the goals. An excellent discussion of requirements and how to develop them is found in Wertz and Larson [1998]. Mission goals may change during the design process, and when this happens, the requirements must be reevaluated.
2. Before beginning a methodical approach to the design, it is almost always helpful to bring the design team together and conduct a brainstorming session. For those who are unfamiliar with brainstorming, Adams [1986] is recommended. The brainstorming session should be expected to identify several unorthodox candidate scenarios or components for the mission and spacecraft.
3. Develop a conceptual model for the spacecraft and the mission, identifying major systems and subsystems, and most important, the interfaces between systems, both within the spacecraft itself and between the spacecraft and its support elements on the ground and in space. A preliminary mission scenario and rough timeline should also be developed at this time. These conceptual elements should be developed from the mission and spacecraft requirements. This step will allow the definition of major systems and subsystems and will identify major interactions between mission events and spacecraft hardware elements. Preliminary indications of pointing requirements, required sensor fields of view, ΔV requirements, allowable spacecraft mass, and required and desired component lifetimes should come from these considerations. Brown [1998], Fortescue and Stark [2003], Griffin and French [1991], and Isakowitz [1999] give information appropriate to this topic.

4. The role of heritage in spacecraft design is important. Systems and technologies that have worked well on past spacecraft are often good candidates for new spacecraft with similar missions. Examine the recent past for similar missions, spacecraft with similar requirements, and so on. Although sufficiently detailed systems overviews of recent spacecraft are often difficult to obtain, the effort necessary to obtain them is almost always worth the effort. However, the design team should be careful to avoid early adoption of a candidate system from earlier spacecraft in order to avoid being locked into a system that only marginally meets or does not meet design requirements.
5. Once the first four steps have been taken (some more than once), the design team should develop preliminary spacecraft design candidates (spacecraft/scenario/timeline combinations), concentrating on systems and subsystems and their performance, masses, power requirements, system interactions, thermal input/output, and costs. Several candidate designs should be considered at this stage and their predicted relative characteristics compared. These considerations allow the design team to learn more about the requirements and how best to meet them. It is likely that the design team will recycle through some or all of the design process at this point for one or more of the candidate designs. The possibility of developing a new composite design with the best features of several candidate designs should not be ignored.
6. As candidate designs are refined, the design team should develop criteria for use in choosing among candidate designs. The information on the candidate designs should be organized and presented at a preliminary design review. The feedback from those attending the review is valuable in the identification of strengths and weaknesses of candidate designs.
7. At some point, determined by budget, timeline, technical considerations, and the characteristics of the candidate designs, one design concept must be chosen for development. Once the choice is made, the design team should carry out a complete analysis of the chosen design. This analysis should include a detailed mission scenario and timeline, launch vehicle choice, ΔV requirements for every maneuver, hardware choices for every system and subsystem, system interaction analyses, manufacturability considerations, component and overall cost analyses, and failure mode effects analyses. Any remaining system/subsystem hardware choices should be made, and the design should be presented at a critical design review. The feedback from the critical design review will often result in major improvements in the design. Questions arising at the critical design review will often precipitate another pass through the design process.
8. The effects of real or imagined environmental impacts on the public of mission and/or spacecraft features and resulting political pressures cannot be overemphasized. The Galileo mission to Jupiter provides good examples. First, there were public protests at the Kennedy Space Center in Florida because Galileo carried a “nuclear” power device (an RTG). Most protestors had no idea that RTGs had been launched safely for over 2 decades and that RTGs carried by Apollo were still in operation on the Moon. Also, since Galileo flew by Venus and then used an Earth fly-by to provide a gravity assist to help get it to Jupiter, there were those who predicted that this “nuclear” device might drift off course and hit the Earth. Mission designers must learn to anticipate such protests and provide pertinent information to the public in a straightforward and clear format.

Defining Terms

Mission scenario — A sequence of events and times that, in their entirety, meet the objectives of the mission.

Specific impulse — The amount of thrust force obtained from a fuel/oxidizer/engine combination when a unit weight of fuel is burned in 1 second. The units of specific impulse are seconds because the force and weight units cancel.

Subsystem — A part of an overall system that can be isolated to some degree. Subsystems interact and cannot actually be isolated, but it is convenient to consider subsystems in sequence rather than all at once.

Mansour Rahimi

University of Southern California

Injuries and illnesses costs were estimated at \$480 billion to the U.S. economy in 1998 [National Safety Council, 2003]. Yet engineered systems are often designed without an extensive evaluation for their potential hazards. A look at multidisciplinary literature in the field of safety and health shows that a large number of tools and techniques are available for hazard identification, analysis, and control. However, little standardization exists for using these techniques across fields such as engineering, physics, chemistry, sociology, psychology, business, and law. Specifically, design engineers do not make extensive use of safety resources commonly recommended by the safety community, nor are they fully familiar with hazard identification and analysis techniques [Main and Frantz, 1994]. In fact, as the systems under study (e.g., product, machine, production cell, shop floor) become more complex in terms of hardware, software, and human, environmental, and organizational variables, the need to employ a more comprehensive hazard evaluation and control methodology becomes more critical. In addition, the recent developments in environmentally conscious design, industrial ecology, and sustainable development require a deeper understanding of hazard consequences within and across the product life-cycle span (i.e., design, development, production, operation, deployment, use, and disposal). Therefore, successful safety programs require significant effort and resources on the part of a multidisciplinary team of investigators with support from all levels of management within a safety-cultured organizational structure [Hansen, 1993].

200.1 Hazard Identification

It is imperative that engineers become aware of *hazard* prevention principles early in their education. Also, the principles and techniques outlined in this chapter work best when applied early in the design

of systems. The negative impact of hazards (e.g., accidents, illnesses) will be far greater (sometimes irreversible) in the later stages of the system development.

One way of classifying the sources of hazards is by the type of dominant (hazardous) energy used in the operation of the system. This energy is normally traced back to the root cause of an injury or illness. In this chapter, the following primary hazards are considered: physical, chemical, airborne contaminants, noise, and fire. Other hazards are extensively considered in the reference material, and ergonomic hazards are discussed elsewhere in this handbook. The objective of any hazard control program is to control losses from injuries and damages by identifying and controlling the degree of exposure to these sources of energy.

200.2 Physical Hazards

Physical hazards are usually in the form of kinematic force or lifting or impact by or against an object. More than 50% of compensable work injuries are included in this category.

Human Impact Injuries

The severity of an injury depends on the velocity of impact, magnitude of deceleration, and body size, orientation, and position. The kinetic energy formula used to describe the impact injury is

$$E_{\text{ft-lb}} = (Wv^2)/2g \quad (200.1)$$

where W is the weight of an object or part of the body (lb), v is the velocity (ft/sec), and g is gravity (ft/sec²). However, if the impacting surface is soft, the kinetic energy for the impact is

$$E_{\text{ft-lb}} = [W(2sA)]/2g \quad (200.2)$$

where s is the stopping distance (ft), and A is the deceleration (ft/sec²). For example, for both of the above cases, the human skull fracture occurs at 50 ft-lb of kinetic energy. Hard hats are expected to prevent the transfer of this energy to the human skull.

Trip, Slip, and Fall

These injuries comprise 17% of all work-related injuries. Falls are the second largest source of accidental deaths in the U.S. (after motor vehicle accidents). Jobs related to manufacturing, construction, and retail and wholesale activities are the most susceptible to these types of hazards, comprising about 27% of all worker compensation claims in the U.S. These hazards include slipping (on level ground or on a ladder), falling from a higher level to a lower one (or to the ground), falling due to the collapse of a piece of floor or equipment, and failure of a structural support or walkway. Principles of tribology are being used to study the control mechanisms for these accidents. Tribology is the science that deals with the design and analysis of friction, wear, and lubrication of interacting surfaces in relative motion. The basic measure of concern is the coefficient of friction (COF), which in its simplest form is the horizontal force divided by the vertical force at the point of relative motion. A COF greater than 0.5 appears to provide sufficient traction for normal floor surfaces. However, a number of other conditions make this hazard evaluation difficult: unexpectedness of surface friction change versus human gait progression, foreign objects and debris on a path, walkway depression, raised projections (more than 0.25 in.), change in surface slope, wet surfaces, improper carpeting, insufficient lighting, improper stair and ramp design, improper use of ladders, guardrails and handrails, and human visual deficiencies (color weakness, lack of depth perception and field of view, inattention, and distraction).

Mechanical Injuries

The U.S. Occupational Safety and Health Act specifically states that one or more methods of machine guarding shall be provided the operator and other employees to protect them from hazards such as those

created by point of operation, ingoing nip points, rotating parts, flying chips, and sparks. Other hazards in this category are cutting by sharp edges, sharp points, poor surface finishes, and splinters from wood and metal parts; shearing by one part of a machine moving across a fixed part (e.g., paper cutters or metal shearers); crushing of skin or tissue caught between two moving parts (e.g., gears, belts, cables on drums); and straining of a muscle (overexertion) in manual lifting, pushing, twisting, or repetitive motions.

Another important category is the hazard caused by pressure vessels and explosions. These hazards are generally divided into two types — boilers that are used to generate heat and steam, and unfired pressure vessels that are used to contain a process fluid, liquid, or gas without direct contact of burning fuel. The American Society of Mechanical Engineers (ASME) covers all facets of the design, manufacture, installation, and testing of most boilers and process pressure vessels in the Boiler and Pressure Vessel Code (total of 11 volumes). The primary safety considerations relate to the presence of emergency relief devices or valves to reduce the possibility of overpressurization or explosion. Explosions can be classified on the basis of the length-to-diameter ratio (L/D) of the container. If the container has an L/D of approximately one, the rise in pressure is relatively slow and the overpressurization will cause the container to rupture. In containers with a large L/D ratio, such as gas transfer pipes and long cylinders, the initial flame propagates, creating turbulence in front of it. This turbulence improves mixing and expansion of the flame area and the speed of travel along the vessel, increasing the pressure by as much as 20 times very rapidly. Other types of explosions are caused by airborne dust particles, boiling liquid and expanding vapor, vessels containing nonreactive materials, deflagration of mists, and runaway chemical reactions.

Explosions may have three types of effects on a human body. First, the blast wave effect that carries kinetic energy in a medium (usually air), which although decaying with distance, can knock a person down (overpressure of 1.0 lb/in.^2) or reach a threshold of lung collapse (overpressure of 11 lb/in.^2). The second type of effect is thermal, usually resulting from the fire. The amount of heat radiated is related to the size of the fireball and its duration of dispersion. The radiant energy is reduced according to the inverse distance-squared law. Most explosive fireballs reach temperatures about 2400°F at their centers. The third effect is the scattering of the material fragments. All three of these injury effects are multifactorial and they are very difficult to predict.

200.3 Chemical Hazards

A Union Carbide plant in Bhopal, India, accidentally leaked methyl isocyanate gas from its chemical process. It left over 2500 dead and about 20,000 injured. There are over 3 million chemical compounds, and an estimated 1000 new compounds are introduced every year.

Hazardous/Toxic Substances

The health hazards of chemicals can be classified into acute or chronic. The acute ones are corrosives, irritants, sensitizers, and toxic and highly *toxic substances*. The chronic ones are carcinogens, liver, kidney and lung toxins, bloodborne pathogens, nervous system damages, and reproductive hazards. For a reference listing of maximum exposures to these substances, refer to the technical committees of the American Conference of Governmental Industrial Hygienists (ACGIH) and American Industrial Hygiene Association (AIHA). Rules and standards related to manufacture, use, and transportation of these chemicals are promulgated and their *compliance* is enforced by governmental agencies such as the Occupational Safety and Health Administration (OSHA), the Environmental Protection Agency (EPA) and the Department of Transportation (DOT).

Routes of Entry

There are four ways by which toxic substances can enter the human body and cause external or internal injuries or diseases [Shell and Simmons, 1990].

1. Cutaneous (on or through the skin)
 - a. Corrosives damage skin by chemical reaction
 - b. Dermatitis is caused by irritants such as strong acids; sensitizers, such as gasoline, naphtha, and some polyethylene compounds
 - c. Absorbed through skin, but affecting other organs
2. Ocular (into or through the eyes)
 - a. Corneal burns due to acids or alkali
 - b. Irritation due to abrasion or chemical reaction
3. Respiratory inhalation (explained later in Section 200.4)
4. Ingestion
 - a. Toxic substances may be ingested with contaminated food
 - b. Fingers contaminated with toxic chemicals may be placed in mouth
 - c. Particles in the respiratory system are swallowed with mucus

Mechanisms of Injury

Toxic agents cause injury by one or a combination of the following mechanisms.

1. Asphyxiants
 - a. Asphyxia refers to a lack of oxygen in the bloodstream or tissues with a high level of carbon dioxide present in the blood or alveoli
 - b. Gas asphyxiants (e.g., carbon dioxide, nitrogen, methane, hydrogen) dilute the air, decreasing oxygen concentration
 - c. Chemical asphyxiants make the hemoglobin incapable of carrying oxygen (carbon monoxide) or keep the body's tissues from utilizing oxygen from the bloodstream (hydrogen cyanide)
2. Irritants that can cause inflammation (heat, swelling, and pain)
 - a. Mild irritants cause hyperemia (capillaries dilate)
 - b. Strong irritants produce blisters
 - c. Respiratory irritants can produce pulmonary edema
 - d. Secondary irritants can be absorbed and act as systemic poisons
3. Systemic poisons
 - a. Poisons may injure the visceral organs, such as the kidney (nephrotoxic agents) or liver (hepatotoxic agents)
 - b. Poisons may injure the bone marrow and spleen, interrupting the production of blood (benzene, naphthalene, lead)
 - c. Poisons may affect the nervous system, causing inflammation of the nerves, neuritis, pain, paralysis, and blindness (methyl alcohol, mercury)
 - d. Poisons may enter the bloodstream and affect organs, bones, and blood throughout the body (usually with prolonged exposure)
4. Anesthetics
 - a. May cause loss of sensation
 - b. May interfere with involuntary muscle actions causing respiratory failure (halogenated hydrocarbons)
5. Neurotoxins
 - a. Neurotics affect the central nervous system
 - b. Depressants cause drowsiness and lethargy (alcohol)
 - c. Stimulants cause hyperactivity
 - d. Hypnotics are sleep-inducing agents (barbiturates, chloral hydrate)
6. Carcinogens
 - a. Cancers of the skin at points of contact (tar, bitumen)
 - b. Cancers of internal organs and systems have numerous known and suspected causes (labeled as suspected carcinogens)

7. Teratogenic effects. A substance that may cause physical defects in the developing embryo or fetus when a pregnant female is exposed to the substance for a period of time.

200.4 Airborne Contaminants

The greatest hazard exists when contaminants are smaller than $0.5\ \mu\text{m}$, and thus can be directly introduced into the bloodstream through alveolar sacs (e.g., zinc oxide, silver iodide). Particles larger than $0.5\ \mu\text{m}$ are entrapped by the upper respiratory tract of trachea and bronchial tubes (e.g., insecticide dust, cement and foundry dust, sulfuric acid mist). There are two main forms of airborne contaminants [Brauer, 1990] — particulates (dusts, fumes, smoke, aerosols, and mists), and gases or vapors.

Dusts are airborne solids, typically ranging in size from 0.1 to $25\ \mu\text{m}$, generated by handling, crushing, grinding, impact, detonation, and so on. Dusts larger than $5\ \mu\text{m}$ settle out in relatively still air due to the force of gravity. Fumes are fine solid particles less than $1\ \mu\text{m}$ generated by the condensation of vapors. For example, heating of lead (in smelters) vaporizes some lead material that quickly condenses to small, solid particles. Smokes are carbon or soot particles less than $0.1\ \mu\text{m}$ resulting from incomplete combustion of carbonaceous material. Mists are fine liquid droplets generated by condensation from the gaseous to liquid state, or by the dispersion of same by splashing, foaming, or atomizing.

Gases are normally formless fluids which occupy space and which can be changed to liquid or solid by a change in pressure and temperature. Vapors are the gaseous form of substances that are normally in a liquid or solid state.

The measures for toxicity of the above substances are given in parts per million (ppm) for gases and vapors, and milligrams per cubic meter (mg/m^3) for other airborne contaminants. The criteria for the degree of toxicity are the threshold limit values (TLVs) based on review of past research and monitory experience. (Early OSHA standards listed permissible exposure limits, or PELs.) TLVs are airborne concentrations of substances which are believed to represent conditions to which nearly all workers may be repeatedly exposed, 8 hours a day, for lifetime employment, without any adverse effects. For acute toxins, short-term exposure levels (STELs) are indicated for a maximum of 15 minutes of exposure, not more than four times a day. Because exposures vary with time, a time-weighted average (TWA) is adopted for calculating TLVs:

$$\text{TLV(TWA)} = \sum (E_i T_i / 8) \quad (200.3)$$

where E_i is the exposure to the substance at concentration level i and T_i is the amount of time for E_i exposure in an 8-hour shift.

In many environments, there are several airborne substances present at the same time. If the effects of these substances are additive and there are no synergistic reactions, the following formula can be used for the combination of TLVs:

$$X = (C_1 / T_1) + (C_2 / T_2) + \dots + (C_n / T_n) \quad (200.4)$$

where C_i is the atmospheric concentration of a substance and T_i is the TLV for that substance. If $X < 1$, the mixture does not exceed the total TLV; if $X \geq 1$, the mixture exceeds the total TLV.

200.5 Noise

Noise-induced hearing loss has been identified as one of the top ten occupational hazards by the National Institute for Occupational Safety and Health (NIOSH). In addition to hearing loss, exposure to excessive amounts of noise can increase worker stress levels, interfere with communication, disrupt concentration, reduce learning potential, adversely affect job performance, and increase accident potential [Mansdorf, 1993]. Among many types of hearing loss, sensorineural hearing loss is the most common form in

occupational environments. Sensorineural hearing loss is usually caused by the loss of ability of the inner ear (cochlea nerve endings) to receive and transmit noise vibrations to the brain. In this case, the middle ear (the bone structures of malleus, incus, and stapes) and the outer ear (ear drum, ear canal, and ear lobe) may be intact.

A comprehensive and effective hearing conservation program can reduce the potential for employee hearing loss, reduce workers compensation costs due to hearing loss claims, and lessen the financial burden of noncompliance with government standards. Current OSHA standards require personal noise dosimetry measurements in areas with high noise levels. Noise dosimeters are instruments which integrate (measure and record) the sound levels over an entire work shift. Noise intensities are measured by the dBA scale, which most closely resembles human hearing sensitivity. For continuous noise levels, OSHA's permissible noise exposure is 90 dBA for an 8-hour shift. If the noise levels are variable, a time-weighted average is computed. For noise levels exceeding the limit values, an employee hearing conservation program must be administered [Mansdorf, 1993:318–320].

200.6 Fire Hazards

Fire is defined as the rapid oxidation of material during which heat and light are emitted. An estimated \$10.5 billion in property damage occurred as a result of fires in 2001 [Karter, 2001]. The most frequent causes of industrial fires are electrical (23%), smoking materials (18%), friction surfaces (10%), overheated materials (8%), hot surfaces (7%), and burner flames (7%). The process of combustion is best explained by the existence of four elements — fuel, oxidizer (O_2), heat, and chain reaction. A material with a flash point below 100°F (vapor pressure < 40 lb/in.²) is considered flammable, and higher than 100°F is combustible. In order to extinguish a fire, one or a combination of the following must be performed: the flammable/combustible material is consumed or removed, the oxidant is depleted or below the necessary amount for combustion, heat is removed or prevented from reaching the combustible material not allowing for fuel vaporization, or the flames are chemically inhibited or cooled to stop the oxidation reaction.

Fire extinguishers are classified according to the type of fire present. Class A involves solids that produce glowing embers or char (e.g., wood, paper). Class B involves gases and liquids which must be vaporized for combustion to occur. Class C includes Class A and B fires involving electrical sources of ignition. Finally, Class D involves oxidized metals (e.g., magnesium, aluminum, titanium). In addition to heat, the most dangerous byproducts of fires are hazardous gases and fumes, such as CO, CO₂, acrolein formed by the smoldering of cellulosic materials and pyrolysis of polyethylene, phosgene (COCl₂) produced from chlorinated hydrocarbons, sulfur dioxide, oxides of nitrogen (NO_x) resulting from wood products, ammonia (NH₃) when compounds containing nitrogen and hydrogen burn in air, and metal fumes from electronic equipment. For a complete reference to facility design requirements and existing requirements, refer to NFPA Code 101.

200.7 An Engineering Approach to Hazard Control

It is impossible to design an absolutely “safe” engineered system. Nevertheless, the following list is suggested to eliminate the critical hazards and reduce other noncritical hazards to an acceptable level, called *risk control*. It is important to mention that the effectiveness of the control mechanism is relatively reduced by using the lower items on this list.

1. Identify and eliminate the source of hazardous energy. For example, do not use high-voltage electricity. Or consider the use of noncombustible and nontoxic material in environments with fire potentials. This approach is not always practical or cost-effective.
2. Reduce the degree of hazardous energy. For example, use low-voltage solid-state devices to reduce heat buildup in areas with explosion hazards. This approach is practical in some cases, yet costly in other design applications.

3. Isolate the source of hazard. Provide barriers of distance, shields, and personal protective equipment to limit the harmful effects of the hazardous agents. To control the sequence of events in time and space, a lockout/tagout procedure is recommended.
4. Minimize failure. Include constant monitoring of critical safety parameters (e.g., gas concentrations or radiation levels). The monitoring system should detect, measure, understand, and integrate the readings, and respond properly.
5. Install a warning system. Similar to consumer product warnings, all system components should be equipped with warning and proper communication systems. Operators (and the general public) should be warned of the type of hazard present and the means by which information can be obtained in case of an accident. However, too many warning signs and display indicators may confuse the operator.
6. Ensure safe procedures. A common cause of accidents is the inadequacy of procedures and the failure to follow proper procedures.
7. Provide for backout and recovery. In case of an accident, this defensive step is taken to reduce the extent of injury and damage. This step incorporates one or more of the following actions: (a) normal sequence restoring, in which a corrective action must be taken to correct the faulty operation; (b) inactivating only malfunctioning equipment which is applied to redundant components or temporarily substituting a component; (c) stopping the entire operation to prevent further injury and damage; and (d) suppressing the hazard (e.g., spill containment of highly hazardous substances).

When hazard exposure cannot be reduced through engineering controls, an effort should be made to limit the employee's exposure through administrative controls, such as (a) rearranging work schedules and (b) transferring employees who have reached their upper exposure limits to an environment where no additional exposure will be experienced.

200.8 Hazard Analysis and Quantification

A number of *hazard analysis techniques* have been developed to study the hazards associated with a system. For a detailed review, see *Guidelines for Hazard Evaluation Procedures* [American Institute of Chemical Engineers, 1985], Gressel and Gideon [1991], and Vincoli [1993]. These techniques vary in terms of their hazard evaluation approaches and the degree to which hazard exposures can be quantified. A precursor to any of these techniques is the system, which is divided into its small and manageable components, analyzed for causes and consequences of any number of potential hazards, and then synthesized to consider hazard effects on the whole system. Five hazard analysis techniques are briefly presented here.

Preliminary Hazard Analysis

Preliminary hazard analysis (PHA) is the foundation for effective systems hazard analysis. It should begin with an initial collection of raw data dealing with the design, production, and operation of the system. The purpose of this procedure is to identify any possible hazards inherent in the system. One example is energy as the source of hazard to explore the multitude of circumstances by which an accident can occur in a system. [Table 200.1](#) demonstrates an actual use of PHA in the design phase of metal chemical vapor deposition. The four main categories of this table are hazard, cause, main effects, and preventive control. The hazard effects and corrective/preventive measures are only tentative indicators of potential hazards and possible solutions.

Failure Mode, Effects, and Criticality Analysis

While PHA studies hazards in the entire system, failure mode, effects, and criticality analysis (FMECA) analyzes the components of the system and all of the possible failures that can occur. This form of analysis identifies items whose failures have a potential for hazardous consequences. In this analysis, each item's

TABLE 200.1 A Sample for Application of Preliminary Hazard Analysis to Design of Metal Organic Chemical Vapor Deposition (Only Two Hazards Are Listed)

| Hazard | Cause | Main Effects | Preventive Control ^a |
|-------------------|--------------------------|--|--|
| Toxic gas release | Leak in storage cylinder | Potential for injury and fatality from large release | Develop purge system to remove gas to another tank Minimize on-site storage Provide warning system Develop procedure for tank inspection and maintenance Develop emergency response system |
| Explosion, fire | Overheat in reactor tube | Potential for fatalities due to toxic release and fire Potential for injuries and fatalities due to flying debris | Design control system to detect overheat and disconnect heater Provide warning system for temperature fluctuation, evacuate reaction tube, shut off input valves, activate cooling system |

^a This column is simplified to show the major categories of hazard control techniques.

function must be determined. Once this is done, the causes and effects of the failure of the components are indicated. Then, the criticality factor of each failure is determined, and a quantified severity rating is given to the factor. Table 200.2 shows an example for FMECA. Because the frequency of each potential occurrence is also an important factor, a risk assessment matrix (depicted in Table 200.3) can be used to codify the risk assignment. A design team (including the safety engineer) can use this FMECA to redesign components or parts of the system to reduce the criticality rating to predetermined acceptable regions (preferably a hazard risk index between one and five).

Hazard and Operability Study

Hazard and operability study (HAZOP) is one of the most tedious, yet thorough, forms of hazard analysis. It identifies potentially complex hazards in a system. HAZOP examines a combination of every part of the system and analyzes the collected data to locate potentially hazardous areas. The first step is to define the system and all specific areas from which data will be collected. This will help in defining the HAZOP team. Next, a team of experts in these areas is assembled to analyze the collected data. The team usually consists of experts in the fields of engineering, human behavior, hygiene, and organization and management, and other personnel who may have operational expertise related to the specific system being analyzed. Once this is done, an intensive information gathering process begins. All aspects of the system's operation and its human interfaces are documented. The information is then broken down into small information nodes. Each node contains information on the procedure or specific machine being used in

TABLE 200.3 Hazard Risk Assessment Matrix

| Frequency of Occurrence | Hazard Category | | | |
|-------------------------|-------------------|----------------|-----------------|------------------|
| | I Catastrophic | II Critical | III Marginal | IV Negligible |
| Frequent | 1 | 3 | 7 | 13 |
| Probable | 2 | 5 | 9 | 16 |
| Occasional | 4 | 6 | 11 | 18 |
| Remote | 8 | 10 | 14 | 19 |
| Improbable | 12 | 15 | 17 | 20 |

Note: The hazard risk index numbers and related suggested criteria are 1–15, unacceptable; 6–9, undesirable; 10–17, acceptable with review; and 18–20, acceptable without review.

TABLE 200.4 HAZOP Data Table for Vacuum Air Vent Node and Reverse Flow Guide Word (Design Intention: To Vent Air into the Sterilizer following a Vacuum Stage)

| Guide Word | Cause | Consequence | Recommendation |
|--------------|-----------------------|---------------------------------------|---|
| Reverse flow | Control valve leakage | Ethylene oxide leak into utility room | Air vent should not receive air from utility room, but from exhaust duct to reduce risk from reverse flow leakage of ethylene oxide |

Source: Adapted from *Hazard and Operability Study of an Ethylene Oxide Sterilizer*. 1989. National Institute for Occupational Safety and Health, NTIS Publication No. PB-90-168-980. Springfield, VA, p. 27.

the system. Each node is then interconnected logically with other nodes in the system. Each node is also given guide words that help identify its conditions. Table 200.4 gives an example of guide words. Each guide word is a functional representation of subsystem hazard. The team can analyze and determine the criticality or likelihood that this node could produce a hazard. At this point, the HAZOP team will need to determine what course of action to take. This procedure is one of the most comprehensive, yet time consuming, of the analysis tools. It is widely used in large and complex systems with critical safety components, such as petrochemical facilities.

Fault Tree Analysis

Fault tree analysis (FTA) uses deductive reasoning to qualitatively and quantitatively depict possible hazards that occur due to failure of the relationships between the system components (e.g., equipment, plant procedures). FTA uses a pyramid style tree analysis to start from a top undesired event (e.g., accident, injury) down to the initial causes of the hazard (e.g., a joint separation under vibrating forces, erroneous operating procedure). There are four main types of event symbols — a fault event, basic event, undeveloped event, and normal event. A fault event is considered to be an in-between event and never the end event. A basic event is considered to be the final event. An undeveloped event is an event which requires more investigation because of its complexity or lack of analytical data. A normal event is an event which may or may not occur. Each one of these events is joined in the tree by a logic symbol. These gates explain the logic relationship between each of the events. For example, a main event is followed in the tree by two possible basic events. Either event can produce the main event. The logic gate in this case would be an *or* gate, but if both events could have contributed to the main event an *and* gate would be used. FTA's ability to combine causal events together to prevent or investigate accidents makes it a powerful accident investigation and analysis tools.

Event Tree Analysis

Event tree analysis (ETA) is similar to FTA, with the exception that ETA uses inductive reasoning to determine the undesired events which are caused by an earlier event. ETA uses the same pyramid structure

as the previous analysis. However, rather than working from top to bottom, ETA works from left to right, dividing the possibility of each event into two outcomes — true (event happening) or false (event not happening). By taking an initial failure of an event, the tree designer tries to incorporate all possible desired and undesired results of the event. The advantage to this system is that it helps predict failures in a step-by-step procedure. This helps the analyst to provide a solution or a countermeasure at each analysis node under consideration. ETA's main weakness lies with its inability to incorporate multiple simultaneous events.

Other techniques such as management oversight, risk tree, “what-if” analysis, software hazard analysis, and sneak circuit analysis are discussed in the sources listed in the Further Information section.

Defining Terms

Compliance — The minimum set of requirements by which an environment conforms to local, state, and federal rules, regulations, and standards. According to the seriousness of the violation, a workplace may be cited by OSHA for imminent danger, serious violation, nonserious hazards, and de minimis violations. In addition to penalties (fines of up to \$70,000 per violation), other civil and criminal charges may be brought against responsible supervisors and managers.

Hazard — A set of (or change in) a system's potential and inherent characteristics, conditions, or activities that can produce adverse or harmful consequences, including injury, illness, or property damage (antonym to safety).

Hazard analysis techniques — A number of analytical methods by which the nature and causes of hazards in a product or a system are identified. These methods are generally designed to evaluate the effects of hazards and offer corrective measures or countermeasures.

Mechanical injuries — A type of physical injury caused by excessive forces applied to human body components, such as cutting, crushing, and straining (ergonomic hazards).

Risk control — The process by which the probability, severity, and exposure to hazards (per mission and unit of time) are considered to reduce the potential loss of lives and property.

Toxic substances — Those substances that may, under specific circumstances, cause injury to persons or damage to property because of reactivity, instability, spontaneous decomposition, flammability, or volatility (including those compounds that are explosive, corrosive, or have destructive effects on human body cells and tissues).

Regulations and Standards

A. Keith Furr

*Virginia Polytechnic Institute and
Virginia State University*

201.1 Engineering Practices

Engineers and corporations in the United States and other industrial nations have long recognized the need for the establishment of basic minimum standards for safe design and construction of structures and equipment. As a result, many technical groups and associations have established guidelines for these minimum standards. However, it generally has been left up to the federal, state, and local governments to decide which of these are mandated. For example, fire codes are usually designed and administered locally. At least one state has virtually no fire codes that apply statewide. In other cases, the application of the codes is not universal. In Virginia, only selected categories of structures are covered by the statewide code, while local building codes vary widely in their scope and interpretation depending on the local officials responsible for their administration. A disaster is often required to reveal the deficiencies in applicable codes and their enforcement. The Hurricane Andrews aftermath is an excellent example of this; as a result, the state has dramatically strengthened its building code standards. Another area needing consideration is the concept of including a design safety factor. The need is well recognized but perhaps the safety factors themselves may need to be reevaluated. Prior to the World Trade Center disaster, no one realistically expected that airliners with virtually full fuel loads would crash into the buildings; the support structure could not withstand the extremely high temperatures created by the burning fuel and the buildings collapsed. Should more consideration of extreme what-ifs be included in building designs? There have been several airline crashes in the past few years that have been blamed on structural failures considered highly unlikely, but which nevertheless occurred.

After World War II, the need was recognized in the United States for “universally” applicable standards, at least in certain fields. One of the earliest defined and adopted national standards was in the field of nuclear energy, a prototype set for many of the agencies that have since been established. The responsible federal agency, the Nuclear Regulatory Commission (NRC) (originally, the Atomic Energy Commission; only current names of regulatory agencies are used in this chapter), set the basic standards by which activities involving radioactive materials created as a result of reactor-related operations were regulated. Note that radiation created by medical devices and natural materials does not fall under the purview of the NRC. States typically have at least partially assumed this responsibility. As more information has been developed, the original standards were modified to accommodate the new data, generally being made more stringent. States were given the option of either allowing the federal agency to supervise the use of these materials or adopting regulations at least as stringent as the federal regulations and administer the same themselves. This model has persisted in many of the other regulatory acts passed since then. In the early 1970s, the Occupational Safety and Health Act (OSHA) was passed, covering a very large number of industries. The standards in the OSHA Act were, for the most part, incorporated directly

from the standards and guidelines established by industrial associations. Unfortunately, the law does not permit changes to the standards to be made easily, so that the legal OSHA standards often lag behind the industrial standards. Recently, there have been revisions to the regulatory provisions to make them more applicable to current safety requirement levels.

Other major federal safety and health standards are those of the Environmental Protection Agency (EPA), the Department of Transportation, the Food and Drug Administration, the Department of Energy, the Federal Aviation Administration, and a host of other specialized agencies. The scope of regulations is a rapidly evolving area. In recent years, federal operations have been brought under both OSHA and EPA regulations from which they were previously excluded. OSHA has taken a very active role in the operations of medical- and health-related organizations with the Bloodborne Pathogens Act, and the problems of the disabled are now regulated under the Americans with Disabilities Act (ADA). A major area possibly to be changed significantly in the future is noise control. Many engineers agree that the current noise safety program is too lenient. The initial threshold may to be changed from 90 dB to 85 dB and the doubling ratio as a measure of sound level intensity changed from 5 dB to 3 dB as more scientifically sound. These two changes will require major engineering modifications in many cases, and probably additional costs.

Another potential regulatory area that will have a significant impact on engineering design is indoor air quality, an area insufficiently researched until recently. As most buildings are currently being built or retrofitted with heating, ventilation, and air conditioning systems to completely manage the building's internal environment, health problems are developing in building occupants. Typically, only a modest fraction of the personnel are affected, but among these significant health problems may exist, often due to biological contaminants. Building materials are also of concern, which were not considered until fairly recently. Everyone by now should be aware of the problems with asbestos, and the enormous expense of abating associated problems. Similar problems appear to exist with effluents from some interior finish materials, such as those that contain formaldehyde.

201.1 Engineering Practices

Incorporated in the standards for nuclear safety, and now in most other safety and health regulatory standards, was the concept of achieving compliance with safety standards by engineering controls wherever possible. For example, it should, in principle, be impossible to operate a nuclear reactor unsafely. Approaching criticality too rapidly should be impossible by having interlocks that would shut down operations automatically if this were done or if one of a number of other conditions existed, such as loss of coolant, excessively high temperatures, excessively high radiation levels in monitored areas, earthquakes, and loss of information in critical circuits. The control mechanisms are supposed to be designed so that redundant failures have to occur to make the them operate unsafely; no single equipment failure should render operations unsafe (in the sense that an automatic or controlled shutdown should always occur when a failure occurs). This example, taken from the nuclear industry, is reflected in many others. Of course, experience has shown that humans can bypass almost any safety feature if they try. The catwalk in the Kansas City hotel fell due to human error. The Chernobyl incident was due to a combination of poor design a small safety margin, and operations that were lax in maintenance, training, and function. In some cases, failure occurs due to the lack of sufficient knowledge or information. The collapse of the Tacoma Narrow Bridge in 1940, only 4 months after completion, is an excellent example. In any case, safety and health standards today require that, wherever feasible, safety engineering principles as identified by the regulations must be the first option in complying with the standards. Procedural rules as a compliance method may be used on occasion but are definitely a second choice. A fairly recently developing problem that engineers should recognize is the substitution of substandard components that look like identical specified items but do not meet necessary quality standards. This has affected a vast range of manufactured items ranging from cars to medical devices to structural components. The engineer needs to take extra care to prevent these substitutions from occurring.

Many of the earlier industrial standards, including those emphasized in the earliest versions of the OSHA standard, and briefly alluded to in the previous paragraph, are intended to prevent physical injuries. Bending brakes and hydraulic presses are required to have controls making it impossible for the machines, if used properly, to injure any part of the operator's body. Grinding tools and other devices with exposed rotating components are supposed to be designed to prevent hair or clothing from being grabbed by the rotating component or for materials to be thrown by the tool and impact a person, particularly in the face and eye. The design of portable electrical tools is required to make it impossible for them to produce a shock under normal operation. Ladders, scaffolds, and guardrails are defined to prevent employees from slipping or falling. Indeed, one of the major weaknesses in the original standards was that they defined safety in such minute detail that they were seen by many to be concerned with trivia, so that they failed to some extent in their mission to increase safety. Nevertheless, even with the original weaknesses, most of which have now been addressed, the creation of OSHA was a major step forward in occupational safety. The general public benefits, as well as employees, since incidents may have an impact outside the immediate area. If a machine or structure is designed properly, it should be safe for everyone with a legitimate need and training to use the device or facility.

Other areas of the original OSHA Act dealt with fire safety by adopting (in some cases modifying them slightly) standards of the National Fire Prevention Association on the storage of flammable materials, limiting bulk storage, storage within facilities, and sizes of containers for appropriate classes of liquids. Similar restrictions have been established for compressed gas systems, especially gases with inherent safety problems, such as hydrogen, oxygen, and ammonia. With few changes, these regulations have remained in effect and are well understood by engineers charged with designing appropriate facilities. Note that not all of the standards mentioned above were incorporated into OSHA, typically only those applying to employee safety, but other portions of the standards are incorporated into other regulatory standards with which engineers must comply.

Recent changes in the OSHA standard are often more concerned with meeting performance specifications than with specific directives, allowing the engineer, owner, or user to decide how best to meet the compliance goal. Meeting safety and health regulatory standards through engineering practices is still required as the first option, with personal protective devices and procedural controls used as options when engineering controls are not practicable. A major opportunity to implement this concept was created a few years ago when OSHA made a distinction between industrial operations, from the pilot plant scale upward, and those of laboratory-scale operations. It was recognized that the designs appropriate to a large plant where a modest number of chemicals are in use, albeit on a substantial scale, are not appropriate for the laboratory environment, where literally hundreds of different chemicals are used on a rapidly changing basis. Therefore, the OSHA Laboratory Safety Act was added to the basic OSHA Act, preempting the OSHA general industry standards for laboratories. Neither section of the Act is more permissive than the other in terms of meeting the intended goal, a healthy and safe environment. The two different environments do lead to substantially different engineering approaches to many problems, and engineers specializing in the two areas need to understand the differences.

One of the major issues, even in the early versions of the OSHA standards, concerns the levels of specific airborne contaminants in the workplace. For various reasons, such as toxicity, neurological risk, fetal hazards, and corrosiveness, permissible exposure levels (PELs) were set by OSHA. Theoretically, a person in good health could work an 8-hour work day without harm if the exposure levels were less than these, but could not be allowed to work if they exceeded the PELs based on an 8-hour time-weighted average. In some cases, higher short-term exposure limits (STELs) were established, and in others, ceiling (C) limits were established. The initial values were essentially the threshold limit values (TLVs) recommended by the American Conference of Governmental Industrial Hygienists (ACGIH). The latter are reviewed on a yearly basis and have changed significantly for specific substances. OSHA attempted to change their PELs (which are legally enforceable) to be the same in most cases to the more current values of the ACGIH (which are guidelines and are not legally enforceable). However, court actions required OSHA to rescind the changes, so that the OSHA PELs are in many cases out of date the current available knowledge. Some states adopted the updated values on their own, so that now engineers must be aware

of the law in their area of expertise. A conservative approach would be to design using the ACGIH guidelines since they normally provide an additional safety level. In neither case should the limits be considered as black and white. Many factors will modify the sensitivity of a specific individual to a given contaminant; for example, natural variations in individual tolerance or tolerance due to current health conditions. A factor receiving increased attention is possible gender and age differences. The PELs and TLVs were based on an 8-hour day, 40-hour work week for a healthy adult male. A good design practice is to maintain an action level no more than 50% of the PEL, and preferably less. Many of the newer OSHA standards now incorporate the 50% action level concept.

Ventilation engineers need to be aware of local factors in designing appropriate systems capable of achieving acceptable levels. The problems of designing ventilation systems to remove air contaminants do not seem to be as highly appreciated by some engineers as might be expected. Routine ventilation designs for offices and homes are geared typically for temperature control. Since hot air rises, inlet and exhaust duct work and openings are typically placed in the ceiling. However most airborne contaminants are heavier than air, so general room exhausts for these contaminants should be located close to the floor, or no lower than waist height. The air flow should not draw or discharge contaminated air indoors through occupants' breathing zone. Various recommendations exist for the amount of fresh air needed depending on the type of occupancy. Typically, in an office environment, a value of 20 cubic feet per minute (cfm) of fresh air is recommended. Relatively few older structures meet this requirement. Even if the original design was satisfactory, if subsequent modifications are not thoroughly reviewed and designed appropriately, they will fall drastically short of meeting employees' needs. In chemically contaminated areas, such as laboratories, the number of air changes per hour is often used as a criterion, with current levels being 10 to 12 per hour. This has serious implications for laboratories since the normal requirement is for this to be 100% fresh air. In office structures, the air is normally partially recycled so that only 15% to 30% may be fresh, but this, while economical, may lead to other problems.

The recycling of air in newer energy-efficient buildings appears to be at least partly responsible for the increasing evidence of health problems in these structures. Recycling air can cause an air quality problem that exists in one part of a building to eventually spread throughout the building. This is especially true when the system is itself the cause of the problem. Most duct systems are not designed for ease of cleaning, and over time become dirty. The dirt and grease that builds up in these systems is an ideal breeding ground for molds and bacteria, to which many individuals are allergic. Not only should high-efficiency filters be used and replaced frequently, but the duct work interior needs to be cleaned periodically. If air quality is brought under regulation, there will be significant engineering requirements on the design of the systems to facilitate cleaning, filter designs, and selection of materials for construction to limit the emission of volatile organic compounds. There is increasing evidence that long-term exposure to some organics, such as formaldehyde, may cause problems to hypersensitive individuals at levels significantly lower than the permissible PELs or TLVs. The National Institutes of Occupational Safety and Health (NIOSH) are already recommending levels substantially below those of both OSHA and the ACGIH for a number of materials due to low, continuous exposures. Unfortunately, our knowledge of health effects in general and especially those related to long-term exposures at low levels leaves a great deal to be desired, although it is improving. Statistically, the problem with low levels of airborne contaminants is very much like the situation with low levels of radioactivity. Health problems may exist, but the experimental evidence is virtually impossible to obtain because of the extremely large number of subjects required for direct measurement. The problems are compounded by the wide variation in individual sensitivities. One individual may be made very ill after exposure to a pollutant while another may be unaffected by it. What if only 1% are affected while the remaining 99% are not? Do you design, at possibly great cost, to prevent problems for the 1%?

The most effective and energy-conserving means of controlling contaminants is to capture them at the source. In a factory, large-scale scavenging systems may be appropriate, while laboratory facilities would be better designed so that all work with the potential to release hazardous vapors, fumes, or gases be done in fume hoods with at least 100 feet per minute (fpm) face velocity. Note that handicapped workers would face difficulties in working in hoods, so specially designed units should be specified where this occurs.

Once contaminated air has left a facility, it is hoped that dilution with the outside air will reduce contaminants to safe levels. Air pollution standards have been established that may or may not be sufficient. Problems such as acid rain and ozone depletion are well documented in the literature and have been extensively publicized in the media. In laboratory buildings, for example, engineers until quite recently typically placed rain caps over fume hood exhausts so that the contaminated air was forced back onto the roof of a building and in many cases was recaptured by the building's air ventilation system. Often, once a laboratory building was completed, subsequent modifications added fume hoods to a duct system that did not have the capacity to handle them. Fire codes typically require laboratories to be at negative pressure with respect to the corridors so that fire within a laboratory cannot spread via the corridors. The negative pressure also prevents contaminated air from spreading via the corridors as well. Exhaust ducts for the newer hoods were often allowed to penetrate floors intended to be fire separations. The fire separation must be maintained. Standards recommended by either the ACGIH, NFPA, or American Society of Heating, Refrigerating and Air Conditioning Engineers (ASHRAE) must still be met.

The Environmental Protection Agency (EPA) has been a major factor in changing engineering practices. For example, one of the most significant standards dealt with underground petroleum storage tanks. A large percentage of organizations with a substantial number of employees, including manufacturing plants, transportation departments, hospitals, and universities, have either buried tanks of heating oil or gasoline. Tanks that have been buried for 20 years or more have an increasing probability of leakage as they age. The EPA regulation required all of these tanks above a certain capacity to be protected from leaking into the environment by 1998. Typically, this involved replacing a tank with a double-shelled unit equipped with appropriate sensors to ensure that leaking does not occur. If environmental contamination has already occurred, the owner was required to clean up the contaminated site. Another example involves the disposal of hazardous medical waste. The EPA set very strict pollution standards for incinerators to burn these wastes that, in effect, caused the practice to be virtually discontinued.

Although addressed in [Chapter 93](#), the related issue of prevention of ground contamination from landfills will be briefly mentioned here. In the last 5 years, a very large number of landfills have been closed due to the enactment of strict standards on landfills. Although no responsible person would deliberately dispose of any kind of hazardous waste routinely at a municipal landfill, it is estimated that 3% to 5% of all municipal solid waste could be characterized as hazardous waste, primarily from households and small business establishments. The engineering problem is to prevent pollutants from seeping from landfills into surrounding groundwater. The landfills must be sealed to prevent leakage and to prevent entry of water. Monitors are required to ensure that the prevention measures are successful. To lengthen the life of existing landfills, and to reduce the cost of new ones, recycling programs have been growing dramatically and have given rise to their own engineering disciplines. Alternative means of hazardous and solid waste disposal have been developed to reduce or eliminate the burial of wastes that could remain hazardous for thousands of years. Various incineration methods have been developed that must comply with EPA's clean air standards (see previous paragraph) as well as being subject to the "not-in-my-back-yard" (NIMBY) syndrome. Dozens of techniques have been developed for disposal of medical wastes, which are regulated by state programs of varying stringency. No matter what engineering approach is involved in any of these environmental issues (and others not mentioned), the net result must be to reduce the level of contaminants in the soil or air below a regulatory-defined level either by destruction or modification. Underground burial has been deemed unacceptable for most hazardous materials, with the notable exception of radioactive isotopes, for which no practical means of destruction exists. The major regulatory act that sets standards for the disposition of materials with hazardous properties is the Resource Conservation and Recovery Act (RCRA). Since most facilities do not process their hazardous waste locally, packaging and transportation of these materials must also meet requirements of the Department of Transportation. These standards have changed significantly within the past several years and now are generally consistent with comparable international requirements. Another major EPA standard is the community-right-to-know standard. Under this act, communities must be made aware of potential industrial chemical hazards in their areas. Several hundred chemicals have been specifically identified for which detailed emergency response plans are required. Localities are required to maintain local emergency planning committees to oversee this regulation.

The original standards for making buildings accessible to the handicapped were less successful than desired, so the ADA was passed in the early 1990s. This standard is much more stringent and carries the potential for much more severe penalties. Not only are the now familiar wheelchair ramps and modified bathroom facilities required, but a number of other engineering changes are specified as well. Safety equipment, such as safety showers and eyewash fountains, must now meet specifications to ensure that a disabled person can use them. Fire alarms must provide a high-intensity visual alarm as well as an audible alarm. Doors must provide means to prevent a disabled person from being trapped or injured by the opening and closing mechanism. Instructions on public signs, including safety signs, must be provided in braille where appropriate. Meetings that could be attended by the disabled must ensure that the information can be received by a disabled person. This could include audio and or visual equipment for the hearing or visually impaired, or possibly a sign-language interpreter. The availability of these resources must be made known at the time the meeting is announced. Places of refuge must be identified to which disabled persons could seek temporary protection while awaiting rescue in the event of a fire or other incident. All new facilities must be designed to comply with the standard, and older ones will have to be brought toward full compliance. There is currently some legal uncertainty as to the interpretation of certain portions of this standard, but it certainly should be considered by engineers and architects in their work.

The Food and Drug Administration (FDA) not only establishes standards for nutritional information and for such things as drugs, pesticides, and residues of these materials on foods, but also regulates or provides guidelines for the design of x-ray machines, lasers, microwave units, and other generators of electromagnetic emissions. Currently cell phone emissions are a matter under consideration. Most FDA safety standards are intended as requirements for the manufacturer and effectively require engineering safeguards to be incorporated into these devices that a user cannot easily bypass. For example, industrial x-ray cameras are required to be interlocked so that the intense radiation areas within the target area cannot be accessed while the beam is on. The radiation levels within this area are such that a serious radiation burn to the hands can occur within 30 seconds. Requirements for the design of x-ray units for diagnostic tests now mandate that the unit define the exposed target area by light so that areas other than the one of interest are not exposed. This has resulted in dramatic reductions for patient exposures. Therapeutic uses of radiation are not regulated and can be quite high but levels are set by prudence and experience. Similar restrictions are imposed on lasers which have sufficient power to cause blindness if a beam were to reach the eye directly or by nondiffuse reflection. The standards also include guidelines for the safe use of the equipment by the operators, although these are recommendations only and are not legally binding. The ACGIH has established TLVs for laser exposures as well as for chemical exposures.

The NRC does not regulate radiation exposures due to x-rays or the use of radioactive materials not related to byproduct materials (materials made radioactive by reactor operations). However, dose rates for x-rays are generally equivalent to those for radiation from radioactive materials. The design of x-ray facilities must take into account radiation levels external to the facility with care since x-rays are normally directed, and hence radiation levels can be high in spots.

Also, states typically regulate the radioactive materials not covered by the NRC in a comparable fashion. In January 1994, the NRC regulations were changed in several significant ways. For example, exposure limits, which had been primarily concerned with external exposures, now must incorporate exposures due to ingestion, inhalation, and possible percutaneous absorption; certain external limits were changed, including those related to the extremities, which now include the area below the knee as well as the areas beyond the elbows, since there are no critical organs within those bodily components; and women who may be pregnant (and so declare) must be limited to 10% of the whole body exposure permissible for other monitored employees, in order to limit exposure to the fetus. The NRC has also stepped up the stringency with which it monitors compliance, and in recent years it has become commonplace for the NRC to impose substantial fines on industrial users, hospitals, and universities.

There are other standards and guidelines that have a significant impact on safety and health. Among these are the OSHA Hazard Communication Act (29 CFR 1910.1200) for industrial users of hazardous materials, and its companion for laboratory employees (OSHA 29 CFR 1450). Both require extensive training of employees and provision for responses to emergencies. The previously mentioned Bloodborne

Pathogens Act (OSHA 29 CFR 1919.1030) is a very strong standard. All of these incorporate significant engineering requirements to protect employees through either provision of emergency measures or uses of protective equipment.

The National Institutes of Health (NIH) Guidelines for Research Involving Recombinant DNA Molecules represent a significant standard which is, in effect, a regulation although it is labeled a guideline. Research programs which do not comply with these guidelines will not receive funding from NIH. Characteristics of the facility in which the research is done, the procedures followed, and the experimental subjects are all carefully defined by the standard. Further, any genetically engineered products of these studies must receive explicit approval prior to being placed on the market since these have implications for genetically modified foods. Even if considered safe, many persons are afraid to eat modified foods. The impact of this standard is still somewhat controversial even if the end product is clearly beneficial, such as making it possible to clone a human fetus for recovery of stem cells that could be used to repair human organs. In a similar vein, the Centers for Disease Control have published standards governing microbiological research practices based on concerns that research workers might contract a contagious disease. This concern is not due to a high probability that contagion may spread beyond the facility, as in fact this has not been known to occur in this country, but is designed to ensure that it does not. A disturbing trend is that modern medicine's disease-fighting capabilities are rapidly decreasing in efficacy as infectious organisms become immune to previously effective treatments.

The preceding material presented a very brief overview of a portion of the regulatory environment. Certain topics that were not mentioned are of comparable importance to those covered. Safety and health programs, once developed only voluntarily by enlightened organizations due to their recognition that they were cost-effective, are now virtually completely defined by regulations and standards applicable to the substantial majority of employees. Engineering subdisciplines have developed to provide the supportive infrastructure for the regulations. This is a rapidly developing field. Many of the regulations cited did not exist a few years ago, and every one of them has undergone significant changes in that time and continue to evolve.

There is a tendency by many to believe that regulations stifle productivity. This may be so if the regulations are applied inflexibly, without common sense. A sensible safety program will without doubt improve productivity. One of the country's most profitable companies is E. I. DuPont, which pioneered many of the safety programs later incorporated into standards. This company is generally regarded as having one of the very best safety and health programs in private industry. Again, DuPont has not undertaken these programs for altruistic reasons, but because they are cost-effective.

Present Worth Analysis

Walter D. Short

National Renewable Energy
Laboratory

202.1 Calculation

Analysis Period • Cash Flows • Discount Rate

202.2 Application

202.3 Other Considerations

Savings vs. Income>Returns • Uncertainty • Externalities

Evaluation of any project or investment is complicated by the fact that there are usually costs and benefits (i.e., cash flows) associated with an investment that occur at different points in time. The typical sequence consists of an initial investment followed by operations and maintenance costs and returns in later years. Present worth analysis is one commonly used method that reduces all cash flows to a single equivalent cash flow or dollar value (Palm and Qayum, 1985). If the investor did not care when the costs and returns occurred, *present worth* (also known as *net present value*) could be easily calculated by simply subtracting all costs from all income or returns. However, to most investors the timing of the *cash flows* is critical due to the time value of money; that is, cash flows in the future are not as valuable as the same cash flow today. Present worth analysis accounts for this difference in values over time by discounting future cash flows to the value in a base year, which is normally the present (hence, the term “present” worth). If the single value that results is positive, the investment is worthwhile from an economic standpoint. If the present worth is negative, the investment will not yield the desired return as represented by the discount rate employed in the present worth calculation.

202.1 Calculation

The present worth (PW), or net present value, of an investment is

$$PW = \sum_{t=0}^N \frac{C_t}{(1+d)^t} \quad (202.1)$$

where N is the length of the analysis period, C_t is the net cash flow in year t , and d is the *discount rate*.

Analysis Period

The analysis period must be defined in terms of its first year and its length, as well as the length of each time increment. The standard approach, as represented in Equation (202.1), is to assume that the present is the beginning of the first year of the analysis period ($t = 0$ in Equation (202.1)), that cash flows will be considered on an annual basis, and that the analysis period will end when there are no more cash flows that result from the investment (e.g., when the project is completed or the investment is retired)

FIGURE 202.1 Comparison of investments.

[Ruegg and Petersen, 1987]. For example, the present worth for a refinery that will require 6 years to construct and then last for 30 years (to 2039) can be represented as

$$PW(2003) = \sum_{t=0}^{36} \frac{C_t}{(1+d)^t} \quad (202.2)$$

In this case the analysis period covers both the construction period and the full operation period, as shown in Figure 202.1. In Equation (202.2) the parenthetical (2003) explicitly presents the base year for which the present worth is calculated. This designation is generally omitted when the base year is the present.

However, any of these assumptions can be varied. For example, the present can be assumed to be the first year of operation of the investment. In the refinery example, the present worth can be calculated as if the present were 6 years from now (2009) — that is, the future worth in the year 2009 — with all investment costs between now and then accounted for in a single turnkey investment cost (C_0) at that time ($t = 0$). In this case the base year is 2009.

$$PW(2009) = \sum_{t=0}^{30} \frac{C_t}{(1+d)^t} \quad (202.3)$$

The length of the analysis period is generally established by the point in time at which no further costs or returns can be expected to result from the investment. This is typically the point at which the useful life of the investment has expired. However, a shorter lifetime can be assumed with the cash flow in the last year accounting for all subsequent cash flows. For the refinery example the analysis period could be shortened from the 36-year period to a 26-year period, with the last year capturing the salvage value of the plant after 20 years of operation.

$$PW = \sum_{t=0}^{26} \frac{C_t}{(1+d)^t} \quad (202.4)$$

where C_{26} is now the sum of the actual cash flows in C_{26} and the salvage value of the refinery after 20 years of operation. One common reason for using a shorter analysis period is to assess the present worth, assuming sale of the investment. In this case, the salvage value would represent the price from the sale minus any taxes paid as a result of the sale.

Finally, the present worth is typically expressed in the dollars of the base year. However, it can be expressed in any year's dollars by adjusting for inflation. For example, in the refinery case, in which the base year is 2009 (Equation (202.3)), the present worth value expressed in the dollars of the year 2009 can be converted to a value expressed in today's (2003) dollars, as follows:

$$PW_{2003\$}(2009) = \frac{1}{(1+i)^{2009-2003}} PW_{2009\$}(2009) \quad (202.5)$$

where i is the annual *inflation rate* between 2003 and 2009 and the subscripts indicate the year of the dollars in which the present worth is presented.

FIGURE 202.2 Analysis period for a refinery.

Cash Flows

Cash flows include all costs and returns where costs are negative and returns or income are positive (see Figure 202.2). The cash flow for each year of the analysis period must include all actual costs and income associated with the investment during that year. Thus, cash flows must include all initial capital costs, all taxes, debt payments, insurance, operations, maintenance, income, and so forth.

Cash flows are typically expressed in terms of the actual dollar bills paid or received (*nominal* or current *dollars*). Alternatively, cash flows can be expressed in terms of the dollars of a base year (*real* or constant *dollars*). Nominal dollar cash flows, C_n , can be converted to real dollar cash flows, C_r (and vice versa) by accounting for the effects of inflation

$$C_0^r = \frac{C_t^n}{(1+i)^t} \quad (202.6)$$

where i is the annual inflation rate and t is the difference in time between the base year ($t = 0$) and the year of the nominal dollar cash flow.

As shown in Figure 202.2 (which used a nominal discount rate of 0.2 or 20%), discounting can significantly reduce the value of cash flows in later years. A discounted cash flow is the present worth of the individual cash flow. Discounted cash flow in period s is shown in Equation 202.7 where the cash flow is assumed to occur at the end of year s .

$$PW_s = \frac{C_s}{(1+d)^s} \quad (202.7)$$

There are instances where the cash flow occurs continuously throughout the year (e.g., product sales). This can be captured by a continuous discount rate d' (see next section for definition) and an integral discount formula.

$$PW_s = \int_{s-1}^s e^{-d't} c(t) dt \quad (202.8)$$

where $c(t)$ is the rate of cash flow throughout the year.

Discount Rate

The discount rate is intended to capture the time value of money to the investor. The value used varies with the type of investor, the type of investment, and the opportunity cost of capital (i.e., the returns that might be expected on other investments by the same investor). In some cases, such as a regulated electric utility investment, the discount rate may reflect the weighted average cost of capital (i.e., the after-tax average of the interest rate on debt and the return on common and preferred stock). Occasionally, the discount rate is adjusted to capture risk and uncertainty associated with the investment. However, this is not recommended; a direct treatment of uncertainty and risk is preferred (discussed later).

As with cash flows, the discount rate can be expressed in either nominal or real dollar terms. A nominal dollar discount rate must be used in discounting all nominal dollar cash flows, whereas a real discount rate must be used in discounting all real dollar cash flows. As with cash flows, a nominal dollar discount rate, d_n , can be converted to a real dollar discount rate, d_r , by accounting for inflation with either of the following:

$$1 + d_n = (1 + d_r)(1 + i)$$
$$d_r = \frac{1 + d_n}{1 + i} - 1 \quad (202.9)$$

Since cash flow should include the payment of taxes as a cost, the discount rate used in the present worth calculation should be an after-tax discount rate (e.g., the after-tax opportunity cost of capital).

As noted in the cash flow section above, it is possible to discount continuous cash flows with a continuous discount rate d' . This continuous discount rate is related to the discrete discount rate d as follows:

$$d' = \ln(1 + d)$$

202.2 Application

Present worth analysis can be used to evaluate a single investment or to compare investments. As stated earlier, a single investment is economic if its present worth is equal to or greater than zero but is not economic if the present worth is less than zero.

Present worth > 0 . The investment is economic.

Present worth < 0 . The investment is not economic.

The use of present worth to compare multiple investments is more complex. There are several possible situations, as shown in [Figure 202.3](#), including investments that impact one another (dependence, point 1 in [Figure 202.3](#)), investments that are mutually exclusive (only one investment is possible from a set of investments, point 2 in [Figure 202.3](#)), and/or investments for which there is a budget limitation (point 3 in [Figure 202.3](#)).

If the investments do have an impact on one another (i.e., they are dependent), then they should be considered together and individually. Investments that impact one another are reevaluated as a package, with new cash flows representing the costs and returns of the combination of investments. The present worth of all individual investments and all combinations of dependent investments should then be compared. This comparison will, by definition, include some mutually exclusive investments (i.e., they cannot all be undertaken because some are subsumed in others). Each set of these mutually exclusive alternatives can be resolved to a single alternative by selecting the combination or individual investment with the highest present worth from each set. For example, if a refinery and a pipeline are being considered as possible investments and the pipeline would serve the refinery as well as other refineries, then the presence of the pipeline might change the value of the refinery products (i.e., the two investments are

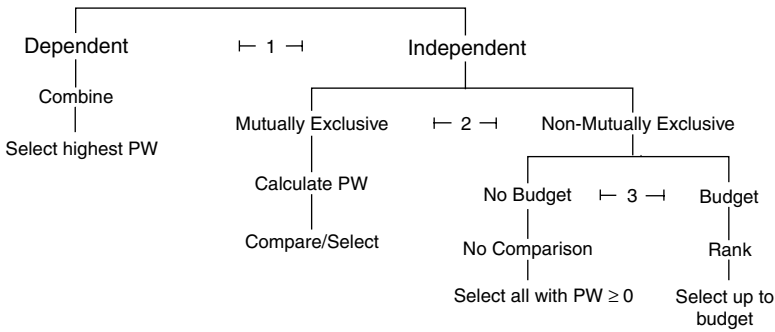

FIGURE 202.3 Cash flows.

not independent). In this case, the present worth of the refinery alone, the present worth of the pipeline alone, and the present worth of the combined pipeline and refinery should be calculated and the one with the highest present worth selected.

Once each set of dependent investments has been resolved to a single independent investment, then the comparison can proceed. If only one investment can be made (i.e., they are mutually exclusive), then the comparison is straightforward; the present worth of each investment is calculated and the investment with the highest present worth is the most economic. This is true even if the investments require significantly different initial investments, have significantly different times at which the returns occur, or have different useful lifetimes. Examples of mutually exclusive investments include different system sizes (e.g., three different refinery sizes are being considered for a single location), different system configurations (e.g., different refinery configurations are being considered for the same site), and so forth.

If the investments are not mutually exclusive, then one must consider whether there is an overall budget limitation that would restrict the number of economic investments that might be undertaken. If there is no budget (i.e., no limitation on the investment funds available) and the investments have no impact on one another, then there is really no comparison to be performed and the investor simply undertakes those investments that have positive present worth and discards those that do not.

If the investments are independent but funds are not available to undertake all of them (i.e., there is a budget), then there are two approaches. The easiest approach is to rank the alternatives, with the best having the highest benefit-to-cost ratio or savings-to-investment ratio. (The investment with the highest present worth will not necessarily be the one with the highest rank, since present worth does not show return per unit investment.) Once ranked, those investments at the top of the priority list are selected until the budget is exhausted. Present worth can be used in the second, less desirable approach by considering the total present worth of each combination of investments whose total initial investment cost is less than the budget. The total present worth of the investment package is simply the sum of the present worth values of all the independent investments in the package. That combination with the greatest present worth is then selected.

202.3 Other Considerations

Three commonly encountered complications to the calculation of present worth are savings versus returns, uncertainty, and externalities.

Savings vs. Income/Returns

In many, if not most, investments, the positive cash flows or benefits are actual cash inflows that result from sales of products produced by the investment. However, there are also a large number of investments in which the positive cash flows or benefits are represented by savings. For example, the benefit of investing in additional insulation for steam pipes within a refinery is savings in fuel costs (less fuel will be required

to produce steam). These savings can be represented in a present worth evaluation of the insulation as positive cash flows (i.e., as income or returns).

Uncertainty

In the present worth discussion up to this point, it has been assumed that all input values to the present worth calculation are known with precision. In fact, for most investments there is considerable uncertainty in these values — especially future cash flows. The preferred method for including such uncertainties in the calculation of present worth is to estimate the probability associated with each possible cash flow stream, calculate the present worth associated with that cash flow stream, and assign the probability of the cash flow to the present worth value. This will produce one present worth value and one probability for each possible cash flow stream (i.e., a probability distribution on the present worth of the investment). This distribution can then be used to find statistics such as the expected present worth value, the standard deviation of the present worth value, confidence intervals, and so forth. These statistics, especially the expected present worth value and confidence intervals, can then be used in the decision process.

Externalities

In many cases, not all costs and benefits are included in the cash flows because they are not easily quantified in terms of dollars or because they do not benefit or cost the investor directly. Such costs and benefits are referred to as *externalities* because they are generally considered external to the direct economic evaluation (i.e., they are not included in the present worth calculation). For example, the cost of air emissions from a refinery are often not considered in a present worth calculation, even though they impact the local community as well as the employees of the refinery. Such emissions may result in lost work days and more sick pay, as well as the loss of the local community's goodwill to the refinery, making future refinery expansion more difficult. Likewise, emissions may affect the health and quality of life of local residents.

Externalities can be considered qualitatively, along with measures such as the present worth, when evaluating an investment. Or externalities can be explicitly considered within a present worth calculation by estimating their costs and benefits in terms of dollars and including these dollars in present worth cash flows. In this case, these costs and benefits are said to have been *internalized* and are no longer externalities.

Defining Terms

Analysis period — The period during which the investor will consider the costs and benefits associated with an investment. This period is usually determined by the period during which the investor will develop, operate, and own the investment.

Cash flow — The dollar value of all costs and benefits in a given period. Cash flows are normally expressed in nominal dollars, but can be expressed in real dollars.

Discount rate — The interest rate that represents the time value of money to the investor. For most investors, this is the opportunity cost of capital (i.e., the rate of return that might be expected from other opportunities to which the same capital could be applied). Discount rates can include inflation (nominal discount rate) or exclude inflation (real discount rate).

Inflation rate — The annual rate of increase in a general price level, frequently estimated as the gross domestic product deflator or the gross national product deflator. Estimates of future value are generally provided by macroeconomic forecasting services.

Nominal dollars — Current dollars; dollars in the year that the cost or benefit is incurred.

Present worth — Net present value; the sum of all cash flows during the analysis period discounted to the present.

Real dollars — Constant dollars; value expressed in dollars of the base year. Real dollars are the value excluding inflation after the base year.

Robert G. Beaves
Robert Morris University

Many decision makers find rate-of-return investment criteria to be more intuitive and therefore easier to interpret than net present value (NPV). As a result the internal rate of return (IRR) continues to be widely used despite its legendary quirks and the well-established superiority of NPV. A second rate-of-return criterion, the modified internal rate of return (MIRR), provides more NPV consistency than does the IRR, but is less widely known and used. This chapter compares NPV, IRR, and MIRR and demonstrates some shortcomings of rate criteria.

203.1 Net Present Value

A project's *net present value* (NPV) represents *the change in the value of the firm* that is expected to result from the implementation of that project. The NPV of a *project* is calculated by summing the present values of all cash flows associated with it while preserving the negative signs of flows into the project and the positive signs of flows from the project. NPV can be defined as follows:

$$\text{NPV} = \sum_{t=0}^n a_t (1+k)^{-t} \quad (203.1)$$

where

- a_t = the cash flow at the time t (end of period t)
- k = the firm's opportunity cost; the discount or "hurdle" rate
- n = the number of periods in the project's life.

Implementation of a project that has a positive NPV increases firm value, whereas implementation of a project having a negative NPV reduces firm value. Because management's goal is to maximize firm value, a project should be rejected if its NPV is negative and accepted otherwise. When forced to choose among competing positive-NPV projects, the project that offers the highest NPV should be preferred because

it provides the largest increase in firm value. It is well established that the NPV criterion provides theoretically correct accept/reject and project-ranking decisions.

203.2 Internal Rate of Return

A project's *internal rate of return* (IRR) is that discount rate k^* for which that project's NPV is equal to zero. Note that a project's IRR is independent of the firm's *opportunity cost* k . A project's IRR represents *the average periodic rate of return earned on funds while they are invested in that project*. Because IRR is an average rather than a constant rate, the rate of return generated by a project in any one period will generally not equal its IRR. Indeed, the internal return earned by a project in any particular period is usually indeterminable.

Consider project A in Table 203.1, which has an IRR of 12.48%. Project A's rate of return during the first period (time 0 to time 1) is unknown. It is impossible to allocate the \$700 payment at time 1 between return of some portion of the initial \$1000 investment and return on that investment. Clearly the investment remaining in project A at time 1 need not be \$424.80 as would be the case if its 12.48% IRR was a constant rate (i.e., allocating \$124.80 of the \$700 released at time 1 to return on the initial investment and the remaining \$575.20 to return of investment). Although a project's IRR represents the average rate of return earned on funds invested in that project, the amount of funds so invested varies from period to period and is usually indeterminable.

A project should be rejected if its IRR is less than the firm's opportunity cost k and accepted otherwise. NPV and IRR provide the same accept/reject decisions for projects that have unique IRRs. The use of IRR for accept/reject decision is complicated, however, by the fact that some projects have multiple IRRs.

It is well established that ranking competing projects on the basis of their IRRs can provide an incorrect choice from among those projects. Consider projects A and B in Table 203.1. Both projects require the same \$1000 initial investment, have been assigned the same 10% opportunity cost and have the same 12.48% IRR. Thus, ranking projects A and B on the basis of their IRRs provides no clear preference. Nonetheless, project A's NPV is only \$34.56, whereas project B's is \$62.12. Project B has the higher NPV because its entire initial investment and any accumulating returns remain invested in project B and earning an average rate of 12.48% for three periods. On the other hand, much of project A's initial investment and accumulating returns are released from project A prior to time 3. Project A is the economic equivalent of project B only if its intermediate cash flows (\$700, \$300) can be "reinvested" to earn a 12.48% periodic return from the time they are released by project A to time 3.

Any two projects can be correctly ranked by examining the IRR of an incremental or "difference" project. Project B-A in Table 203.1 is such an incremental project for projects A and B created by subtracting each cash flow of A from the respective cash flow of B. Because the IRR of incremental project

TABLE 203.1 Projects A, B, and C^a

| | Project A | Project B | Project B-A | Project C |
|----------------------|------------|------------|-------------|------------|
| Time | | | | |
| 0 | -1,000 | -1,000 | 0 | -2,000 |
| 1 | 700 | 0 | -700 | 1,400 |
| 2 | 300 | 0 | -300 | 600 |
| 3 | 200 | 1,423 | 1,223 | 400 |
| Method | | | | |
| IRR | 12.48% | 12.48% | 12.48% | 12.48% |
| NPV | \$34.56 | \$69.12 | | \$69.12 |
| IB | \$1,000.00 | \$1,000.00 | | \$2,000.00 |
| MIRR | 11.25% | 12.48% | | 11.25% |
| MIRR ₂₀₀₀ | 10.63% | 11.25% | | 11.25% |

^a $k = 10\%$.

B-A exceeds the firm's 10% opportunity cost, project B (the project from which a second project was subtracted) should be preferred over A. If the IRR of the incremental project was less than k , project A would have been preferred. Because incremental IRR analysis can only provide pair-wise rankings, its use becomes tedious when more than two projects are being compared.

203.3 Modified Internal Rate of Return

A project's *modified internal rate of return* (MIRR) represents the *average periodic rate earned on a fixed investment amount* over the expected life of the project. That fixed investment amount is known as the project's *investment base*. A project's MIRR can be defined as

$$\text{MIRR} = \left[\frac{(\text{IB} + \text{NPV}) \times (1 + k)^n}{\text{IB}} \right]^{1/n} - 1.0 \quad (203.2)$$

where

NPV = the project's NPV, with k as discount rate

IB = the project's investment base; to be defined in greater detail later.

In calculating a project's MIRR, that project's investment base and any accumulated returns are assumed to earn the project's IRR while invested in the project and to earn the firm's opportunity cost when not retained by the project. Thus a project's MIRR is not really an "internal" rate in the sense that it is based solely on returns earned within the project. MIRR is better described as an "overall" rate that is based on all returns earned over the project's time horizon whether from the project itself or from external "reinvestment" of cash flows. Project B in [Table 203.1](#) has an MIRR of 12.48% because, for its entire 3-period life, that project's \$1000 investment base and all accumulated returns remain invested in the project B earning its 12.48% IRR. Project A's MIRR is lower because significant amounts of its investment base and accumulated returns are released at times 1 and 2 and are assumed to earn the firm's 10% opportunity cost for the balance of project A's life.

Projects with MIRRs greater than or equal to the firm's opportunity cost k should be accepted, whereas those with lower MIRRs should be rejected. As Equation (203.2) suggests, the MIRR always provides accept/reject decisions that are consistent with those provided by NPV. In contrast to the IRR, the MIRR is uniquely defined for projects that have at least one negative and one positive cash flow and is generally a function of the firm's opportunity cost k . Further, the MIRR provides an NPV-consistent ranking of competing projects that have the same scale or investment base IB.

When comparing projects having different investment bases, MIRRs adjusted to some common scale will provide an NPV-consistent ranking. Scale adjustments are required because the MIRR, like all rate criteria, does not preserve scale. Consider project C ([Table 203.1](#)), which was created by doubling project A's cash flows. Although a project's NPV doubles when its size is doubled, its IRR and MIRR are unchanged. This loss of scale in the calculation of rate of return criteria represents a serious shortcoming for their use in ranking projects.

203.4 Project Investment Base

A project's investment base represents the time 0 value of all external funds (i.e., funds not provided by the project itself) needed to finance the project. All projects considered thus far required a single cash inflow (i.e., negative flow), which occurred at time 0. The investment base of such projects is simply the amount of that initial inflow, $-a_0$. Because some projects have more complex cash flow patterns, it is necessary to establish the following general rule for determining a project's investment base: *A project's investment base is determined by multiplying the minimum cumulative present value associated with that project's stream of cash flows times -1.0 .*

TABLE 203.2 Project D^a

| | Cash Flow (<i>at</i>) | Present Value | Cumulative PV |
|--------|-------------------------|---------------|---------------|
| Time | | | |
| 0 | -1,000 | -1,000.00 | -1,000.00 |
| 1 | 300 | 272.73 | -727.27 |
| 2 | -400 | -330.58 | -1,057.85 |
| 3 | 700 | 525.92 | -531.93 |
| 4 | -500 | -341.51 | -873.44 |
| 5 | 1,500 | 931.38 | 57.94 |
| Method | | | |
| IRR | 11.48% | | |
| NPV | \$57.94 | | |
| IB | \$1,057.85 | | |
| MIRR | 11.18% | | |

^a $k = 10\%$.

Consider project D in Table 203.2, for which the firm's opportunity cost is assumed to be 10%. Using 10% as the discount rate, present values and cumulative present values are calculated for each of project D's cash flows. The minimum cumulative present value associated with project D's cash flows is -\$1057.85. Thus, project D's investment base is \$1057.85. Assuming a 10% opportunity cost for all funds not currently needed by project D, \$1057.85 is the minimum time 0 amount that will fund project D to its termination at time 5.

Note that the final cumulative present value listed in Table 203.2 is necessarily project D's NPV of \$57.94. Project D's MIRR is calculated by substituting into Equation (203.2) as follows:

$$\left[\frac{(57.94 + 1057.85) \times (1.10)^5}{1057.85} \right]^{1/5} - 1.0 = .1118$$

In other words, \$1057.85 committed to project D at time 0 will earn an average return of 11.18% per period for five periods.

There are other possible definitions of a project's investment base. One common definition is the sum of the present values of the project's negative cash flows times -1.0. That definition, however, overlooks the fact that negative cash flows can be funded from prior-occurring positive cash flows and any external returns earned on those cash flows. As a result, the project's investment base can be overstated and its MIRR understated. For example, the sum of the present values of the negative cash flows of project D times -1.0 is \$1672.09. Using that figure as project D's investment base would have produced an MIRR of 10.75%.

203.5 Scale-Adjusted MIRR

MIRR as defined in Equation (203.2) should only be used to compare projects of identical scale (i.e., the same investment base). Assuming projects B and C in Table 203.1 are mutually exclusive, they are not directly comparable on the basis of their MIRRs, because project C's 11.25% MIRR is earned on an investment base of \$2000, whereas project B's 12.48% MIRR is earned on an investment base of only \$1000. A project's MIRR can be adjusted to any scale by replacing its investment base (IB) in Equation (203.2) with the desired scale as follows:

$$\text{MIRR}_S = \left[\frac{(S + \text{NPV}) \times (1 + k)^n}{S} \right]^{1/n} - 1.0 \quad (203.3)$$

where MIRR_S is the project's MIRR adjusted to scale S and S is the desired scale to which the project's MIRR is being adjusted.

These scale adjustments are based on the assumption that differences in project scales can be invested at the firm's opportunity cost k . Investing at the firm's opportunity cost increases a project's scale but does not affect its NPV. Where two or more competing projects are being compared, the MIRR of all must be adjusted to a common scale (preferably the largest investment base among the projects). MIRR adjusted to a common scale of \$2000 were calculated in Table 203.1 for projects A, B, and C. Those scale-adjusted MIRR reveal that the firm should be indifferent in choosing between projects B and C but should prefer either to project A. These preferences are consistent with the NPV ranking of these three projects.

203.6 Project Life Differences

Comparing projects that have different project lives creates certain problems — no matter what decision criterion is being used. Such comparisons generally require an assumption as to what occurs at the end of each project's life — that is, whether the project is or is not replaced with a similar project. Where all competing projects are one-time expenditures with no replacement, their NPVs can be directly compared even if they have different project lives. Such comparison assumes that funds released by any project earn the firm's opportunity cost k until the end of the longest-lived project. In contrast, the MIRR of competing one-time projects cannot be directly compared if those projects have different lives. Rate criteria such as MIRR and IRR measure average performance per period over a project's life, whereas NPV measures cumulative performance over a project's life.

Consider projects E and F in Table 203.3. If we assume that both projects are one-time expenditures that will not be replaced at the end of their respective lives, the MIRR of projects E and F are not directly comparable. Project E earns an average rate of 13.05% per period for three periods, whereas project F earns an average rate of 11.92% per period for five periods. The MIRR of any project can be calculated over a common life z periods longer than its project life as follows, by assuming that all funds can be invested at the firm's opportunity cost k during those z additional periods:

$$\text{MIRR}_{S,n+z} = \left[\frac{(S + \text{NPV}) \times (1+k)^{(n+z)}}{S} \right]^{1/(n+z)} - 1.0 \quad (203.4)$$

where $\text{MIRR}_{S,n+z}$ is the project's MIRR adjusted to common scale S and common life $n + z$, and $n + z$ is the common life over which the project's MIRR is being calculated. Adjusted to project F's five-period life, project E's MIRR is 11.82% and is less than project F's MIRR of 11.92%. Thus, MIRR calculated over a common five-period life provide the same ranking of projects E and F as is provided by their NPVs.

TABLE 203.3 Project E and F^a

| | Project E | Project F |

| IB | \$25,000.00 | | \$15,478.26 | |
| MIRR | 16.34% | | 17.57% | |
| MIRR _{25000,5} | 16.34% | | 16.29% | |

^a $k = 15\%$.

Where competing projects are assumed to be replaced at the end of their initial project lives, project rankings for projects having different lives cannot simply be based on the NPVs of the respective projects. Instead, revised projects are generated for each competing project by extending their cash flow streams to some common terminal point. NPVs and MIRRs calculated for such revised projects should provide consistent project rankings.

Example: Project Analyses

A firm has been approached by two different manufacturers who want to sell it machines that offer labor savings. The firm will buy one machine at most because both machines perform virtually the same services and either machine has sufficient capacity to handle the firm's entire needs (i.e., mutually exclusive projects). The firm's cost accounting department has provided management with projected cash flow streams for each of these machines (Table 203.4) and has suggested a 15% opportunity cost for these machines. When one considers of the IRRs and unadjusted MIRR of machines A and B in Table 203.4, it is clear that both are acceptable, since the IRR and the MIRR of each exceeds the firm's 15% opportunity cost. It may appear that machine B should be favored because both its IRR and its unadjusted MIRR are higher than those of machine A. Note, however, that machines A and B have different investment bases and different lives. Adjusting machine B's MIRR to A's larger scale of \$25,000 and to project A's longer five-period life lowers it from 17.57% to 16.29%. When adjusted to a common scale and a common life, the MIRR of machines A and B provide the same ranking of those two projects as does NPV.

203.7 Conclusion

Rate-of-return criteria can provide correct accept or reject decisions for individual projects and can correctly rank competing projects when used properly. The concept of a rate of return seems easier to understand than NPV. After all, most personal investments (stocks, bonds, CDs, etc.) are ranked according to their rates of return. The NPV criterion, however, is the "gold standard" and its characteristics of preserving project scale and measuring cumulative performance make it more convenient to use when ranking projects.

Rate-of-return criteria should be viewed as complementing the NPV by providing project performance information in a slightly different form. The IRR provides the average rate earned per period on funds invested in the project itself while they remain so invested. In contrast, the MIRR provides the average

rate earned per period on the project's investment base over the entire life of the project, assuming that funds earn the firm's opportunity cost when not invested in the project itself.

Defining Terms

Internal rate of return — The average periodic rate earned on funds invested in the project itself.

Investment base — The time 0 value of the funds that must be provided to (invested in) the project during its life.

Modified internal rate of return — The average periodic rate earned on the project's investment base over the life of the project.

Net present value — The expected increase in a firm's value if and when it implements the project.

Opportunity cost — The rate of return the firm believes it can earn on projects of similar risk. Also referred to as the *minimum required return*, the *discount rate*, or the project's *hurdle rate*.

Project — A potential investment represented by a stream of cash flows of which at least one cash flow is positive and at least one is negative.

[204.5 Conclusion](#)

Practical engineering and management requires choices among competing alternatives. Which boiler should be used in a plant? What kind of instrumentation should be planned for a new multistory building? Which financing scheme would be most desirable for a new facility? These are practical questions that arise in the ordinary course of engineering design, organizational management, and even personal finances. This chapter is intended to present methods for choosing the best among distinct alternatives.

204.1 Problem Statement for Project Selection

The economic project selection problem is to identify the best from a set of possible alternatives. Selection is made on the basis of a systematic analysis of expected revenues and costs over time for each project alternative. Usually, the objective is to maximize the overall net benefits of the selected project or projects, although other objectives such as minimizing environmental impact might be pursued. Here, we focus on the overall net benefits.

Project selection falls into three general classes of problems. Accept-reject problems (also known as a *determination of feasibility*) require an assessment of whether an investment is worthwhile. For example, the hiring of an additional engineer in a design office is an accept-reject decision. Selection of the best project from a set of mutually exclusive projects is required when there are several competing projects or options and only one project can be built or purchased. For example, three different configurations of a new sewage treatment plant may be considered, but only one configuration will be built. Finally, capital budgeting problems are concerned with the selection of a set of projects when there is a budget constraint and many, not necessarily competing, options. For example, a state highway agency will consider many different highway rehabilitation projects for a particular year, but generally the budget is insufficient to allow all to be undertaken, although they may all be feasible.

204.2 Steps in Carrying Out Project Selection

A systematic approach for economic evaluation of projects includes the following major steps [Hendrickson and Au, 1989]:

1. Generate a set of project or purchase *alternatives* for consideration. Each alternative represents a distinct component or combination of components constituting a purchase or project decision. We shall denote project alternatives by the subscript x , where $x = 1, 2, \dots$ refers to projects 1, 2, and so on.
2. Establish a *planning horizon* for economic analysis. The planning horizon is the set of future periods used in the economic analysis. It could be very short or long. The planning horizon may be set by organizational policy (e.g., 5 years for new computers or 50 years for new buildings), by the expected economic life of the alternatives, or by the period over which reasonable forecasts of operating conditions may be made. The planning horizon is divided into discrete periods — usually years, but sometimes shorter units such as months. We shall denote the planning horizon as a set of $t = 0, 1, 2, 3, \dots, n$, where t indicates different periods, with $t = 0$ being the present, $t = 1$, the first period, and $t = n$ representing the end of the planning horizon.
3. Estimate the *cash flow profile* for each alternative. The cash flow profile should include the revenues and costs for the alternative being considered during each period in the planning horizon. For public projects, revenues may be replaced by estimates of benefits for the public as a whole. In some cases, revenues may be assumed to be constant for all alternatives, so only costs in each period are estimated and the problem simplifies to one of cost minimization. Cash flow profiles should be specific to each alternative, so the costs avoided by not selecting one alternative (say, $x = 5$) are not included in the cash flow profile of the alternatives ($x = 1, 2$, and so on). Revenues for an alternative x in period t are denoted $B(t, x)$, and costs are denoted $C(t, x)$. Revenues and costs should initially be in *base-year* or constant dollars. Base-year dollars do not change with inflation or deflation. For tax-exempt organizations and government agencies, there is no need to speculate on inflation if the cash flows are expressed in terms of base-year dollars and a MARR without an inflation component is used in computing the net present value (NPV). For private corporations that pay taxes on the basis of then-current dollars, some modification should be made to reflect the projected inflation rates when considering depreciation and corporate taxes.
4. Specify the *minimum attractive rate of return (MARR)* for discounting. Revenues and costs incurred at various times in the future are generally not valued equally to revenues and costs occurring in the present. After all, money received in the present can be invested to obtain interest income over time. The MARR represents the tradeoff between monetary amounts in different periods and does not include inflation. The MARR is usually expressed as a percentage change per year. For many public projects, the MARR is based on the guidelines provided by the Office of Management and Budget (OMB 1992, OMB 2003). In 2003, the recommended MARR on 30-year projects is 3.2%. The value of MARR is usually set for an entire organization based upon the opportunity cost of investing funds internally rather than externally in the financial markets. For public projects the value of MARR is a political decision, so MARR is often called the *social rate of discount* in such cases. The equivalent value of a dollar in a following period is calculated as $(1 + \text{MARR})$, and the equivalent value two periods in the future is $(1 + \text{MARR})(1 + \text{MARR}) = (1 + \text{MARR})^2$. In general, if you have Y dollars in the present — denoted $Y(0)$, then the future value in time t — denoted $Y(t)$ is

$$Y(t) = Y(0)(1 + \text{MARR})^t \quad (204.1)$$

or the present value, $Y(0)$, of a future dollar amount $Y(t)$ is

$$Y(0) = Y(t) / (1 + \text{MARR})^t \quad (204.2)$$

5. Establish the criterion for accepting or rejecting an alternative and for selecting the best among a group of mutually exclusive alternatives. The most widely used and simplest criterion is the *net present value* criterion. Projects with a positive NPV are acceptable. From a set of mutually exclusive alternatives (from which only one alternative may be selected), the alternative with the highest

NPV is best. The next section details the calculation steps for the NPV and also some other criterion for selection.

6. Perform sensitivity and uncertainty analysis. Calculation of NPVs assumes that cash flow profiles and the value of MARR are reasonably accurate. In many cases, assumptions are made in developing cash flow profile forecasts. Sensitivity analysis can be performed by testing a variety of such assumptions, such as different values of MARR, to see how alternative selection might change. Formally treating cash flow profiles and MARR values as stochastic variables can be done with probabilistic and statistical methods.

204.3 Selection Criteria

Net Present Value

Calculation of NPVs to select projects is commonly performed on electronic calculators, on commercial spreadsheet software, or by hand. The easiest calculation approach is to compute the net revenue in each period for each alternative, denoted $A(t, x)$:

$$A(t, x) = B(t, x) - C(t, x) \quad (204.3)$$

where $A(t, x)$ may be positive or negative in any period. Then, the NPV of the alternative, $NPV(x)$, is calculated as the sum over the entire planning horizon of the discounted values of $A(t, x)$:

$$NPV(x) = \sum_{t=0}^n A(t, x) / (1 + \text{MARR})^t \quad (204.4)$$

Other Methods

Several other criteria may be used to select projects. Other discounted flow methods include *net future value*, denoted $NFV(x)$, and *equivalent uniform annual value*, denoted $EUAV(x)$. It can be shown [Au and Au, 1992] that these criteria are equivalent where

$$NFV(x) = NPV(x)(1 + \text{MARR})^n \quad (204.5)$$

$$EUAV(x) = \frac{NPV(x) \cdot \text{MARR} \cdot (1 + \text{MARR})^n}{[(1 + \text{MARR})^n - 1]} \quad (204.6)$$

The net future value is the equivalent value of the project at the end of the planning horizon. The equivalent uniform annual value is the equivalent series in each year of the planning horizon.

Alternatively, benefit-to-cost ratio (the ratio of the discounted benefits to discounted costs) and the internal rate of return (the equivalent MARR at which $NPV[x] = 0$) are merit measures, each of which may be used to formulate a decision. For accept-reject decisions, the benefit-to-cost ratio must be greater than one and the internal rate of return greater than the MARR. However, these measures must be used in connection with incremental analyses of alternatives to provide consistent results for selecting among mutually exclusive alternatives (see, for instance, Au and Au [1992]).

Similarly, the payback period provides an indication of the time it takes to recoup an investment but does not indicate the best project in terms of expected net revenues over the entire planning horizon. Algebraically, the payback period is calculated by summing up cash flows until the sum becomes positive:

$$PBP(x) = \text{lowest } k \text{ for which } \sum_{t=0}^k B(t, x) \geq \sum_{t=0}^k C(t, x)$$

204.4 Applications

To illustrate the application of these techniques and the calculations involved, two examples are presented.

Example 204.1: Alternative Bridge Designs

A state highway agency is planning to build a new bridge and is considering two distinct configurations. The initial costs and annual costs and benefits for each bridge are shown in the following table. The bridges are each expected to last 30 years.

| | Alternative 1 | Alternative 2 |
|--|---------------|---------------|
| Initial cost | \$15,000,000 | \$25,000,000 |
| Annual maintenance and operating costs | \$15,000 | \$10,000 |
| Annual benefits | \$1,200,000 | \$1,900,000 |
| Annual benefits less costs | \$1,185,000 | \$1,890,000 |

Solution. The NPVs for a MARR of 0.05 (5%) are given as follows:

$$\begin{aligned} \text{NPV}(1) &= (-15\,000\,000) + (1\,185\,000)/(1+0.05) + (1\,185\,000)/(1+0.05)^2 \\ &\quad + (1\,185\,000)/(1+0.05)^3 + \dots + (1\,185\,000)/(1+0.05)^{30} \\ &= \$3\,216\,354 \end{aligned}$$

$$\begin{aligned} \text{NPV}(2) &= (-15\,000\,000) + (1\,890\,000)/(1+0.05) + (1\,890\,000)/(1+0.05)^2 \\ &\quad + (1\,890\,000)/(1+0.05)^3 + \dots + (1\,890\,000)/(1+0.05)^{30} \\ &= \$4\,053\,932 \end{aligned}$$

Therefore, the department of transportation should select the second alternative, which has the largest NPV. Both alternatives are acceptable since their NPVs are positive, but the second alternative has a higher net benefit.

Example 204.2: Equipment Purchase

Consider two alternative systems for providing side collision warnings for transit buses [McNeil et al., 2002]. The first method is a manual one based on the alertness of the driver; and the second is a driver aid using specialized sensors. Which method should be used? We shall solve this problem by analyzing whether the new driver aid has benefits in excess of the existing manual method minus the additional costs.

Solution. Following the steps outlined earlier, the problem is solved as follows:

1. The alternatives for consideration are the existing driver-based method, and the sensor-based warning system. The alternatives are mutually exclusive because the adoption of one precludes the other.
2. The planning horizon is assumed to be 3 years to coincide with the expected life of the sensors.
3. A transit agency in a medium-sized city has approximately 900 buses.
4. The side collision warning systems is expected to either eliminate or reduce the severity of crashes, saving \$4 million per year
5. The cash flow profile for alternative 2 is given in the following table.

| | |
|--|-----------------|
| System acquisition costs | \$5,000 per bus |
| Annual maintenance and operating costs | \$1,000 per bus |
| Annual crash savings | \$4,000,000 |
| Annual savings over costs | \$3,100,000 |

TABLE 204.1 Relative Net Present Value of New Equipment with Different Assumptions

| Acquisition Cost (per bus) (\$) | Annual Crash Savings (\$) | Annual Maintenance and Operation (per bus) (\$) | MARR | | |
|---------------------------------------|---------------------------------|---|---------------|---------------|---------------|
| | | | 0.02 | 0.05 | 0.08 |
| 3,000 | 2,500,000 | 1,000 | \$1,914,213 | \$1,657,197 | \$1,423,355 |
| 5,000 | 2,500,000 | 1,000 | \$114,213 | (\$142,803) | (\$376,645) |
| 7,000 | 2,500,000 | 1,000 | (\$1,685,787) | (\$1,942,803) | (\$2,176,645) |
| 3,000 | 4,000,000 | 1,000 | \$6,240,038 | \$5,742,069 | \$5,289,001 |
| 5,000 | 4,000,000 | 1,000 | \$4,440,038 | \$3,942,069 | \$3,489,001 |
| 7,000 | 4,000,000 | 1,000 | \$2,640,038 | \$2,142,069 | \$1,689,001 |

The values are estimated using engineering judgment, an analysis of historical crash records, and widely accepted estimates of the costs of crashes.. The MARR is assumed to be 0.05 (5%). The NPV is computed as follows.

$$\begin{aligned}
 NPV(2) = & -4,500,000 + 3,100,000/(1 + 0.05) + 3,100,000/(1 + 0.05)^2 \\
 & + 3,100,000/(1 + 0.05)^3 = \$3,942,069 \qquad (204.7)
 \end{aligned}$$

- Using the criterion $NPV(2) > 0$, so alternative 2 is selected.
- To determine the sensitivity of the result to some of the assumptions, consider Table 204.1. The table indicates that if the annual saving in crash costs is reduced to \$2,500,000 per year, the additional investment in the side collision warning system is justifiable at the MARR of 0.02 (2%) but not at a MARR of 0.05 (5%).

This example illustrates the use of the NPV criteria for an incremental analysis, which assumes that the benefits are constant for both alternatives and examines incremental costs for one project over another.

204.5 Conclusion

This chapter has presented the basic steps for assessing economic feasibility and selecting the best project from a set of mutually exclusive projects, with NPV as a criterion for making the selection.

Defining Terms

- Alternatives** — A distinct option for a purchase or project decision.
- Base year** — The year used as the baseline of price measurement of an investment project.
- Cash flow profile** — Revenues and costs for each period in the planning horizon.
- Equivalent uniform annual value** — Series of cash flows with a discounted value equivalent to the net present value.
- Minimum attractive rate of return (MARR)** — Percentage change representing the time value of money.
- Net future value** — Algebraic sum of the computed cash flows at the end of the planning horizon.
- Net present value** — Algebraic sum of the discounted cash flows over the life of an investment project to the present.
- Payback period** — The first period for which the sum of revenues exceeds the sum of costs.
- Planning horizon** — Set of time periods from the beginning to the end of the project; used for economic analysis.

The government levies taxes on corporations and individuals to meet its cost of operations. Regulations on depreciation allowances are part of taxation policy. The tax laws promulgated by the federal government profoundly influence capital investments undertaken by private corporations. Economic valuation of the after-tax cash flows of an investment project based on projected tax rates and inflation effects provides a rational basis for accepting or rejecting investment projects.

205.1 Depreciation as Tax Deduction

Depreciation refers to the decline in value of physical assets over their estimated useful lives. In the context of tax liability, *depreciation allowance* refers to the amount allowed as a deduction in computing taxable income, and *depreciable life* refers to the estimated useful life over which depreciation allowances are computed. The depreciation allowance is a systematic allocation of the cost of a physical asset over time. A *fully depreciated* asset has received depreciation allowances equal to its original purchase price.

The methods of computing depreciation and the estimated useful lives for various classes of physical assets are specified by government regulations as a part of the tax code, which is subject to periodic revisions. Different methods of computing depreciation lead to different annual depreciation allowances and hence have different effects on taxable income and the taxes paid.

Let P be the purchase cost of an asset, S its estimated salvage value, and N the depreciable life in years. Let D_t denote the depreciable allowance in year t , and T_t denote the accumulated depreciation up to and including year t . Then for $t = 1, 2, \dots, N$,

$$T_t = D_1 + D_2 + \dots + D_t \quad (205.1)$$

An asset's book value B_t is simply its historical cost less any accumulated depreciation. Then

$$B_t = P - T_t \quad (205.2)$$

or

$$B_t = B_{t-1} - D_t \quad (205.3)$$

Among the depreciation methods acceptable under the tax regulations, the straight-line method is the simplest. Using this method, the uniform annual allowance in each year is

$$D_t = (P - S) / N \quad (205.4)$$

Other acceptable methods, known as *accelerated depreciation methods*, yield higher depreciation allowances in the earlier years of an asset and less in the later years than those obtained by the straight-line method. Examples of such methods are sum-of-the-years'-digits depreciation and double-declining-balance depreciation [Au and Au, 1992]. For example, the double-declining-balance depreciation allowance in any year t is:

$$D_t = \frac{2P}{N} (1 - 2/N)^{t-1} \quad (205.5)$$

Under the current IRS regulations on depreciation, known as the Modified Accelerated Cost Reduction System (MACRS), the estimated useful life of an asset is determined by its characteristics that fit one of the eight specified categories. Furthermore, the salvage value S for all categories is assumed to be zero and all assets with a life of 10 years or less are assumed to be purchased and sold at mid-year. The MACRS schedules are generally double-declining balance switching to straight-line depreciation or straight-line depreciation alone for the longer property life periods. The MACRS depreciation schedules for 3-, 5-, 7- and 10- year recovery periods are shown in Table 205.1, where each entry in the table is the allowable percentage of the purchase cost depreciation allowance in that year. Table 205.2 shows some example assets for the 3- to 10-year recovery schedules. Note that the MACRS schedule can be changed at any time, so accessing up-to-date information for computing allowable depreciation amounts is advisable.

205.2 Tax Laws and Tax Planning

Capital projects are long-lived physical assets for which the promulgation and revisions of tax laws may affect tax liability. For the purpose of planning and evaluating capital projects, it is important to under-

TABLE 205.2 Recovery Period and Examples of Property Class for MACRS Depreciation

| Recovery Period | Examples of Depreciable Assets |
|-----------------|---|
| 3 years | Qualified rent-to-own property, race horse |
| 5 years | Automobiles, office equipment |
| 7 years | Office furniture, railroad track |
| 10 years | Vessels, barges, and tugs, fruit- or nut-bearing trees or vines |

Source: Internal Revenue Service. 2002. *Instructions for Form 4562 Depreciation and Amortization*. U.S. Department of the Treasury, Washington, DC.

stand the underlying principles, including adjustments for the transition period after each revision and for multiyear “carry-back” or “carry-forward” of profits and losses.

The federal income tax is important to business operations because profits are taxed annually at substantial rates on a graduated basis. Except for small businesses, the corporate taxes on ordinary income may be estimated with sufficient accuracy by using the marginal tax rate. *Capital gain*, which represents the difference between the sale price and the book value of an asset, is taxed at a rate lower than on ordinary income for private individuals if it is held longer than a period specified by tax laws. For corporations in 2003, capital gains are taxed at the same rate as other taxable income.

Some state and/or local governments also levy income taxes on corporations. Generally, such taxes are deductible for federal income tax to avoid double taxation. The computation of income taxes can be simplified by using a combined marginal tax rate to cover the federal, state, and local income taxes. If F is the federal marginal rate on taxable income, R is the state marginal tax rate and X is the combined rate, then:

$$X = F + R - F \cdot R \quad (205.6)$$

Tax planning is an important element of private capital investment analysis because the economic feasibility of a project is affected by the taxation of corporate profits. In making estimates of tax liability, several factors deserve attention: (1) number of years for retaining the asset, (2) depreciation method used, (3) method of financing, including purchase versus lease, (4) capital gain upon the sale of the asset, and (5) effects of inflation. Appropriate assumptions should be made to reflect these factors realistically.

205.3 Decision Criteria for Project Selection

The economic evaluation of an investment project is based on the merit of the *net present value (NPV)*, which is the algebraic sum of the discounted net cash flows over the life of the project to the present. The discount rate is the minimum attractive rate of return specified by the corporation.

The evaluation of proposed investment projects is based on NPV criteria, which specify the following: (1) an independent project should be accepted if the NPV is positive and rejected otherwise; and (2) among all acceptable projects that are mutually exclusive, the one with the highest positive NPV should be selected.

205.4 Inflation Consideration

Consideration of the effects of inflation on economic evaluation of a capital project is necessary because taxes are based on then-current dollars in future years. The year in which the useful life of a project begins is usually used as the baseline of price measurement and is referred to as the *base year*. A *price index* is the ratio of the price of a predefined package of goods and service at a given year to the price of the same package in the base year. The common price indices used to measure inflation include the

consumer price index, published by the Department of Labor, and the gross domestic product price deflator, compiled by the Department of Commerce.

For the purpose of economic evaluation, it is generally sufficient to project the future inflation trend by using an average annual inflation rate j . Let A_t be the cash flow in year t , expressed in terms of base-year (year 0) dollars, and A'_t be the cash flow in year t , expressed in terms of then-current dollars. Then

$$A'_t = A_t(1 + j)^t \quad (205.7)$$

$$A_t = A'_t(1 + j)^{-t} \quad (205.8)$$

In the economic evaluation of investment proposals in an inflationary environment, two approaches may be used to offset the effects of inflation. Each approach leads to the same result if the discount rate i , excluding inflation, and the rate i' , including inflation, are related as follows:

$$i' = (1 + i)(1 + j) - 1 = i + j + ij \quad (205.9)$$

$$i = (i' - j) / (1 + j) \quad (205.10)$$

The NPV of an investment project over a planning horizon of n years can be obtained by using the constant price approach as follows:

$$\text{NPV} = \sum_{t=0}^n A_t (1 + i)^{-t} \quad (205.11)$$

Similarly, the NPV obtained by using the then-current price approach is

$$\text{NPV} = \sum_{t=0}^n A'_t (1 + i')^{-t} \quad (205.12)$$

In some situations the prices of certain key items affecting the estimates of future incomes and/or costs are expected to escalate faster than the general inflation. For such cases the differential inflation for those items can be included in the estimation of the cash flows for the project.

205.5 After-Tax Cash Flows

The economic performance of a corporation over time is measured by the net cash flows after tax. Consequently, after-tax cash flows are needed for economic evaluation of an investment project. Since interest on debts is tax deductible according to the federal tax laws, the method of financing an investment project could affect net profits. Although the projected net cash flows over the years must be based on then-current dollars for computing taxes, the depreciation allowances over those years are not indexed for inflation under the current tax laws.

It is possible to separate the cash flows of a project into an operating component and a financing component for the purpose of evaluation. Such separation will provide better insight to the tax advantage of borrowing to finance a project, and the combined effect of the two is consistent with the computation based on a single combined net cash flow. The following notations are introduced to denote various items in year t over a planning horizon of n years:

A_t = net cash flow of operation (excluding financing cost) before tax

A_f = net cash flow of financing before tax

$A_t = A_t + A_t =$ combined net cash flow before tax
 $Y_t =$ net cash flow of operation (excluding financing cost) after tax
 $Y_t =$ net cash flow of financing after tax
 $Y_t = Y_t + Y_t =$ combined net cash flow after tax
 $D_t =$ annual depreciation allowance
 $I_t =$ annual interest on the unpaid balance of a loan
 $Q_t =$ annual payment to reduce the unpaid balance of a loan
 $W_t =$ annual taxable income
 $X_t =$ annual marginal income tax rate
 $K_t =$ annual income tax

Thus, for operation in year $t = 0, 1, 2, \dots, n$,

$$W_t = A_t - D_t \quad (205.13)$$

$$K_t = X_t W_t \quad (205.14)$$

$$Y_t = A_t - X_t(A_t - D_t) \quad (205.15)$$

For financing in year $t = 0, 1, 2, \dots, n$,

$$I_t = Q_t - A_t \quad (205.16)$$

$$Y_t = A_t + X_t I_t \quad (205.17)$$

where the term $X_t I_t$ is referred to as the *tax shield* because it represents a gain from debt financing due to the deductibility of interest in computing the income tax.

Alternately, the combined net cash flows after tax may be obtained directly by noting that both depreciation allowance and interest are tax deductible. Then,

$$W_t = A_t - D_t - I_t \quad (205.18)$$

$$Y_t = A_t - X_t(A_t - D_t - I_t) \quad (205.19)$$

It can be verified that Equation (205.19) can also be obtained by adding Equations (205.15) and (205.17), while noting $A_t = A_t + A_t$ and $Y_t = Y_t + Y_t$.

When an asset is sold, capital gains taxes must be paid on the difference between the sale price and the book value (as calculated by Equations (205.1) and (205.2)). If the sale price is less than the book value, a capital loss is incurred. Capital losses can be used to offset capital gains.

205.6 Evaluation of After-Tax Cash Flows

For private corporations, the decision to invest in a capital project may have side effects on the financial decisions of the firm, such as taking out loans or issuing new stock. These financial decisions will influence the overall equity-debt mix of the entire corporation, depending on the size of the project and the risk involved.

Traditionally, many firms have used an adjusted cost of capital, which reflects the opportunity cost of capital and the financing side effects, including tax shields. Thus, only the net cash from operation Y_t obtained by Equation (205.15) is used when the NPV is computed. The after-tax net cash flows of a proposed project are discounted by substituting Y_t for A_t in Equation (205.11), using after-tax adjusted

cost of capital of the corporation as the discount rate. If inflation is anticipated, Y_t' can first be obtained in then-current dollars and then substituted into Equation (205.12). The selection of the project will be based on the NPV thus obtained without further consideration of tax shields, even if debt financing is involved. This approach, which is based on the adjusted cost of capital for discounting, is adequate for small projects such as equipment purchase.

In recent years another approach, which separates the investment and financial decisions of a firm, is sometimes used for evaluation of large capital projects. In this approach, the net cash flows of operation are discounted at a risk-adjusted rate reflecting the risk for the class of assets representing the proposed project, whereas tax shields and other financial side effects are discounted at a risk-free rate corresponding to the yield of government bonds. An adjusted NPV reflecting the combined effects of both decisions is then used as the basis for project selection. Detailed discussion of this approach may be found elsewhere [Brealey and Myers, 2000].

205.7 Effects of Various Factors

Various depreciation methods will produce different effects on the after-tax cash flows of an investment. Since the accelerated depreciation methods generate larger depreciation allowances during the early years, the NPV of the after-tax cash flows using one of the accelerated depreciation methods is expected to be more favorable than that obtained by using the straight-line method.

If a firm lacks the necessary funds to acquire a physical asset that is deemed desirable for operation, it can lease the asset by entering into a contract with another party, which will legally obligate the firm to make payments for a well-defined period of time. The payments for leasing are expenses that can be deducted in full from the gross revenue in computing taxable income. The purchase-or-lease options can be compared after their respective NPVs are computed.

When an asset is held for more than a required holding period under tax laws, the capital gain is regarded as long-term capital gain. In a period of inflation the sale price of an asset in then-current dollars increases, but the book value is not allowed to be indexed to reflect the inflation. Consequently, capital gain tax increases with the surge in sale price resulting from inflation.

Example 205.1

Suppose a light, general-purpose truck is purchased for \$25,000 in February. This truck is expected to generate a before-tax uniform annual revenue of \$7,000 over the next 6 years, with no salvage value at the end of 6 years. According to the current IRS regulations, this truck is assigned to a 5-year property class with no salvage value after the depreciation period. The MACRS schedule in [Table 205.1](#) is used to compute the annual depreciation allowance. The combined federal and state income tax rate is 38%. Assuming no inflation, the after-tax discount rate of 8%, based on the adjusted cost of capital of the corporation, is used. Determine whether this investment proposal should be accepted.

Solution. Using the 5-year recovery period schedule in [Table \(205.1\)](#), the annual depreciation allowance D_t is found to be \$25,000 multiplied by the allowable percentage depreciation allowance in each year. We assume that the tax loss in year 2 may be offset by income elsewhere, so the loss results in a tax shield of \$380. Tax amounts are rounded to the nearest dollar.

| Period T | Capital Investment | Before-Tax Cash Flow, A_t | Depreciation Allowance D_t | Taxable Cash Flow $A_t - D_t$ | Taxes Kt | After-Tax Cash Flow Y_t' |
|-------------|-----------------------|--------------------------------|---------------------------------|----------------------------------|---------------|-------------------------------|
| 0 | -25,000 | | — | — | — | -25,000 |
| 1 | | 7,000 | 5,000 | 2,000 | 760 | 6,240 |
| 2 | | 7,000 | 8,000 | -1,000 | -380 | 7,380 |
| 3 | | 7,000 | 4,800 | 2,200 | 836 | 6,164 |
| 4 | | 7,000 | 2,880 | 4,120 | 1,566 | 5,434 |

| Period T | Capital Investment | Before-Tax Cash Flow, A_t | Depreciation Allowance D_t | Taxable Cash Flow $A_t - D_t$ | Taxes Kt | After-Tax Cash Flow Y_t |
|-------------|-----------------------|--------------------------------|---------------------------------|----------------------------------|---------------|------------------------------|
| 5 | | 7,000 | 2,880 | 4,120 | 1,566 | 5,434 |
| 6 | | 7,000 | 1,440 | 5,560 | 2,113 | 4,887 |

Using the adjusted cost of capital approach, the NPV of the after-tax net cash flows discounted at 8% is obtained by substituting Y_t for A_t in Equation (205.11),

$$\begin{aligned} \text{NPV} = & -25\,000 + (6240)(P|F, 8\%, 1) + (7380)(P|F, 8\%, 2) + (6194)(P|F, 8\%, 3) \\ & + (5434)(P|F, 8\%, 4) + (5434)(P|F, 8\%, 5) + (4887)(P|F, 8\%, 6) = 2794 \end{aligned}$$

in which $(P|F, 8\%, t) = 1/(1.08)^t$ is the present worth factor of a future amount discounted at an 8% rate for t years. Since NPV = \$2,794 is positive, the proposed investment should be accepted.

Example 205.2

Consider a proposal for the purchase of a computer workstation that costs \$20,000 and has no salvage value at disposal after 4 years. This investment is expected to generate a before-tax uniform annual revenue of \$7,000 in base-year dollars over the next 4 years. An average annual inflation rate of 5% is assumed. The MACRS 5-year property depreciation schedule is used to compute the annual depreciation allowance. The combined federal and state income tax rate is 38%. Based on the adjusted cost of capital of the corporation, the after-tax discount rate, including inflation, is 10%. Determine whether this investment proposal should be accepted.

Solution. Depreciation in each year is calculated by multiplying the 5-year depreciation percentage in each year by \$20,000. This annual depreciation allowance will not be indexed for inflation, according to the IRS regulations. At the end of the 4 years, the computer has a book value of \$3,456 (as calculated from Equation 205.1 and 205.2). When the computer is disposed of with no salvage value, this amount would represent a capital loss that could be used to offset capital gains accumulated elsewhere in the business. Taxes in year 4 would then be \$3,509 multiplied by the combined marginal tax rate (0.38) less the capital-gain tax shield of \$3,456 multiplied by the combined marginal tax rate (0.38).

The annual before-tax revenue of \$7,000 in base-year dollars must be expressed in then-current dollars before computing the income taxes. From Equation (205.7),

$$A'_t = (7000)(1 + 0.05)^t$$

where $t = 1$ to 4 refers to each of the next 4 years. The after-tax cash flow Y'_t for each year can be computed by Equation (205.15). The step-by-step tabulation of the computation for each year is shown in the following table.

| Period T | Capital Investment | Before Tax Cash Flow (Base Year \$) A_t | Before Tax Cash Flow (Current Year \$) A'_t | Depreciation D_t | Taxable Income $A'_t - D_t$ | Capital Loss | Taxes Kt | After Tax Cash Flow Y'_t |
|-------------|-----------------------|---|---|-----------------------|-----------------------------------|-----------------|---------------|----------------------------------|
| 0 | -20,000 | | | | | | | -20,000 |
| 1 | | 7,000 | 7,350 | 4,000 | 3,350 | | 1,273 | 6,077 |
| 2 | | 7,000 | 7,718 | 6,400 | 1,318 | | 501 | 7,217 |
| 3 | | 7,000 | 8,013 | 3,840 | 4,123 | | 1,586 | 6,427 |
| 4 | | 7,000 | 8,509 | 2,304 | 6,205 | 3,456 | 1,045 | 7,464 |

Using the adjusted cost of capital approach, the NPV of the after-tax cash flows discounted at $i' = 10\%$, including inflation, can be obtained by substituting the value of Y'_t for A'_t in Equation (205.10) as follows:

$$\begin{aligned} \text{NPV} &= -20\,000 + (6077)(1.1)^{-1} + (7217)(1.1)^{-2} + (6427)(1.1)^{-3} + (7464)(1.1)^{-4} \\ &= 1416 \end{aligned}$$

Since $\text{NPV} = \$1416$ is positive, the investment proposal should be accepted.

Example 205.3

A developer bought a plot of land for \$100,000 and spent \$1.6 million to construct an apartment building on the site for a total price of \$1.7 million. The before-tax annual rental income after the deduction of maintenance expenses is expected to be \$300,000 in the next 6 years, assuming no inflation. The developer plans to sell this building at the end of 6 years when the property is expected to appreciate to \$2.1 million, including land. Suppose the entire cost of construction can be depreciated over 32 years based on the straight-line depreciation method, whereas the original cost of land may be treated as the salvage value at the end. The tax rates are 34% for ordinary income and 28% for capital gain, respectively. Based on the adjusted cost of capital, the developer specifies an after-tax discount rate of 10%.

Solution. Using Equation (205.4), the annual depreciation allowance D_t over 32 years is found to be \$50,000. Noting that $P = 1\,700,000$ and $T_t = (6)(50\,000) = 300,000$, the book value of the property after 6 years is found from Equation (205.2) to be \$1.4 million.

Ignoring the assumption of mid-year purchase to simplify the calculation and assuming no inflation, the after-tax annual net income in the next 6 years is given by Equation (205.13):

$$Y_t = 300\,000 - (34\%)(300\,000 - 50\,000) = 215\,000$$

The capital gain tax for the property at the end of 6 years is

$$(28\%)(2\,100\,000 - 1\,400\,000) = 196\,000$$

Using the adjusted cost of capital approach, the NPV of after-tax net cash flows in the next 6 years, including the capital gain tax paid at the end of 6 years discounted at 10%, is

$$\begin{aligned} \text{NPV} &= -1\,700\,000 + (215\,000)(P|U, 10\%, 6) \\ &\quad + (2\,100\,000 - 196\,000)(P|F, 10\%, 6) \\ &= 311\,198 \end{aligned}$$

in which $(P|U, 10\%, 6)$ is the discount factor to present at 10% for a uniform series over 6 years, and $(P|F, 10\%, 6)$ is the discount factor to present at 10% for a future sum at the end of 6 years. Since $\text{NPV} = \$311,198$ is positive, the proposed investment should be accepted.

Defining Terms

Base year — The year used as the baseline of price measurement of an investment project.

Capital gain — Difference between the sale price and the book value of an asset.

Depreciable life — Estimated useful life over which depreciation allowances are computed.

Depreciation — Decline in value of physical assets over their estimated useful lives.

Depreciation allowance — Amount of depreciation allowed in a systematic allocation of the cost of a physical asset between the time it is acquired and the time it is disposed of.

Net present value — Algebraic sum of the discounted cash flows over the life of an investment project to the present.

Price index — Ratio of the price of a predefined package of goods and service at a given year to the price of the same package in the base year.

Tax shield — Gain from debt financing due to deductibility of interest in computing the income tax.

Charles Fazzi

Saint Vincent College

Financing activities, broadly speaking, relate to a firm's decision as to where to obtain the funds necessary to operate the business. The objective of this article is to describe the different approaches that a firm considers when making this decision as it relates to investment alternatives. The market for funds is divided into the money market and the capital market. The money market includes short-term debt securities, that is, securities that will mature in 1 year or less. The capital market is the market for longer-term borrowings, that is, sources of cash with a time horizon of more than 1 year. The capital market is further subdivided into an intermediate capital market that includes debt securities with a maturity of more than 1 but less than 10 years in duration; and a long-term capital market which includes debt securities which generally have a maturity of more than 10 years. Financing activities for capital projects rarely utilizes money market funds.

The capital market also encompasses the market for equity securities. These sources of funds include the issuance of both preferred stock and common stock. They have the longest time horizon since these securities are normally issued for the life of the corporation. Thus they may be thought of as sources of financing with an infinite time horizon.

This chapter deals with the major sources and forms of capital market funds. In addition, leasing will be discussed. Leasing is a specific type of economic transaction that blends both the acquisition of an asset (an investment decision) with a long-term loan commitment (a financing decision). Under the right conditions, leasing can represent a most attractive approach to the financing process for a firm.

206.1 Debt Financing

There are three primary sources of intermediate and long-term debt financing: term loans, mortgage loans, and bonds.

Term Loans

A **term loan** is simply a loan that is paid off over some number of years called the term of the loan. Term loans may or may not be secured by the assets of the firm. These loans are usually negotiated with commercial banks, insurance companies, or some other financial institution. They can generally be

negotiated fairly quickly and at a low administrative cost. The amount borrowed (principal) and the interest is paid off in installments over the life of the loan. The rate of interest on the term loan can be fixed over the life of the loan but usually it is a variable interest rate that is linked to the prime rate. Thus the rate of interest for a term loan can be set at “2% over the prime rate,” the borrower may pay 8% when the prime rate is 6% in the first year, and 9% in the second year when the prime rate is 7%. Variable rate loans of this type can include a “collar,” which sets upper and lower limits on the interest rate that can be charged, or a “cap,” which sets an upper limit only. The prime rate of interest is the rate charged on short-term business loans to financially sound companies. Term loans can often carry restrictive provisions or constraints on the financial activities of the borrower such as a dividend restriction.

Mortgage Loans

Mortgage loans are essentially term loans that are secured by the real estate that was purchased with the cash proceeds from the loan. They infrequently extend past a time period of 20 years and may be repaid only over 5 years.

Bonds

Bonds are intermediate to long-term debt agreements issued by corporations, governments, or other organizations, generally in units of \$1,000 principal value per bond. A bond represents two commitments on the part of the issuing organization, the promise to pay the stated interest rate periodically and the commitment to repay the \$1,000 principal when the bond matures. Most bonds pay interest semiannually at one-half the annual stated or coupon rate of interest. The term *coupon rate* refers to the fact that bonds often have coupons attached that may be detached and redeemed for each interest payment.

A company that floats a bond issue may have the bonds sold directly to the public by placing the bond issue with an investment banker. A bond issue can also be privately placed with a financial institution such as a commercial bank, insurance company, corporate pension fund, or a university endowment fund. The contract between the issuer and the lender is called the bond indenture. If the bond is publicly marketed, a trustee is named to ensure compliance with the bond indenture. In most cases the trustee is a commercial bank or an investment banker. In a private placement, the purchasing institution normally acts as its own trustee.

Bonds are issued in a wide variety of circumstances. A debenture is an unsecured bond that is backed by the full faith and credit of the issuer. No specific assets are pledged as collateral. In the event of default, debenture holders become general creditors of the issuer.

A mortgage bond, like a mortgage loan, is collateralized by a mortgage on some type of asset such as land, building, or equipment.

Convertible bonds are bonds that may be converted into shares of common stock, at a predetermined conversion rate. The decision to convert the bond to common stock is at the option of the bondholder. The conversion feature is attractive to investors and therefore lowers the cost of borrowing.

Most bond issues include a call feature among the provisions. This feature gives the issuer a chance to buy back the bonds at a stated price prior to maturity. Callable bonds give the issuer flexibility in financing their activities. The callable feature favors the borrower and therefore increases the effective cost of borrowing.

A sinking fund requirement establishes a procedure for the orderly retirement of a bond issue over its life. This provision requires the periodic repurchase of a stated percentage of the outstanding bonds. The issuing company can accomplish this through purchases of their bonds in the open market or through use of the call provision previously described.

206.2 Equity Financing

Equity financing utilizes a corporation's ability to sell ownership interest in the organization through the sale of capital stock in the corporation. This stock can be issued as either preferred stock or common

stock. While a corporation can choose to issue preferred stock, it must issue common stock as a representation of the individual ownership interest of the investors.

Preferred Stock

Preferred stock is legally an equity security that represents an ownership interest in a corporation. The term preferred arises from the fact that preferred stock has two important preferences over common stock: preference as to payment of dividends and preference as to stockholders' claims on the assets of the business in the event of bankruptcy.

Preferred stock is often characterized as a hybrid security that possesses some of the features of bonds and some of the features of common stock. Preferred dividends are fixed in amount similar to bond interest, and must be paid before common dividends are paid. Like bondholders, preferred stockholders do not participate in the growth of corporate earnings and collect only the dividends that are stated on the stock certificate. Like common stockholders, each dividend payment must be voted on and approved by the board of directors of the corporation. Most preferred stock issuances are cumulative, meaning that missed dividends accumulate as "dividends in arrears" which must be paid before any common dividends can be paid. Timely payment of preferred dividends is very important to the corporation. Corporations with preferred dividends in arrears find it very difficult to raise other forms of capital. Therefore, payment of preferred dividends is almost as important as timely payment of bond interest to the corporation. Preferred stock can also be both convertible and callable which was discussed earlier in conjunction with bonds.

Common Stock

The common stockholders are the owners of the corporation, as evidenced by the voting rights that are normally associated with **common stock**. Each share of common stock normally has one vote in electing the corporation's board of directors. The board is the ultimate corporate authority and is the group to whom the president of the corporation reports. The board selects the president and approves the appointment of all corporate officers. The board members are responsible to the stockholders, and the stockholders have the authority to elect a new board if their performance is deemed unsatisfactory.

Common stock is often referred to as the residual equity of the corporation. Money paid to the corporation for common stock does not have to be repaid, and dividends on common stock are only paid when approved by the board of directors. Common dividends are never in arrears, and common stockholders never have a claim to any specified dividend level. If a corporation prospers and grows the board will normally vote to increase the dividend level to reflect this growth. As dividends grow, the value of the stock increases and the stockholders also benefit from capital gains that accrue from the increased value. Of course, all of this can also work in reverse if the corporation does not prosper. The shareholders could ultimately lose their investment if the corporation goes bankrupt.

Corporations sometimes issue two classes of common stock, one of which does not include any voting rights. Thus, voting rights are retained by one class of common stock, and the other class will not have any voting rights but will have the ability to participate in earnings growth. This will allow one group of owners to retain voting control, but allow another group to participate in earnings and dividends without giving up control. This is a way to raise additional equity capital without losing control of the corporation. Large publicly held corporations rarely have multiple classes of common stock.

206.3 Leasing

A **lease** can be defined as a contractual relationship in which the owner of the property or asset (lessor) conveys to a business or person (lessee) the right to use the property or asset for a specified period of time in exchange for a series of payments. Thus, in a lease contract the lessee is able to use the leased assets without assuming ownership. Leasing has become a very popular way for many businesses to

acquire the necessary resources to run their operations. The leasing event is a hybrid transaction which combines the acquisition of necessary resources with a commitment to finance the acquisition. In general two types of leases are offered in the market today: operating leases and financial or capital leases.

Operating Lease

An **operating lease** is a short-term lease written usually for a period of time that is substantially shorter than the asset's useful life. The lessor assumes most of the risks of ownership including maintenance, service, insurance, liability, and property taxes. The lessee can cancel an operating lease on short notice. Thus, the operating lease does not involve the long-term fixed future commitment of financial resources and is similar to renting. There are no balance sheet effects recorded with an operating lease and the rental payments are treated as period expenses.

Financial Lease

A **financial lease** or capital lease is a contract by which the lessee agrees to pay the lessor a series of payments whose sum equals or exceeds the purchase price of the asset. Typically, the total cash flows from the lease payments, the tax savings, and the residual value of the asset at the end of the lease will be sufficient to pay back the lessor's investment and provide a profit. Most financial leases are "net" leases, in that the fundamental ownership responsibilities such as maintenance, insurance, and property and sales taxes are placed upon the lessee. The lease agreement is a long-term agreement between both parties and is noncancellable. In the case of an unforeseen event, the contract may be cancellable, but the lessor will typically impose a substantial prepayment penalty. The decision to use financial leasing as a means of acquiring an asset is often viewed as an alternative to a purchase transaction using long-term debt financing to generate the necessary cash.

Sale and Leaseback

A sale and leaseback is a fairly common arrangement in which a firm sells an asset to a lender/lessor and then immediately leases back the property. The advantage to the seller/lessee is that the selling firm receives a large infusion of cash that may be used to finance other business activities. In return for this cash, the selling firm issues a long-term lease obligation to the lessor in order to make economic use of the asset during the lease period. Title to the asset is transferred to the lessor and the lessor will realize any residual value the asset may have at the end of the lease. The lessee may realize a tax advantage in this situation if the lease involves a building on owned land. Land is not depreciable if owned outright, but the full amount of the lease payment may be tax deductible. This allows the lessee to indirectly depreciate the cost of the land through the deductibility of the lease payment.

Accounting Treatment of Leases

Accounting for leases has changed dramatically over time. Prior to 1977, lease financing was attractive to some firms because the lease obligation did not appear on the company's balance sheet. As a result leasing was regarded as a form of "off-balance-sheet financing." In 1977, the Financial Accounting Standards Board issued an accounting standard that clearly set out criteria that distinguish a capital lease from an operating lease. Any lease that does not meet the criteria for a capital lease must be classified as an operating lease. A lease is considered to be a capital lease if it meets any one of the following conditions:

1. The title of the asset being leased is transferred to the lessee at the end of the lease term.
2. The lease contains an option for the lessee to purchase the asset at a very low price.
3. The term of the lease is greater than or equal to 75% of the economic life of the asset.
4. The present value of the lease payments is greater than or equal to 90% of the fair value of the leased property.

A capital lease is recorded on the lessee's balance sheet as a lease asset with an associated lease liability. The amount of the asset and liability is equal to the present value of the minimum future lease payments. Thus, for capital leases, leasing no longer provides a source of off-balance sheet financing. Operating leases must be fully disclosed in the footnotes to the financial statements.

Lessees like the operating lease method for lease accounting. One obvious reason is that the operating method never reflects the cumulative liability for all future lease payments. The term off-balance sheet financing means the lessee has financed the acquisition of asset services without recognizing an asset or liability on the financial statements. This leads to more favorable financial performance measures for the company.

Tax Treatment of Leases

For tax purposes, the lessee can deduct the full amount of the lease payment in a properly structured lease. The Internal Revenue Service (IRS) wants to be sure that the lease contract truly represents a lease and not an installment purchase of the asset. To ensure itself that a true lease is present, the IRS will look for a meaningful residual value at the end of the lease term. This is usually construed to mean that the term of the lease cannot exceed 90% of the economic life of the asset. In addition, the lessee should not be given the option to purchase the asset for any thing less than the fair market value of the leased asset at the end of the lease term. The lease payments should be reasonable in that they provide the lessor not only a return of principal, but also a reasonable interest return as well. In addition, the lease term must be for less than 30 years; otherwise it will be construed as an installment purchase of the asset. The IRS wants to assure itself that the transaction is not a disguised installment purchase that has more rapid payments that will lead to deductions than would be allowed from the depreciation deduction under an outright purchase. With leasing, the cost of any land is amortized in the lease payments. In an outright purchase of land, depreciation is not allowable. When the value of a lease includes land, lease financing can offer a tax advantage to the firm. Offsetting this tax advantage is the likely residual value of the land at the end of the lease period.

Evaluating Lease Financing

To evaluate whether or not a lease financing proposal makes economic sense, it should be compared with financing the asset with debt. Whether leasing or borrowing is best will depend on the patterns of cash flow for each financing method and on the opportunity cost of funds. The method of analysis will require the calculation of the present values for the lease alternative and the present value of the borrowing alternative. The alternative with the lower present value of the cash outflows will be the better choice. The calculations can be rather extensive and complicating. Moreover, the calculations deal with uncertainty that must be considered in making the final decision.

Defining Terms

Bond — A long-term debt instrument issued by a corporation or government.

Common stock — The stock representing the most basic rights to ownership in the corporation.

Financial lease — A long-term lease that is not cancellable.

Lease — A contract under which one party, the owner of an asset (lessor), agrees to grant the use of the asset to another party (lessee), in exchange for periodic payments.

Operating lease — A short-term lease that is often cancellable.

Preferred stock — A type of stock that usually promises a fixed dividend, with the approval of the board of directors. It has preference over common stock in the payment of dividends and claims on assets.

Term loan — Debt originally scheduled for repayment in more than 1 year, but generally less than 10 years.

207.4 Risk Communication

Bilal M. Ayyub

University of Maryland

Risk is associated with all projects and business ventures undertaken by individuals and organizations regardless of their size, nature, and time and place of execution and use. Risk is present in various forms and levels even in small domestic projects such as adding a deck to a residence, and in large multibillion-dollar projects such as developing and producing a space shuttle. These risks could result in significant budget overruns, delivery delays, failures, financial losses, environmental damage, and even injuries and loss of life. Risks are taken even though they could lead to devastating consequences because of potential benefits, rewards, survival, and future return on investment. Risk taking is viewed as an expression of higher levels of intelligence. This chapter defines and discusses risk and its dimensions, risk assessment processes and their fundamental analytical tools, risk management and control, and risk communication.

207.1 Risk Terminology

Definitions necessary for presenting risk-based technology methods and analytical tools are presented in this section.

Hazards

A hazard is an act or phenomenon posing potential harm to some person(s) or thing(s), that is, a source of harm and its potential consequences. For example, uncontrolled fire is a hazard, water can be a hazard, and strong wind is a hazard. In order for the hazard to cause harm, it needs to interact with person(s) or thing(s) in a harmful manner. The magnitude of the hazard is the amount of harm that might result,

including the seriousness and exposure levels of people and the environment. Hazards need to be identified and considered in project lifecycle analyses since they could pose threats and lead to project failures.

The interaction between a person (or a system) and a hazard can be voluntary or involuntary. For example, exposing a marine vessel to a sea environment might lead to its interaction with extreme waves in an uncontrollable manner, that is, an involuntary manner. Although the decision of a navigator of the vessel to go through a storm system that is developing can be viewed as a voluntary act in nature, and might be needed to meet schedule or other constraints, the potential rewards of delivery of shipment or avoidance of delay charges offer an incentive that warrants such action. Other examples can be constructed where individuals interact with hazards for potential financial rewards, fame, and self-fulfillment and satisfaction, ranging from undertaking investments to climbing cliffs.

Reliability

Reliability can be defined for a system or a component as its ability to fulfill its design functions under designated operating or environmental conditions for a specified time period. This ability is commonly measured using probabilities. Reliability is, therefore, the occurrence probability of the complementary event to failure as provided in the following expression:

$$\text{Reliability} = 1 - \text{Failure Probability} \quad (207.1)$$

Event Consequences

For an event of failure, consequences can be defined as the degree of damage or loss from some failure. Each failure of a system has some consequence(s). A failure could cause economic damage, environmental damage, injury or loss of human life, or other possible events. Consequences need to be quantified in terms of failure-consequence severities using relative or absolute measures for various consequence types to facilitate risk analysis.

For a successful event, consequences can be defined as the degree of reward or return or benefits from success. Such an event could cause economic outcomes, environmental effects, or other possible events. Consequences need to be quantified using relative or absolute measures for various consequence types to facilitate risk analysis.

Risk

The concept of risk can be linked to uncertainties associated with events. Within the context of projects, risk is commonly associated with an uncertain event or condition that, if it occurs, has a positive or a negative effect on a project's objectives.

Risk originates from the Latin term *risicum* meaning the challenge presented by a barrier reef to a sailor. The Oxford dictionary defines risk as the chance of hazard, bad consequence, loss, and so on. Also, risk is the chance of a negative outcome. To measure risk we must accordingly assess both of its defining components, including the chance for negativity and potential rewards or benefits. Estimation of risk is usually based on the expected result of the conditional probability of the event occurring times the consequence of the event given that it has occurred.

A risk results from an event or sequence of events called a scenario. The event or scenario can be viewed as a cause and, if it occurs, results in consequences with severities. For example, an event or cause may be shortage of personnel needed to perform a task needed to produce a project. The event in this case of personnel shortage for the task will lead to a consequence on project cost, schedule, and/or quality. The events can reside in the project environment that may contribute to project success or failure, such as project management practices, or external partners or subcontractors.

Risk has certain characteristics that should be used in the risk assessment process. Risk is a characteristic of an uncertain future, and is neither a characteristic of the present nor the past. Once uncertainties are resolved and/or the future is attained, the risk becomes nonexistent. Therefore, we cannot

describe risks for historical events or risks for events that are currently being realized. Similarly, risks cannot be directly associated with a success. Although risk management through risk mitigation of selected events could result in project success leading to rewards and benefits, these rewards and benefits cannot be considered as outcomes only of the nonoccurrence of these events associated with the risks. The occurrence of risk events leads to adverse consequences that are clearly associated with their occurrence; however, their nonoccurrences are partial contributors to the project success that lead to rewards and benefits. The credit in the form of rewards and benefits cannot be given solely to the nonoccurrence of these risk events. Some risk assessment literature defines risk to include both potential losses and rewards. They need to be treated separately as (1) risks leading to adverse consequences, and (2) risks that contribute to benefits or rewards in tradeoff analyses. An appropriate risk definition in this context is a threat (or opportunity) that could affect adversely (or favorably) achievement of the objectives of a project and its outcomes.

Developing an economic, analytical framework for a decision situation involving risks requires examining the economic and finance environments of a project. This environment could have significant impacts on the occurrence probabilities of events associated with risks. This complexity might be needed for certain projects in order to obtain justifiable and realistic results. The role of such an environment in risk analysis is discussed in subsequent sections.

Formally, risk can be defined as the potential of losses and rewards resulting from an exposure to a hazard or as a result of a risk event. Risk should be based on identified risk events or event scenarios. Risk can be viewed to be a multidimensional quantity that includes event-occurrence probability, event-occurrence consequences, consequence significance, and the population at risk; however, it is commonly measured as a pair of the probability of occurrence of an event, and the outcomes or consequences associated with the event's occurrence. This pairing can be represented by the following equation:

$$Risk \equiv [(p_1, c_1), (p_2, c_2), \dots, (p_i, c_i), \dots, (p_n, c_n)] \quad (207.2)$$

where p_i is the occurrence probability of an outcome or event i out of n possible events, and c_i is the occurrence consequences or outcomes of the event. A generalized definition of risk can be expressed as

$$Risk \equiv [(l_1, o_1, u_1, cs_1, po_1), (l_2, o_2, u_2, cs_2, po_2), \dots, (l_n, o_n, u_n, cs_n, po_n)] \quad (207.3)$$

where l is likelihood, o is outcome, u is utility (or significance), cs is causal scenario, po is population affected by the outcome, and n is the number of outcomes. The definition according to Equation 207.3 covers all attributes measured in risk assessment that are described in this chapter, and offers a complete description of risk, from the causing event to the affected population and consequences. The population-size effect should be considered in risk studies since society responds differently for risks associated with a large population in comparison to a small population. For example, a fatality rate of 1 in 100,000 per event for an affected population of 10 results in an expected fatality of 10^{-4} per event whereas the same fatality rate per event for an affected population of 10 million results in an expected fatality of 100 per event. Although, the impact of the two scenarios might be the same on the society (same risk value), the total number of fatalities per event/accident is a factor in risk acceptance. Plane travel may be "safer" than for example recreational boating, but 200 to 300 injuries per accident are less acceptable to society. Therefore, the size of the population at risk and the number of fatalities per event should be considered as factors in setting acceptable risk.

Risk is commonly evaluated as the product of likelihood of occurrence and the impact severity of occurrence of the event:

$$RISK \left(\frac{\text{Consequence}}{\text{Time}} \right) = LIKELIHOOD \left(\frac{\text{Event}}{\text{Time}} \right) \times IMPACT \left(\frac{\text{Consequence}}{\text{Event}} \right) \quad (207.4)$$

FIGURE 207.1 Example risk profile.

FIGURE 207.2 Uncertain risk profile.

In Equation 207.4, the likelihood can also be expressed as a probability. Equation 207.4 presents risk as an expected value of loss or an average loss. A plot of occurrence probabilities and consequences is called a risk profile or a Farmer curve. An example Farmer curve is given in Figure 207.1 based on a nuclear case study, provided herein for illustration purposes. It should be noted that the abscissa provides the number of fatalities, and the ordinate provides the annual frequency of exceedence for the corresponding number of fatalities. These curves are sometimes constructed using probabilities instead of frequencies. The curves represent median average values. Sometimes, bands or ranges are provided to represent uncertainty in these curves. They represent confidence intervals for the average curve or for the risk curve. Figure 207.2 shows example curves with uncertainty bands. This uncertainty is sometimes called meta-uncertainty.

The occurrence probability (p) of an outcome (o) can be decomposed into an occurrence probability of an event or threat (t), and the outcome-occurrence probability given the occurrence of the event ($o|t$). The occurrence probability of an outcome can be expressed as follows using conditional probability concepts:

$$p(o) = p(t)p(o|t) \tag{207.5}$$

In this context, threat is defined as a hazard or the capability and intention of an adversary to undertake actions that are detrimental to a system or an organization's interest. In this case, threat is a function of only the adversary or competitor, and usually cannot be controlled by the owner or user of the system. However, the adversary's intention to exploit his capability may be encouraged by vulnerability of the system or discouraged by an owner's countermeasures. The probability ($p(o|t)$) can be interpreted as the vulnerability of the system in case of this threat occurrence. Vulnerability is a result of any weakness in the system or countermeasure that can be exploited by an adversary or competitor to cause damage to the system.

Performance

The performance of a system or component can be defined as its ability to meet functional requirements. The performance of an item can be described by various elements including such items as speed, power,

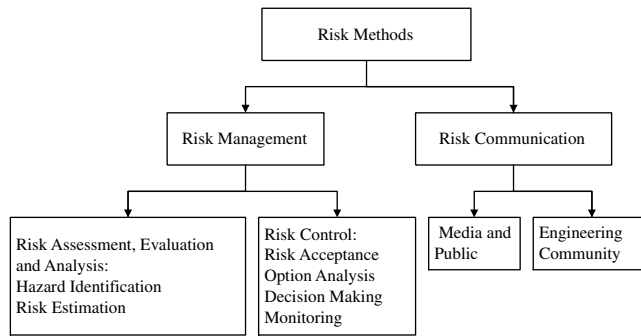

FIGURE 207.3 Risk-based technology methods.

reliability, capability, efficiency, and maintainability. The design and operation of the product or system influence performance.

Risk-Based Technology

Risk-based technologies (RBTs) are methods or tools and processes used to assess and manage the risks of a component or system. RBT methods can be classified into risk management, which includes risk assessment/risk analysis and risk control using failure prevention and consequence mitigation, and risk communication as shown in Figure 207.3.

Risk assessment consists of hazard identification, event-probability assessment, and consequence assessment. Risk control requires the definition of acceptable risk and comparative evaluation of options and/or alternatives through monitoring and decision analysis. Risk control also includes failure prevention and consequence mitigation. Risk communication involves perceptions of risk, which depends on the audience targeted, and thus is classified into risk communication to the media, the public, and to the engineering community.

Safety

Safety can be defined as the judgment of risk acceptability for the system. Safety is a relative term since the decision of risk acceptance may vary depending on the individual making the judgment. Different people are willing to accept different risks as demonstrated by different factors such as location, method or system type, occupation, and lifestyle. The selection of these different activities demonstrates an individual's safety preference despite a wide range of risk values. [Table 207.1](#) identifies varying annual risks for different activities based on typical exposure times for these activities. Also [Figure 207.4](#), from Imperial Chemical Industries, Ltd. shows the variation of risk exposure during a typical day that starts by waking up in the morning from sleep and getting ready to go to work, then commuting and working during morning hours, followed by a lunch break, then additional work hours followed by commuting back to having dinner, and a round trip on a motorcycle to a local pub. The ordinate in this figure is the fatal accident frequency rate (FAFR) with a FAFR of 1.0 corresponding to one fatality in 11,415 years, or 87.6 fatalities per 1 million years. The figure is based on an average number of deaths in 10^8 hours of exposure to a particular activity.

Risk perceptions of safety may not reflect the actual level of risk in some activity. [Table 207.2](#) shows the differences in risk perception by the League of Women Voters, college students, and experts regarding 29 risk items. Only the top items are listed in the table. Risk associated with nuclear power was ranked the highest by League members and college students, whereas experts ranked it as the 20th. Experts placed motor vehicles as the highest risk. Public perception of risk and safety varies by age, gender, education, attitudes, and culture, among other factors. Individuals sometimes do not recognize uncertainties associated with a risk event or activity, which causes an unwarranted confidence in an individual's

TABLE 207.1 Relative Risk Comparisons

| Risk of Death | Occupation | Lifestyle | Accidents/Recreation | Environmental Risk |
|-----------------|---|--|---|---|
| 1 in 100 | Stunt person | | | |
| 1 in 1,000 | Race car driver | Smoking (one pack/day) | Skydiving, rock climbing, snowmobiling | |
| 1 in 10,000 | Fire fighter, miner, farmer, police officer | Heavy drinking | Canoeing, automobile, all home accidents, frequent air travel | |
| 1 in 100,000 | Truck driver, engineer, banker, insurance agent | Using contraceptive pills, light drinking | Skiing, home fire | Substance in drinking water, living downstream of a dam |
| 1 in 1,000,000 | | Diagnostic X-rays, smallpox vaccination (per occasion) | Fishing, poisoning, occasional air travel (one flight per year) | Natural background radiation, living at boundary of nuclear power |
| 1 in 10,000,000 | | Eating charcoal-broiled steak (once a week) | | Hurricane, tornado, lightning, animal bite, or insect sting |

FIGURE 207.4 Daily death-risk exposure for a working healthy adult.

perception of risk or safety. Rare causes of death are often overestimated and common causes of death are often underestimated. Perceived risk is often biased by the familiarity of the hazard. The significance or the impact of safety perceptions stems from that decisions are often made on subjective judgments. If the judgments hold misconceptions about reality, this bias affects the decision. For example, the choice of a transportation mode — train, automobile, motorcycle, bus, bicycle, and so on — results in a decision based on many criteria including such items as cost, speed, convenience, and safety. The weight and evaluation of the decision criteria in selecting a mode of transportation rely on the individual’s perception of safety that may deviate sometimes significantly from the actual values of risks. Understanding these differences in risk and safety perceptions is vital to performing risk management decisions and risk communications as provided in subsequent sections on risk management and control.

207.2 Risk Assessment

Risk Assessment Methodologies

Risk studies require the use of analytical methods at the system level that considers subsystems and components in assessing their failure probabilities and consequences. Systematic, quantitative, qualitative, or semiquantitative approaches for assessing the failure probabilities and consequences of engineering systems are used for this purpose. A systematic approach allows an analyst to evaluate expediently and easily complex systems for safety and risk under different operational and extreme conditions. The ability to quantitatively evaluate these systems helps cut the cost of unnecessary and often expensive redesign, repair, and strengthening or replacement of components, subsystems, and systems. The results of risk analysis can also be utilized in decision analysis methods that are based on cost-benefit tradeoffs.

Risk assessment is a technical and scientific process by which the risks of a given situation for a system are modeled and quantified. Risk assessment can require and/or provide both qualitative and quantitative data to decision makers for use in risk management.

Risk assessment or risk analysis provides the process for identifying hazards, event probability assessment, and consequence assessment. The risk assessment process answers three basic questions: (1) What can go wrong? (2) What is the likelihood that it will go wrong? (3) What are the consequences if it does go wrong? Answering these questions requires the utilization of various risk methods as discussed in this chapter.

A risk assessment process should utilize experiences gathered from project personnel including managers, other similar projects and data sources, previous risk assessment models, experiences from other

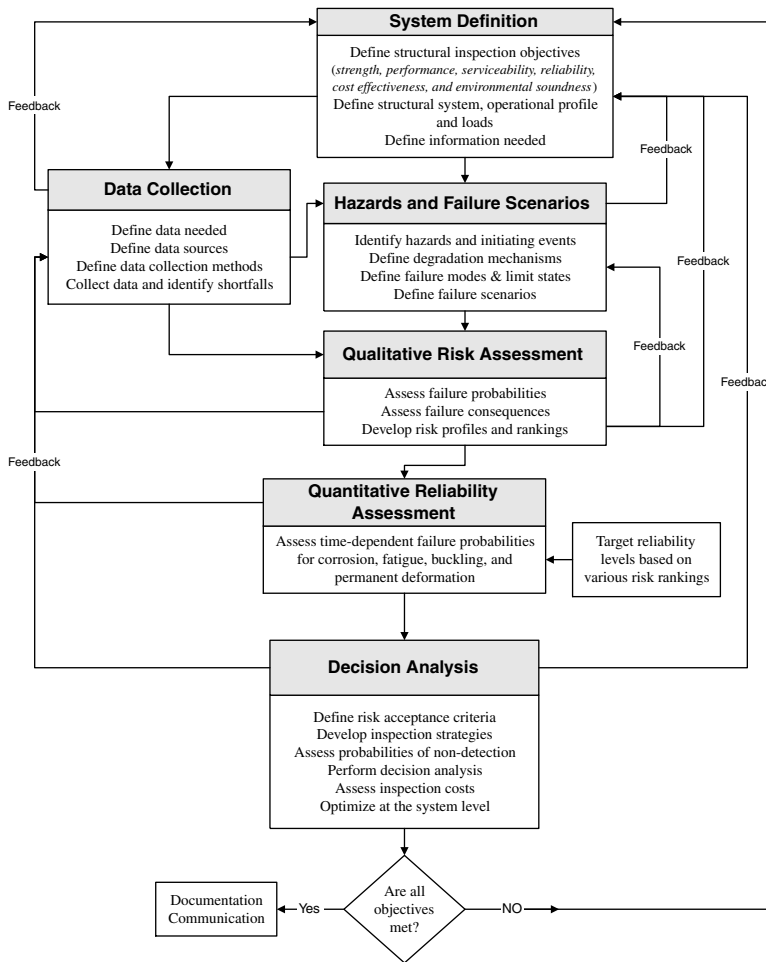

FIGURE 207.5 Methodology for risk-based, life-cycle management of structural systems.

industries and experts, in conjunction with analysis and damage evaluation/prediction tools. A risk assessment process is commonly part of a risk-based or risk-informed methodology that should be constructed as a synergistic combination of decision models, advanced probabilistic reliability analysis algorithms, failure-consequence assessment methods, and conventional performance assessment methodologies that have been employed in related industry for performance evaluation and management. The methodology should realistically account for the various sources and types of uncertainty involved in the decision-making process.

In this section, a typical overall methodology is provided in the form of a workflow or block diagram. The various components of the methodology are described in subsequent sections. Figure 207.5 provides an overall description of a methodology for risk-based management of structural systems for the purpose of demonstration. The methodology consists of the following primary steps:

1. Definition of analysis objectives and systems
2. Hazard analysis, definition of failure scenarios, and hazardous sources and their terms
3. Collection of data in a life-cycle framework
4. Qualitative risk assessment
5. Quantitative risk assessment
6. Management of system integrity through failure prevention and consequence mitigation using risk-based decision making

These steps are briefly described below with additional background materials provided in subsequent sections.

The first step of the methodology is to define the system. This definition should be based on a goal that is broken down into a set of analysis objectives. A system can be defined as an assemblage or combination of elements of various levels and/or details that act together for a specific purpose. Defining the system provides the risk-based methodology with the information that it needs to achieve the analysis objectives. The system definition phase of the proposed methodology has four main activities. The activities are to

1. Define the goal and objectives of the analysis
2. Define the system boundaries
3. Define the success criteria in terms of measurable performances
4. Collect information for assessing failure likelihood
5. Collect information for assessing failure consequences

For example, structural systems require a structural integrity goal that can include objectives stated in terms of strength, performance, serviceability, reliability, cost-effectiveness, and environmental soundness. The objectives can be broken down further to include other structural integrity attributes, such as alignment and watertightness in case of marine vessels. A system can be defined based on a stated set of objectives. The same system can be defined differently depending on these stated objectives. A marine vessel structural system can be considered to contain individual structural elements such as plates, stiffened panels, stiffeners, longitudinals, and so on. These elements could be further separated into individual components and/or details. Identifying all of the elements, components and details allows an analysis team to collect the necessary operational, maintenance, and repair information throughout the life cycle on each item so that failure rates, repair frequencies, and failure consequences can be estimated. The system definition might need to include nonstructural subsystems and components that would be affected in case of failure. The subsystems and components are needed to assess the consequences.

In order to understand failure and the consequences of failure, the states of success need to be defined. For the system to be successful, it must be able to perform its designed functions by meeting measurable performance requirements. But the system may be capable of various levels of performance, all of which might not be considered a successful performance. While a marine vessel may be able to get from point A to point B only at a reduced speed due to a fatigue failure that results in excessive vibration at the engine room, its performance would probably not be considered successful. The same concept can be applied to individual elements, components, and details. It is clear from this example that the vessel's success and failure impacts should be based on the overall vessel performance that can easily extend beyond the structural systems.

With development of the definition of success, one can begin to assess the likelihood of occurrence and causes of failures. Most of the information required to develop an estimate of the likelihood of failure might exist in maintenance and operating histories available on the systems and equipment, and based on judgment and expert opinion. This information might not be readily accessible, and its extraction from its current source might be difficult. Also, assembling it in a manner that is suitable for the risk-based methodology might be a challenge.

Operation, maintenance, engineering, and corporate information on failure history needs to be collected and analyzed for the purpose of assessing the consequences of failures. The consequence information might not be available from the same sources as the information on the failure itself. Typically there are documentations of repair costs, reinspection or recertification costs, lost person-hours of labor, and possibly even lost opportunity costs due to system failure. Much more difficult to find and assess are costs associated with the effects on other systems, the cost of shifting resources to cover lost production, and things like environmental, safety loss, or public relations costs. These may be attained through carefully organized discussions and interviews with cognizant personnel including the use of expert opinion elicitation.

Risk Events and Scenarios

In order to adequately assess all risks associated with a project, the process of identifying risk events and scenarios is an important stage in risk assessment. Risk events and scenarios can be categorized as follows:

- Technical, technological, quality, or performance risks, such as unproven or complex technology, unrealistic performance goals, and changes to the technology used or to the industry standards during the project
- Project-management risks, such as poor allocation of time and resources, inadequate quality of the project plan, and poor use of project management disciplines
- Organizational risks, such as cost, time, and scope objectives that are internally inconsistent, lack of prioritization of projects, inadequacy or interruption of funding, resource conflicts with other projects in the organization, errors by individuals or an organization, and inadequate expertise and experience by project personnel
- External risks, such as shifting legal or regulatory environment, labor issues, changing owner priorities, country risk, and weather
- Natural hazards, such as earthquakes, floods, strong wind, and waves generally require disaster recovery actions in addition to risk management.

Within these categories, several risk types can be identified.

Identification of Risk Events and Scenarios

The risk assessment process starts with the question, “What can go wrong?” The identification of what wrong can go entails defining hazards, risk events, and risk scenarios. The previous section provided categories of risk events and scenarios. Risk identification involves determining which risks might affect the project and documenting their characteristics. Risk identification generally requires participation from a project team, risk management team, subject matter experts from other parts of the company, customers, end users, other project managers, stakeholders, and outside experts on an as needed basis. Risk identification can be an iterative process. The first iteration may be performed by selected members of the project team or by the risk management team. The entire project team and primary stakeholders may take a second iteration. To achieve an unbiased analysis, persons who are not involved in the project may perform the final iteration. Risk identification can be a difficult task because it is often highly subjective, and there are no unerring procedures that may be used to identify risk events and scenarios other than relying heavily on the experience and insight of key project personnel.

The development of the scenarios for risk evaluation can be created deductively (e.g., fault tree) or inductively (e.g., failure mode and effect analysis (FMEA)) as provided in [Table 207.3](#). The table shows methods of multiple uses including likelihood or frequency estimation expressed either deterministically or probabilistically. In addition, they can be used to assess varying consequence categories including items such as economic loss, loss of life, or injuries.

The risk identification process and risk assessment requires the utilization of these formal methods as shown in [Table 207.3](#). These different methods contain similar approaches to answer the basic risk assessment questions; however, some techniques may be more appropriate than others for risk analysis depending on the situation.

Risk Breakdown Structure

Risk sources for a project can be organized and structured to provide a standard presentation that would facilitate understanding, communication, and management. The previously presented methods can be viewed as simple linear lists of potential sources of risk, providing a set of headings under which risks can be arranged. These lists are sometimes called risk taxonomy. A simple list of risk sources might not provide the richness needed for some decision situations since it only presents a single level of organization. Some applications might require a full hierarchical approach to define the risk sources, with as

TABLE 207.3 Risk Assessment Methods

| Method | Scope |
|---|--|
| Safety/review Audit | Identifies equipment conditions or operating procedures that could lead to a casualty, or result in property damage or environmental impacts. |
| Checklist | Ensures that organizations are complying with standard practices. |
| What if | Identifies hazards, hazardous situations, or specific accident events that could result in undesirable consequences. |
| Hazard and operability study (HAZOP) | Identifies system deviations and their causes that can lead to undesirable consequences and determine recommended actions to reduce the frequency and/or consequences of the deviations. |
| Preliminary hazard analysis (PrHA) | Identifies and prioritizes hazards leading to undesirable consequences early in the life of a system. It determines recommended actions to reduce the frequency and/or consequences of the prioritized hazards. This is an inductive modeling approach. |
| Probabilistic risk analysis (PRA) | Methodology for quantitative risk assessment developed by the nuclear engineering community for risk assessment. This comprehensive process may use a combination of risk assessment methods. |
| Failure modes and effects analysis (FMEA) | Identifies the components (equipment) failure modes and the impacts on the surrounding components and the system. This is an inductive modeling approach. |
| Fault tree analysis (FTA) | Identifies combinations of equipment failures and human errors that can result in an accident. This is a deductive modeling approach. |
| Event tree analysis (ETA) | Identifies various sequences of events, including both failures and successes that can lead to an accident. This is an inductive modeling approach. |
| Delphi technique | Assists in reaching consensus of experts on a subject such as project risk while maintaining anonymity by soliciting ideas about the important project risks that are collected and circulated to the experts for further comment. Consensus on the main project risks may be reached in a few rounds of this process. |
| Interviewing | Identifies risk events by interviews of experienced project managers or subject matter experts. The interviewees identify risk events based on experience and project information. |
| Experience-based identification | Identifies risk events based on experience including implicit assumptions. |
| Brainstorming | Identifies risk events using facilitated sessions with stakeholders, project team members, and infrastructure support staff. |

many levels as are required to provide the necessary understanding of risk exposure. Defining risk sources in such a hierarchical structure is called a risk breakdown structure (RBS). The RBS is defined as a source-oriented grouping of project risks organized to define the total risk exposure of a project of interest. Each descending level represents an increasingly detailed definition of risk sources for the project. The value of the RBS can be in aiding an analyst to understand the risks faced by the project.

An example RBS is provided in [Table 207.4](#). In this example, four risk levels are defined as shown in the table. The project's risks are viewed as Level 0. Three types of Level-1 risks are provided in the table for the purpose of demonstration. The number of risk sources in each level varies and depends on the application at hand. The subsequent Level 2 risks are provided in groups that are detailed further in Level 3. The RBS provides a means to systematically and completely identify all relevant risk sources for a project.

The risk breakdown structure should not be treated as a list of independent risk sources since commonly they have interrelations and common risk drivers. Identifying causes behind the risk sources is a key step toward an effective risk management plan including mitigation actions. A process of risk interrelation assessment and root cause identification can be utilized to potentially lead to identifying credible scenarios that could lead to snowball effects for risk management purposes.

System Definition for Risk Assessment

Defining the system is an important first step in performing a risk assessment. A system can be defined as a deterministic entity comprising an interacting collection of discrete elements that is commonly defined using deterministic models. The word *deterministic* implies that the system is identifiable and

TABLE 207.4 Risk Breakdown Structure for a Project

| Level 0 | Level 1 | Level 2 | Level 3 | |

| | | ... | | |

not uncertain in its architecture. The definition of the system is based on analyzing its functional and/or performance requirements. A description of a system may be a combination of functional and physical elements. Usually functional descriptions are used to identify high information levels on a system. A system may be divided into subsystems that interact. Additional detail leads to a description of the physical elements, components, and various aspects of the system.

The examination of a system needs to be made in a well-organized and repeatable fashion so that risk analysis can be consistently performed, which ensures that important elements of a system are defined and extraneous information is omitted. The formation of system boundaries is based on the objectives of the risk analysis.

The establishment of system boundaries can assist in developing the system definition. The system boundary decision is partially based on what aspects of the system's performance are of concern. The selection of items to include within the external boundary region also relies on the goal of the analysis. Beyond the established system boundary is the external environment of the system.

Boundaries beyond the physical/functional system can also be established. For example, time may also be a boundary since an overall system model may change as a product is further along in its life cycle. The life cycle of a system is important because some potential hazards can change throughout the life

cycle. For example, material failure due to corrosion or fatigue may not be a problem early in the life of a system; however, this may be an important concern later in the life cycle of the system.

Along with identifying the boundaries, it is also important to establish a resolution limit for the system. Resolution is important since it limits analysis detail. Providing too little detail might not provide enough information for the problem. Too much information may make the analysis more difficult and costly due to the added complexity. The depth of the system model needs to be sufficient for the specific problem. Resolution is also limited by the feasibility of determining the required information for the specific problem. For failure analysis, the resolution should be to the components level where failure data are available. Further resolution is not necessary and would only complicate the analysis.

The system breakdown structure is the top-down division of a system into subsystems and components. This architecture provides internal boundaries for the system. Often the systems/subsystems are identified as functional requirements that eventually lead to the component level of detail. The functional level of a system identifies the function(s) that must be performed for the operation of the system. Further system decomposition into “discrete elements” leads to the physical level of a system definition identifying the hardware within the system. By organizing a system hierarchy using a top-down approach rather than fragmentation of specific systems, a rational, repeatable, and systematic approach to risk analysis can be achieved.

Further system analysis detail is addressed from modeling the system using some of the risk assessment methods described in [Table 207.3](#). These techniques develop processes that can assist in decision making about the system. The logic of modeling based on the interaction of a system’s components can be divided into induction and deduction. This difference in the technique of modeling and decision making is significant. Induction logic provides the reasoning of a general conclusion from individual cases. This logic is used when analyzing the effect of a fault or condition on a systems operation. Inductive analysis answers the question, “What are the system states due to some event?” In reliability and risk studies, this “event” is some fault in the system. Several approaches using the inductive approach include: PrHA, FMEA, and ETA. Deductive approaches provide reasoning for a specific conclusion from general conditions. For system analysis, this technique attempts to identify what modes of a system/subsystem/component failure can be used to contribute to the failure of the system. This technique answers the question, “How a system state can occur?” Inductive reasoning provides the techniques for FTA or its complement success tree analysis (STA).

Selected Risk Assessment Methods

Qualitative versus Quantitative Risk Assessment

Risk assessment methods can be categorized according to how the risk is determined by quantitative or qualitative analysis. Qualitative risk analysis uses judgment and sometimes “expert” opinion to evaluate the probability and consequence values. This subjective approach may be sufficient to assess the risk of a system, depending on available resources.

Quantitative analysis relies on probabilistic and statistical methods, and databases that identify numerical probability values and consequence values for risk assessment. This objective approach examines the system in greater detail to assess risks.

The selection of a quantitative or qualitative method depends on the availability of data for evaluating the hazard and the level of analysis needed to make a confident decision. Qualitative methods offer analyses without detailed information, but the intuitive and subjective processes may result in differences in outcomes by those who use them. Quantitative analysis generally provides a more uniform understanding among different individuals, but requires quality data for accurate results. A combination of both qualitative and quantitative analyses can be used depending on the situation.

Risk assessment requires estimates of the failure likelihood at some identified levels of decision-making. The failure likelihood can be estimated in the form of lifetime failure likelihood, annual failure likelihood, mean time between failures, or failure rate. The estimates can be in numeric or non-numeric form. An example numeric form for an annual failure probability is 0.00015, and for a mean time between failures

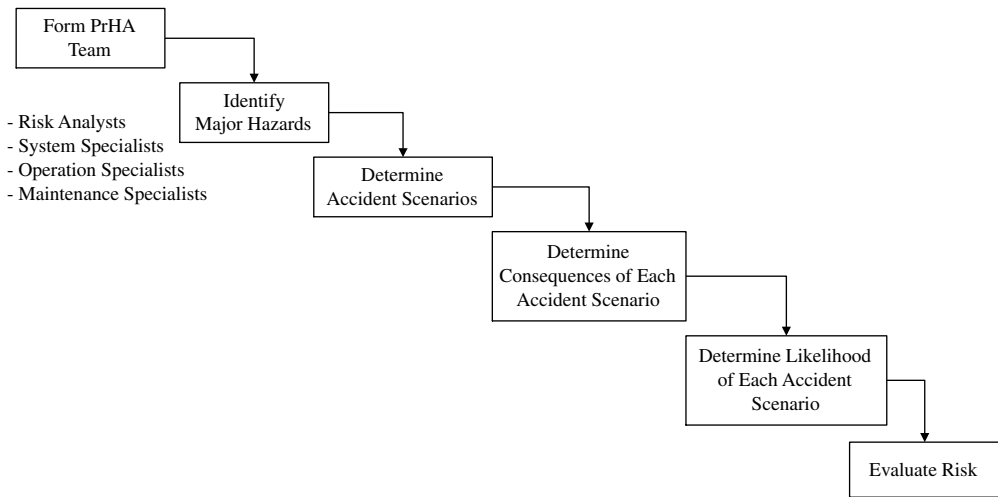

FIGURE 207.6 Preliminary hazard analysis process.

is 10 years. An example non-numeric form for “an annual failure likelihood” is large, and for a “mean time between failures” is medium. In the latter non-numeric form, guidance needs to be provided regarding the meaning of terms such as large, medium, small, very large, very small, and so on. The selection of the form should be based on the availability of information, the ability of the personnel providing the needed information to express it in one form or another, and the importance of having numeric versus non-numeric information in formulating the final decisions.

The types of failure consequences that should be considered in a study need to be selected. They can include production loss, property damage, environmental damage, and safety loss in the form of human injury and death. Approximate estimates of failure consequences at the identified levels of decision making need to be determined. The estimates can be in numeric or non-numeric form. An example numeric form for production loss is 1,000 units. An example non-numeric form for production loss is large. In the latter non-numeric form, guidance needs to be provided regarding the meaning of terms such as large, medium, small, very large, very small, and so on. The selection of the form should be based on the availability of information, the ability of the personnel providing the needed information to express it in one form or another, and the importance of having numeric versus non-numeric information in formulating the final decisions.

Risk estimates can be determined as a pair of the likelihood and consequences, and computed as the arithmetic multiplication of the respective failure likelihood and consequences for the equipment, components and details. Alternatively, for all cases, plots of failure likelihood versus consequences can be developed. Then, approximate ranking of them as groups according to risk estimates, failure likelihood, and/or failure consequences can be developed.

Preliminary Hazard Analysis

Preliminary hazard analysis (PrHA) is a common risk-based technology tool with many applications. The general process is shown in Figure 207.6. This technique requires experts to identify and rank the possible accident scenarios that may occur. It is frequently used as a preliminary method to identify and reduce the risks associated with major hazards of a system.

Failure Mode and Effects Analysis

Failure mode and effects analysis (FMEA) is another popular risk-based technology tool as shown in [Figure 207.7](#). This technique has been introduced both in the national and international regulations for the aerospace (US MIL-STD-1629A), processing plant, and marine industries. The Society of Automotive Engineers in its recommended practice introduces two types of FMEA: design and process FMEA. This

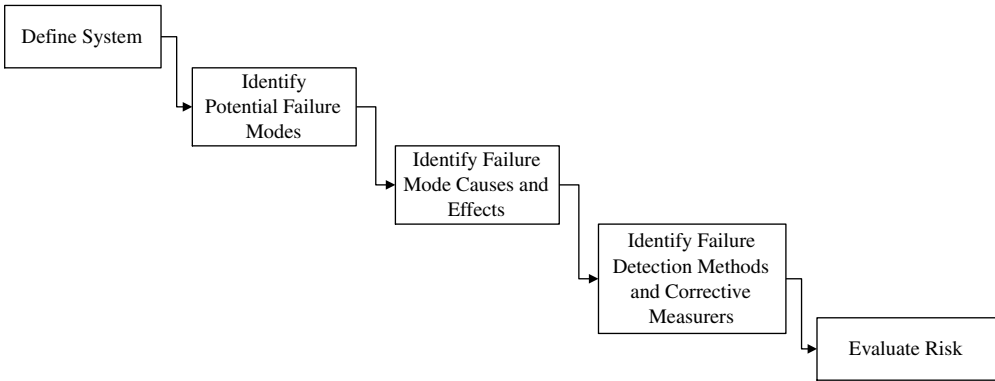

FIGURE 207.7 Failure mode and effects analysis process.

analysis tool assumes that a failure mode occurs in a system/component through some failure mechanism; the effect of this failure on other systems is then evaluated. A risk ranking can be developed for each failure mode for the effect on the overall performance of the system.

The various terms used in FMEA with examples based on the manufacturing of personal flotation devices (PFDs) are provided under subsequent headings to include failure mode, failure effect, severity rating, causes, occurrence rating, controls, detection rating, and risk priority number.

Risk Matrices

Risk can be assessed and presented using matrices for preliminary screening by subjectively estimating probabilities and consequences in a qualitative manner. A risk matrix is a two-dimensional presentation of likelihood and consequences using qualitative metrics for both dimensions. According to this method, risk is characterized by categorizing probability and consequence on the two axes of a matrix. Risk matrices have been used extensively for screening various risks. They may be used alone or as a first step in a quantitative analysis. Regardless of the approach used, risk analysis should be a dynamic process, that is, a living process where risk assessments are reexamined and adjusted. Actions or inactions in one area can affect risk in another; therefore continuous updating is necessary.

The likelihood metric can be constructed using the categories shown in Table 207.5, whereas the consequences metric can be constructed using the categories shown in Table 207.6 with an example

TABLE 207.5 Likelihood Categories for a Risk Matrix

| Category | Description | Annual Probability Range |
|----------|--------------------|---------------------------------------|
| A | Likely | ≥ 0.1 (1 in 10) |
| B | Unlikely | ≥ 0.01 (1 in 100) but < 0.1 |
| C | Very unlikely | ≥ 0.001 (1 in 1,000) but < 0.01 |
| D | Doubtful | ≥ 0.0001 (1 in 10,000) but < 0.001 |
| E | Highly unlikely | ≥ 0.00001 (1 in 100,000) but < 0.0001 |
| F | Extremely unlikely | < 0.00001 (1 in 100,000) |

TABLE 207.6 Consequence Categories for a Risk Matrix

| Category | Description | Examples |
|----------|--------------|--|
| I | Catastrophic | Large number of fatalities, and/or major long-term environmental impact. |
| II | Major | Fatalities, and/or major short-term environmental impact. |
| III | Serious | Serious injuries, and/or significant environmental impact. |
| IV | Significant | Minor injuries, and/or short-term environmental impact. |
| V | Minor | First aid injuries only, and/or minimal environmental impact. |
| VI | None | No significant consequence. |

TABLE 207.7 Example Consequence Categories for a Risk Matrix in 2003 Monetary Amounts (US\$)

| Category | Description | Cost |
|----------|--------------------|--|
| I | Catastrophic loss | ≥ \$10,000,000,000 |
| II | Major loss | ≥ \$1,000,000,000 but < \$10,000,000,000 |
| III | Serious loss | ≥ \$100,000,000 but < \$1,000,000,000 |
| IV | Significant loss | ≥ \$10,000,000 but < \$100,000,000 |
| V | Minor loss | ≥ \$1,000,000 but < \$10,000,000 |
| VI | Insignificant loss | < \$1,000,000 |

provided in Table 207.7. The consequence categories of Table 207.6 focus on the health and environmental aspects of consequences. The consequence categories of Table 207.7 focus on the economic impact, and should be adjusted to meet specific needs of industry and/or applications. An example risk matrix is shown in Figure 207.8. In the figure, each boxed area is shaded depending on a subjectively assessed risk level. Three risk levels are used herein for illustration purposes of low (L), medium (M), and high (H). Other risk levels may be added using a scale of five levels instead of three levels if needed. These risk levels are also called *severity factors*. The high (H) level can be considered as unacceptable risk level, the medium (M) level can be treated as either undesirable or as acceptable with review, and the low (L) level can be treated as acceptable without review.

Event Modeling: Event, Success Trees, and Fault Trees

Event modeling is a systematic, and often the most complete, way to identify accident scenarios and quantify risk for risk assessment. This risk-based technology tool provides a framework for identifying scenarios to evaluate the performance of a system or component through system modeling. The combination of event tree analysis (ETA), success tree analysis (STA), and fault tree analysis (FTA) can provide a structured analysis of system safety.

Event tree analysis is often used if the successful operation of a component/system depends on a discrete (chronological) set of events. The initiating event is first followed by other events leading to an overall result (consequence). The ability to address a complete set of scenarios is developed since all combinations of both the success and failure of the main events are included in the analysis. The probability of occurrence of the main events in the event tree can be determined using a fault tree or its complement, the success tree. The scope of analysis for event trees and fault trees depends on the objective of the analysis.

Event tree analysis is appropriate if the operation of some system/component depends on a successive group of events. Event trees identify the various combinations of event successes and failures as a result of an initiating event to determine all possible scenarios. The event tree starts with an initiating event followed by some reactionary event. This reaction can be a success or failure. If the event succeeds, the most commonly used indication is the upward movement of the path branch. A downward branch of the event tree marks the failure of an event. The remaining events are evaluated to determine the different possible scenarios. The scope of the events can be functions/systems that can provide some reduction to

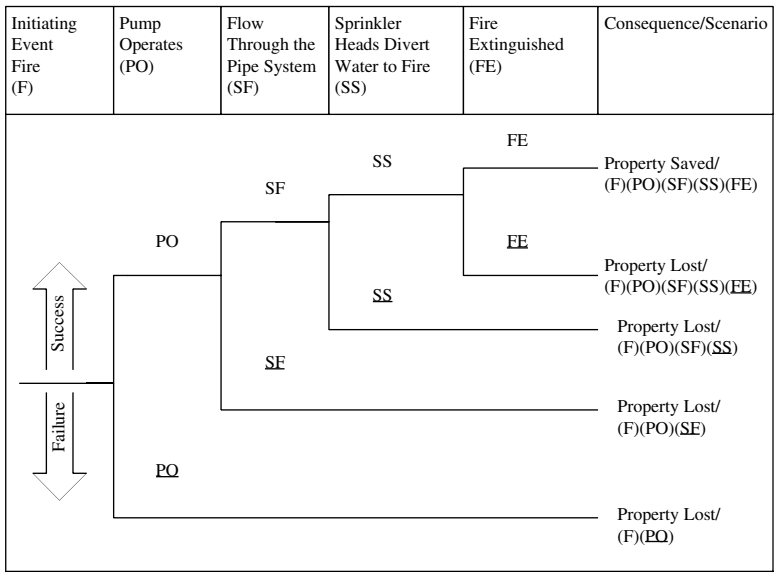

FIGURE 207.9 Event tree example for sprinkler system.

the possible hazards from the initiating event. The final outcome of a sequence of events identifies the overall state resulting from the scenario of events. Each path represents a failure scenario with varying levels of probability and risk. Different event trees can be created for different event initiators. Figure 207.9 shows an example event tree for the basic elements of a sprinkler system that might be critical for maintaining the integrity of a marine vessel.

Based on the occurrence of an initiating event, event tree analysis examines possible system outcomes or consequences. This analysis tool is particularly effective in showing the interdependence of system components that is important in identifying events and that at first might appear insignificant, but due to interdependency result in devastating results. Event tree analysis is similar to fault tree analysis because both methods use probabilistic reliability data of the individual components and events along each path to compute the likelihood of each outcome.

A quantitative evaluation of event tree probability values can be used for each event to evaluate the probability of the overall system state. Probability values for the success or failure of the events can be used to identify the probability for a specific event tree sequence. The probabilities of the events in a sequence can be provided as an input to the model or evaluated using fault trees. These probabilities for various events in a sequence can be viewed as conditional probabilities and therefore can be multiplied to obtain the occurrence probability of the sequence. The probabilities of various sequences can be summed up to determine the overall probability of a certain outcome. The addition of consequence evaluation for a scenario allows generation of a risk value. For example, the occurrence probability of the top branch scenario in Figure 207.9 is computed as the product of the probabilities of the events that comprise this scenario, that is,

$$F \cap PO \cap SF \cap SS \cap FE$$

or (F)(PO)(SF)(SS)(FE) for short.

Complex systems are often difficult to visualize and the effect of individual components on the system as a whole is difficult to evaluate without an analytical tool. Two modeling methods that have greatly improved the ease of assessing system reliability/risk are fault trees (FT) and success trees (ST). A fault tree is a graphical model created by deductive reasoning that leads to various combinations of events, which in turn leads to the occurrence of some top event failure. A success tree shows the combinations

of successful events leading to the success of the top event. A success tree can be produced as the complement (opposite) of the fault tree as illustrated in this section. Fault trees and success trees are used to further analyze event tree headings (the main events in an event tree) to provide further detail to understand system complexities. In constructing the FT/ST, only failure/success events that are considered significant are modeled. This determination is assisted by defining system boundaries. For example, the event “pump operates” (PO) in [Figure 207.9](#) can be analyzed by developing a top-down logical breakdown of failure or success using fault trees or event trees, respectively.

Fault tree analysis (FTA) starts by defining a top event that is commonly selected as an adverse event. An engineering system can have more than one top event. For example, a ship might have the following top events for the purpose of reliability assessment: power failure, stability failure, mobility failure, or structural failure. Then, each top event needs to be examined using the following logic: in order for the top event to occur, other events must occur. As a result, a set of lower-level events is defined. Also, the form in which these lower level events are logically connected (i.e., in parallel or in series) needs to be defined. The connectivity of these events is expressed using AND or OR gates. Lower-level events are classified into the following types:

- *Basic events.* These events cannot be decomposed further into lower level events. They are the lowest events that can be obtained. For these events, failure probabilities need be obtained.
- *Events that can be decomposed further.* These events can be decomposed further to lower levels. Therefore, they should be decomposed until basic events are obtained.
- *Undeveloped events.* These events are not basic and can be decomposed further. However, because they are not important, they are not developed further. Usually, the probabilities of these events are very small or the effect of their occurrence on the system is negligible, or can be controlled or mediated.
- *Switch (or house) events.* These events are not random, and can be turned on or off with full control.

The symbols shown in [Figure 207.10](#) are used for these events. Also, a continuation symbol is shown, which is used to break up a fault tree into several parts for the purpose of fitting it in several pages.

FTA requires the development of a tree-looking diagram for the system that shows failure paths and scenarios that can result in the occurrence of a top event. The construction of the tree should be based on the building blocks and the Boolean logic gates.

The outcome of interest from the fault tree analysis is the occurrence probability of the top event. Since the top event was decomposed into basic events, its occurrence can be stated in the form of AND and OR of the basic events. The resulting statement can be restated by replacing the AND with the intersection of the corresponding basic events, and the OR with the union of the corresponding basic events. Then, the occurrence probability of the top event can be computed by evaluating the probabilities of the unions and intersections of the basic events. The dependence between these events also affects the resulting probability of the system.

For large fault trees, the computation of the occurrence probability of the top event can be difficult because of their size. In this case, a more efficient approach is needed for assessing the reliability of a system, such as the minimal cut set approach. According to this approach, each cut set is defined as a set of basic events where the joint occurrence of these basic events results in the occurrence of the top event. A minimal cut set is a cut set with the condition that the non-occurrence of any one basic event from this set results in the non-occurrence of the top event. Therefore, a minimal cut set can be viewed as a subsystem in parallel. In general, systems have more than one minimal cut sets. The occurrence of the top event of the system can, therefore, be due to any one of these minimal cut sets. As a result, the system can be viewed as the union of all the minimal cut sets for the system. If probability values are assigned to the cut sets, a probability for the top event can be determined.

A simple example of this type of modeling is shown in [Figure 207.11](#) for a pipe system using a reliability block diagram. If the goal of the system is to maintain water flow from one end of the system to the other, then the individual pipes can be related with a Boolean logic. Both pipe (a) and pipe (d) and pipe (b) or pipe (c) must function for the system to meet its goal as shown in the success tree [Figure 207.12\(a\)](#).

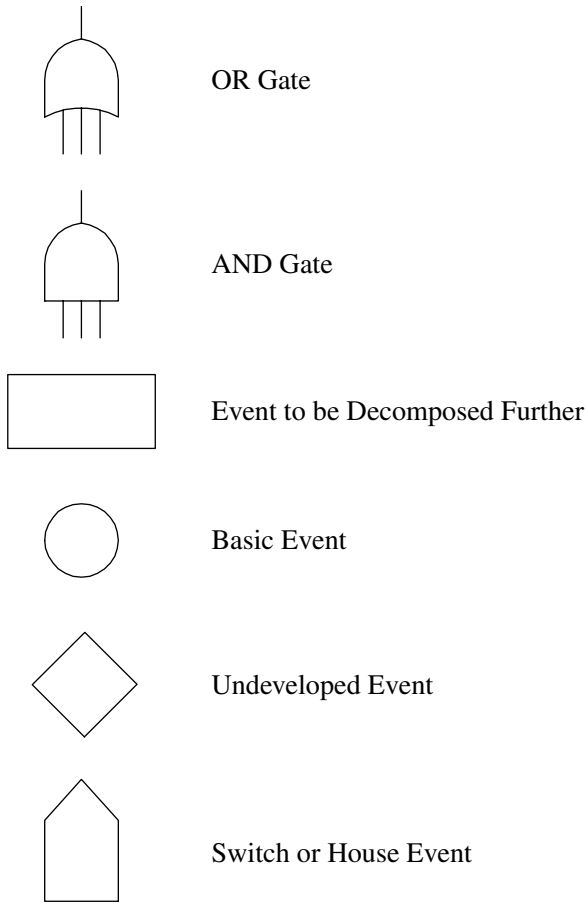

FIGURE 207.10 Symbols used in fault tree analysis.

FIGURE 207.11 A reliability block diagram for a piping system.

The complement of the success tree is the fault tree. The goal of the fault tree model is to construct the logic for system failure as shown in [Figure 207.12\(b\)](#). Once these tree elements have been defined, possible failure scenarios of a system can be defined.

As was previously described, a failure path is often referred to as a cut set. One objective of the analysis is to determine the entire minimal cut sets, where a minimal cut set is defined as a failure combination of all essential events that can result in the failure top event. A minimal cut set includes in its combination all essential events, that is, the nonoccurrence of any of these essential events in the combination of a minimal cut set results in the nonoccurrence of the minimal cut set. These failure combinations are used to compute the failure probability of the top event. The concept of the minimal cut sets applies only to the fault trees. A similar concept can be developed in the complementary space of the success trees, and is called the minimal pass set. In this case, a minimal pass set is defined as a survival (or success)

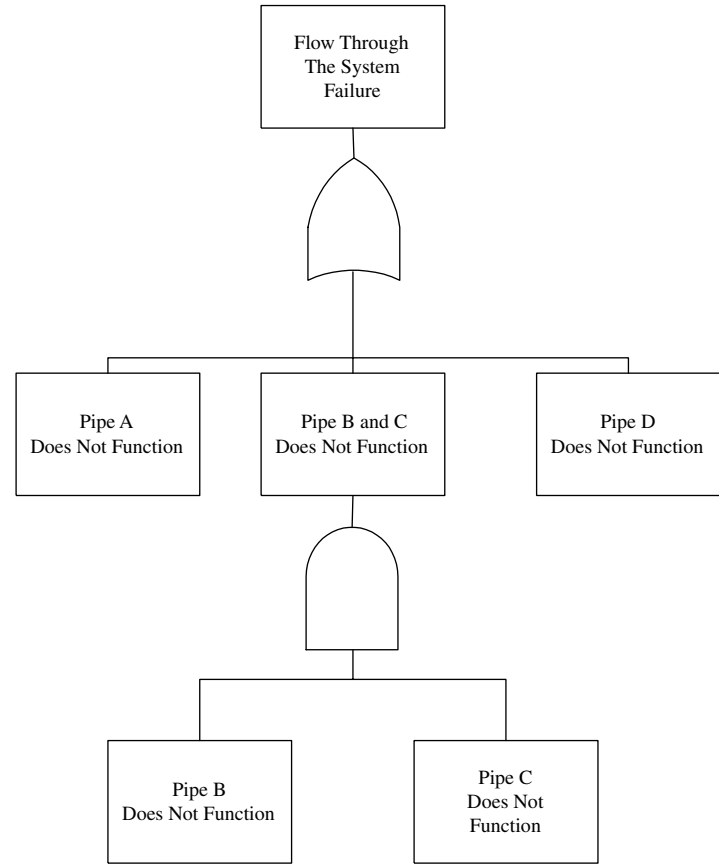

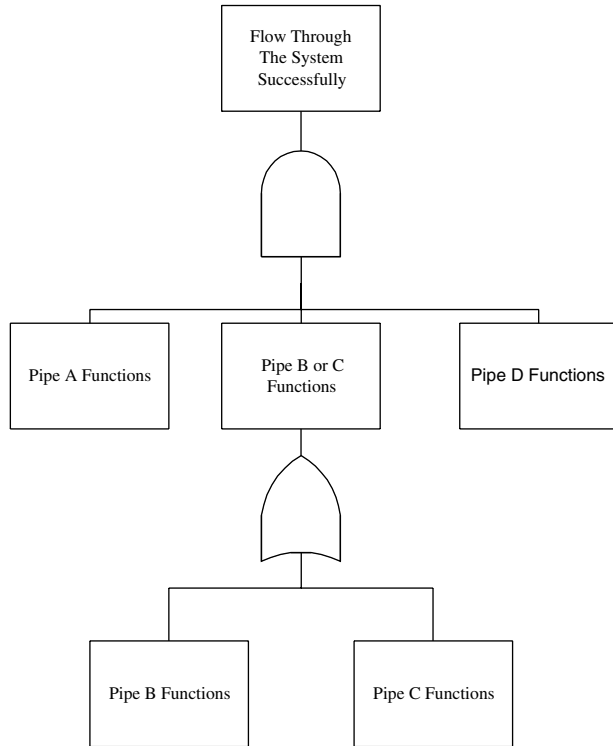

FIGURE 207.12 (a) Success tree for pipe system example. (b) Fault tree for pipe system example.

combination of all essential success events that can result in success as defined by the top event of the success tree. For the piping example, the minimal cut sets are

$$A \tag{207.6a}$$

$$D \tag{207.6b}$$

$$B \text{ and } C \tag{207.6c}$$

A minimal cut set includes events that are all necessary for the occurrence of the top event. For example, the following cut set is not a minimal cut set:

$$A \text{ and } B \tag{207.7}$$

Example 207.1: Trends in Fault Tree Models and Cut Sets

This example demonstrates how the cut sets can be identified and constructed for different arrangements of OR and AND gates logically defining a top-event occurrence. Generally, the number of cut sets increases by increasing the number of OR gates in the tree. For example, Figure 207.13 shows this trend by comparing cases a, b, and d. On the other hand, increasing the number of AND gates results in increasing the number of events included in the cut sets as shown in case c in Figure 207.13.

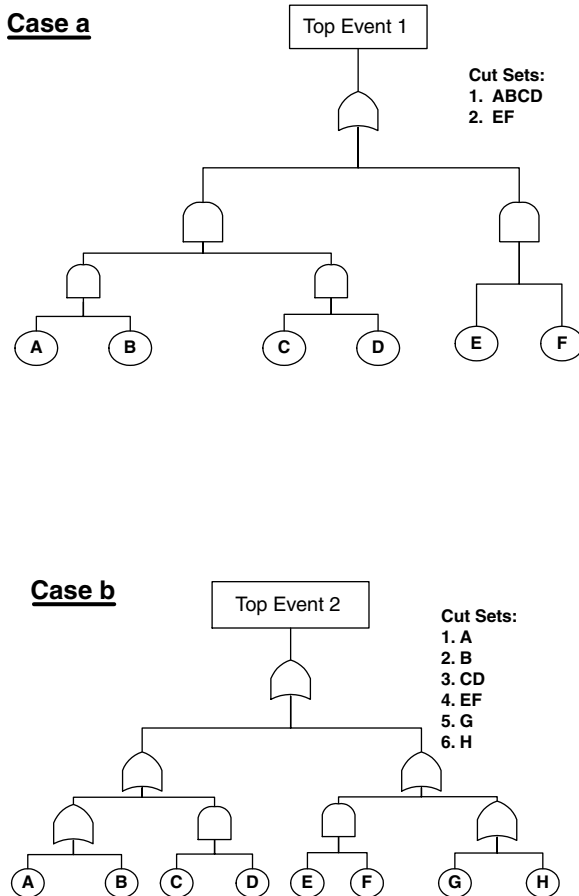

FIGURE 207.13 Trends in fault tree models and cut sets.

Continued on next page.

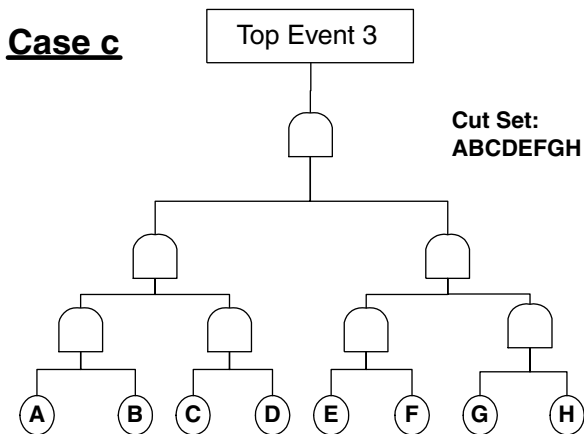

FIGURE 207.13 Continued.

Common-cause scenarios are events or conditions that result in the failure of seemingly separate systems or components. Common cause failures complicate the process of conducting risk analysis because a seemingly redundant system can be rendered ineffective by a common cause failure. For example, an emergency diesel generator fed by the same fuel supply as the main diesel engine will fail with the main diesel generator, if the fuel supply is the root source of the failure. The redundant emergency diesel generator is not truly redundant due to a common cause failure. Another example of common cause events is the failure of two separate but similar pieces of machinery due to a common maintenance problem, two identical pieces of equipment failing due to a common manufacturing defect, or two pieces of equipment failing due to a common environmental condition such as the flooding of a compartment or a fire in the vicinity of both pieces of machinery. A method for calculating the reliability of a system while taking into account common cause effects is the beta-factor model. Other methods include multiple Greek-letter model, alpha factor model, and beta binomial failure-rate model.

Part of risk-based decision analysis is pinpointing the system components that result in high-risk scenarios. Commercial system reliability software provides this type of analysis in the form of system-reliability sensitivity factors to changes in the underlying component reliability values. In performing risk analysis, it is desirable to assess the importance of events in the model, or the sensitivity of final results to changes in the input failure probabilities for the events. Several sensitivity or importance factors are available and can be used. The most commonly used factors include the Fussell–Vesely factor, and the Birnbaum factor. In addition, a weighted combination of these factors can be used as an overall measure.

Human-Related Risks

Risk assessment requires the performance analysis of an entire system composed of a diverse group of components. The system definition readily includes the physical components of the system; however, humans are also part of most systems and provide significant contributions to risk. It has been estimated that nearly 90% of the accidents at sea are attributable to human error. The human contribution to risk can be estimated from an understanding of behavioral sciences. Both “hardware failure” and human error should be addressed in the risk assessment since they both contribute to risks associated with the system. Once the human error probabilities are determined, human error/failures are treated in the same fashion as hardware failures in performing risk assessment quantification.

The determination of the human error contribution to risk is determined by human reliability analysis (HRA) tools. HRA is the discipline that enables the analysis and impact of humans on the reliability and safety of systems. Important results of HRA are determining the likelihood of human error as well as

ways in which human errors can be reduced. When combined with system risk analysis, HRA methods provide an assessment of the detrimental effects of humans on system performance. HRA is generally considered to be composed of three basic steps: error identification, modeling, and quantification.

Other sources of human-related risks are in the form of deliberate sabotage of a system from within the system or threat from outside the system, such as a computer hacker or a terrorist. The hazard in this case is not simply random but intelligent. The methods introduced in earlier sections might not be fully applicable for this risk type. The threat scenarios to the system in this case have a dynamic nature that are affected by the defense or risk mitigation and management scenarios that would be implemented by an analyst. The use of game theory methods might be needed in this case in combination with other risk analysis and management methods. Game theory is introduced later in this section.

Human Error Identification

Human errors are unwanted circumstances caused by humans that result in deviations from expected norms that place systems at risk. It is important to identify the relevant errors that are necessary to render a complete and accurate risk assessment. Human error identification techniques should provide a comprehensive structure for determining significant human errors within a system. Quality HRA allows for accuracy in both the HRA assessment and overall system risk assessment.

Identification of human errors requires knowledge about the interactions of humans with other humans or machines (physical world). It is the study of these interfaces that allows for the understanding of human errors. Potential sources of information for identifying human error may be determined from task analysis, expert judgment, laboratory studies, simulation, and reports. Human errors may be considered active or latent depending on the time delay between when the error occurs and when the system fails.

It is important to note the distinction between human errors and human factors. Human errors are generally considered separately from human factors in the application of information about human behavior, abilities, limitations, and other characteristics in the design of tools, machines, system tasks, jobs, and environments for productive, safe, comfortable, and effective human use. Human factors are determined from performing descriptive studies to characterize populations and experimental research. However, human factors analysis may contribute to human reliability analysis.

Human Error Modeling

Once human errors have been identified, they must be represented in a logical and quantifiable framework along with other components that contribute to system risk. This framework can be determined from development of a risk model. Currently, there is no consensus on how to model human reliably. Many of these models use human event trees and fault trees to predict human reliability values. The identifications of human failure events can also be identified using FMEA. The human-error rate estimates are often based on simulation tests, models, and expert estimation.

Human Error Quantification

Quantification of human error reliability promotes the inclusion of the human element in risk analysis. This is still a developing science requiring understanding of human performance, cognitive processing, and human perceptions. Since an exact model for human cognition has not been developed, much of the current human reliability data are based on accident databases and simulation and other empirical approaches. Many of the existing data sources were developed from specific industry data, such as the nuclear and aviation industries. The application of these data sources for a specific problem should be thoroughly examined prior to application for a specific model. The result of the quantification of human reliability in terms of probability of occurrence is typically called a human error probability (HEP). There are many techniques that have been developed to help predict the HEP values. The technique for human error rate prediction (THERP) is one of the most widely used methods for HEP. This technique is based on data gathered from the nuclear and chemical processing industries. THERP relies on HRA event tree modeling to identify the events of concern. Quantification is performed from data tables of basic HEP for specific tasks that may be modified based on the circumstances affecting performance.

The degree of human reliability is influenced by many factors often called performance-shaping factors (PSF). PSFs are those factors that affect the ability of people to carry out required tasks. For example, the knowledge that people have on how to don/activate a personal flotation device (PFD) will affect the performance of this task. Training (another PSF) in donning PFDs can also assist in the ability to perform this task. Another example is the training that is given to passengers on airplanes before takeoff on using seatbelts, emergency breathing devices, and flotation devices. Often the quantitative estimates of reliability are generated from a base error rate that is then altered based on the PSFs of the particular circumstances. Internal PSFs are an individual's own attributes (experience, training, skills, abilities, attitudes) that affect the ability of the person to perform certain tasks. External PSFs are the dynamic aspects of situation, tasks, and system that affect the ability to perform certain tasks. Typical external factors include environmental stress factors (such as heat, cold, noise, situational stress, time of day), management, procedures, time limitations, and quality of the person-machine interface. With these PSFs, it is easy to see the dynamic nature of HEP evaluation based on the circumstances of the analysis.

Reducing Human Errors

Error reduction is concerned with lowering the likelihood for error in an attempt to reduce risk. The reduction of human errors may be achieved by human factors interventions or by engineering means. Human factors interventions include improving training or improving the human-machine interface (such as alarms, codes, and so on) based on an understanding of the causes of error. Engineering means of error reduction may include automated safety systems or interlocks. Selection of corrective actions to take can be done through decision analysis considering cost-benefit criteria.

Game Theory for Intelligent Threats

Game theory can be used to model human behavior, herein considered as a threat to a system. Generally, game theory utilizes mathematics, economics, and the other social and behavioral sciences to model human behavior.

An example of intelligent threats is terrorism and sabotage as an ongoing battle between coordinated opponents representing a two-party game, where each opponent seeks to achieve their own objectives within a system. In the case of terrorism, the game involves a well-established political system versus an emerging organization that uses terrorism to achieve partial or complete dominance. Each player in this game seeks a utility, or benefit, that is a function of the desired state of the system. In this case, maintaining system survival is the desired state for the government; whereas the opponent seeks a utility based on the failure state of the system. The government, as an opponent, is engaged in risk mitigation, whose actions seek to reduce the threat, reduce system vulnerability, and/or mitigate the consequences of successful attacks. The terrorists, as an opponent, can be viewed as the aggressor who strives to alter or damage their opponent's desired system state. This game involves an intelligent threat, and is dynamic. The game is ongoing until the probability of a successful disruptive attempt of the aggressor reaches an acceptable level of risk, a stage where risk is considered under control, and the game is brought to an end. Classical game theory can be used in conjunction with probabilistic risk analysis to determine optimal mitigation actions that maximize benefits.

A classical example used to introduce game theory is called the prisoner's dilemma and is based on two suspects captured near the scene of a crime and are questioned separately by authorities such as the police. Each has to choose whether or not to confess and implicate the other. If neither person confesses, then both will serve, say, 1 year on a charge of carrying a concealed weapon. If each confesses and implicates the other, both will go to prison for, say, 10 years. However, if one person confesses and implicates the other, and the other person does not confess, the one who has collaborated with the police will go free, while the other person will go to prison for, say, 20 years under the maximum penalty. The strategies in this case are confess or don't confess. The payoffs (penalties here) are the sentences served. The problem can be expressed compactly in a payoff table of a kind that has become fairly standard in game theory, illustrated in [Table 207.8](#). The entries in this table mean that each prisoner chooses one of the two strategies, that is, the first suspect chooses a row and the second suspect chooses a column. The

two numbers in each cell of the table provide the outcomes for the two suspects for the corresponding pair of strategies chosen by the suspects as an ordered pair. The number to the left of the comma is the payoff to the person who chooses the rows, that is, the first suspect. The number to the right of the comma is the payoff to the person who chooses the columns, that is, the second suspect. Thus, reading down the first column, if they both confess, each gets 10 years, but if the second suspect confesses and first suspect does not, the first suspect gets 20 years and second suspect goes free. This example is not a zero-sum game since the payoffs are all losses. However, many problems can be cast with losses (negative numbers) and gains (positive numbers) with a total for each cell in the payoff table. A zero-sum game occurs when the payoffs in each cell add up to zero.

TABLE 207.8 Payoff Table in Years for Prisoner's Dilemma Game

| | | Second Suspect | |
|---------------|---------------|----------------|---------------|
| | | Confess | Don't Confess |
| First Suspect | Confess | (10, 10) | (0, 20) |
| | Don't confess | (20, 0) | (1, 1) |

The solution to this problem needs to be based on identifying rational strategies that can be based on both persons wanting to minimize the time they spend in jail. One suspect might reason that “two things can happen: either the other suspect confesses or keeps quiet. Suppose the second suspect confesses, I will get 20 years if I don't confess, 10 years if I do; therefore in this case it's best to confess. On the other hand, if the other suspect doesn't confess, and I don't either, I get a year; but in that case, if I confess I can go free. Either way, it's best if I confess. Therefore, I'll confess.” But the other suspect can and presumably will reason in the same way. In this case, they both confess and go to prison for 10 years each, although if they had acted irrationally, and kept quiet, they each could have gotten off with 1 year each. The rational strategies of the two suspects have fallen into something called dominant-strategy equilibrium. The meaning of the term dominant-strategy equilibrium requires defining the term *dominant strategy*, which results from an individual player (suspect in this case) in a game evaluating separately each of the strategy combinations being faced, and, for each combination, choosing from these strategies the one that gives the greatest payoff. If the same strategy is chosen for each of the different combinations of strategies that the player might face, that strategy is called a dominant strategy for that player in that game. The dominant strategy equilibrium occurs if, in a game, each player has a dominant strategy, and each player plays the dominant strategy; then that combination of (dominant) strategies and the corresponding payoffs are said to constitute the dominant strategy equilibrium for that game. In the prisoner's dilemma game, to confess is a dominant strategy, and when both suspects confess, a dominant-strategy equilibrium is achieved. The dominant-strategy equilibrium is also called Nash equilibrium. When no player can benefit by changing his/her strategy while the other players keep their strategies unchanged, that set of strategies and corresponding payoffs constitute the Nash equilibrium.

The prisoner's dilemma game is based on two strategies per suspect that can be viewed as deterministic in nature, that are, nonrandom. In general, many games, especially those that permit repeatability in choosing strategies by players, can be constructed with strategies that have associated probabilities. For example, strategies can be constructed based on probabilities of 0.4 and 0.6 that add up to 1. Such strategies with probabilities are called mixed strategies as opposed to pure strategies that do not involve probabilities of the prisoner's dilemma game. A mixed strategy occurs in a game if a player chooses among two or more strategies at random according to specific probabilities.

In general, gaming could involve more than two players. In the prisoner's dilemma game, a third player that could be identified is the authority and its strategies. The solution might change as a result of adding the strategies of this third player. The use of these concepts in risk analysis and mitigation needs further development and exploration.

Economic and Financial Risks

Economic and financial risks can be grouped into categories that include market risks, credit risks, operation risks, and reputation risks. These four categories are described in subsequent sections.

Market Risks

Governments and corporations operate in economic and financial environments with some levels of uncertainty and instability. A primary contributor to defining this environment is interest rates. Interest rates can have a significant impact on the costs of financing a project, corporate cash flows, and asset values. For example, interest rates in the U.S. shot up in 1979 and peaked in 1981, followed by gradual decline with some fluctuations until 2002.

For projects that target global markets, exchange rate instability can be a major risk source. Exchange rates have been volatile ever since the breakdown of the Bretton Woods system to fixed exchange rates in the early 1970s. An example of a bust-up in exchange rates is plummeting value of the British pound and Italian lira due to failure of the exchange-rate mechanism in September 1992.

Many projects are dependent on availability of venture capital and the stock performance of a corporation, thereby introducing another risk source related to stock market volatility. Stock prices rose significantly in the inflationary booms of the early 1970s, and then fell considerably a little later. They recovered afterward, and fell again in the early 1981. The market rose to a peak until it crashed in 1987, followed by an increase with some swings until reaching a new peak fueled by Internet technologies until its collapse in 2001.

Other contributing factors to economic and financial instability is commodity prices in general and energy prices in particular, primarily crude oil. The hikes in oil prices in 1973 to 1974 affected commodity prices greatly and posed series challenges to countries and corporations.

Another contributing source to volatility is derivatives for commodities, foreign currency exchange rates, and stock prices and indices, among others. Derivatives are defined as contracts whose values or payoffs depend on those of other assets, such as options to buy commodities in the future or options to sell commodities in the future. They offer not only opportunities for hedging positions and managing risks that can be stabilizing, but also speculative opportunities to others that can be destabilizing and a contributor to volatility.

Credit Risks

Credit risks are associated with potential defaults on notes or bonds by corporations including subcontractors. Credit risks can be associated with market sentiments that determine a company's likelihood of default that could affect its bond rating, ability to borrow money, and maintain projects and operations.

Operational Risks

Operational risks are associated with several sources that include out-of-control operations risk that could occur when a corporate branch undertake significant risk exposure that is not accounted for by corporate headquarters, leading potentially to its collapse. An example is the British Barings Bank that collapsed primarily as a result of its failure to control market exposure created within a small overseas branch of the bank.

Another category here is liquidity risk in which a corporation needs more funding than it can arrange. It could also include money transfer risks and breaches of agreement.

Operational risks include model risks. Model risks are associated with the models and underlying assumptions used to incorrectly value financial instruments and cash flows.

Reputation Risks

The loss of business attributable to loss in a corporation's reputation can pose another risk source. This risk source can affect its credit rating, and ability to maintain clients, workforce, and so on. This risk source usually occurs at a slow attrition rate, and may be an outcome of poor management decisions and business practices.

Data Needs for Risk Assessment

In risk assessment, the methods of probability theory are used to represent engineering uncertainties. In this context, it refers to event occurrence likelihoods that occur with periodic frequency, such as weather,

yet also to conditions that exist but are unknown, such as the probability of an extreme wave. It applies to the magnitude of an engineering parameter, yet also to the structure of a model. By contrast, probability is a precise mathematical concept with an explicit definition. We use the mathematics of probability theory to represent uncertainties, despite the fact that those uncertainties take many forms.

Although the term *probability* has a precise mathematical definition, its meaning when applied to the representation of uncertainties is subject to differing interpretations. The *frequentist* view holds that probability is the propensity of a physical system in a theoretically infinite number of repetitions; that is, the frequency of occurrence of an outcome in a long series of similar trials (e.g., the frequency of a coin landing heads-up in an infinite number of flips is the probability of that event). In contrast, the *Bayesian* view holds that probability is the rational degree of belief that one holds in the occurrence of an event or the truth of a proposition; probability is manifest in the willingness of an observer to take action upon this belief. This latter view of probability, which has gained wide acceptance in many engineering applications, permits the use of quantified professional judgment in the form of subjective probabilities. Mathematically, such subjective probabilities can be combined or operated on as any other probability.

Data are needed to perform quantitative risk assessment or provide information to support qualitative risk assessment. Information may be available if data have been maintained on a system and components of interest. The relevant information for risk assessment includes possible failures, failure probabilities, failure rates, failure modes, possible causes, and failure consequences. In the case of a new system, data may be used from similar systems if this information is available. Surveys are a common tool used to provide data. Statistical analysis can be used to assess confidence intervals and uncertainties in estimated parameters of interest. Expert judgment may also be used as another source of data. Uncertainties regarding data quality should be identified to assist in the decision-making process.

Data can be classified to include generic and project- or plant-specific types. Generic data are information from similar systems and components. This information may be the only information available in the initial stages of system design. Therefore, potential differences due to design or uncertainty may result from using generic data on a specific system. Plant-specific data are specific to the system being analyzed. This information is often developed after the operation of a system. Relevant data need to be identified and collected, as data collection can be costly. The data collected can then be used to update the risk assessment. Bayesian techniques can be used to combine objective and subjective data.

Data can be classified as failure probability data and failure consequence data. Failure probability data can include failure rates, hazard functions, times between failures, results from reliability studies, and any influencing factors and their effects. Failure-consequence data include loss reports, damages, litigation outcomes, repair costs, injuries, and human losses, as well as influencing factors and effects of failure-prevention and consequence-mitigation plans. Areas of deficiency in terms of data availability should be identified, and sometimes failure databases need to be constructed. Data deficiency can be used as a basis for data collection and expert-opinion elicitation.

207.3 Risk Management and Control

Adding risk control to risk assessment produces risk management. Risk management is the process by which system operators, managers, and owners make safety decisions, regulatory changes, and choose different system configurations based on the data generated in the risk assessment. Risk management involves using information from the previously described risk assessment stage to make educated decisions about system safety. Risk control includes failure prevention and consequence mitigation.

Risk management requires the optimal allocation of available resources in support of group goals. Therefore, it requires the definition of acceptable risk, and comparative evaluation of options and/or alternatives for decision making. The goals of risk management are to reduce risk to an acceptable level and/or prioritize resources based on comparative analysis. Risk reduction is accomplished by preventing an unfavorable scenario, and reducing the frequency and/or reducing the consequence. A graph showing the risk relationship is shown in [Figure 207.14](#) as linear contours of constant risk, although due to risk aversion these lines are commonly estimated as nonlinear curves and should be treated as nonlinear

FIGURE 207.14 Risk graph.

curves. Moreover, the vertical axis is termed as probability whereas it is commonly expressed as an annual exceedance probability or frequency as shown in [Figure 207.1](#). In cases involving qualitative assessment, a matrix presentation can be used as shown in [Figure 207.8](#). The figure shows probability categories, severity categories, and risk ratings. A project's base value is commonly assumed as zero. Each risk rating value requires a different mitigation plan.

Risk Acceptance

Risk acceptance constitutes a definition of safety as discussed in previous sections. Therefore, risk acceptance is considered a complex subject that is often subject to controversial debate. The determination of acceptable levels of risk is important to determine the risk performance that a system needs to achieve to be considered safe. If a system has a risk value above the risk acceptance level, actions should be taken to address safety concerns and improve the system through risk reduction measures. One difficulty with this process is defining acceptable safety levels for activities, industries, structures, and so on. Since the acceptance of risk depends on society perceptions, acceptance criteria do not depend on the risk value alone. This section describes several methods that have been developed to assist in determining acceptable risk values as summarized in [Table 207.9](#).

Risk managers make decisions based on risk assessment and other considerations including economic, political, environmental, legal, reliability, producibility, safety, and other factors. The answer to the question "How safe is safe enough?" is difficult and constantly changes due to varying perceptions and understandings of risk. To determine "acceptable risk," managers need to analyze alternatives for the best choice. In some industries, an acceptable risk has been defined by consensus. For example, the U.S. Nuclear Regulatory Commission requires that reactors be designed such that the probability of a large radioactive release to the environment from a reactor incident shall be less than 1×10^{-6} per year. Risk levels for certain carcinogens and pollutants have also been given acceptable concentration levels based on some assessment of acceptable risk. However, risk acceptance for many other activities are not stated.

For example, qualitative implications for risk acceptance are identified in several existing maritime regulations. The International Maritime Organization High Speed Craft Code [2002] and the U.S. Coast Guard Navigation and Vessel Inspection Circular [1993] for passenger submersible guidance both state that if the end effect is hazardous or catastrophic, a backup system and a corrective operating procedure are required. These references also state that a single failure must not result in a catastrophic event, unless the likelihood is extremely remote.

TABLE 207.9 Methods for Determining Risk Acceptance

| Risk Acceptance Method | Summary |
|---|--|
| Risk conversion factors | This method addresses the attitudes of the public about risk through comparisons of risk categories. It also provides an estimate for converting risk acceptance values between different risk categories. |
| Farmer's curve | It provides an estimated curve for a cumulative probability risk profile for certain consequences (e.g., deaths). It demonstrates graphical regions of risk acceptance/nonacceptance. |
| Revealed preferences | Through comparisons of risk and benefit for different activities, this method categorizes societal preferences for voluntary and involuntary exposure to risk. |
| Evaluation of magnitude of consequences | This technique compares the probability of risks to the consequence magnitude for different industries to determine acceptable risk levels based on consequences. |
| Risk effectiveness | This method provides a ratio for the comparison of cost to the magnitude of risk reduction. Using cost-benefit decision criteria, a risk reduction effort should not be pursued if the costs outweigh the benefits. This may not coincide with societal values about safety. |
| Risk comparison | The risk acceptance method provides a comparison between various activities, industries, and so on, and is best suited to comparing risks of the same type. |

Often the level of risk acceptance with various activities is implied. Society has reacted to risks through the developed level of balance between risk and potential benefits. Measuring this balance of accepted safety levels for various risks provides a means for assessing society values. These threshold values of acceptable risk depend on a variety of issues including the activity type, industry, and users, and society as a whole.

Target risk or reliability levels are required for developing procedures and rules for ship structures. For example, the selected reliability levels determine the probability of failure of structural components. The following three methods were used to select target reliability values:

- Agreeing on a reasonable value in cases of novel structures without prior history
- Calibrating reliability levels implied in current successfully used design codes
- Choosing a target reliability level that minimizes total expected costs over the service life of the structure in dealing with a design for which failure results in only economic losses and consequences

The first approach can be based on expert opinion elicitation. The second approach called *code calibration* is the most commonly used approach, as it provides the means to build on previous experience. For example, rules provided by classification and industry societies can be used to determine the implied reliability and risk levels in respective rules and codes, and then target risk levels can be set in a consistent manner, and new rules and codes can be developed to produce future designs and vessels that are of similar levels that offer reliability and/or risk consistency. The third approach can be based on economic and tradeoff analysis. In subsequent sections, the methods of Table 207.9 for determining risk acceptance are discussed.

Risk Conversion Factors

Risk analysis shows that there are various taxonomies that demonstrate risk categories often called “risk factors.” These categories can be used to analyze risks on a dichotomous scale that compares risks that invoke the same perceptions in society. For example, the severity category may be used to describe both ordinary and catastrophic events. Grouping events that could be classified as ordinary and comparing the distribution of risk to a similar grouping of catastrophic categories yields a ratio describing the degree of risk acceptance of ordinary events as compared to catastrophic events. Comparison of various categories determined the risk conversion values as provided in [Table 207.10](#). These factors are useful in comparing the risk acceptance for various activities, industries, and so on. By computing the acceptable risk in one activity, an estimate of acceptable risk in other activities can be calculated based on risk conversion factors. A comparison of several common risks based on origin and volition is shown in [Table 207.11](#).

TABLE 207.10 Risk Conversion Values for Various Risk Factors

| Risk Factors | Risk Conversion Factor | Computed RF Value |
|-----------------|--------------------------|-------------------|
| Origin | Natural/human-made | 20 |
| Severity | Ordinary/catastrophic | 30 |
| Volition | Voluntary/involuntary | 100 |
| Effect | Delayed/immediate | 30 |
| Controllability | Controlled/uncontrolled | 5 to 10 |
| Familiarity | Old/new | 10 |
| Necessity | Necessary/luxury | 1 |
| Costs | Monetary/nonmonetary | NA |
| Origin | Industrial/regulatory | NA |
| Media | Low profile/high profile | NA |

NA = not available.

TABLE 207.11 Classification of Common Risks

| Source | Size | Voluntary | | Involuntary | |
|------------|--------------|------------------------------|----------------------------------|---|--------------------------|
| | | Immediate | Delayed | Immediate | Delayed |
| Human made | Catastrophic | Aviation | | Dam failure, building fire, nuclear accident | Pollution, building fire |
| | Ordinary | Sports, boating, automobiles | Smoking, occupation, carcinogens | Homicide | |
| Natural | Catastrophic | | | Earthquakes, hurricanes, tornadoes, epidemics | |
| | Ordinary | | | Lightning, animal bites | Disease |

Farmer's Curve

The farmer's curve is a graph of the cumulative probability versus consequence for some activity, industry, or design as shown in [Figures 207.1](#) and [207.2](#). This curve introduces a probabilistic approach in determining acceptable safety limits. The probability (or frequency) and consequence values are calculated for each level of risk generating a curve that is unique to the hazard of concern. The area to the right (outside) of the curve is generally considered unacceptable since the probability and consequence values are higher than the average value delineated by the curve. The area to the left (inside) of the curve is considered acceptable since probability and consequence values are less than the estimated value of the curve.

Method of Revealed Preferences

The method of revealed preferences provides a comparison of risk versus benefit and categorization for different risk types. The basis for this relationship is that risks are not taken unless there is some form of benefit. Benefit may be monetary or some other item of worth such as pleasure. The different risk types are for the risk category of voluntary versus involuntary actions as shown in [Figure 207.15](#).

Magnitudes of Risk Consequence

Another factor affecting the acceptance of risk is the magnitude of consequence of the event that can result from some failure. In general, the larger the consequence, the less the likelihood that this event may occur. This technique has been used in several industries to demonstrate the location of the industry within society's risk acceptance levels based on consequence magnitude as shown in [Figure 207.16](#). Further evaluation has resulted in several estimates for the relationship between the accepted probability of failure and the magnitude of consequence for failure as provided by Allen in 1981 and called herein the CIRIA (Construction Industry Research and Information Association) equation:

FIGURE 207.15 Accepted risk of voluntary and involuntary activities.

FIGURE 207.16 Target risk based on consequence of failure for industries.

$$P_f = 10^{-4} \frac{KT}{n} \quad (207.8)$$

where T is the life of the structure, K is a factor regarding the redundancy of the structure, and n is the number of people exposed to risk. Another estimate is Allen's [1981] equation:

$$P_f = 10^{-5} \frac{TA}{W\sqrt{n}} \quad (207.9)$$

where T is the life of the structure, n is the number of persons exposed to risk, and A and W are factors regarding the type and redundancy of the structure. Equation 207.8 offers a lower bound, whereas Equation 207.9 offers a middle line.

Risk Reduction Cost-Effectiveness Ratio

Another measuring tool to assess risk acceptance is the determination of risk reduction effectiveness:

$$\text{Risk Reduction Effectiveness} = \frac{\text{Cost}}{\Delta \text{Risk}} \quad (207.10)$$

where the cost should be attributed to risk reduction, and ΔRisk is the level of risk reduction as follows:

$$\Delta \text{Risk} = (\text{Risk before mitigation action}) - (\text{Risk after mitigation action}) \quad (207.11)$$

The difference in Equation 207.11 is also called the benefit attributed to a risk reduction action. Risk effectiveness can be used to compare several risk reduction efforts. The initiative with the smallest risk effectiveness provides the most benefit for the cost. Therefore, this measurement may be used to help determine an acceptable level of risk. The inverse of this relationship may also be expressed as cost effectiveness.

Risk Comparisons

This technique uses the frequency of severe incidents to directly compare risks between various areas of interest to assist in justifying risk acceptance. Risks can be presented in different ways that impact how the data are used for decisions. Often risk values are manipulated in different forms for comparison reasons as demonstrated in Table 207.12. Comparison of risk values should be taken in the context of the values' origin and the uncertainties involved.

TABLE 207.12 Ways to Identify Risk of Death

| Ways to Identify Risk of Death | Summary |
|----------------------------------|---|
| Number of fatalities | This measure shows the impact on society in terms of the number of fatalities. Comparison of these values is cautioned since the number of persons exposed to the particular risk may vary. Also, the time spent performing the activity may vary. Different risk category types should also be considered to compare fatality rates. |
| Annual mortality rate/individual | This measure shows the mortality risk normalized by the exposed population. This measure adds additional information about the number of exposed persons; however, the measure does not include the time spent on the activity. |
| Annual mortality | This measure provides the most complete risk value since the risk is normalized by the exposed population and the duration of the exposure. |
| Loss-of-life exposure (LLE) | This measure converts a risk into a reduction in the expected life of an individual. It provides a good means of communicating risks beyond probability values. |
| Odds | This measure is a layperson format for communicating probability, for example, 1 in 4. |

This technique is most effective for comparing risks that invoke the same human perceptions and consequence categories. Comparing risks of different categories is cautioned since the differences between risk and perceived safety may not provide an objective analysis of risk acceptance. The use of risk conversion factors may assist in transforming different risk categories. Conservative guidelines for determining risk acceptance criteria can be established for voluntary risks to the public from the involuntary risk of natural causes.

Rankings Based on Risk Results

Another tool for risk management is the development of risk ranking. The elements of a system within the objective of analysis can be analyzed for risk and consequently ranked. This relative ranking may be based on failure probabilities, failure consequences, risks, or other alternatives with concern toward risk. Generally risk items ranked highly should be given high levels of priority; however, risk management decisions may consider other factors such as costs, benefits, and effectiveness of risk reduction measures. The risk ranking results may be presented graphically as needed.

Decision Analysis

Decision analysis provides a means for systematically dealing with complex problems to arrive at a decision. Information is gathered in a structured manner to provide the best answer to the problem. A decision generally deals with three elements: alternatives, consequences, and preferences. The alternatives are the possible choices for consideration. The consequences are the potential outcomes of a decision. Decision analysis provides methods for quantifying preference tradeoffs for performance along multiple decision attributes while taking into account risk objectives. Decision attributes are the performance scales that measure the degree to which objectives are satisfied. For example, one possible attribute is reducing lives lost for the objective of increasing safety. Additional examples of objectives may include minimize cost, maximize utility, maximize reliability, and maximize profit. The decision outcomes may be affected by uncertainty; however, the goal is to choose the best alternative with the proper consideration of uncertainty. The analytical depth and rigor for decision analysis depend on the desired detail in making the decision. Cost-benefit analysis, decision trees, influence diagrams, and the analytic hierarchy process are some of the tools to assist in decision analysis. Also, decision analysis should consider constraints, such as availability of the system for inspection, availability of inspectors, preferences of certain inspectors, and availability of inspection equipment.

Benefit-Cost Analysis

Risk managers commonly weigh various factors including cost and risk. The analysis of three different alternatives is shown graphically in [Figure 207.17](#) as an example. The graph shows that alternative (C) is the best choice since the levels of risk and cost are less than for alternatives (A) and (B). However, if the only alternatives were A and B, the decision would be more difficult. Alternative (A) has higher cost and lower risk than alternative (B); alternative (B) has higher risk but lower cost than alternative (A). A risk manager needs to weigh the importance of risk and cost in making decisions, as well as resource availability, and to make use of risk-based decision analysis.

Risk-benefit analysis can also be used for risk management. Economic efficiency is important to determine the most effective means of expending resources. At some point the costs for risk reduction do not provide adequate benefits. This process compares the costs and risk to determine where the optimal risk value is on a cost basis. This optimal value occurs, as shown in [Figure 207.18](#), when costs to control risk are equal to the risk cost due to the consequence (loss). Investing resources to reduce risks below this equilibrium point does not provide a financial benefit. This technique may be used when cost values can be attributed to risks. This analysis might be difficult to perform for certain risk such as risk to human health and environmental risks since the monetary values are difficult to estimate for human life and the environment.

FIGURE 207.17 Risk benefit for three alternatives.

FIGURE 207.18 Comparison of risk and control costs.

The present value of incremental costs and benefits can be assessed and compared among alternatives that are available for risk mitigation or system design. Several methods are available to determine which, if any, option is most worth pursuing. In some cases, no alternative will generate a net benefit relative to the base case. Such a finding would be used to argue for pursuit of the base case scenario. The following are the most widely used present-value comparison methods: (1) net present value (NPV), (2) benefit-cost ratio, (3) internal rate of return, and (4) payback period. The NPV method requires that each alternative need to meet the following criteria to warrant investment of funds: positive NPV and the highest NPV of all alternatives considered. The first condition ensures that the alternative is worth undertaking relative to the base case; for example, it contributes more in incremental benefits than it absorbs in incremental costs. The second condition ensures that maximum benefits are obtained in a situation of unrestricted access to capital funds. The NPV can be calculated as follows:

$$NPV = \sum_{t=0}^k \frac{(B-C)_t}{(1+r)^t} = \sum_{t=0}^k \frac{B_t}{(1+r)^t} - \sum_{t=0}^k \frac{C_t}{(1+r)^t} \quad (207.12)$$

where B is future annual benefits in constant dollars, C is future annual costs in constant dollars, r is annual real discount rate, k is number of years from the base year over which the project will be evaluated, and t is an index running from 0 to k representing the year under consideration.

The benefit of a risk mitigation action can be assessed as follows:

$$\text{Benefit} = \text{unmitigated risk} - \text{mitigated risk} \quad (207.13)$$

The cost in Equation 207.13 is the cost of the mitigation action. The benefit minus the cost of mitigation can be used to justify the allocation of resources. The benefit-to-cost ratio can be computed, and may also be helpful in decision making. The benefit-to-cost ratio can be computed as

$$\text{Benefit-to-Cost Ratio } (B/C) = \frac{\text{Benefit}}{\text{Cost}} = \frac{\text{Unmitigated Risk} - \text{Mitigated Risk}}{\text{Cost of Mitigation Action}} \quad (207.14)$$

Ratios greater than 1 are desirable. In general, the larger the ratio, the better the mitigation action.

Accounting for the time value of money would require defining the benefit-cost ratio as the present value of benefits divided by the present value of costs. The benefit-cost ratio can be calculated as follows:

$$B/C = \frac{\sum_{t=0}^k \frac{B_t}{(1+r)^t}}{\sum_{t=0}^k \frac{C_t}{(1+r)^t}} \quad (207.15)$$

where B_t is future annual benefits in constant dollars, C_t is future annual costs in constant dollars, r is annual real discount rate, and t is an index running from 0 to k representing the year under consideration. A proposed activity with a B/C ratio of discounted benefits to costs of 1 or more is expected to return at least as much in benefits as it costs to undertake, indicating that the activity is worth undertaking.

The internal rate of return (IRR) is defined as the discount rate that makes the present value of the stream of expected benefits in excess of expected costs zero. In other words, it is the highest discount rate at which the project will not have a negative NPV . To apply the IRR criterion, it is necessary to compute the IRR and then compare it with a base rate of, say, a 7% discount rate. If the real IRR is less than 7%, the project would be worth undertaking relative to the base case. The IRR method is effective in deciding whether or not a project is superior to the base case; however it is difficult to utilize it for ranking projects and deciding among mutually exclusive alternatives. Project rankings established by the IRR method might be inconsistent with those of the NPV criterion. Moreover, a project might have more than one IRR value, particularly when it entails major final costs, such as cleanup costs. Solutions to these limitations exist in capital budgeting procedures and practices that are often complicated or difficult to employ in practice and present opportunities for error.

The payback period measures the number of years required for net undiscounted benefits to recover the initial investment in a project. This evaluation method favors projects with near-term and more certain benefits, and fails to consider benefits beyond the payback period. The method does not provide information on whether an investment is worth undertaking in the first place.

The previous models for benefit-cost analysis presented in this section do not account for the full probabilistic characteristics of B and C in their treatment. Concepts from reliability assessment 4 can be used for this purpose. Assuming B and C to normally distributed, a benefit-cost index ($\beta_{B/C}$) can be defined as follows:

$$\beta_{B/C} = \frac{\mu_B - \mu_C}{\sqrt{\sigma_B^2 + \sigma_C^2}} \quad (207.16)$$

where μ and σ are the mean and standard deviation. The failure probability can be computed as

$$P_{f,B/C} = P(C > B) = 1 - \Phi(\beta) \quad (207.17)$$

In the case of log-normally distributed B and C , the benefit-cost index ($\beta_{B/C}$) can be computed as

$$\beta_{B/C} = \frac{\ln\left(\frac{\mu_B}{\mu_C} \sqrt{\frac{\delta_C^2 + 1}{\delta_B^2 + 1}}\right)}{\sqrt{\ln[(\delta_B^2 + 1)(\delta_C^2 + 1)]}} \quad (207.18)$$

where δ is the coefficient of variation. Equation 207.18 also holds for the case of log-normally distributed B and C . In the case of mixed distributions or cases involving basic random variables of B and C , the advanced second moment method or simulation method can be used. In cases where benefit is computed as revenue minus cost, benefit might be correlated with cost, requiring the use of other methods.

Example 207.2: Protection of Critical Infrastructure

This example is used to illustrate the cost of cost-benefit analysis using a simplified decision situation. As an illustration, assume that there is a 0.01 probability of an attack on a facility containing hazardous material during the next year. If the attack occurs, the probability of a serious release to the public is 0.01 with a total consequence of \$100 billion. The total consequence of an unsuccessful attack is negligible. The unmitigated risk can therefore be computed as

$$\text{Unmitigated risk} = 0.01(0.01)(\$100 \text{ billion}) = \$10 \text{ million}$$

If armed guards are deployed at each facility, the probability of attack can be reduced to 0.001 and the probability of serious release if an attack occurs can be reduced to 0.001. The cost of the guards for all plants is assumed to be \$100 million per year. The mitigated risk can therefore be computed as

$$\text{Mitigated risk} = 0.001(0.001)(\$100 \text{ billion}) = \$0.10 \text{ million}$$

The benefit in this case is

$$\text{Benefit} = \$10 \text{ million} - \$0.1 \text{ million or } \sim \$10 \text{ million}$$

The benefit-to-cost ratio is about 0.1. Therefore, the \$100 million cost might be difficult to justify.

Risk Mitigation

A risk mitigation strategy can be presented from a financial point of view. Risk mitigation in this context can be defined as an action to either reduce the probability of an adverse event occurring or to reduce the adverse consequences if it does occur. This definition captures the essence of an effective management process of risk. If implemented correctly, a successful risk mitigation strategy should reduce any adverse (or downside) variations in the financial returns from a project, which are usually measured by either (1) the NPV, defined as the difference between the present value of the cash flows generated by a project and its capital cost and calculated as part of the process of assessing and appraising investments; or (2) the IRR, defined as the return that can be earned on the capital invested in the project, that is, the discount rate that gives an NPV of zero, in the form of the rate that is equivalent to the yield on the investment.

Risk mitigation involves direct costs like increased capital expenditure or the payment of insurance premiums; hence, risk mitigation might reduce the average overall financial returns from a project. This reduction is often a perfectly acceptable outcome, given the risk aversion of many investors and lenders.

A risk mitigation strategy is the replacement of an uncertain and volatile future with one where there is less exposure to adverse risks and so less variability in the return, although the expected NPV or IRR may be reduced. These two aspects are not necessarily mutually exclusive. Increasing risk efficiency by simultaneously improving the expected NPV or IRR and simultaneously reducing the adverse volatility is sometimes possible and should be sought. Risk mitigation should cover all phases of a project from inception to closedown or disposal.

Four primary ways are available to deal with risk within the context of a risk management strategy as follows:

- Risk reduction or elimination
- Risk transfer, such as to a contractor or an insurance company
- Risk avoidance
- Risk absorbance or pooling

These four methods are described in subsequent sections.

Risk Reduction or Elimination

Risk reduction or elimination is often the most fruitful form for exploration. For example, could a system design be amended so as to reduce or eliminate either the probability of occurrence of a particular risk event or adverse consequences if it occurs? Alternatively, could the risks be reduced or eliminated by retaining the same design but using different materials or a different method of assembly? Other possible risk mitigation options in this category include a better labor relations policy to minimize the risk of stoppages, training of staff to avoid hazards, better site security to avoid theft and vandalism, preliminary investigation of possible site pollution, advance ordering of key components, noise abatement measures, good sign posting, and liaisons with the local community.

Risk Transfer

A general principle of an effective risk management strategy is that commercial risks in projects and other business ventures should be borne wherever possible by the party that is best able to manage them, and thus mitigate the risks. Contracts and financial agreements are the principal forms to transfer risks. Companies specializing in risk transfer can be consulted that could appropriately meet the needs of a project. Risks can be transferred alternately to an insurance company which, in return for a payment (i.e., premium) linked to the probability of occurrence and severity associated with the risk, is obliged by the contract to offer compensation to the party affected by the risk. Insurance coverage can range from straight insurance for expensive risks with a low probability, such as fire, through performance bonds, which ensure that the project will be completed if the contractor defaults; to sophisticated financial derivatives such as hedge contracts to avoid risks such as unanticipated losses in foreign exchange markets.

Risk Avoidance

A most intuitive way of avoiding a risk is to avoid undertaking the project in a way that involves that risk. For example, if the objective is to generate electricity but a nuclear power source, although cost-efficient, is considered to have a high risk due to potentially catastrophic consequences, even after taking all reasonable precautions, the practical solution is to turn to other forms of fuel to avoid that risk. Another example would be the risk that a particularly small contractor would go bankrupt. In this case, the risk could be avoided by using a well-established contractor instead for that particular job.

Risk Absorbance and Pooling

In cases where risks cannot economically (or at all) be eliminated, transferred, or avoided, they must be absorbed if the project is to proceed. Normally, a sufficient margin in the project's finances needs to be created to cover the risk event should it occur. However, it is not always essential for one party alone to bear all these absorbed risks. Risks can be reduced through pooling, possibly through participation in a consortium of contractors, when two or more parties are able to exercise partial control over the

incidence and impact of risk. Joint ventures and partnerships are other examples of organizational forms for pooling risks.

Uncertainty Characterization

Risk can be mitigated through proper uncertainty characterization. The presence of improperly characterized uncertainty could lead to the higher likelihood of adverse event occurrence and consequences. Also, it could result in increasing estimated cost margins as a means of compensation. Therefore, risk can be reduced by a proper characterization of uncertainty. The uncertainty characterization can be achieved through data collection and knowledge construction.

Example 207.3: Cost-Benefit Analysis for Selecting a Transport Method

Table 207.13 shows four transportation methods considered by the warehouse owner discussed in previous examples in this chapter to supply components from the warehouse to one of its major customers in a foreign country. The available alternatives for the modes of transport are (1) air, (2) sea, (3) road and ferry, and (4) rail and ferry. The company management team has identified four relevant attributes for this decision situation: (1) punctuality, (2) safety of cargo, (3) convenience, and (4) costs. The first three attributes are considered to be a benefits parameter against the fourth one that is the cost of transportation. The weights of importance scores allocated to the three benefits attributes are 30 for punctuality, 60 for safety of cargo, and 10 for convenience. After a brainstorming session by the management team, the performance of each transportation mode was assessed according to these attributes. The assessment results are shown in Table 207.13. The optimal alternative can be selected by applying the concept of cost-benefit analysis. The results are shown in Table 207.14. Inspection of the table reveals that the fourth alternative gives the highest ratio of 1.16. Therefore, the rail and ferry transportation mode can be selected as the best alternative. The plot in Figure 207.19 of the value of benefit against the value of cost for each alternative can be constructed to show that alternative 4 is the best option with the highest weighted benefit of 81 against a cost of \$70,000, confirming previous weighted-benefit-to-cost-ratio computations. Alternative 3 comes as second option using the weighted benefit-to-cost ratio but at a low-cost value of only \$40,000. A cost-benefit tradeoff analysis can be made between alternatives 4 and 3. A cost-

TABLE 207.13 Assessments of Modes of Transportation for Delivery to Foreign Clients

| Alternatives | Cost (in thousands of dollars) | Attribute (0100) | | |
|--------------------|-----------------------------------|------------------|--------|-------------|
| | | Punctuality | Safety | Convenience |
| A1: Air | 150 | 100 | 70 | 60 |
| A2: Sea | 90 | 0 | 60 | 80 |
| A3: Road and ferry | 40 | 60 | 0 | 100 |

FIGURE 207.19 Cost-benefit analysis of transportation modes.

conscious decision maker might choose alternative 3, whereas a benefit-driven decision maker might select alternative 4. If a decision maker is concerned with both, the weighted benefit-to-cost ratio of 1.16 of alternative 4 makes it the optimal choice.

207.4 Risk Communication

Risk communication can be defined as an interactive process of exchange of information and opinion among stakeholders such as individuals, groups, and institutions. It often involves multiple messages about the nature of risk, or expresses concerns, opinions, or reactions to risk managers or to legal and institutional arrangements for risk management. Risk communication greatly affects risk acceptance and defines the acceptance criteria for safety.

Risk communication provides the vital link between risk assessors, risk managers, and the public to understand risk. However, this does not necessarily mean that risk communication will always lead to agreement among different parties. An accurate perception of risk provides for rational decision making. The Titanic was deemed the unsinkable ship, yet was lost on its maiden voyage. Space shuttle flights were perceived to be safe enough for civilian travel until the Space Shuttle Challenger disaster. These modes of transport obviously had risks that were not perceived as significant until after the disaster. Risk communication is a dynamic process that must be considered prior to management decisions.

The communication process deals with technical information about controversial issues. Therefore, it needs to be skillfully performed by risk managers and communicators who might be viewed as adversaries by the public. Risk communication between risk assessors and risk managers is necessary to effectively apply risk assessments in decision making. Risk managers must participate in determining the criteria for determining what type and level of risk are acceptable and unacceptable. This communication between the risk managers and risk assessors is necessary for a better understanding of risk analysis in making decisions.

Risk communication also provides the means for risk managers to gain acceptance and understanding by the public. Risk managers need to go beyond the risk assessment results and consider other factors in making decisions. One of these concerns is politics, which is, of course, largely influenced by the public. Risk managers often fail to convince the public that risks can be kept to acceptable levels. Problems here are shown by the public's perception of toxic waste disposal and nuclear power plant operation safety. As a result of public perceptions (fears), risk managers may make decisions that are conservative to appease the public.

The value of risk calculated from risk assessment is not the only consideration for risk managers. All risks are not created equal, and society has established risk preferences based on public preferences. Decision makers should take these preferences into consideration when making decisions concerning risk.

To establish a means of comparing risks based on the societal preferences, risk conversion factors (RCFs) may be used. An RCF expresses the relative importance of different attributes concerning risk. An example of possible RCFs is shown in [Table 207.10](#). These values were determined by inferences of public preferences from statistical data with the consequence of death considered.

For example, the voluntary and involuntary classification depends on whether the events leading to the risk are under the control of the persons at risk or not, respectively. Society, in general, accepts a higher level of voluntary risk than involuntary risk by an estimated factor of 100. Therefore, an individual will accept a voluntary risk that is 100 times greater than an involuntary risk.

The process of risk communication can be enhanced and improved in three aspects: (1) process, (2) message, and (3) consumers. The risk assessment and management process needs to have clear goals with openness, balance, and competence. The contents of the message should account for audience orientation and uncertainty, provide risk comparison, and be complete. There is a need for consumer guides that introduce risks associated with a specific technology, the process of risk assessment and management, acceptable risk, decision making, uncertainty, costs and benefits, and feedback mechanisms. Improving risk literacy of consumers is an essential component of the risk communication process.

Listed below are considerations for communicating risk recommended by the U.S. Army Corps of Engineers [1992].

- Risk communication must be free of jargon.
- Consensus of expert needs to be established.
- Materials cited and their sources must be credible.
- Materials must be tailored to audience.
- The information must be personalized to the extent possible.
- Motivation discussion should stress a positive approach and the likelihood of success.
- Risk data must be presented in a meaningful manner.

Defining Terms

Risk — The assessment of potential consequences.

Safety — The judgment of risk acceptability.

Reliability — The ability of a system to meet performance requirements for a specified time period and operation/environmental conditions.

Technology*

208.1 Sensitivity Analysis Applications

Sensitivity Table for Programmable Control System • Sensitivity
Graph for Gas Heating Systems • Spider Diagram for a
Commercial Building Investment

208.2 Advantages and Disadvantages

Sensitivity analysis measures the impact on project outcomes of changing one or more key input values about which there is uncertainty. For example, a pessimistic, expected, and optimistic value might be chosen for an uncertain variable. Then an analysis could be performed to see how the outcome changes as each of the three chosen values is considered in turn, with other things held the same.

In engineering economics, sensitivity analysis measures the economic impact resulting from alternative values of uncertain variables that affect the economics of the project. When computing **measures of project worth**, for example, sensitivity analysis shows just how sensitive the economic payoff is to uncertain values of a critical input, such as the **discount rate** or project maintenance costs expected to be incurred over the project's **study period**. Sensitivity analysis reveals how profitable or unprofitable the project might be if input values to the analysis turn out to be different from what is assumed in a single-answer approach to measuring project worth.

Sensitivity analysis can also be performed on different combinations of input values. That is, several variables are altered at once and then a measure of worth is computed. For example, one scenario might include a combination of all pessimistic values, another all expected values, and a third all optimistic values. Note, however, that sensitivity analysis can in fact be misleading [Hillier, 1969] if all pessimistic assumptions or all optimistic assumptions are combined in calculating economic measures. Such combinations of inputs would be unlikely in the real world.

Sensitivity analysis can be performed for any measure of worth. And since it is easy to use and understand, it is widely used in the economic evaluation of government and private-sector projects. Office of Management and Budget [1992] Circular A-94 recommends sensitivity analysis to federal agencies as one technique for treating uncertainty in input variables. The American Society for Testing and Materials [2002], in its *Standards on Buildings Economics*, describes sensitivity analysis for use in government and private-sector applications.

208.1 Sensitivity Analysis Applications

How to use sensitivity analysis in engineering economics is best illustrated with examples of applications. Three applications are discussed. The first two focus on changes in project worth as a function of the change in one variable only. The third allows for changes in more than one uncertain variable.

The results of sensitivity analysis can be presented in text, tables, or graphs. The following discussion of sensitivity analysis applied to a programmable control system uses text and a simple table. Subsequent

TABLE 208.1 Energy Price Escalation Rates

| Energy Price Escalation Rate | Net Savings |
|------------------------------|-------------|
| Low | \$15,000 |
| Moderate | 20,000 |
| High | 50,000 |

analyses use graphs. The advantage of using a graph comes from being able to show in one picture the outcome possibilities over a range of input variations for one or several input factors.

Sensitivity Table for Programmable Control System

Consider a decision on whether to install a programmable time clock to control heating, ventilating, and air conditioning (HVAC) equipment in a commercial building. The time clock would reduce electricity consumption by turning off that part of the HVAC equipment that is not needed during hours when the building is unoccupied.

Using **net savings** (NS) as the measure of project worth, the time clock is acceptable on economic grounds if its NS is positive — that is, if its **present value** savings exceed present value costs. The control system purchase and maintenance costs are felt to be relatively certain. The savings from energy reductions resulting from the time clock, however, are not certain. They are a function of three factors: the initial price of energy, the rate of change in energy prices over the life cycle of the time clock, and the number of kilowatt hours (kWh) saved. Two of these, the initial price of energy and the number of kWh saved, are relatively certain. But future energy prices are not.

To test the sensitivity of NS to possible energy price changes, three values of energy price change are considered: a low rate of energy price escalation (slowly increasing benefits from energy savings), a moderate rate of escalation (moderately increasing benefits), and a high rate of escalation (rapidly increasing benefits). Table 208.1 shows three NS estimates that result from repeating the NS computation for each of the three energy price escalation rates.

To appreciate the significance of these findings, it is helpful to consider what extra information is gained over the conventional single-answer approach, where, say, a single NS estimate of \$20,000 was computed. Table 208.1 shows that the project could return up to \$50,000 in NS if future energy prices escalated at a high rate. On the other hand, it is evident that the project could lose as much as \$15,000. This is considerably less than **breakeven**, where the project would at least pay for itself. It is also \$35,000 less than what was calculated with the single-answer approach. Thus, sensitivity analysis reveals that accepting the time clock could lead to an uneconomic outcome.

There is no explicit measure of the likelihood that any one of the NS outcomes will happen. The analysis simply shows what the outcomes will be under alternative conditions. However, if there is reason to expect energy prices to rise, at least at a moderate rate, then the project very likely will make money, other factors remaining the same. This adds helpful information over the traditional single-answer approach to measures of project worth.

Sensitivity Graph for Gas Heating Systems

[Figure 208.1](#) shows how sensitive NS is to the time over which two competing gas heating systems might be used in a building. The sensitivity graph helps you decide which system to choose on economic grounds.

Assume that you have an old electric heating system that you are considering replacing with a gas furnace. You have a choice between a high-efficiency or low-efficiency gas furnace. You expect both to last at least 15 to 20 years, and you do not expect any significant difference in building resale value or salvage value from selecting one system over the other. So you compute the NS for each gas furnace as compared to the old electric system. You will not be able to say which system is more economical until you decide how long you will hold the building before selling it. This is where the sensitivity graph is particularly helpful.

FIGURE 208.1 Sensitivity of net savings to holding period.

Net savings are measured on the vertical axis, and time on the horizontal axis. The longer you hold the building, the greater will be the present value of NS from installing either of the new systems, up to the estimated life of the systems. But note what happens in the 9th year. One line crosses over another. This means that the low-efficiency system is more **cost-effective** than the high-efficiency system for any holding period up to 9 years. To the left of the crossover point, NS values are higher for the low-efficiency system than for the high-efficiency system. But for longer holding periods, the high-efficiency system is more cost-effective than the low-efficiency system. This is shown to the right of the crossover point.

How does the sensitivity graph help you decide which system to install? First, it shows that neither system is more cost-effective than the other for all holding periods. Second, it shows that the economic choice between systems is sensitive to the uncertainty of how long you hold the building. You would be economically indifferent between the two systems only if you plan to hold the building 9 years. If you plan to hold the building longer than 9 years, for example, then install the high-efficiency unit. But if you plan to hold it less than 9 years, then the low-efficiency unit is the better economic choice.

Spider Diagram for a Commercial Building Investment

Another useful graph for sensitivity analysis is the **spider diagram**. It presents a snapshot of the potential impact of uncertain input variables on project outcomes. Figure 208.2 shows — for a prospective commercial building investment — the sensitivity of the **adjusted internal rate of return (AIRR)** to three uncertain variables: project life (PL), reinvestment rate (RR), and operation, maintenance, and replacement costs (OM&R). The spider diagram helps the investor decide if the building is likely to be a profitable investment.

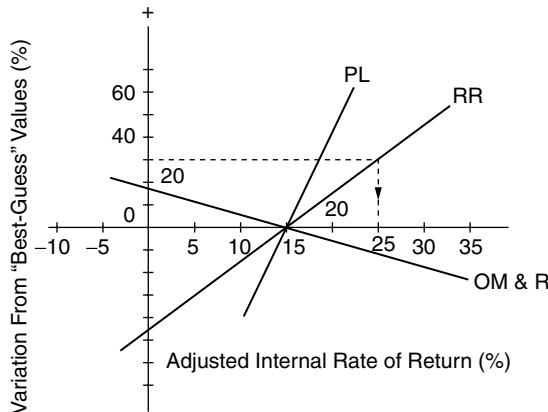

FIGURE 208.2 Spider diagram showing sensitivity of the adjusted internal rate of return to variations in uncertain variables. PL = project life; RR = reinvestment rate; and OM&R = operation, maintenance, and replacement costs.

Each of the three uncertain variables is represented by a labeled function that shows what AIRR value results from various values of the uncertain variable. (Although these functions are not necessarily linear, they are depicted as linear here to simplify exposition.) For example, the downward-sloping OM&R function indicates that the AIRR is inversely proportional to OM&R costs. By design, the OM&R function (as well as the other two functions) passes through the horizontal axis at the “best-guess” estimate of the AIRR (15% in this case), based on the best-guess estimates of the three uncertain variables. Other variables (e.g., occupancy rate) will impact the AIRR, but these are assumed to be known for the purpose of this analysis. Since each of the variables is measured by different units (years, percent, and dollars), the vertical axis is denominated in positive and negative percent changes from the best-guess values fixed at the horizontal axis. The AIRR value corresponding to any given percent variation indicated by a point on the function is found by extending a line perpendicular to the horizontal axis and directly reading the AIRR value. Thus a 30% increase in the best-guess reinvestment rate would yield a 25% AIRR, assuming that other values remain unchanged. Note that if the measure of AIRR were also given in percent differences, then the best-guess AIRR would be at the origin.

The spider diagram’s contribution to decision making is its instant picture of the relative importance of several uncertain variables. In this case, the lesser the slope of a function is, the more sensitive is the AIRR to that variable. For example, any given percent change in OM&R will have a greater impact on the AIRR than will an equal percent change in RR or PL, and a percentage change in RR will have a greater impact than an equal percentage change in PL. Thus an investor will want to know as much as possible about likely OM&R costs for this project, because a relatively small variation in estimated costs could make the project a loser.

208.2 Advantages and Disadvantages

There are several advantages of using sensitivity analysis in engineering economics. First, it shows how significant any given input variable is in determining a project’s economic worth. It does this by displaying the range of possible project outcomes for a range of input values, which shows decision makers the input values that would make the project a loser or a winner. Sensitivity analysis also helps identify critical inputs in order to facilitate choosing where to spend extra resources in data collection and in improving data estimates.

Second, sensitivity analysis is an excellent technique to help in anticipating and preparing for the “what-if” questions that are asked in presenting and defending a project. For instance, if asked what the outcome will be if operating costs are 50% more expensive than expected, an answer is forthcoming. Generating answers to “what-if” questions will help assess how well a proposal will stand up to scrutiny.

Third, sensitivity analysis does not require the use of probabilities, as do many techniques for treating uncertainty.

Fourth, sensitivity analysis can be used on any measure of project worth.

Finally, sensitivity analysis can be used when there are little information, resources, and time for more sophisticated techniques.

The major disadvantage of sensitivity analysis is that there is no explicit probabilistic measure of **risk exposure**. That is, although one might be sure that one of several outcomes might happen, the analysis contains no explicit measure of their respective likelihoods.

Defining Terms

Adjusted internal rate of return (AIRR) — The annual percentage yield from a project over the study period, taking into account the returns from reinvested receipts.

Breakeven — A combination of benefits (savings or revenues) that just offset costs, such that a project generates neither profits nor losses.

Cost-effective — The condition whereby the present value benefits (savings) of an investment alternative exceed its present value costs.

Discount rate — The minimum acceptable rate of return used in converting benefits and costs occurring at different times to their equivalent values at a common time. Discount rates reflect the investor's time value of money (or opportunity cost). "Real" discount rates reflect time value apart from changes in the purchasing power of the dollar (i.e., exclude inflation or deflation) and are used to discount constant dollar cash flows. "Nominal" or "market" discount rates include changes in the purchasing power of the dollar (i.e., include inflation or deflation) and are used to discount current dollar cash flows.

Measures of project worth — Economic methods that combine project benefits (savings) and costs in various ways to evaluate the economic value of a project. Examples are life-cycle costs, net benefits or net savings, benefit-to-cost ratio or savings-to-investment ratio, and adjusted internal rate of return.

Net savings — The difference between savings and costs, where both are discounted to present or annual values. The net savings method is used to measure project worth.

Present value — The time-equivalent value at a specified base time (the present) of past, present, and future cash flows.

Risk exposure — The probability that a project's economic outcome is different from what is desired (the target) or what is acceptable.

Sensitivity analysis — A technique for measuring the impact on project outcomes of changing one or more key input values about which there is uncertainty.

Spider diagram — A graph that compares the potential impact, taking one input at a time, of several uncertain input variables on project outcomes.

Study period — The length of time over which an investment is evaluated.

209.6 Summary

A major portion of the projected **life-cycle cost (LCC)** for a specific product, system, or structure is traceable to decisions made during conceptual and preliminary design. These decisions pertain to operational requirements, performance and effectiveness factors, the design configuration, the maintenance concept, production methods and quantity, utilization factors, logistic support, phaseout planning, and disposal. Such decisions guide subsequent design and production activities, product distribution functions, and aspects of sustaining system support. Accordingly, if the final life-cycle cost is to be minimized, it is essential that considerable cost emphasis be applied during the early stages of system design and development.

209.1 Life-Cycle Costing Situation

The combination of inflation, cost growth, reduction in purchasing power, budget limitations, increased competition, and related factors has created an awareness and interest in the total cost of products, systems, and structures. Not only are the acquisition costs associated with new systems rising, but the costs of operating and maintaining systems already in use are also increasing. This is due primarily to a combination of inflation and cost growth factors traceable to the following:

1. Unsatisfactory quality of products, systems, and structures in use
2. Engineering changes mandated during design and development
3. Changing suppliers in the procurement of system components
4. System production and/or construction changes
5. Changes in logistic support capability
6. Estimating and forecasting errors
7. Unforeseen events and problems

*Material presented in this chapter is adapted from Chapter 6 in W. J. Fabrycky and B. S. Blanchard, *Life-Cycle Cost and Economic Analysis*, Prentice Hall, Englewood Cliffs, NJ, 1991.

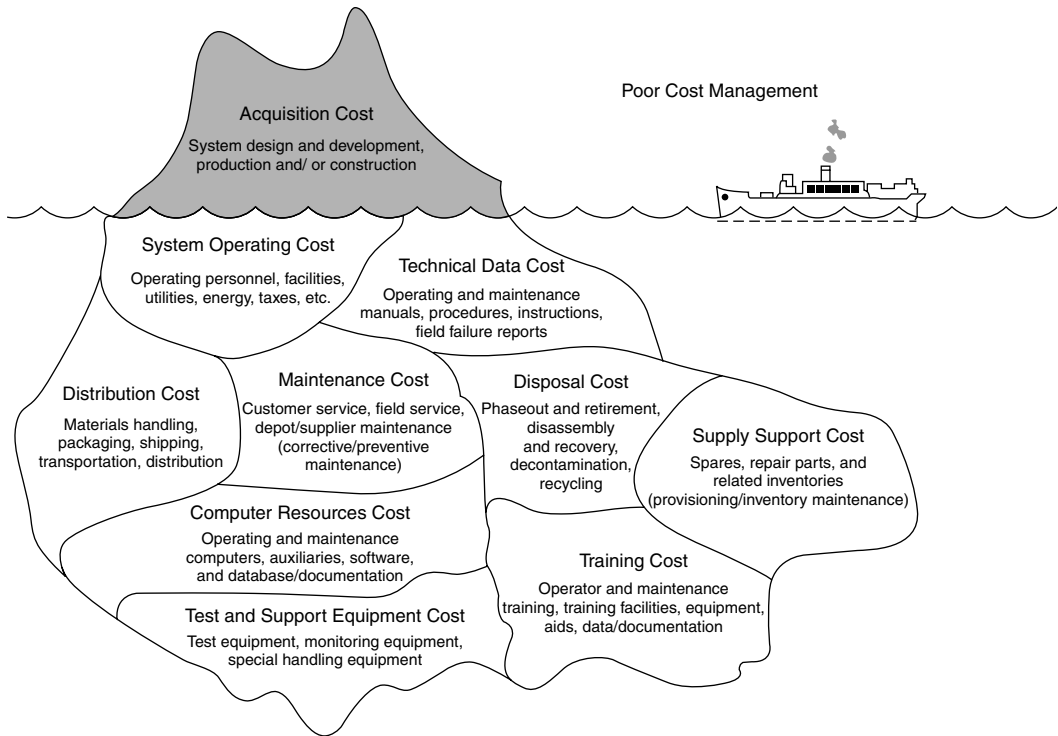

FIGURE 209.1 The problem of total cost visibility.

Experience over the past several decades indicates that cost growth due to various causes has ranged from five to ten times the rate of inflation. At the same time, budget allocations for many programs are decreasing from year to year. The result is that fewer resources are available for acquiring and operating new systems or products and for maintaining and supporting existing systems. Available funds for new projects, when inflation and cost growth are considered, are decreasing rapidly.

The current economic situation is further complicated by some additional problems related to the actual determination of system and/or product cost. Some of these are listed below.

1. Total system cost is not fully visible, particularly those costs associated with operation and support. The cost visibility problem is due to an “iceberg” effect, as is illustrated in Figure 209.1.
2. Individual cost factors are often improperly applied. Costs are identified and frequently included in the wrong category: variable costs are treated as fixed (and vice versa), indirect costs are treated as direct costs, and so on.
3. Existing accounting procedures do not always permit a realistic and timely assessment of total cost. In addition, it is often difficult (if not impossible) to determine costs on a functional basis.
4. Budgeting practices are often inflexible regarding the shift in funds from one category to another, or from year to year, to facilitate cost improvements in system acquisition and utilization.

Current trends of inflation and cost growth, combined with the problems listed above, have led to inefficiencies in the utilization of valuable resources. Systems and products have been developed that are not cost-effective. It is anticipated that these conditions will worsen unless an increased degree of cost consciousness is assumed by engineers and project managers.

LCC is determined by identifying the applicable functions in each phase of the life cycle, costing these functions, applying the appropriate costs by function on a year-to-year basis, and then accumulating the costs over the entire span of the life cycle. To be complete, LCC must include all producer and consumer costs from origin of concept to phase-out and disposal.

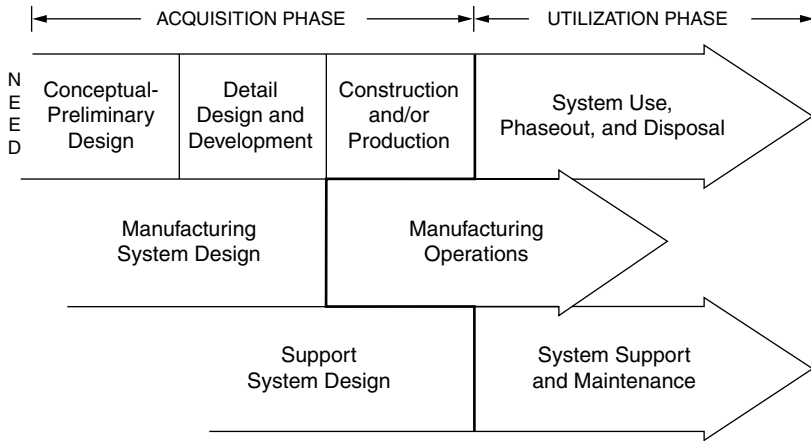

FIGURE 209.2 Product, process, and support life cycles.

209.2 Cost Generated over Life Cycle

LCC includes all costs associated with the product, system, or structure that are anticipated over the defined life cycle. The life cycle and major functions associated with each phase are illustrated in Figure 209.2. Life-cycle costing is employed in the evaluation of alternative system design configurations, alternative production schemes, alternative logistic support policies, alternative disposal concepts, and so on. The life-cycle concept, tailored to the specific system being addressed, forms the basis for life-cycle costing.

There are many technical and nontechnical decisions and actions required throughout the product or system life cycle. Most actions, particularly those in the earlier phases, have life-cycle implications and directly affect LCC. The analysis constitutes a step-by-step approach employing LCC figures of merit as a criterion to arrive at a cost-effective solution. This analysis process is iterative in nature and can be applied to any phase of the life cycle of the product, system, or structure. Cost considerations over the system/product life cycle are summarized in the following sections.

Conceptual System Design

In the early stages of planning and conceptual design (when requirements are being defined), quantitative cost figures of merit should be established to which the system or product is to be designed, tested, produced (or constructed), and supported. A **design-to-cost (DTC)** goal may be adopted to establish cost as a system or product design constraint, along with performance, effectiveness, capacity, accuracy, weight, reliability, maintainability, supportability, and so on. Cost must be an active rather than a resultant factor throughout the system design process.

Preliminary System Design

With quantitative cost requirements established, the next step includes an iterative process of synthesis, tradeoff and optimization, and system/product definition. The criteria defined in the conceptual system design are initially allocated (or apportioned) to various segments of the system to establish guidelines for the design and/or the procurement of needed element(s). Allocation is accomplished from the system level down to the level necessary to provide an input to design and to ensure adequate control. The factors projected reflect the target cost per individual unit (i.e., a single equipment unit or product in a deployed population) and are based on system operational requirements, the system maintenance concept, and the plan for disposal.

As system development evolves, various approaches are considered that may lead to a preferred configuration. LCC analyses are accomplished in (1) evaluating each possible candidate, with the objective

of ensuring that the candidate selected is compatible with the established cost targets, and (2) determining which of the various candidates being considered is preferred from an overall cost-effectiveness standpoint. Numerous tradeoff studies are accomplished using LCC analysis as an evaluation method, until a preferred design configuration is chosen. Areas of compliance are justified, and noncompliant approaches are discarded. This is an iterative process with an active-feedback and corrective-action loop.

Detail Design and Development

As the system or product design is further refined and design data become available, the LCC analysis process involves the evaluation of specific design characteristics (as reflected by design documentation and engineering or prototype models), the prediction of cost-generating sources, the estimation of costs, and the projection of LCC as a **life-cycle cost profile (LCCP)**. The results are compared with the initial requirement and corrective action is taken as necessary. As before, this is an iterative process, but at a lower level than what is accomplished during preliminary system design.

Production, Utilization, and Support

Cost concerns in the production, utilization, support, and disposal stages of the system or product life cycle are addressed through data collection, analysis, and an assessment function. High-cost contributors are identified, cause-and-effect relationships are defined, and valuable information is gained and utilized for the purposes of product improvement through redesign or reengineering.

209.3 Cost Breakdown Structure

In general, costs over the life cycle fall into categories based on organizational activity needed to bring a system into being. These categories and their constituent elements constitute a **cost breakdown structure (CBS)**, as illustrated in Figure 209.3. The main CBS categories are as follows:

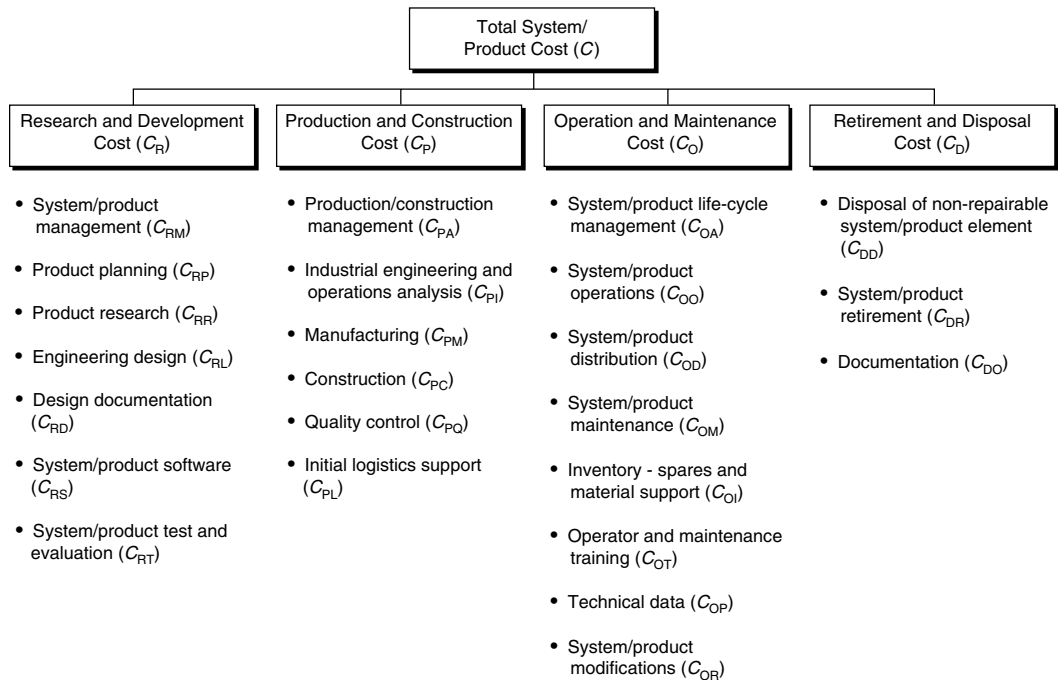

FIGURE 209.3 A general cost breakdown structure.

1. *Research and development cost.* Initial planning, market analysis, feasibility studies, product research, requirements analysis, engineering design, design data and documentation, software, testing and evaluation of engineering models, and associated management functions.
2. *Production and construction cost.* Industrial engineering and operations analysis, manufacturing (fabrication, assembly, and test), facility construction, process development, production operations, quality control, and initial logistic support requirements (e.g., initial customer support, the manufacture of spare parts, the production of test and support equipment, etc.).
3. *Operation and support cost.* Customer or user operation of the system or product in the field, product distribution (marketing and sales, transportation, and traffic management), and sustaining maintenance and logistic support throughout the system or product life cycle (e.g., customer service, maintenance activities, supply support, test and support equipment, transportation and handling, technical data, facilities, system modifications, etc.).
4. *Retirement and disposal cost.* Disposal of nonrepairable items throughout the life cycle, system/product retirement, material recycling, and applicable logistic support requirements.

The cost breakdown structure links objectives and activities with organizational resource requirements. It constitutes a logical subdivision of cost by functional activity area, major system elements, and/or one or more discrete classes of common or like items. The CBS provides a means for initial resource allocation, cost monitoring, and cost control.

209.4 Life-Cycle Cost Analysis

The application of life-cycle costing methods during product and system design and development is realized through the accomplishment of **life-cycle cost analyses (LCCAs)**. An LCCA may be defined as a systematic analytical process of evaluating various designs or alternative courses of action with the objective of choosing the best way to employ scarce resources.

Where feasible alternative solutions exist for a specific problem and a decision is required for the selection of a preferred approach, there is a formal analysis process that should be followed. Specifically, the analyst should define the need for analysis, establish the analysis approach, select a model to facilitate the evaluation process, generate the appropriate information for each alternative being considered, evaluate each alternative, and recommend a proposed solution that is responsive to the opportunity.

Cost Analysis Goals

There are many questions that the decision maker might wish to address. There may be a single overall analysis goal (e.g., design to minimum LCC) and any number of subgoals. The primary question should be as follows: What is the purpose of the analysis and what is to be learned through the analysis effort?

In many cases the nature of the problem appears to be obvious, but its precise definition may be the most difficult part of the entire process. The design problem must be defined clearly and precisely and presented in such a manner as to be easily understood by all concerned. Otherwise, it is doubtful whether an analysis of any type will be meaningful. The analyst must be careful to ensure that realistic goals are established at the start of the analysis process and that these goals remain in sight as the process unfolds.

Analysis Guidelines and Constraints

Subsequent to definition of the problem and the goals, the cost analyst must define the guidelines and constraints (or bounds) within which the analysis is to be accomplished. Guidelines are composed of information concerning such factors as the resources available for conducting the analysis (e.g., necessary technical skills, availability of appropriate software, etc.), the time schedule allowed for completion of the analysis, and/or related management policy or direction that may affect the analysis.

In some instances, a decision maker or manager may not completely understand the problem or the analysis process and may direct that certain tasks be accomplished in a prescribed manner or time frame

that may not be compatible with the analysis objectives. On other occasions, a manager may have a preconceived idea as to a given decision outcome and direct that the analysis support the decision. Also, there could be external inhibiting factors that may affect the validity of the analysis effort. In such cases the cost analyst should make every effort to alleviate the problem by educating the manager and documenting unresolved issues.

Relative to the technical characteristics of a system or product, the analysis output may be constrained by bounds (or limits) that are established through the definition of system performance factors, operational requirements, the maintenance concept, and/or through advanced program planning. For example, there may be a maximum weight requirement for a given product, a minimum reliability requirement, a maximum allowable first cost per unit, a minimum rated capacity, and so on. These various bounds, or constraints, should provide the bases for tradeoffs in the evaluation of alternatives. Candidates that fall outside these bounds are not allowable.

Identifying Alternatives

Within established bounds and constraints, there may be any number of approaches leading to a possible solution. All possible alternatives should be considered, with the most likely candidates selected for further evaluation. Alternatives are frequently proposed for analysis even though there seems to be little likelihood that they will prove feasible. This is done with the thought that it is better to consider many alternatives than to overlook one that may be very good. Alternatives not considered cannot be adopted, no matter how desirable they may actually prove to be.

Applying Cost Breakdown Structure

Applying the cost breakdown structure is one of the most significant steps in life-cycle costing. The CBS constitutes the framework for defining LCC categories and provides the communications link for cost reporting, analysis, and ultimate cost control.

In developing the CBS one needs to proceed to the depth required to provide the necessary information for a true and valid assessment of the system or product LCC, identify high-cost contributors and enable determination of the cause-and-effect relationships, and illustrate the various cost parameters and their application in the analysis. Traceability is required from the system-level LCC figure of merit to each specific input factor.

209.5 Cost Treatment over Life Cycle

With the system/product cost breakdown structure defined and cost-estimating approaches established, it is appropriate to apply the resultant data to the system life cycle. To accomplish this, the cost analyst needs to understand the steps required in developing cost profiles that include aspects of inflation, the effects of learning curves, the time value of money, and so on.

In developing a cost profile, there are different procedures that may be used. The following steps are suggested:

1. Identify all activities throughout the life cycle that will generate costs of one type or another. This includes functions associated with planning, research and development, testing and evaluation, production/construction, product distribution, system/product operational use, maintenance and logistic support, and so on.
2. Relate each activity identified in step 1 to a specific cost category in the cost breakdown structure. All program activities should fall into one or more of the CBS categories.
3. Establish the appropriate cost factors in constant dollars for each activity in the CBS, where constant dollars reflect the general purchasing power of the dollar at the time of decision (i.e., today). Relating costs in terms of constant dollars will allow for a direct comparison of activity levels from year to year prior to the introduction of inflationary cost factors, changes in price

FIGURE 209.4 Development of life-cycle cost profiles.

levels, economic effects of contractual agreements with suppliers, and so on, which can often cause some confusion in the evaluation of alternatives.

4. Within each cost category in the CBS, the individual cost elements are projected into the future on a year-to-year basis over the life cycle as applicable. The result should be a cost stream in constant dollars for the activities that are included.
5. For each cost category in the CBS and for each applicable year in the life cycle, introduce the appropriate inflationary factors, economic effects of learning curves, changes in price levels, and so on. The modified values constitute a new cost stream and reflect realistic costs as they are anticipated for each year of the life cycle (i.e., expected 2004 costs in 2004, 2005 costs in 2005, etc.). These costs may be used directly in the preparation of future budget requests, since they reflect the actual dollar needs anticipated for each year over the life cycle.
6. Summarize the individual cost streams by major categories in the CBS and develop a top-level cost profile.

Results from the sequence of steps above are presented in Figure 209.4. First, it is possible and often beneficial to evaluate the cost stream for individual activities of the life cycle such as research and development, production, operation and support, and so on. Second, these individual cost streams may be shown in the context of the total cost spectrum. Finally, the total cost profile may be viewed from the standpoint of the logical flow of activities and the proper level and timely expenditure of dollars. The profile in Figure 209.4 represents a budgetary estimate of future resource needs in monetary terms.

When dealing with two or more alternative system configurations, each will include different levels of activity, different design approaches, different logistic support requirements, and so on. No two systems alternatives will be identical. Thus, individual profiles will be developed for each alternative and ultimately compared on an equivalent basis utilizing the economic analysis techniques found in textbooks on engineering economics. Figure 209.5 illustrates LCC profiles for several alternatives.

209.6 Summary

Life-cycle costing is applicable in all phases of system design, development, production, construction, operational use, and logistic support. Cost emphasis is created early in the life cycle by establishing quantitative cost factors as “design to” requirements. As the life cycle progresses, cost is employed as a major parameter in the evaluation of alternative design configurations and in the selection of a preferred approach. Subsequently, cost data are generated based on established design and production characteristics and used in the development of LCC projections. These projections, in turn, are compared with the initial requirements to determine the degree of compliance and the necessity for corrective action. In essence, LCC evolves from a series of rough estimates to a relatively refined methodology and is employed as a management tool for decision-making purposes.

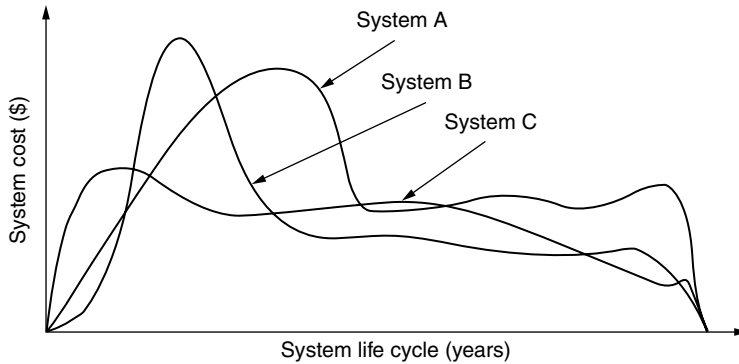

FIGURE 209.5 Life-cycle cost profiles of alternatives.

Defining Terms

Cost breakdown structure (CBS) — A framework for defining life-cycle costs, it provides the communications link for cost reporting, analysis, and ultimate cost control.

Design-to-cost (DTC) — A concept that may be adopted to establish cost as a system or product design constraint, along with performance, effectiveness, capacity, accuracy, size, weight, reliability, maintainability, supportability, and others.

Life-cycle cost (LCC) — All costs associated with the product or system as anticipated over the defined life cycle.

Life-cycle cost analysis (LCCA) — A systematic analytical process for evaluating various alternative courses of action with the objective of choosing the best way to employ scarce resources.

Life-cycle cost profile (LCCP) — A budgetary estimate of future resource needs over the life cycle.

Few decisions are more fundamental to business viability than resource allocations for new projects. Virtually every organization selects and implements projects, ranging from product developments to organizational improvements, and from customer contracts to R&D activities and bid proposals. Pursuing the “wrong” project not only (1) drains a company’s resources, but also causes the enterprise to (2) miss alternative opportunities, (3) operate less flexibly and responsively in the marketplace, and (4) miss opportunities for leveraging core competencies. Project opportunities must be analyzed relative to their potential value, viability, and importance to the enterprise. Four major dimensions should be considered: (1) added value of the new project, (2) cost of the project, (3) readiness of the enterprise to execute the project, and (4) managerial desire. A well-organized *project evaluation and selection process* provides the framework for systematic data gathering and informed decision making toward resource allocation. Typically, these decisions can be broken into four principal categories:

1. *Deciding initial feasibility.* Screening and filtering, quick decision on the viability of an emerging project for further evaluation
2. *Deciding strategic value to enterprise.* Identifying alternatives and options to proposed project
3. *Deciding detailed feasibility.* Determining the chances of success for a proposed project.
4. *Deciding project go/no-go.* Committing resources for a project implementation.

While these decisions look logical and straightforward, developing meaningful support data is a complex process. It is also expensive, time consuming, and often highly eclectic. Typically, decision making requires the following inputs:

- Specific resource requirements
 - Specific implementation risks
-

TABLE 210.1 Typical Criteria for Project Evaluation and Selection

The criteria relevant to the evaluation and selection of a particular project depend on the specific project type and business situation, such as project development, custom project, process development, industry, and market. Typically, evaluation procedures include the following criteria:

- Development cost
- Development time
- Technical complexity
- Risk
- Return on investment
- Cost-benefit
- Product life cycle
- Sales volume
- Market share
- Project business follow-on
- Organizational readiness and strength
- Consistency with business plan
- Resource availability
- Cash flow, revenue, and profit
- Impact on other business activities

Note: Each criterion is based on a complex set of parameters and variables.

- Specific benefits (economics, technology, markets, etc.)
- Benchmarking and comparative analysis
- Strategic perspective

While there are plenty of challenges in evaluating project opportunities in terms of cost, time, risks, and benefits, such as those shown in Table 210.1, it is relatively straightforward in comparison to *predicting project success*. The difficulty here is in defining a meaningful *aggregate measure for rating project value and success*. Methods range from purely intuitive to highly analytical. No method is seen as truly reliable in predicting success, especially for more complex types of projects. Yet, some companies have a better track record in selecting “winning” projects than others, which seems to be related to the ability to create an integrated picture of the potential benefits, costs, and risks for the proposed project relative to the company’s strengths and strategic objectives. Producing such a composite is both a science and an art. Traditionally, managers have used predominately *rational selection processes* to support project selections. However, purely rational/analytical processes apply to only a limited number of business situations. Many of today’s complex project scenarios require the integration of both analytical and judgmental techniques to evaluate projects in a meaningful way toward conclusions on *right, successful, or best choice*.

Yet, in spite of the intricacies involved in project selection, systematic information gathering and standardized methods are at the heart of any project evaluation process, and provide the best assurance for reliably predicting project outcome and repeatability of the decision process. Approaches to project evaluation and selection fall into one of three principal classes:

- Primarily *quantitative* and *rational* approaches
- Primarily *qualitative* and *intuitive* approaches
- *Mixed approaches*, combining both quantitative and qualitative methods

Because of the interdisciplinary complexities involved, analyzing a new project opportunity is a highly interactive effort among various resource groups of the enterprise and its partners. Often, many meetings are needed before (1) a clear picture emerges of potential benefits, costs, and risks involved, and (2) data emerge that are useful for the project evaluation and selection process, regardless of their quantitative, qualitative, or combined nature.

TABLE 210.2 Description of Four Project Proposals

| | |
|-------------------|---|
| Project option P1 | Do not accept any new project proposal; hence, no investment capital is required, nor is revenue generated. |
| Project option P2 | This opportunity requires a \$1,000 investment at the beginning of the first year, and generates a \$200 revenue at the end of <i>each</i> of the following 5 years. |
| Project option P3 | This opportunity requires a \$2,000 investment at the beginning of the first year, and generates a variable stream of net revenues at the end of <i>each</i> of the next 5 years as follows: \$1,500, \$1,000, \$800, \$900, \$1,200. |
| Project option P4 | This opportunity requires a \$5,000 investment at the beginning of the first year, and generates a variable stream of net revenues at the end of <i>each</i> of the next 5 years as follows: \$1,000, \$1,500, \$2,000, \$3,000, \$4,000. |

TABLE 210.3 Cash Flow of Four Project Options or Proposals, Assuming MARR of $i = 10\%$

| End of Year | Do-Nothing Option P1 | Project Option P2 | Project Option P3 | Project Option P4 |
|--------------------|-------------------------|----------------------|----------------------|----------------------|
| 0 | 0 | -1,000 | -2,000 | -5,000 |
| 1 | 0 | 200 | 1,500 | 1,000 |
| 2 | 0 | 200 | 1,000 | 1,500 |
| 3 | 0 | 200 | 800 | 2,000 |
| 4 | 0 | 200 | 900 | 3,000 |
| 5 | 0 | 200 | 1,200 | 4,000 |
| Net cash flow | 0 | 0 | +3,400 | +7,500 |
| $NPV N = 5$ | 0 | -242 | +2,153 | +3,192 |
| $NPV N =$ | 0 | +1,000 | +9,904 | +28,030 |
| $ROI N = 5$ | 0 | 20% | 54% | 46% |
| $CB=ROI_{NPV N=5}$ | 0 | 76% | 108% | 164% |
| $N_{PBP} i=0$ | 0 | 5 | 1.5 | 3.3 |
| $N_{NPV} i$ | 0 | 7.3 | 5 | 3.8 |

Note: CB, cost-benefit; NPV, net present value; PBP, payback period; ROI, return on investment.

210.1 Quantitative Approaches to Project Evaluation and Selection

Quantitative approaches are often favored to support project evaluation and selection if the decision requires economic justification. They are also commonly used to support judgment-based project selection. One of the features of quantitative approaches is the generation of numeric measures for simple and effective comparison, ranking, and selection. These approaches also help to establish quantifiable norms and standards, and lead to repeatable processes. Yet, the ultimate usefulness of these methods depends on the assumption that the decision parameters, such as cash flow, risks, and the underlying economic, social, political, and market factors can actually be quantified and reliably estimated over the project life cycle. Therefore, quantitative techniques are effective and powerful decision support tools, if meaningful estimates of cost-benefits, such as capital expenditures and future revenues, can be obtained and converted into net present values for comparison. As an example, Table 210.2 describes four project options that will be evaluated in this chapter using various quantitative methods, with results summarized in Table 210.3.

Net Present Value Comparison

The net present value (NPV) method uses discounted cash flow as the basis for comparing the relative merit of alternative project opportunities. It assumes that all investment costs and revenues are known, and that economic analysis is a valid basis for project selection.

We can determine the NPV of a single revenue, stream of future revenues, or costs expected in the future. Two types of presentations are common: present worth (PW) and net present value.

PW is the single revenue or cost (also called annuity A) that occurs at the end of period n , subject to the prevailing interest rate i . Depending on management philosophy and enterprise policies, this interest rate can be *internal rate of return (IRR)* realized by the company on similar investments, **minimum attractive rate of return (MARR)** acceptable to company management, or the prevailing discount rate. PW is calculated as follows:

$$PW(A | i, n) = PW_n = A \frac{1}{(1 + i)^n}$$

For the examples used in this chapter, we consider the IRR as the prevailing interest rate.

The NPV is defined a series of revenues or costs, A_n , over N periods of time, at a prevailing interest rate i :

$$NPV(A_n | i, N) = \sum_{n=1}^N A_n \frac{1}{(1 + i)^n} = \sum_{n=1}^N PW_n$$

Three special cases exist for NPV calculation: (1) *for a uniform series of revenues or costs over N periods, $NPV(A_n | i, N) = A[(1 + i)^N - 1]/i(1 + i)^N$* ; (2) *for an annuity or interest rate i approaching zero, $NPV = A * N$* ; and (3) *for the revenue or cost series to continue forever, $NPV = A/i$* .

Table 210.3 applies these formulas to four project alternatives described in Table 210.2, showing the most favorable 5-year NPV of \$3,192 for project option P3.

Return on Investment Comparison

Perhaps one of the most popular measures for project evaluation is the *return on investment (ROI)*:

$$ROI = \frac{\text{Revenue}(R) - \text{Cost}(C)}{\text{Investment}(I)}$$

ROI calculates the ratio of net revenue over investment. In its simplest form the stream of cash flow is *not* discounted. One can look at the revenue on a year-by-year basis, relative to the initial investment. For example, project option 1 in Table 210.3 would produce a 20% ROI each year, while project option 2 would produce a 75% ROI during the first year, 50% during the second year, and so on. Although this is a popular measure, it does not permit a meaningful comparative analysis of alternative projects with fluctuating costs and revenues. Furthermore, it does not consider the time value of money. In a more sophisticated way, we can calculate the *average ROI per year*:

$$\overline{ROI}(A_n, I_n | N) = \left[\sum_{n=1}^N \frac{A_n}{I_n} \right] / N$$

We can then *compare the average ROI to the minimum attractive rate of return, MARR*. Given a MARR of 10% for our project environment, all three project options P1, P2, and P3 compare favorably, with project P2 yielding the highest average return on investment of 54%.

Cost-Benefit

Alternatively, we can calculate the NPV of the total ROI over the project lifecycle. This measure, known as *cost-benefit (CB)*, is calculated as the present-value stream of net revenues divided by the present-

value stream of investments. It is an effective measure for comparing project alternatives with fluctuating cash flows:

$$CB = ROI_{NPV}(A_n, I_n | i, N) = \left[\sum_{n=1}^N NPV(A_n | i, N) \right] / \left[\sum_{n=1}^N NPV(I_n | i, N) \right]$$

In our example of four project options (Table 210.3), project proposal P2 produces the highest cost-benefit of 206% under the given assumption of $i = \text{MARR} = 10\%$.

Payback Period Comparison

Another popular figure of merit for comparing project alternatives is the *payback period (PBP)*. It indicates the time period of net revenues required to return the capital investment made on the project. For simplicity, *undiscounted* cash flows are often used to calculate a quick figure for comparison, which is quite meaningful if we deal with an initial investment and a steady stream of net revenue. However, for fluctuating revenue and/or cost streams, the *NPV* must be *calculated for each period individually* and cumulatively added up to the “break-even point” in time, N_{PBP} , when the *NPV* of revenue equals the investment. Mathematically,

$$N_{PBP} \dots \gg \gg \gg \text{ when } \sum_{n=1}^N NPV(A_n | i) \geq \sum_{n=1}^N NPV(I_n | i)$$

In our example of four project options (Table 210.3), project proposal P2 produces the shortest, most favorable payback period of 1.9 years under the given assumption of $i = \text{MARR} = 10\%$.

Pacifico and Sobelman Project Ratings

The previously discussed methods of evaluating projects rely heavily on the assumption that technical and commercial success is ensured, and all costs and revenues are predictable. Because these assumptions do not always hold, many companies have developed their own special procedures and formulas for comparing project alternatives. Two examples illustrate this special category of project evaluation metrics. The *project rating factor (PR)* was originally developed by Carl Pacifico for assessing chemical products and predicting commercial success:

$$PR = \frac{pT * pC * R}{TC}$$

Pacifico’s formula is in essence an ROI calculation adjusted for risk. It includes the probability of technical success ($0.1 < pT < 1.0$), probability of commercial success ($0.1 < pC < 1.0$), total net revenue over project lifecycle (R), and total capital investment for product development, manufacturing setup, marketing, and related overheads (TC).

The second example shows a formula developed by Sobelman:

$$z = (P * T_{LC}) - (C * T_D)$$

It represents a modified cost-benefit measure that takes into account both the development time and the commercial life cycle of the product. It also includes average profit per year (P), estimated product lifecycle (T_{LC}), average development cost per year (C), and years of development (T_D).

TABLE 210.4 Comparison of Quantitative and Qualitative Approaches to Project Evaluation

| Quantitative Methods | Qualitative Methods |
|---|--|
| Benefits | Benefits |
| Simple comparison, ranking, selection | Search for meaningful evaluation metrics |
| Repeatable process | Broad-based organizational involvement |
| Encourages data gathering and measurability | Understanding of problems, benefits, opportunities |
| Benchmarking opportunities | Problem solving as part of selection process |
| Programmable | Broad knowledge base |
| Useful input to sensitivity analysis and simulation | Multiple solutions and alternatives |
| Limitations | Multifunctional involvement leads to buy-in |
| Many success factors are nonquantifiable | Risk sharing |
| Probabilities and weights may change | Limitations |
| True measures do not exist | Complex, time-consuming process |
| Analyses and conclusions are often misleading | Biases via power and politics |
| Methods mask unique problems and opportunities | Difficult to proceduralize or repeat |
| Stifle innovative decision making | Conflict and energy intensive |
| Lack people involvement, buy-in, commitment | Does not fit conventional decision processes |
| Do not deal well with multifunctional issues and dynamic situations | Intuition and emotion dominates over facts |
| May mask hidden costs and benefits | Justify wants over needs |
| Pressure to act quickly and possibly prematurely | Lead to more fact finding than decision making |

Going Beyond Simple Formulas

While quantitative methods of project evaluation have the benefit of producing relatively quickly a measure of merit for simple comparison and ranking, they also have many limitations, as summarized in Table 210.4. Because of these limitations, alternatives to these strictly quantitative methods have been developed that use a broader set of measures in determining the long-range cost and benefits of a project proposal to the enterprise. These methods rely to a large degree on *qualitative, judgmental decision making*. They cast a broad data-gathering net and consider a wide spectrum of factors that are often difficult to quantify or even to describe. Yet, in spite of the limitations of quantitative evaluation and the increased use of qualitative approaches, virtually every organization supports its project selections with some form of quantitative measures, the most popular being cost-benefit and payback period.

210.2 Qualitative Approaches to Project Evaluation and Selection

Especially for project evaluations that involve complex sets of business criteria, the narrowly focused quantitative methods must often be supplemented by broad-scanning, intuitive processes and collective, multifunctional decision making such as *Delphi, nominal group technology, brainstorming, focus groups, sensitivity analysis, and benchmarking*. Each of these techniques can either be used by itself to determine the *best, most successful, or most valuable* option. Or, these techniques can be integrated into an analytical framework for *collective multifunctional decision making*.

Collective Multifunctional Evaluations

This process relies on subject experts from various functional areas for collectively defining and evaluating broad **project success** criteria, while employing both quantitative and qualitative methods. The first step is to define the specific organizational areas critical to project success and to assign expert evaluators. For a typical product development project, these organizations may include R&D, engineering, testing, manufacturing, marketing, product assurance, and customer services. These function experts should be

given the time necessary for the evaluation. They also should have a commitment from senior management for full organizational support. Ideally, these evaluators should have the responsibility of implementing the project, should it be selected.

The next step is for the evaluation team to define the factors that appear critical to the ultimate success of the projects under evaluation and arrange them into a concise list that includes both quantitative and qualitative factors. A mutually acceptable scale must be worked out for scoring the evaluation criteria. Studies of collective multifunctional assessment practices show that simplicity of scales is crucial to a workable team solution. Three types of scale have produced the most favorable results in field studies: (1) 10-point scale, ranging from +5 = most favorable to -5 = most unfavorable; (2) 3-point scale, +1 = favorable, 0 = neutral or cannot judge, and -1 = unfavorable; and (3) 5-point scale, A = highly favorable, B = favorable, C = marginally favorable, D = most likely unfavorable, and F = definitely unfavorable. **Weighing of criteria** is not recommended for most applications as it complicates and often distorts the collective evaluation.

Evaluators first score individually all factors that they feel qualified to make an expert judgement on. Collective discussions follow. Initial discussions of project alternatives, their markets, business opportunities, and technologies involved, are usually beneficial, but not necessary for the first round of the evaluation process. The objective of this first round of expert judgments is to get calibrated on the opportunities and challenges presented. Further, each evaluator has the opportunity to recommend (1) actions needed for better project assessment; (2) whether additional data are needed; and (3) suggestions that would enhance project success and the evaluation score. Before meeting at the next group session, agreed-on action items and activities for improving the decision process should be completed. With each iteration, the function expert meetings are enhanced with more refined project data. Typically, between three and five iterations are required before a project selection can be finalized.

210.3 Recommendations for Effective Project Evaluation and Selection

Effective evaluation and selection of project opportunities involves many variables of the organizational and technological environment, often reaching far beyond cost and revenue measures. While economic models provide an important dimension of the project selection process, most situations are too complex to use simple quantitative methods as the sole basis for decision making. Many of today's project evaluation procedures include a broad spectrum of variables and rely on a combination of rational and intuitive processes for defining the value of a new project venture to the enterprise. The better a firm understands its business processes, markets, customers, and technologies, the better it will be able to evaluate the value of a new project venture. Further, manageability of the evaluation process is critical to its results, especially in complex situations. The process must have a certain degree of structure, discipline, and measurability to be conducive to the intricate multivariable analysis. One method of achieving structure and manageability of the process calls for grouping the evaluation variables into four categories: (1) consistency and strength of the project with the business mission, strategy, and plan; (2) multifunctional ability to produce the project results, including technical, cost, and time factors; (3) success in the customer environment; and (4) economics, including profitability. Modern **phase management** and **stage-gate processes** provide managers with the tools for organizing and conducting project evaluations in a systematic way. The following section summarizes suggestions that can help managers in effectively evaluating projects for successful implementation.

Seek out relevant information. Meaningful project evaluations require relevant quality information.

The four categories of variables identified above can provide a framework for establishing the proper metrics and detailed data gathering.

Ensure competence and relevancy. Ensure that the right people become involved in the data collection and evaluation processes.

Take top-down look first; detail comes later. Detail is less important than information relevancy and evaluator expertise. Do not get hung up on lack of data during the early phases of project evaluation.

Evaluation processes should iterate. It does not make sense to spend a lot of time and resources in gathering perfect data to justify a no-go decision.

Select and match the right people. Whether the project evaluation consists of a simple economic analysis or a complex multifunctional assessment, competent people from functions critical to the overall success of the project should be involved.

Define success criteria. Deciding on a single project or choosing among alternatives, evaluation criteria must be defined. They can be quantitative, such as ROI, or qualitative, such as the chances of winning a contract. In either case, these evaluation criteria should cover the true spectrum of factors affecting success and failure of the project(s). Only functional experts, discussed previously, are qualified to identify these success criteria. Often, people from outside the company, such as vendors, subcontractors, or customers, must be included in this expert group.

Strictly quantitative criteria can be misleading. Be aware of evaluation procedures based on quantitative criteria only (ROI, cost, market share, MARR, etc.). The input data used to calculate these criteria are likely to be based on rough estimates and are often unreliable. Evaluations based on predominately quantitative criteria should at least be augmented with some expert judgment as a “sanity check.”

Condense criteria list. Combine evaluation criteria, especially among the judgment categories, to keep the list manageable. As a goal, try to stay within 12 criteria for each category.

Gain broad perspective. The inputs to the project selection process should include the broadest possible spectrum of data from the business environment that affect success, failure, and limitations of the new project opportunity. Assumptions should be carefully examined.

Communicate. Facilitate communications among evaluators and functional support groups. Define the process for organizing the team and conducting the evaluation and selection process.

Ensure cross-functional representation and cooperation. People on the evaluation team must share a strategic vision across organizational lines. They also must sense the desire of their host organizations to support the project if selected for implantation. The purpose, goals, objectives, and relationships of the project to the business mission should be clear to all parties involved in the evaluation/selection process.

Do not lose the big picture. As discussions go into detail during the evaluation, the team should maintain a broad perspective. Two global judgment factors can help to focus on the big picture of project success: (1) overall benefit-to-cost perception, and (2) overall risk of failure perception. These factors can be recorded on a 10-point scale, -5 to +5. This also leads to an effective two-dimensional graphic display of competing project proposals.

Do your homework between iterations. As project evaluations are most likely conducted progressively, action items for more information, clarification, and further analysis surface. These action items should be properly assigned and followed up, thereby enhancing the quality of the evaluation with each consecutive iteration.

Take a project-oriented approach. Plan, organize, and manage your project evaluation/selection process as a project.

Resource availability and timing. Do not forget to include in your selection criteria the availability and timing of resources. Many otherwise successful projects fail because they cannot be completed within a required time period.

Use red team reviews. Set up a special review team of senior personnel. This is especially useful for large and complex projects with major impact on overall business performance. This review team examines the decision parameters, qualitative measures, and assumption used in the evaluation process. Limitations, biases, and misinterpretations that may otherwise remain hidden can often be identified and dealt with.

Stimulate creativity and candor. Senior management should foster an innovative ambience for the evaluation team. Evaluating complex project situations for potential success or failure involves intricate sets of variables that are linked among the organization, technology, and business environment. It also involves dealing with risks and uncertainty. Innovative approaches are required to evaluate the true potential of success for these projects. Risk sharing by senior management,

recognition, visibility, and a favorable image in terms of high priority, interesting work, and importance of the project to the organization, have been found to be strong drivers toward attracting and holding quality people on the evaluation team, and to gain their active and innovative participation in the process.

Manage and lead. The evaluation team should be chaired by someone who has trust, respect, and leadership credibility with team members. Senior management can positively influence the work environment and the process by providing guidelines, charters, visibility, resources, and active support to the project evaluation team.

In summary, effective project evaluation and selection require a broad-scanning process across all segments of the enterprise and its environment to deal with the risks, uncertainties, ambiguities, and imperfections of data available for assessing the value of a new project venture relative to other opportunities. No single set of broad guidelines exist that guarantees the selection of successful projects. However, the process is not random! A better understanding of the organizational dynamics that affects project performance and the factors that drive cost, revenue, and other benefits, can help in gaining a better, more meaningful insight into the future value of a prospective new project. Seeking out both quantitative and qualitative measures incorporated into a combined rational/judgmental evaluation process often yields the most reliable predictor of future project value and desirability. Equally important, the process requires managerial leadership and skills in planning, organizing, and communicating. Above all, leaders of the project evaluation team must be social architects who can unify the multifunctional process and its people. They must share risks and foster an environment that is professionally stimulating and strongly linked with the support organizations eventually needed for project implementation. This is an environment that is conducive to cross-functional communication, cooperation, and integration of the intricate variables needed for effective project evaluation and selection.

Defining Terms

Annuity (A) — Present worth of a revenue or cost at the end of period n .

Cost-benefit (CB) — Net present value of all returns on investment in dollars.

Cross-functional — Actions that span organizational boundaries.

Internal rate of return (IRR) — Average return on investment realized by a firm on its investment capital.

Minimum attractive rate of return (MARR) — The minimum rate of return on new investments acceptable to an organization.

Net present value (NPV) — Net present value of a stream of future revenues or costs.

Payback period (PBP) — Time period needed to recover original investment.

Phase management — Projects are broken into natural implementation phases, such as development, production, and marketing, as a basis for project planning, integration, and control. Phase management also provides the framework for *concurrent engineering* and *stage-gate processes*.

Project rating (PR) factor — Measure developed by Carlo Pacifico for predicting project success.

Project success — A comprehensive measure, defined in both quantitative and qualitative terms that include economic, market, and strategic objectives.

Present worth (PW) — Present value of a revenue or cost at the end of period n (also called annuity).

Stage-gate process — Framework for executing projects within predefined stages (see also *phase management*) with measurable deliverables (*gate*) at the end of each stage. The gates provide the review metrics for ensuring successful transition and integration of the project into the next stage.

Weighing of criteria — A multiplier associated with specific evaluation criteria.

z — Project rating factor, a measure developed by Sobelman for predicting project success.

John L. Richards
University of Pittsburgh

The purpose of this chapter is to describe the three-step, iterative decision-making process of planning, scheduling, and controlling with the critical path method (CPM). CPM is a network-based analytical tool that models a project's activities and their predecessor/successor interrelationships. **Planning** is the development of a **work breakdown structure (WBS)** of the project's activities. **Scheduling** is the calculation of **activity parameters** by doing a forward and a backward pass through the network. **Controlling** is the monitoring of the schedule during project execution by **updating** and **upgrading**, as well as the modifying of the schedule to achieve feasibility and optimality using cost duration analysis and critical resource analysis.

211.1 Planning the Project

Project planning requires the development of a work breakdown structure, which then becomes the basis for a network model of the project. This model can then be used to evaluate the project by comparing regular measures of performance.

Project Performance Measures

The three common performance measures in project management are *time*, *cost*, and *quality*. The overall objective is to accomplish the project in the least time, at the least cost, with the highest quality. Individually, these objectives conflict with each other. Thus, the manager must seek an overall solution by trading off among them. Further, since the overall project is defined by the activities that must be done, the overall project duration, cost, and quality will be determined by individual activity times, cost, and quality levels.

FIGURE 211.1 Activity time-cost tradeoff curve. The normal time (point a) is the least cost/longest activity duration. The crash time (point b) is the least activity duration/highest cost.

Activity Time-Cost Tradeoff

For a specified quality level for a given activity, the manager initially selects that combination of resources (labor, equipment, and material) that accomplishes that particular activity at the least cost. This is the *normal* duration on an *activity time-cost tradeoff curve* (Figure 211.1). Thus, since each activity is to be done at its least cost, the overall project will be done at the least total cost. However, in order to reduce an activity's duration, the activity cost must increase. For example, one can work overtime at premium rates or use more expensive equipment, which increases cost, in order to reduce an activity's duration. *Crash* is the shortest possible activity duration, no matter how high the cost. The inverse relationship between time and cost yields curves with negative slopes.

Activity Interrelationships

There are two possible relationships between a pair of activities in a project network: (1) one must immediately precede the other (*predecessor*), or (2) one must immediately follow the other (*successor*). If there is no predecessor/successor relationship, the activities may be done simultaneously. These predecessor/successor relationships are derived from absolute constraints such as physical/technological, safety, and legal factors; or imposed constraints such as the selection of resources, methods, and financing. The manager should initially incorporate relationships derived only from absolute constraints. Relationships derived from imposed constraints should be added only as necessary to achieve feasibility. This approach to predecessor/successor relationships yields the least constrained project network initially.

The basic predecessor/successor relationship is finish to start with no lead or lag. However, more sophisticated models allow three other types: start to finish, finish to finish, and start to start. In addition, each of the four could have a lead time or a lag time. Thus there are twelve possible ways to describe a particular predecessor/successor relationship.

Work Breakdown Structure

The WBS of a project is the listing of all the individual activities that make up the project, their durations, and their predecessor/successor relationships. It should be the least costly and least constrained method of executing the project, that is, normal durations and absolute constraints only. Therefore, if the schedule resulting from this initial WBS is feasible, then it is also optimal. If, however, the schedule is infeasible because of time and/or resource considerations, then the manager would want to achieve feasibility with the least additional cost. (Scheduling and feasibility/optimality are discussed in later sections.)

TABLE 211.1 WBS of Swimming Pool Construction

| Activity ID | Duration | Description | Immediate Predecessors |
|-------------|----------|--|------------------------|
| A101 | 10 | Order and deliver filtration equipment | — |
| A202 | 5 | Order and deliver liner/piping | — |
| B301 | 4 | Excavate for pool | — |
| B202 | 3 | Install liner/piping | A202, B301 |
| B102 | 2 | Install filtration equipment | A101 |
| C301 | 2 | Fill pool | B202 |
| B401 | 5 | Construct deck | B202 |
| C302 | 2 | Connect and test system | C301, B102 |
| B501 | 3 | Landscape area | B401 |

There are three approaches to developing a WBS: (1) by physical components, (2) by process components, and (3) by spatial components. *Physical components* model a constructed product (e.g., build wall). *Process components* model a construction process (e.g., mix concrete). *Spatial components* model a use of time or space (e.g., order steel or cure concrete). No matter which of the three approaches is used to define a particular activity in a WBS, each should be described by an action verb to distinguish an activity from an event. (Note: There can be special activities in a WBS that involve time only and no cost, such as curing concrete. There can also be dummy activities for logic only that have no time or cost.)

A project's WBS must be developed to an appropriate level of detail. This means that activities must be broken down sufficiently to model interrelationships among them. Also, a standard time period (hour, shift, day, week, etc.) must be chosen for all activities. An appropriate WBS will have a reasonable number of activities and reasonable activity durations.

Example 211.1: Work Breakdown Structure

Table 211.1 shows a WBS for constructing a backyard in-ground swimming pool with a vinyl liner. Note that a time period of days was selected for all activities.

211.2 Scheduling the Project

The critical path method of project scheduling is based upon a network model that can be analyzed by performing a forward and a backward pass to calculate activity parameters.

CPM Network Models

There are two types of network models: activity oriented and event oriented. Both types have nodes connected by arrows that model events (points in time) and activities (processes over time).

Activity-Oriented Diagram

The activity-oriented diagram is also called an *arrow diagram* (ADM) or *activity on arrow* (AOA). The activities are the arrows, and the events are the nodes. Dummy activities (depicted as dashed arrows) may be required to correctly model the project for logic only. Activity identification is by node pairs (node *i* to node *j*). This was the original diagramming method, which is easy to visualize but difficult to draw.

Event-Oriented Diagram

The event-oriented diagram is also called a *precedence diagram* (PDM), *activity on node* (AON), or *circle network*. The activities are the nodes, and the events are the ends of arrows. There are no dummies. All arrows are for logic only, which also allows for modeling the twelve types of activity interrelationships

FIGURE 211.2 Activity graphical models. The activity identification (ID) and duration (DUR) are from the WBS. The EST and LFT are calculated from the forward and backward passes, respectively.

discussed earlier. This diagramming method is easier to draw and well suited to computer use. Although developed after AOA, the AON has become the preferred method.

CPM Network Calculations

There are three steps in the manual analysis of a CPM network that determine the activity parameters. The forward pass determines the *earliest start time* (EST) of each activity. The backward pass determines the *latest finish time* (LFT) of each activity. The other times, the *earliest finish time* (EFT) and the *latest start time* (LST), and the floats, *total float* (TF), and *free float* (FF), are then determined from a table. The calculation process is the same for either type of network (ADM or PDM). Before beginning the process, one needs to establish a time convention — beginning of time period or end of time period. The example in this chapter uses beginning of time period, thus the first day is day one. (The end-of-time-period convention would begin with day zero.)

Forward Pass

To determine the EST of an activity, one compares all the incoming arrows — that is, the *heads* of arrows — choosing the *largest* earliest event time. The comparison is made among all the immediately preceding activities by adding their ESTs and respective durations. The process begins at the start node (the EST being zero or one) and proceeds to the end node, taking care that all incoming arrows get evaluated. At the completion of the forward pass, one has determined the overall project duration. The ESTs can be placed on diagrams as shown in Figure 211.2.

Backward Pass

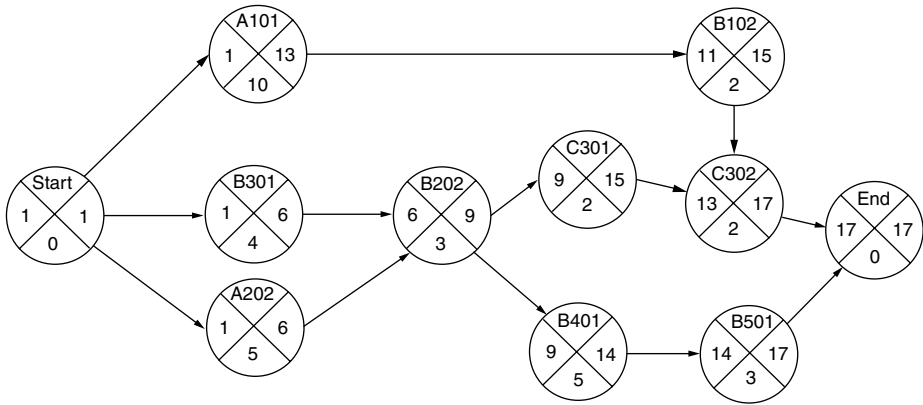

The backward pass begins at the end node with the overall project duration (which is the LFT) and proceeds to the start node. This process determines the LFT for each activity by comparing the outgoing arrows — that is, the *tails* of arrows — choosing the *smallest* latest event time. The comparison is made among all the immediately succeeding activities by subtracting their durations from their respective LFTs. At the completion of the backward pass one should calculate the original project start time. The LFTs can be placed on diagrams as shown in Figure 211.2.

Floats

The other two times (EFT and LST) and floats (TF and FF) are determined in a tabular format using the following relationships: (1) $EFT = EST + \text{duration}$, (2) $LST = LFT - \text{duration}$, (3) $TF = LFT - EFT$ or $TF = LST - EST$, and (4) $FF = EST$ (of following activities) $- EFT$. Activities with a $TF = 0$ are on a **critical path**. There may be more than one critical path in a network. If the duration of any critical path activity is increased, the overall project duration will increase. Activities with $TF > 0$ may be increased without affecting the overall project duration. On the other hand, free float is that amount of total float that can be used by the activity without affecting any other activities. If TF equals 0, then FF equals 0, necessarily. Free float may comprise some, all, or no portion of total float.

(a) Activity-Oriented Network (ADM or AOA)
 Note that activity 4-3 is a dummy and is also on the critical path.

(b) Event-Oriented Network (PDM or AON)
 Note that implied start and end nodes are shown with zero durations.

FIGURE 211.3 CPM network calculations (forward and backward passes). The overall project duration was determined to be 16 days ($17 - 1 = 16$).

Example 211.2: CPM Scheduling

This example continues with the project introduced in [Table 211.1](#). The CPM calculations for the forward and backward passes are shown in [Figure 211.3](#) for both network types. [Table 211.2](#) lists all times and floats.

211.3 Controlling the Project

CPM-based project management provides the tools to control time and money in a dynamic and hierarchical project environment during project execution.

Managing Time and Money

Computerized project management systems can provide a variety of informational outputs for use in managing a project. These include network diagrams showing activity interrelationships, bar charts showing activity durations, tabular listings showing activity parameters, and profiles showing cash flows or resource utilization during the project.

TABLE 211.2 Activity Times and Floats

| Activity ID | Duration | EST | EFT | LST | LFT | TF | FF |
|-------------------|----------|-----|-----|-----|-----|----|----|
| A101 | 10 | 1 | 11 | 3 | 13 | 2 | 0 |
| A202 ^a | 5 | 1 | 6 | 1 | 6 | 0 | 0 |
| B102 | 2 | 11 | 13 | 13 | 15 | 2 | 0 |
| B202 ^a | 3 | 6 | 9 | 6 | 9 | 0 | 0 |
| B301 | 4 | 1 | 5 | 2 | 6 | 1 | 1 |
| B401 ^a | 5 | 9 | 14 | 9 | 14 | 0 | 0 |
| B501 ^a | 3 | 14 | 17 | 14 | 17 | 0 | 0 |
| C301 | 2 | 9 | 11 | 13 | 15 | 4 | 2 |
| C302 | 2 | 13 | 15 | 15 | 17 | 2 | 2 |

^a Activities on critical path.

Hierarchical Management

Project management generally occurs in a multiproject environment with multiple time parameters and multiple managerial levels. Multiple project models integrate cash flow and resource profiles of several projects. Multiple calendar models allow activities to be done at different time frames (e.g., some may be done 5 days per week, and others 7 days per week). Project management information systems can provide summary information for upper-level management and detailed information for workers in the field.

Managing the Schedule

The project schedule is a dynamic managerial tool that changes during project execution.

Updating the Schedule

As the project proceeds the schedule should be **updated** at periodic intervals to reflect actual activity progress. Such updates can incorporate percent complete, remaining durations, and actual start and end dates for each activity. The updates can be the basis for evaluating overall project objectives (time and money) and for making progress payments. After any update, a new schedule calculation must be done to determine new times and floats.

Upgrading the Schedule

Any change to an existing schedule either by changing a planned duration or an activity relationship is a schedule **upgrade**. A schedule upgrade can occur either prior to start of the project, or any time during the project, based on new information. After any upgrade, a new schedule calculation must be done to determine new times and floats.

Managing the Floats

A negative total float indicates that the project will overrun the stated completion date. A positive (>0) total float indicates that the project will be completed earlier than the stated completion date. A particular network will generally have many different total float paths, including negative ones if it is behind schedule, and no zero ones if it is ahead of schedule.

Free float indicates that amount of time an activity can be manipulated without affecting any other activity (and therefore the project as a whole). When managing the floats, one would want to use free float before total float. Once total float is used, the activity becomes part of a new critical path.

The use of the floats can be a difficult contractual issue among the parties. It is a good idea to decide beforehand how the floats can be used. Otherwise the issue may be part of a delay claim at completion of the project.

TABLE 211.3 Activity Times and Floats (Update)

| Activity ID | Duration | EST | EFT | LST | LFT | TF | FF |
|-------------------|----------|-----|-----|-----|-----|----|----|
| A101 ^a | 9 | 6 | 15 | 6 | 15 | 0 | 0 |
| A202 ^a | 2 | 6 | 8 | 6 | 8 | 0 | 0 |
| B102 ^a | 2 | 15 | 17 | 15 | 17 | 0 | 0 |
| B202 ^a | 3 | 8 | 11 | 8 | 11 | 0 | 0 |
| B301 | 0 | — | — | — | — | — | — |
| B401 ^a | 5 | 11 | 16 | 11 | 16 | 0 | 0 |
| B501 ^a | 3 | 16 | 19 | 16 | 19 | 0 | 0 |
| C301 | 2 | 11 | 13 | 15 | 17 | 4 | 4 |
| C302 ^a | 2 | 17 | 19 | 17 | 19 | 0 | 0 |

^a Activities on critical path.

TABLE 211.4 Activity Times and Floats (Upgrade)

| Activity ID | Duration | EST | EFT | LST | LFT | TF | FF |
|-------------------|----------|-----|-----|-----|-----|----|----|
| A101 ^a | 9 | 6 | 15 | 6 | 15 | 0 | 0 |
| A202 | 2 | 6 | 8 | 7 | 9 | 1 | 0 |
| B102 ^a | 2 | 15 | 17 | 15 | 17 | 0 | 0 |
| B202 | 3 | 8 | 11 | 9 | 12 | 1 | 0 |

| B501 | 3 | 16 | 19 | 17 | 20 | 1 | 1 |
| C301 | 2 | 11 | 13 | 15 | 17 | 4 | 4 |
| C302 ^a | 3 | 17 | 20 | 17 | 20 | 0 | 0 |

^a Activities on critical path.

Example 211.3: Updating and Upgrading

This example continues with the project introduced in [Table 211.1](#) and originally scheduled in [Table 211.2](#).

1. *Updating.* Assume that it is the beginning of day 6 and that activity B301 is done, and A101 has 9 days left and A202 has 2 days left. These updated durations are used in [Figure 211.3](#) to recalculate activity times and floats as shown in [Table 211.3](#). Note that a second critical path has developed and that the overall project duration has been extended 2 days.
2. *Upgrading.* Now assume that immediately after updating, the duration for activity C302 gets changed to 3 days and B401 must precede it. These upgrades could be incorporated into a revised [Figure 211.3](#) (not shown) to recalculate another set of activity times and floats as shown in [Table 211.4](#). Note that there is now only one critical path and the overall project duration has been extended another day to day 20.

211.4 Modifying the Project Schedule

Project planning, scheduling, and controlling are iterative decision-making processes. It is highly unlikely for an initial schedule to be both feasible and optimal in the first iteration. Likewise, it is highly unlikely that the actual project execution will match the original project plan exactly. Therefore, one must know how to modify the project schedule in order to achieve feasibility and optimality. The modification process involves changing activity duration, changing activity relationships, or both.

Cost Duration Analysis

Cost duration analysis (CDA) utilizes activity time/cost tradeoff curves (discussed earlier) in order to compress the overall project schedule. The objective is to buy back each time unit in the cheapest possible

manner until the desired completion date is reached (feasibility). Only activities on a critical path need be reduced. The others with positive float simply have the float reduced. The problem can become very complex in a large network with multiple critical paths where the incremental additional costs for the activities are different.

Critical Resource Analysis

The approach to **critical resource analysis (CRA)** is different from CDA in that it seeks to extend the overall project duration the least amount in order to resolve resource conflicts (i.e., achieve feasibility). CRA can be viewed from one of two perspectives: (1) constrained resources — staying below a specified limit, or (2) resource leveling — selecting a constant limit. The solution approach for either is the same. The problem is one of ordering (predecessor/successor relationships) those activities that have resource conflicts during the same time period. The pairwise comparison of all such activities in a large network with many critical resources presents a huge combinatorial problem. The only viable solution approaches are based upon heuristic decision rules. (A simple rule could be that the predecessor activity should be the one with the smaller LST.)

Combined CDA and CRA

Combining CDA and CRA to achieve a feasible and optimal schedule is virtually impossible for all but the simplest networks. Although the CDA problem does have rigorous mathematical solutions, they are not incorporated in most commercial software. On the other hand, the software generally does incorporate heuristic-based solutions for the CRA problem. Therefore, one should use the software in an interactive decision-making manner.

Example 211.4: CDA and CRA

Assume that after the upgrade as shown in [Table 211.4](#), it is decided that the desired completion date is day 19, and also that activities B102 and B401 cannot be done simultaneously because of insufficient labor. Further, assume that B401 can be reduced from 5 days to 3 days at an additional cost of \$200 per day and that C302 can be reduced from 3 days to 2 days at an additional cost of \$400.

Solution. The solution approach to this problem is to work two cases: (1) B102 precedes B401, and compress B401 and/or C302 if they lie on a critical path; and (2) B401 precedes B102, and again compress B401 and/or C302. Case 1 would yield an overall project duration of 25 days, and one can readily see that it is impossible to reduce it by 6 days (one can only gain a total of 3 days from activities B401 and C302). Case 2 (B401 precedes B102) yields an overall project duration of 21 days, with both B401 and C302 on the same critical path. One should choose the least expensive method to gain 1 day — that is, change B401 to 4 days for \$200. This yields a project duration of 20 days and an additional critical path. Therefore, reducing B401 another day to 3 days does not get the project to 19 days. Instead, the more expensive activity (C302) must be reduced from 3 to 2 days for \$400. The answer to the problem, then, is B401 goes from 5 to 4 days for \$200, and C302 goes from 3 to 2 days for \$400. Thus, the overall project duration is compressed from 21 to 19 days from a total additional cost of \$600.

211.5 Project Management Using CPM

CPM was first developed in the late 1950s by the Remington Rand Corporation and the DuPont Chemical Company. Since then, many software manufacturers have developed sophisticated computer-based management information systems using CPM. In addition to performing the CPM calculations discussed in this chapter, such systems can provide data for creating the historical file of an ongoing project, for developing estimating information for a future project, and for performance evaluation of both the

project and the participating managers. CPM has even become a well-accepted means for analyzing and resolving construction disputes.

The successful use of CPM as a managerial tool involves not only the analytical aspects discussed in this chapter, but also the attitude that is displayed by those using it in actual practice. If CPM is used improperly as a weapon, rather than as a tool, there will be project management failure. Therefore, successful project management must include positive team building among all project participants, along with the proper application of the critical path method.

Defining Terms

Activity parameters — Activity times (EST, EFT, LFT, and LST) and activity floats (TF and FF) calculated in the scheduling step.

Controlling — Third step in the interactive decision-making process that monitors the accomplishments of the project by updating and upgrading, and seeks feasibility and optimality by cost duration analysis and critical resource analysis.

Cost duration analysis (CDA) — Reducing durations of selected activities in the least costly manner in order to achieve a predetermined project completion date.

Critical path (CP) — String of activities from start to finish that has zero total floats. There may be more than one CP, and the CPs may change after an update or upgrade.

Critical resource analysis (CRA) — Sequencing selected activities in such a manner so as to minimize the increase in project duration in order to resolve resource conflicts among competing activities.

Planning — The first step in the interactive decision-making process that determines the work breakdown structure.

Scheduling — The second step in the interactive decision-making process that determines the activity parameters by a forward and a backward pass through a network.

Update — Changing remaining activity durations due to progress only, and then rescheduling.

Upgrade — Changing activity durations and interrelationships due to new information only, and then rescheduling.

Work breakdown structure (WBS) — Listing of individual activities that make up the project, and their duration and predecessor/successor relationships.

[212.1 Patents](#)

[212.2 Trade Secrets](#)

[212.3 Licenses](#)

[212.4 Copyrights and Anticircumvention Rights](#)

[212.5 Trademarks](#)

An engineer's work can be legally protected in a number of different ways. The legal rights to the work (and sometimes the work itself) are referred to as intellectual property.

Because an engineer's work is normally a useful product, patents — which protect useful inventions — are the typical means of obtaining the exclusive legal right to use or distribute the engineer's work. For those inventions or technologies that are unpatentable, difficult to patent, or may be maintained in secrecy despite commercial exploitation, a good practical substitute can be trade secret protection, which requires only that the work product be useful and that it be kept confidential. When the engineer's work product must be shared with another in order to make commercial use of it, license agreements covering such distribution can be used to preserve control over the engineer's work.

Copyrights protect what the Copyright Act calls “works of authorship,” which include nonfunctional work products and the nonfunctional aspects of functional works, namely, the parts or aspects that are not necessary to the work's functionality. In addition, copyrights can protect some rights to even such functional things as computer programs, diagrams, textbooks, and architectural drawings, although the courts try not to protect (with copyrights) the underlying ideas and functionality that such things express or contain.

Trademarks protect not work product itself, but the engineer's (or his or her employer's) right to be known as the source of the work product. Trademark law forbids others to falsely claim to be the source, origin or sponsor of the engineer's work, or to falsely claim that the engineer is the source, origin, or sponsor of the work of another.

Thus, a computer program used in manufacturing a new drug can be protected by a patent or trade secret, a copyright, a trademark, and one or more licenses. A patent can be obtained for the logic of the program, the computer readable medium containing the program, or the process of manufacturing and the use of the computer program in that process. A copyright can be obtained in the program's code, which prevents the copying of the program. If the owner of the program does not wish to publicly reveal how it works, the program can be protected by keeping it confidential as a trade secret. If the program

is to be distributed to others, the code can be protected by a legally enforceable access-control device. A trademark can be used to identify the origin of the computer program. Finally, through license agreements, the program's owner can control further use or distribution of the product.

212.1 Patents

A patent gives the inventor or assignee the right to exclude others from making, using, selling, or offering for sale an invention, for a limited period, typically 20 years from the filing date of an application in a particular country or jurisdiction (e.g., the European Community). In order to be patentable in the U.S., an invention must be filed on behalf of the first and true inventors, be useful, novel, and nonobvious, and the application must include a written description of the invention, an enabling disclosure, a description of the best mode for practicing the invention, and at least one claim that defines the scope of legal protection. Outside the U.S., the owner of the invention is the applicant, and the first to file gains priority. Further, in various countries, the standards for patentability differ, as do the requirements for the application, although a single comprehensive application may be prepared and translated as necessary. A patent is like a contract between the inventor and the government that, in exchange for a disclosure of the invention, the patentee receives a limited period of exclusive use. A patent is not considered an absolute monopoly nor an exception to antitrust law, and therefore the enforcement of patent rights may be limited by other considerations.

The main type of patent is the regular utility patent, which protects a functional invention, which may be a product, composition, or process. Other types of patents include design patents, which protect non-functional ornamental features of industrial designs, and plant patents, which protect asexually reproduced plants. Sexually reproduced plants are protected by a parallel system of Plant Variety Protection Act certificates.

In the U.S., a regular utility patent application must be filed within 1 year of the first publication, offer for sale, or use; outside the U.S., an absolute novelty bar is often imposed, without any grace period. Therefore, an applicant seeking international protection should file a priority application, that is, one meeting the requirements of most or all countries in which protection might be sought, before any publication, offer for sale, or use. If protection is desired only within the U.S., the application may be delayed for up to 1 year. This priority application can be a provisional patent application, a regular utility application, or a Patent Cooperation Treaty (International) patent application designating the countries of interest. According to international treaties covering almost all countries, the priority claim from a first-filed regular utility patent application in any one country must be followed up by an International patent application or respective national patent applications in the countries of interest within one year from the priority date. An International application can delay the filing of national patent applications by at least 30 months from the priority date, allowing consolidated initial examination by a single examiner, in a single language prior to prosecution in each country or regional office. Patent applications (including International applications) are typically published 18 months after the priority date, although in the U.S. there are some exceptions. Once a patent application is published, damages based on the published claims may begin to accrue. The granted patent issues after examination, allowance, and payment of an issue or registration fee, and only then can it be enforced. Maintenance fees or annuities may be required.

A provisional patent application in the U.S. is similar to a regular utility application, except that it remains unexamined, and need not have claims. All other requirements are the same, and therefore the description should meet the same standards of completeness. The regular utility patent application or International patent application claiming priority from the provisional application must be filed within 1 year. The utility application may be completely revised and updated without prejudice in the U.S., so long as the provisional application was filed before publication, use or offer for sale. The use of a provisional application potentially extends the life of a patent by 1 year, since the expiration is calculated from the filing of the utility application.

Computer software, either as a general-purpose machine that is programmed to perform specific functions, or as a method performed in accordance with the software, is generally considered patentable in most countries. Algorithms may therefore be protected in context, although laws of science in the abstract are unpatentable. In the U.S., computer-readable media containing code is also patentable, thus allowing computer software *per se* to be protected.

In the U.S., the so-called business method patent has become popular. This type of patent typically has claims that de-emphasize the underlying technology in favor of the application of the technology to the internal business processes. Business method patent applications often encompass an entire business model, including both technologies and their context within the organization, and therefore can be voluminous. Such patents may meet significant resistance outside of the U.S.

The patent examination process reviews both the formalities of the application, as well as the patentability of the claims in view of the prior art. In the U.S., there is a requirement to disclose material prior art known to applicants. During examination, the patent examiner seeks to identify the closest prior art that expressly or inherently meets each and every element of a claim, rendering the claim anticipated, or one or more references that, alone or together, would have rendered the invention obvious to one of ordinary skill in the art. In International applications, such an obviousness rejection is called “lack of inventive step.” In response, the applicant can identify errors or inconsistencies in the rejection, or provide additional evidence in support of patentability. Typically, no new matter may be added to the description of the invention, although in some cases it may be possible to overcome a rejection by filing a new application with an amended text. In the U.S., the applicant is typically given two opportunities to overcome the rejection, after which a Request for Continued Examination with fee must be filed, or the rejection appealed. In many cases, the examination in a single application or continuation application is limited to a single invention. A single original patent application may thus form the basis for a number of patents, through filing of division or continuation applications.

A patent does not provide a right to use an invention. Others may have concurrent patent rights that would be infringed by commercializing a patented technology. The publication of the patent or patent application may allow others with earlier priority to draft claims encompassing the disclosed embodiments. When two U.S. applicants claim the same invention, an interference proceeding may be instituted, with the patent awarded to the earlier inventor who has not suppressed or concealed the invention, and has pursued the invention with diligence between conception and reduction to practice or patent application filing. After publication of a claim in a patent or patent application, another seeking to interfere with it has one year to copy the claim in another patent application.

A prior art reference in the U.S., claiming a different invention, may be overcome by documented evidence of conception by the inventor prior to the effective date of the reference. For this reason, and for purposes of interference, inventors are encouraged to document their inventions in notebooks, pages of which are contemporaneously witnessed and dated by two noninventors who understand the contents, to provide evidence of the date of conception and progress toward reduction to practice. Electronic lab notebooks and other evidence might also be acceptable.

U.S. patents are enforced by lawsuits in federal District Courts. Infringement may be found either by literal infringement, that is, an accused method, composition or apparatus directly corresponds to each element of a patent claim, or under the Doctrine of Equivalents, where an equivalent to a claim element will suffice in order to prove infringement. Remedies are also available against those who engage in “contributory infringement” (selling goods that have no substantial noninfringing use in commerce) and those who induce others to infringe.

A prevailing patentee is entitled to proven damages, with an award no less than a reasonable royalty. Patent infringement is not considered criminal, and indeed no intent to infringe need be shown in order for liability to attach. However, in the U.S., intentional infringement is one factor in awarding enhanced damages, which can be up to three times actual damages, and attorneys’ fees. A prevailing patentee is entitled to an injunction; that is, an order of court against further infringement of the patent. The injunction is a powerful weapon that may lead to a settlement based on the value of the infringing business, rather than merely the damages to the patentee, which can be less.

An engineer will often be concerned with three types of opinions from patent counsel: patentability or validity, infringement, and clearance. A patentability opinion provides an estimate of the issues that will be encountered in obtaining patent protection, most often focusing on the prior art identified in a search. A patentability opinion is typically requested prior to preparation of a patent application. A validity opinion investigates an issued patent, which has a presumption of validity attached to it. An infringement opinion provides an analysis of patent claims against a product or method, and typically arises in cases where a patent or published application is identified as a concern. Often, this analysis presumes validity, although this may also be investigated. The infringement analysis generally requires review of the proceedings before the Patent Office, called the “file wrapper,” since statements made by applicant during prosecution may limit the scope of protection or define claim terms. A clearance opinion seeks to determine the degree of risk that a company will incur by launching a new product or service. Therefore, a search of unexpired patents is made to determine potentially relevant claims, which are then analyzed for scope and validity.

212.2 Trade Secrets

A broad group of things can be legally protected as trade secrets. Anything commercially useful — not just inventions or processes — can be protected as long as it gives its owner a commercial advantage over competitors who do not know the secret.

Trade secret protection can be obtained for things that are not patentable or copyrightable. They need not be novel or original. The sole requirements for trade secret protection are that the information be useful and secret.

Trade secret protection is most useful when, whether or not a patent or copyright can be obtained, the commercial value of the work or information can best be preserved by keeping it confidential. For example, the structure or design of a computer program may be valuable but insufficiently novel to be patentable and too functional to be copyrightable. By distributing the program solely in object code and maintaining the secrecy of the source code and documentation, however, the program can be protected from the use by another who learns of the program structure or design in violation of an individual’s agreement or duty of confidentiality.

The legal essence of a trade secret is the obligations of people privy to the secret to keep it secret. Those who learn a trade secret without violating an obligation to keep it secret and without someone else violating such an obligation are free to use it and publicly disclose it. Consequently, it is advisable for a company intending to maintain its trade secrets to promulgate secrecy policies and to obtain written agreements from its personnel and from third parties who become privy to the secret, such as distributors or licensees, to adhere to those policies. Even inside the company, it is useful, in later persuading a court that the trade secret is indeed secret, to distribute information related to trade secrets on a restricted basis and to institute security procedures to keep trade secrets restricted to company premises and personnel. While employees who leave for another job cannot be prevented from remembering what they know of their former employer’s trade secrets, they can sometimes be prevented from taking another job where their knowledge will inevitably be used to confer the secret’s advantages upon the new employer.

Unlike patents, however, trade secret protection does not protect against reverse engineering. If the secret is contained in a product distributed without an agreement from the recipient not to reverse engineer the product (or to further distribute it to some one not bound by such an agreement), the recipient or its transferee can use the secret if they can figure it out by reverse engineering.

212.3 Licenses

One of the principal ways to exploit intellectual property is to let others use it. An agreement allowing another to use intellectual property, while retaining ownership of it, is referred to as a license.

Licenses are flexible tools. They can, for example, permit (or forbid) commercial use of the intellectual property, permit (or forbid) further disclosure, use, or distribution of the intellectual property, limit or

regulate the rights of the licensee in the event of malfunction, and cover any other subject in any other way that the law will permit and enforce.

A license can be granted by the owner of a patent, trade secret, copyright, or trademark. Where the licensee is to make commercial use of the licensed thing, compensation to the licensor may (but need not) take the form of a royalty. The intellectual property rights in a product need not be licensed all together. For, example, a patent owner has the exclusive right to make, use, and sell its invention. The three rights can be licensed separately, in combination with one another or piecemeal. They can be divided in time and territory. The licensee may get the exclusive right to the invention or the nonexclusive right. (An exclusive license prohibits the patent owner from licensing the same right to another, whereas a nonexclusive license does not.)

Licenses binding on consumers have become commonplace in recent years. So-called shrink-wrap licenses and, for products distributed on the Internet, click-wrap licenses, commonly restrict what users can do with the products they buy and what their recourse is if any kind of problem occurs. While the validity of these licenses and some of their terms have been and continue to be challenged, most courts enforce them.

212.4 Copyrights and Anticircumvention Rights

Copyrights protect original works of authorship, a phrase that has come to mean almost any original expression of an idea that is put in a tangible form. Works that can be copyrighted include literary works, musical works, dramatic works, pantomimes and choreographic works, pictorial, graphic, and sculptural works, motion pictures and other audiovisual works, sound recordings, and architectural works. As noted above, however, copyrights only protect nonfunctional features of a work.

Associated with the Copyright Act are recently created protections for certain engineering products. Under the Digital Millennium Copyright Act of 1998, the creator of a software device that prevents unauthorized access to a copyrightable work can legally prevent circumvention of that device. Copyright-like protection has also been extended to mask works for semiconductor chip products and designs of useful articles, such as boat hulls.

The U.S. is a signatory to the Berne Convention, and as a result copyrighted works of U.S. citizens enjoy the same copyright protection as other signatory countries accord their nationals.

A copyright prohibits others from, most importantly, copying and distributing a work. It also prohibits others from adapting the work for other works, from displaying and performing it, where applicable, and from importing copies of it from outside the U.S. Because a copyright also prevents others from authorizing the exercise of rights under copyright, the copyright owner has the exclusive right to license rights to the work.

The author (or authors) of the work owns the copyright when it is created. They are free to transfer all of their rights under copyright from the date of creation, except for some rights-recapture rules that generally become effective many years later. However, if the work is produced during the course of regular employment of the author and within the scope of that employment, the employer is treated as the author and original owner of the copyright. Such works are referred to as works made for hire. Certain categories of works not created by regular employees, including, for example, contributions to collective works, can also be works made for hire, if so agreed in writing.

Unlike patents, no official grant of a copyright is necessary to own a valid copyright. Copyright arises automatically when an original work of authorship is fixed in a tangible medium of expression. It is a procedural prerequisite to suing for copyright infringement that an attempt be made to register the owner's claim to copyright with the United States Copyright Office (if the work was created by U.S. nationals or was first published in the U.S.), but the copyright subsists without registration and can be sold or licensed.

The former rule that a work had to be published with a copyright notice to protect copyright was repealed in 1989, and notice of copyright is no longer required. Nevertheless, the notice has a practical use in warning that copyright is claimed in the work and thereby in deterring infringement, and in preserving the owner's rights to certain categories of damages.

Unless outweighed by other considerations, it is advisable to promptly register any copyrightable work that may be worth protecting against infringement. The principal advantages of prompt registration are (1) an infringer will be liable for a special kind of damages called “statutory damages,” which are available whether or not the copyright owner can prove any actual damages; (2) an infringer may, in the court’s discretion, be required to pay the copyright owner’s attorney fees incurred in pursuing the infringement case; and (3) the copyright owner will be presumed to have a valid copyright, casting the burden on the infringer to disprove it. Considerations that might outweigh registration are the (relatively minimal) cost and, more importantly, the deposit requirement.

To register the copyright in most works, two copies of the best edition of the copyrighted work must be deposited with the Copyright Office. This requirement raises an obvious problem when the work is one that contains trade secrets. A prominent example is a computer program. The Copyright Office has therefore agreed to accept only portions of computer programs as deposit copies, and there are other categories of works where the deposit requirement has been modified for practical reasons.

The term of a copyright depends on its date of publication or creation or the date of the author’s death, depending upon the dates of creation and publication and whether the work was made for hire. For new works the most important duration rule is the life of the author plus 70 years, except for works made for hire, in which copyright lasts 95 years from date of publication (or 120 years from creation, if shorter). For works published before 1978, the term of protection is 95 years from first publication, if renewal was made. As a general but not invariable rule, no work predating 1923 is still copyrighted in the U.S.

For an infringement of copyright, the copyright owner is entitled to an injunction, to its damages from the infringement and, to the extent that they do not overlap the owner’s damages, the profits made by the infringer from the infringement. If the copyright was registered before the infringement began, the owner has the additional remedies noted above. In extreme cases, all infringing copies and the materials used to make them may be seized and impounded pending final determination of the case. However, the defendant in a frivolous infringement case can be awarded its counsel fees.

212.5 Trademarks

A trademark or service mark (both referred to here as marks) is a word, phrase, picture, or other thing that is used to indicate the source, origin, or sponsor of goods or services. It need not be original or novel, but may not be chosen to suggest a connection with another person or company and may not be the generic name for the goods or services involved. That is, “You’ve Got Mail,” for example, cannot be a trademark for an Internet email delivery service. Ownership of a mark gives the owner the exclusive right to use the mark to indicate the source, origin, or sponsorship of the goods or services with which it is associated.

As with copyrights, marks need not be registered to be valid. Although marks can be registered federally and with state governments, trademark rights are actually obtained by use of the mark in connection with the owner’s goods or services. Rights in a mark can be reserved by registering with the USPTO the claimant’s intent to use the mark, but the intent to use never ripens into a mark unless the claimant actually uses the mark in interstate commerce.

Unlike copyrights, trademarks do not need to be registered or subject to attempted registration as a procedural prerequisite for an infringement lawsuit. Federal registration, however, confers the following important procedural rights and practical benefits:

- Registration prevents someone else who starts using the same mark for the same goods or services after the registration from acquiring any rights in it in the U.S. Otherwise, if the users are geographically separated, it is possible for a so-called junior user to acquire rights in its own territory.
- The registration can be found by another prospective user or registrant, in many cases deterring them without legal action from starting to use or trying to register the same mark. If a prospective

registrant does try to register the same mark, the earlier registration should be found by the trademark examiner and registration of the second mark may then be refused.

- As with a copyright registration, a federal trademark registration is presumed valid, casting on an infringer the burden of disproving registrant's trademark rights.

A trademark registration has a term of 10 years from the date of registration, which can be renewed for 10-year periods indefinitely.

Trademark infringement is established if someone else uses the mark or something similar and that use creates a likelihood of confusion as to the source of the second user's goods or services. That is, there will be infringement if either the second user's goods or services are thought to come from the trademark owner or if the trademark owner's goods or services are thought to come from the second user. The principal factors in determining whether likely confusion, and therefore trademark infringement, has occurred are the similarity of marks and the similarity of goods, although many other factors, such as the sophistication of the purchasers and the good faith of the second user, can be considered. Actual confusion resulting from the second user's use, such as customer complaints to the trademark owner from consumers who bought the second user's goods, is, of course, strong evidence of likely confusion, but is not necessary to a finding of trademark infringement.

Federal remedies for trademark infringement include injunction, the mark owner's damages, and the (nonoverlapping) infringer's profits resulting from the infringement. In exceptional cases, the courts can award the trademark owner its counsel fees and treble damages (i.e., damages three times the trademark owner's actual damages). Seizure of infringing goods can also be ordered. State law may also allow the recovery of punitive damages in extreme cases.

Recently, a federal prohibition against so-called dilution of a trademark was enacted (antidilution laws previously existed in many states). Dilution means the use of a mark by a second user in such a way that the identification of the mark with its owner is blurred or tarnished. Dilution is different from infringement in that it does not require likely confusion — the goods on which the second user puts the mark can be completely different from the owner's goods. Dilution protects only famous trademarks, but courts' determinations of which marks are famous have been inconsistent.

One important note about trademark licenses: because trademark rights are granted to allow the trademark owner to protect its commercial reputation, conversely, for a trademark license to be valid the licensor must control the nature and the quality of the goods or services sold under the mark. If the trademark owner fails to control the quality of licensed goods and services, the mark no longer has any meaning, since it is not telling the public anything about the source of the goods or services. Consequently, a mark owner that grants such so-called "naked" licenses runs the risk of a court declaring that the mark has lost its meaning and therefore has been abandoned.

Defining Terms

Copyright — A set of exclusive rights granted to authors of original works of authorship. Copyright includes the exclusive rights to copy, adapt, distribute, or offer for distribution, import, and, depending on the work, to perform or display the work, including by electronic transmission.

Trademark — One or more words or pictures used by an entity to indicate that it is the source, origin, or sponsor of goods or services. Trademarks may be registered or unregistered and include trade names and service marks.

Patent — A set of exclusive rights to make, use, sell, offer for sale, or import a product made by the patented process. Patents are granted upon examination for useful inventions, defined by a set of claims that are novel and nonobvious. The application for a patent must demonstrate possession of the invention, be enabling to practice the invention, and include a description of the best mode.

Trade secret — A trade secret is any information maintained in confidence that gives its owner a business advantage. Trade secrets can include scientific or engineering information, business information, databases, or any other information meeting the foregoing description.

Further Information

The U.S. Patent and Trademark Office can be accessed at www.uspto.gov. The website provides a vast amount of information, including procedures and forms for filing applications, and online searches of existing patents and trademarks. Nevertheless, an application to register either a patent or trademark should not be undertaken without legal counsel, and legal counsel should also be secured if a search is to be conducted in preparation of filing an application.

The U.S. Copyright Office can be accessed at www.loc.gov/copyright. Like the USPTO site, it provides a vast amount of information about existing registered copyrights and the procedures and forms used to obtain copyright registrations. As with patents and trademarks, it is highly advisable to consult legal counsel before filing an application to register a copyright.

- 213.4 Mechanical Properties
- 213.5 Thermal Properties
- 213.6 Chemical Properties
- 213.7 Electrical and Optical Properties

The term *materials science and engineering* refers to that branch of engineering dealing with the processing, selection, and evaluation of solid-state materials [Shackelford, 2000]. As such, this is a highly interdisciplinary field. This chapter reflects the fact that engineers outside of the specialized field of materials science and engineering largely need guidance in the selection of materials for their specific applications. A comprehensive source of property data for engineering materials is available in *The CRC Materials Science and Engineering Handbook* [Shackelford and Alexander, 2001]. This brief chapter will be devoted to defining key terms associated with the properties of engineering materials and providing representative tables of such properties. Because the underlying principle of the fundamental understanding of solid-state materials is the fact that atomic- or microscopic-scale structure is responsible for the nature of materials properties, we shall begin with a discussion of structure, which will be followed by a discussion of the importance of specifying the chemical composition of commercial materials. These discussions will be followed by the definition of the main categories of material properties.

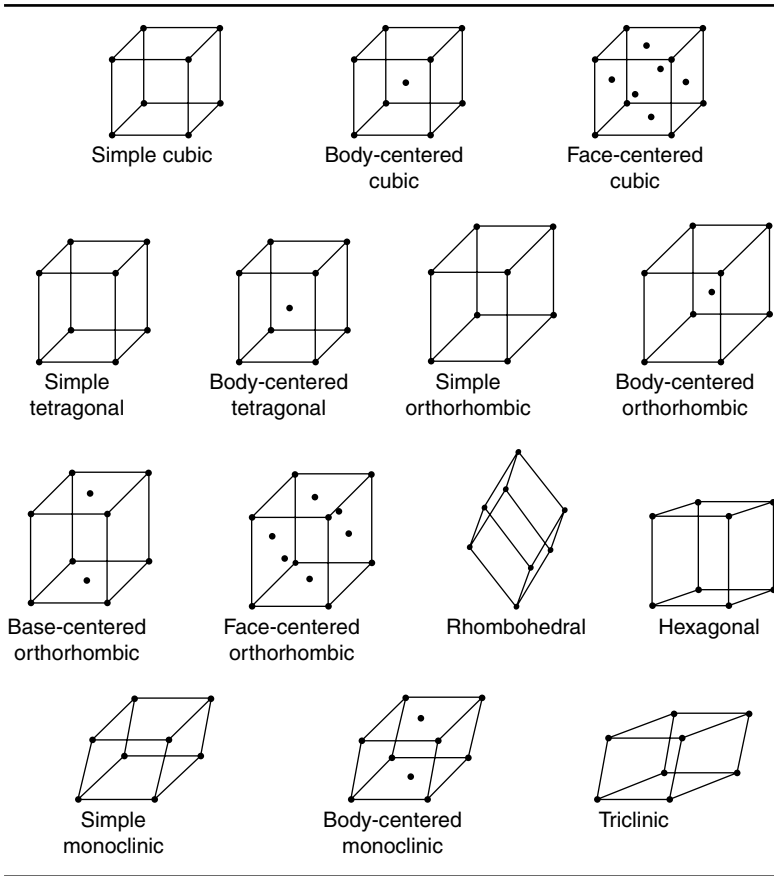

213.1 Structure

A central tenet of materials science is that the behavior of materials (represented by their **properties**) is determined by their structure on the atomic and microscopic scales [Shackelford, 2000]. Perhaps the most fundamental aspect of the structure-property relationship is to appreciate the basic skeletal arrangement of atoms in **crystalline** solids. [Table 213.1](#) illustrates the fundamental possibilities, known as the 14 **Bravais lattices**. All crystalline structures of real materials can be produced by “decorating” the unit cell patterns of [Table 213.1](#) with one or more atoms and repetitively stacking the unit cell structure through three-dimensional space.

213.2 Composition

The properties of commercially available materials are determined by chemical composition as well as structure [Shackelford, 2000]. As a result, extensive numbering systems have been developed to label materials, especially metal **alloys**. [Table 213.2](#) gives an example for gray cast irons.

213.3 Physical Properties

Among the most basic and practical characteristics of engineering materials are their physical properties. [Table 213.3](#) gives the **density** of a wide range of materials in units of Mg/m^3 ($= \text{g/cm}^3$), whereas [Table 213.4](#) gives the **melting points** for several common metals and ceramics.

TABLE 213.3 Density of Selected Materials (Mg/m³)

| Metal | | Ceramic | | Glass | | Polymer | |
|-------|-------|---|--------------|--|-------|---------------|-----------|
| Ag | 10.50 | Al ₂ O ₃ | 3.97–3.986 | SiO ₂ | 2.20 | ABS | 1.05–1.07 |
| Al | 2.7 | BN (cub) | 3.49 | SiO ₂ 10 wt% Na ₂ O | 2.291 | Acrylic | 1.17–1.19 |
| Au | 19.28 | BeO | 3.01–3.03 | SiO ₂ 19.55 wt% Na ₂ O | 2.383 | Epoxy | 1.80–2.00 |
| Co | 8.8 | MgO | 3.581 | SiO ₂ 29.20 wt% Na ₂ O | 2.459 | HDPE | 0.96 |
| Cr | 7.19 | SiC (hex) | 3.217 | SiO ₂ 39.66 wt% Na ₂ O | 2.521 | Nylon, type 6 | 1.12–1.14 |
| Cu | 8.93 | Si ₃ N ₄ (α) | 3.184 | SiO ₂ 39.0 wt% CaO | 2.746 | Nylon 6/6 | 1.13–1.15 |
| Fe | 7.87 | Si ₃ N ₄ (β) | 3.187 | | | Phenolic | 1.32–1.46 |
| Ni | 8.91 | TiO ₂ (rutile) | 4.25 | | | Polyacetal | 1.425 |

213.4 Mechanical Properties

Central to the selection of materials for structural applications is their behavior in response to mechanical loads. A wide variety of mechanical properties are available to help guide materials selection [Shackelford and Alexander, 2001]. The most basic of the mechanical properties are defined in terms of the **engineering stress** and the **engineering strain**. The engineering stress, σ , is defined as

$$\sigma = P/A_o \quad (213.1)$$

where P is the load on the sample with an original (zero stress) cross-sectional area A_o . The engineering strain, ϵ , is defined as

$$\epsilon = [l - l_o]/l_o = \Delta l/l_o \quad (213.2)$$

where l is the sample length at a given load and l_o is the original (zero stress) length. The maximum engineering stress that can be withstood by the material during its load history is termed the *ultimate*

TABLE 213.5 Tensile Strength of Selected Wrought Aluminum Alloys

tensile strength, or simple **tensile strength**, TS. An example of the tensile strength for selected wrought (meaning “worked,” as opposed to cast) aluminum alloys is given in Table 213.5. The “stiffness” of a material is indicated by the linear relationship between engineering stress and engineering strain for relatively small levels of load application. The **modulus of elasticity**, E , also known as **Young's modulus**, is given by the ratio

$$E = \sigma/\epsilon \quad (213.3)$$

Table 213.6 gives values of Young's modulus for selected compositions of glass materials. The “ductility” of a material is indicated by the percent elongation at failure ($= 100 \times \epsilon_{\text{failure}}$), representing the general ability of the material to be plastically (i.e., permanently) deformed. The percent elongation at failure for selected polymers is given in Table 213.7.

213.5 Thermal Properties

Many applications of engineering materials depend on their response to a thermal environment. The **thermal conductivity**, k , is defined by **Fourier's law**:

TABLE 213.7 Total Elongation at Failure of Selected Polymers

$$k = -[dQ/dt]/[A(dT/dx)] \quad (213.4)$$

where dQ/dt is the rate of heat transfer across an area A due to a temperature gradient dT/dx . It is also important to note that the dimensions of a material will, in general, increase with temperature. Increases in temperature lead to greater thermal vibration of the atoms and an increase in average separation distance of adjacent atoms. The **linear coefficient of thermal expansion**, α , is given by

$$\alpha = dl/l dT \quad (213.5)$$

with α having units of mm/(mm°C). Examples of thermal conductivity and thermal expansion coefficient for alloy cast irons are given in Table 213.8.

213.6 Chemical Properties

A wide variety of data are available to characterize the nature of the reaction between engineering materials and their chemical environments [Shackelford and Alexander, 2001]. Perhaps no such data are more fundamental and practical than the **electromotive force series** of metals shown in Table 213.9. The

TABLE 213.9 Electromotive Force Series of Metals

voltage associated with various half-cell reactions in standard aqueous environments are arranged in order, with the materials associated with more anodic reactions tending to be corroded in the presence of a metal associated with a more cathodic reaction.

213.7 Electrical and Optical Properties

To this point, we have concentrated on various properties dealing largely with the structural applications of engineering materials. In many cases the electromagnetic nature of the materials may determine their engineering applications. Perhaps the most fundamental relationship in this regard is **Ohm's law**, which states that the magnitude of current flow, I , through a circuit with a given resistance R and voltage V is related by:

$$V = IR \quad (213.6)$$

where V is in units of volts, I is in amperes, and R is in ohms. The resistance value depends on the specific sample geometry. In general, R increases with sample length, l , and decreases with sample area, A . As a result, the property more characteristic of a given material and independent of its geometry is **resistivity**, ρ , defined as

$$\rho = [RA]/l \quad (213.7)$$

The units for resistivity are ohm \cdot m (or $\Omega \cdot$ m). [Table 213.10](#) gives the values of electrical resistivity for various materials, indicating that metals typically have low resistivities (and correspondingly high electrical conductivities) and ceramics and polymers typically have high resistivities (and correspondingly low conductivities).

An important aspect of the electromagnetic nature of materials is their optical properties. Among the most fundamental optical characteristics of a light-transmitting material is the **index of refraction**, n , defined as

$$n = v_{\text{vac}}/v \quad (213.8)$$

where v_{vac} is the speed of light in vacuum (essentially equal to that in air) and v is the speed of light in a transparent material. The index of refraction for a variety of polymers is given in [Table 213.11](#).

TABLE 213.10 Electrical Resistivity of Selected Materials

| Metal (Alloy Cast Iron) | ρ ($\Omega \cdot \text{m}$) | Ceramic | ρ ($\Omega \cdot \text{m}$) | Polymer | ρ ($\Omega \cdot \text{m}$) |
|----------------------------|------------------------------------|-------------------------|------------------------------------|---------------|------------------------------------|

Defining Terms

Alloy — Metal composed of more than one element.

Bravais lattice — One of the 14 possible arrangements of points in three-dimensional space.

Crystalline — Having constituent atoms stacked together in a regular, repeating pattern.

Density — Mass per unit volume.

Electromotive force series — Systematic listing of half-cell reaction voltages.

Engineering strain — Increase in sample length at a given load divided by the original (stress-free) length.

Engineering stress — Load on a sample divided by the original (stress-free) area.

Fourier's law — Relationship between rate of heat transfer and temperature gradient.

Index of refraction — Ratio of speed of light in vacuum to that in a transparent material.

Linear coefficient of thermal expansion — Material parameter indicating dimensional change as a function of increasing temperature.

Melting point — Temperature of transformation from solid to liquid upon heating.

Ohm's law — Relationship between voltage, current, and resistance in an electrical circuit.

Property — Observable characteristic of a material.

Resistivity — Electrical resistance normalized for sample geometry.

Tensile strength — Maximum engineering stress during a tensile test.

Thermal conductivity — Proportionality constant in Fourier's law.

Young's modulus (modulus of elasticity) — Ratio of engineering stress to engineering strain for relatively small levels of load application.

Failure Analysis

- 214.1 Types of Failures
- 214.2 Failure Analysis Methodology
- 214.3 Fracture Mechanics
- 214.4 Nondestructive Testing
 - Radiographic Testing • Ultrasonic Testing • Other Methods of Nondestructive Testing
- 214.5 Engineering Design for Failure Prevention

James F. Shackelford
University of California, Davis

Failure analysis and prevention are important, practical considerations relative to the applications of materials in engineering design [ASM International, 2002]. This chapter begins by exploring the various types of failures that can occur. There is now a well-established, systematic methodology for the analysis of failures of engineering materials. Beyond **failure analysis** as a “postmortem” examination, the related issue of **failure prevention** is equally important as the basis for avoiding future disasters. Fracture mechanics provides a powerful technique for both analyzing failures and modifying engineering designs for the prevention of future failures. Similarly, nondestructive testing serves as one set of techniques for a comprehensive analysis of failures, as well as a primary strategy for the prevention of future failures, especially in the identification of critical flaws. The two primary techniques on which we will focus are radiographic testing (typically using X rays) and ultrasonic testing.

The issues of failure analysis and failure prevention are taking on increasing levels of importance with the growing awareness of the responsibilities of the professional engineer. Ethical and legal demands for the understanding of engineering failures and the prevention of such future catastrophes are moving the field of materials science and engineering into a central role in the broader topic of engineering design.

214.1 Types of Failures

A wide spectrum of failure modes has been identified. To illustrate the range of these types of failures, we will begin with a brief description of several of the most common failures in structural metals.

Ductile fracture is observed in a large number of the failures occurring in metals due to overload — that is, simply taking a material beyond the elastic limit, beyond its ultimate tensile strength, and, subsequently, to fracture. The microscopic result of ductile fracture is a characteristic “dimpled” fracture surface morphology.

Brittle fracture is characterized by rapid crack propagation without significant plastic deformation on a macroscopic scale. The cleavage texture of a brittle fracture surface comes from both *transgranular* fracture, involving the cleavage of microstructural grains, and *intergranular* fracture, occurring by crack propagation between adjacent grains.

Fatigue failure is the result of cyclic stresses that would, individually, be well below the yield strength of the material. The fatigue mechanism of slow crack growth gives a distinctive “clamshell” fatigue fracture surface.

Corrosion-fatigue failure is due to the combined actions of a cyclic stress and a corrosive environment. In general, the fatigue strength (or fatigue life at a given stress) of the metal will be decreased in the presence of an aggressive, chemical environment.

Stress-corrosion cracking (SCC) is another combined mechanical and chemical failure mechanism in which a noncyclic tensile stress (below the yield strength of the metal) leads to the initiation and propagation of fracture in a relatively mild chemical environment. Stress-corrosion cracks may be intergranular, transgranular, or a combination thereof.

Wear failure encompasses a broad range of relatively complex surface-related damage phenomena. Both surface damage and wear debris can constitute “failure” of materials intended for sliding contact applications.

Liquid erosion failure is a special form of wear damage in which a liquid, rather than another solid, is responsible for the removal of material. Liquid-erosion damage typically results in a pitted or honeycomb-like surface region.

Liquid-metal embrittlement is another form of material failure caused by a liquid. In this case the solid loses some degree of ductility or fractures below its yield stress in conjunction with its surface being wetted by a lower-melting-point liquid metal. This failure mode occurs in specific solid-liquid metal combinations.

Hydrogen embrittlement is perhaps the most notorious form of catastrophic failure in high-strength steels. A few parts per million of hydrogen dissolved in these materials can lead to fine “hairline” cracks and a loss of ductility. A variety of commercial environments serve as sources of hydrogen gas that, in turn, dissociates into atomic hydrogen, which can readily diffuse into the alloy.

Creep and *stress-rupture failures* can occur above about one-half the absolute melting point of an alloy. *Creep* is defined as plastic deformation over an extended period of time under a fixed load. Failure of this type can occur near room temperature for many polymers and certain low-melting-point metals, such as lead, but may occur above 1,000°C in many ceramics and certain high-melting-point metals, such as the superalloys.

Complex failures are those in which the failure occurs by the sequential operation of two distinct fracture mechanisms. An example would be initial cracking due to stress-corrosion cracking and, then, ultimate failure by fatigue after a cyclic load is introduced simultaneously with the removal of the corrosive environment. The possibility of such sequences should always be considered when conducting a failure analysis.

214.2 Failure Analysis Methodology

A systematic sequence of procedures has been developed for the analysis of the failure of an engineering material. Although the specific methodology will vary with the specific failure, the principal components of the investigation and analysis are given in [Table 214.1](#). This specific set of components is given in the *ASM Handbook* volume on failure analysis and prevention [ASM International, 2002]. Because of the general utility of **nondestructive testing** for failure prevention as well as failure analysis, the subject is covered in detail later in this chapter. **Fracture mechanics** is the general analysis of the failure of structural materials with preexisting flaws. This subject will be discussed separately in the next section. Regarding failure analysis methodology, fracture mechanics has provided a quantitative framework for evaluating structural reliability.

214.3 Fracture Mechanics

The **fracture toughness**, K_{Ic} , is the most widely used material parameter associated with fracture mechanics [Shackelford, 2000] and is, in general, of the simple form

TABLE 214.1 Principal Components of Failure Analysis Methodology

| |
|---|
| Collection of background data and samples |
| Preliminary (visual) examination of the failed part |
| Preliminary record keeping |
| Mechanical testing |

| Simulated-service testing |
| Analyzing the evidence, formulating conclusions, and writing the report |

Source: Adapted from ASM International. 2002. *ASM Handbook, Volume 11: Failure Analysis and Prevention*. ASM International, Materials Park, OH.

$$K_{Ic} = \sigma_f (\pi a)^{1/2} \quad (214.1)$$

where σ_f is the overall applied stress at failure and a is the length of a surface crack (or one-half the length of an internal crack). Fracture toughness has units of $\text{MPa}\cdot\text{m}^{1/2}$. Typical values of fracture toughness for various metals and alloys range between 20 and 200 $\text{MPa}\cdot\text{m}^{1/2}$. Values of fracture toughness for ceramics and glass are typically in the range of 1 to 9 $\text{MPa}\cdot\text{m}^{1/2}$, values for polymers are typically 1 to 4 $\text{MPa}\cdot\text{m}^{1/2}$, and values for composites are typically 10 to 60 $\text{MPa}\cdot\text{m}^{1/2}$. Although Equation (214.1) is widely used for predicting flaw-induced or “fast” fracture, one must keep in mind that the subscript I refers to “mode I ” loading — that is, simple, uniaxial tension. Fortunately, mode I conditions predominate in most practical systems, and the wide use of K_{Ic} is justified. Another aspect of fracture mechanics is the relationship to fatigue and other mechanical phenomena in which flaw size increases incrementally prior to failure.

214.4 Nondestructive Testing

As with fracture mechanics, nondestructive testing can serve to analyze an existing failure or be used to prevent future failures [Bray and Stanley, 1997]. The dominant techniques within this field are radiography and ultrasonics.

Radiographic Testing

X-rays compose a portion of the electromagnetic spectrum. Although diffraction techniques allow dimensions on the order of the x-ray wavelength (typically less than one nanometer) to be determined, x radiography produces a “shadow graph” of the internal structure of a part with a much coarser resolution (typically on the order of 1 mm). The common chest x-ray is a routine example of this technology. In industrial applications, x radiography is widely used for the inspection of castings and weldments. A schematic of the technique is given in [Figure 214.1](#).

A key factor in this test is the thickness of material through which the x-ray beam can penetrate. For a given material being inspected by a given energy x-ray beam, the intensity of the beam, I , transmitted through a thickness of material, x , is given by Beer’s law:

$$I = I_0 e^{-\mu x} \quad (214.2)$$

where I_0 is the incident beam intensity and μ is the linear absorption coefficient for the material. The intensity is proportional to the number of photons in the beam and should not be confused with the energy of photons in the beam. The absorption coefficient is a function of the beam energy and of the elemental composition of the material. Experimental values for the linear absorption coefficient of iron as a function of energy are given in [Table 214.2](#). The general trend is a steady drop in the magnitude of

A schematic of x-radiography.

TABLE 214.2 Linear Absorption Coefficient of Iron as a Function of x-ray Beam Energy

| Energy (MeV) | μ (mm^{-1}) |
|--------------|----------------------------|
| 0.05 | 1.52 |
| 0.10 | 0.293 |
| 0.50 | 0.0662 |
| 1.00 | 0.0417 |
| 2.00 | 0.0334 |
| 4.00 | 0.0260 |

Source: Selected data from Bray, D. E. and Stanley, R. K. 1997. *Non-destructive Evaluation*. CRC Press, Boca Raton, FL.

μ with increasing beam energy until above 1 MeV, where μ levels off. Below 1 MeV the absorption of the beam is due to mechanisms of photon absorption and photon scattering. Above 1 MeV, however, an additional absorption mechanism comes into play (electron-positron pair production).

The dependence of the linear absorption coefficient on elemental composition is illustrated by the data of Table 214.3. The general trend of data is that μ for a given beam energy increases with atomic number. As a result, low-atomic-number metals such as aluminum are relatively transparent and high-atomic-number metals such as lead are relatively opaque.

Ultrasonic Testing

X radiography was seen to be based on a portion of the electromagnetic spectrum with relatively short wavelengths in comparison to the visible region. Similarly, ultrasonic testing is based on a portion of the acoustic spectrum with frequencies above those of the audible range (20 to 20 000 cycles/second or Hz). Typical ultrasonic inspections are made in the 1- to 25-MHz range. A key distinction between x radiography and ultrasonic testing is that the ultrasonic waves are mechanical in nature and require a transmitting medium, whereas electromagnetic waves can be transmitted in a vacuum.

TABLE 214.3 Linear Absorption Coefficient of Various Elements for an x-ray Beam with Energy = 100 keV (= 0.1 MeV)

| Element | Atomic Number | μ (mm ⁻¹) |
|----------|---------------|---------------------------|
| Titanium | 22 | 0.124 |
| Iron | 26 | 0.293 |
| Nickel | 28 | 0.396 |
| Copper | 29 | 0.410 |
| Zinc | 30 | 0.356 |
| Tungsten | 74 | 8.15 |
| Lead | 82 | 6.20 |

Whereas attenuation of the x-ray beam in the solid was a dominant consideration for x radiography, typical engineering materials are relatively transparent to ultrasonic waves. The key consideration for ultrasonic testing is the reflection of the ultrasonic waves at dissimilar material interfaces. The reflection coefficient, R , defined as the ratio of reflected beam intensity, I_r , to incident beam intensity, I_i , is given by

$$R = I_r/I_i = [(Z_2 - Z_1)/(Z_2 + Z_1)]^2 \quad (214.3)$$

where Z is the acoustic impedance, defined as the product of the material's density and velocity of sound, with the subscripts 1 and 2 referring to the two dissimilar materials on either side of the interface. The high degree of reflectivity by a typical flaw, such as an internal crack, is the basis for defect inspection. Figure 214.2 illustrates a typical "pulse echo" ultrasonic inspection based on this principle. The oscillations in the figure represent voltage fluctuations in a piezoelectric transducer that is used to both send and detect the ultrasonic signal. The horizontal scale is proportional to time in a time frame of several microseconds. The initial pulse on the left is reflected back from a flaw and seen in the mid-range, with a small pulse on the right representing a reflection from the back side of the sample. The insert is a C-scan in which numerous adjacent A-scan pulses are viewed together to represent the spatial location of the flaw (impact damage in a NASA graphite/epoxy wind tunnel blade). The dashed line corresponds to the displayed A-scan. The limitations of this method include the difficulty of applying the techniques in complex-shaped parts and the loss of information due to microstructural complexities such as porosity and precipitates.

Other Methods of Nondestructive Testing

A wide spectrum of additional methods are available in the field of nondestructive testing. The following four methods are among the most widely used for failure analysis and prevention.

Eddy current testing is a versatile technique for inspecting electrically conductive materials. The impedance of an inspection coil is affected by the presence of an adjacent test piece, in which alternating (eddy) currents have been induced by the coil. The net impedance is a function of the composition or geometry of the test piece. The popularity of eddy current testing is due to the convenient, rapid, and non-contact nature of the method. By varying the test frequency the method can be used for both surface and subsurface flaws. Limitations include the qualitative nature and the need for an electrically conductive test piece.

Magnetic-particle testing is a simple, traditional technique widely used due to its convenience and low cost. Its primary limitation is the restriction to magnetic materials. (This is not as restrictive as one might initially assume, given the enormous volume of structural steels used in engineering.) The basic mechanism of this test involves the attraction of a fine powder of magnetic particles (Fe or Fe₃O₄) to the "leakage flux" around a discontinuity such as a surface or near-surface crack.

FIGURE 214.2 Typical ultrasonic pulse echo A-scan of a structural defect. (Ultrasonic imaging software provided courtesy of D. Bailey, United States Air Force.)

Liquid-penetrant testing is, like magnetic-particle testing, an inexpensive and convenient technique for surface defect inspection. It is largely used on nonmagnetic materials for which magnetic-particle inspection is not possible. The basic mechanism for this method is the capillary action of a fine powder on the surface of a sample in which a high-visibility liquid has penetrated into surface defects. The limitations of this technique include the inability to inspect subsurface flaws and the loss of resolution on porous materials.

Acoustic-emission testing has assumed a unique role in failure prevention. This nondestructive test, in addition to being able to locate defects, can provide an early warning of impending failure due to those defects. In contrast to conventional ultrasonic testing, in which a transducer provides the source of ultrasound, acoustic emission is the set of ultrasonic waves produced by defects within the microstructure of a material in response to an applied stress. With the material as the source of ultrasound, transducers serve only as receivers. In general, the rate of acoustic-emission events rises sharply just prior to failure. By continuously monitoring these emissions, the structural load can be removed in time to prevent that failure. The primary example of this preventive application is in the continuous surveillance of pressure vessels.

214.5 Engineering Design for Failure Prevention

Finally, it is important to note that engineering designs can be improved as a result of the application of concepts raised in Sections 214.1 and 214.2 — that is, failure analysis can lead to failure prevention. An example of this approach includes the avoidance of structural discontinuities that can serve as stress concentrators.

Defining Terms

Failure analysis — The systematic examination of a failed engineering part to determine the nature of the failure.

Failure prevention — The application of the principles of failure analysis to prevent future catastrophes.

Fracture mechanics — Analysis of failure of structural materials with preexisting flaws.

Fracture toughness — Critical value of the stress-intensity factor at a crack tip necessary to produce catastrophic failure.

Nondestructive testing — A family of techniques for observing material flaws and characteristics without impairing the future usefulness of the part under inspection.

Liquids and Gases

Bruce E. Poling
University of Toledo

215.1 Viscosity
215.2 Thermal Conductivity
215.3 Heat Capacity
215.4 Vapor Pressure

There are a number of thermodynamic and kinetic properties of gases and liquids that are important in engineering applications. Properties that are discussed in this chapter include viscosity, thermal conductivity, heat capacity, and vapor pressure. In the material that follows, a brief description of each of these four properties is given. However, engineers often do not want a description; rather, they want a number or an equation. The strategy that should be used to accomplish this latter task depends on the particular situation, but many features of this strategy are independent of the desired property. Thus, a general strategy is presented first.

For gases at low pressures and pure liquids, experimental data for many substances are available and have generally been correlated by equations and sometimes by nomographs. Daubert et al. [1997] present references to data, an evaluation of the quality of the data, and correlating equations for all the properties discussed in this section for over 1300 substances. Yaws [1999] presents correlating equations for all the properties discussed in this section for 1700 substances, but unlike Daubert et al. [1997], Yaws' data sources are not so well documented. Daubert et al. [1997] have chosen correlating equations that give the best fit or have some basis in theory; Yaws [1999] uses polynomials in his correlations that have the advantage of mathematical simplicity. Yaws' equation forms especially should not be extrapolated outside the temperature range over which data have been fit. There are many other correlations, summaries of data sources, and tabulations of values. Some of these are summarized in [Table 215.1](#) and others are described in the section that relates to a specific property. If information for a compound is not available, or information at temperatures or pressures outside the range where experimental data have been measured is required, estimation methods such as those described in Poling et al. [2001] may be used. Poling et al. [2001] also present recommended methods for finding properties for gases that cannot be considered ideal (at high pressure) and for mixtures of compounds.

215.1 Viscosity

The *viscosity* of a fluid is a measure of its thickness, or how easily it flows. The viscosity, η , of a substance is defined as the shear stress per unit area divided by the velocity gradient. Fluids for which the viscosity is independent of shear stress are called *Newtonian fluids*, and this class includes gases and most common liquids. Polymer solutions, inks, coatings, and paints are often non-Newtonian — that is, their thickness and flow characteristics change with shear stress. Viscosity has dimensions of mass per length per time. A common viscosity unit is the poise, defined as one gram per centimeter per second. The kinematic

^a 1. Dean [1999]; 2. Lide [2002]; 3. Vargaftik et al. [1996]; 4. Perry and Green [1997]; 5. Yaws [1999]; 6. Daubert et al. [1997]; 7. Kaye and Laby [1986].

Note: E = equation, V = values, N = nomograph.

viscosity is defined as the ratio of viscosity to density. A common unit for the kinematic viscosity is the stoke, defined as cm²/s.

For pure liquids or pure gases at low pressure (near 1 atm) the viscosity is a function of temperature but is insensitive to changes in pressure. Vapor viscosity varies approximately linearly with temperature; the temperature dependence of liquid viscosity is approximately exponential. The viscosity of many common gases at low pressure can be found from the nomograph in Perry and Green [1997]. Viswanath and Natarajan [1989] have compiled liquid-viscosity data for over 900 compounds. Daubert et al. [1997] have fit vapor viscosity, η^v , to

$$\eta^v = \frac{AT^B}{1 + \frac{C}{T} + \frac{D}{T^2}} \quad (215.1)$$

Daubert et al. [1997] correlate liquid viscosity, η^L , with the equation

$$\ln \eta^L = A + B/T + C \ln(T) + DTE \quad (215.2)$$

Constants to be used in Equations (215.1) and (215.2) for water are listed in [Table 215.2](#). In both equations, T is in K.

215.2 Thermal Conductivity

The *thermal conductivity* of a fluid, λ , is a measure of the rate at which heat is transferred through the fluid by conduction, that is, in the absence of convection. Units used for thermal conductivity are W/(m K). These may be converted to English or cgs units by

$$W/(m K) \times 0.5778 = \text{Btu}/(\text{h} \cdot \text{ft} \cdot ^\circ\text{R})$$

$$W/(m K) \times 0.8604 = \text{kcal}/(\text{cm} \cdot \text{h} \cdot \text{K})$$

Unlike liquid viscosity which shows a strong temperature dependence, both vapor and liquid thermal conductivity shows a more nearly linear temperature dependence. Vargaftik et al. [1994] have compiled thermal conductivity data for over 700 compounds. Yaws [1999] correlates vapor thermal conductivity, λ^v , with the equation:

TABLE 215.2 Constants to be Used in Chapter Equations for Water

^a In Equation (215.9), for water, use $P_c = 221.2$ bar, and $T_c = 647.3$ K.

$$\lambda^V = A + BT + CT^2 \quad (215.3)$$

For liquid thermal conductivity, λ^L , Daubert et al. [1997] use the equation:

$$\lambda^L = A + BT + CT^2 + DT^3 + ET^4 \quad (215.4)$$

Constants to be used for water vapor in Equation (215.3) and liquid water in Equation (215.4) appear in Table 215.2. T is in K.

215.3 Heat Capacity

Generally speaking, the *heat capacity* of a fluid is the amount of heat required to increase a unit mass of the substance by one degree. Heat capacities are used to calculate sensible heat effects and are important in the design of heat exchangers. From a historic point of view, the heat capacity of water is of particular significance because, at one time, a calorie was defined as the amount of heat required to heat 1 gram of water 1°C. The term *specific heat* is the ratio of the heat capacity of a substance to that of water. Although the definition of the calorie is now in terms of joules, and although the heat capacity of water varies slightly with temperature, for engineering purposes the heat capacity of liquid water may still be taken as 1 cal/(g · °C) over the range of 0 to 100°C. This is particularly convenient because the four sets of units — cal/(g · °C), cal/(g · K), Btu/(lb · °F), and Btu/(lb · °R) — are all numerically equivalent. Note that the temperature units in these four sets refer to temperature changes, so °C and K, for example, are equivalent. Because the heat capacity of water is 1 cal/(g · °C), the specific heat is numerically equal to the heat capacity when the units are cal/(g · °C). For gases particularly, heat capacities are often given in molar units. Thus, if a heat capacity with units of cal/(g · °C) is multiplied by a substance's molecular weight, the molar heat capacity in cal/(g · mol · °C) is obtained. The units, cal/(g · °C), may be converted to J/(g · °C) by multiplying by 4.186.

From a rigorous thermodynamic point of view, the term *heat capacity* means heat capacity at constant pressure, C_p , and is the change in enthalpy with respect to temperature in a constant pressure experiment. However, other heat capacities can be defined. The heat capacity at constant volume, C_v , is the change in enthalpy with respect to temperature at constant volume, and for liquids and solids these two heat capacities are essentially the same number. For ideal gases

$$C_p = C_v + R \quad (215.5)$$

Two other heat capacities that are sometimes seen are the change in enthalpy of a saturated liquid with respect to temperature (this path is at neither constant P nor V but, rather, along the vapor pressure curve) and the amount of energy required to effect a temperature change while maintaining the liquid in a saturated state. Fortunately, for liquids not close to the critical point and for ideal gases, these latter two heat capacities are essentially the same number as C_p .

For engineering applications, the heat capacities most often needed are *ideal gas heat capacities* and heat capacities of a condensed phase, that is, liquid or solid. The ideal gas heat capacity, C_p^o , for a monatomic gas in the ideal gas state (examples of monatomic compounds include mercury, neon, helium, and argon) is $20.8 \text{ J}/(\text{g} \cdot \text{mol} \cdot \text{K})$. This is $2.5R$, where R is the gas constant. For compounds that contain more than one atom, C_p^o is a function of temperature (but not pressure) and its value generally increases with increasing temperature. The heat capacity of a mixture of ideal gases, $C_{p,\text{mix}}^o$ may be calculated with the following equation:

$$C_{p,\text{mix}}^o = \sum_i x_i C_{p,i}^o \quad (215.6)$$

where x_i is the mole fraction of component i and $C_{p,i}^o$ is for pure i .

Liquid heat capacities are weak functions of temperature below the normal boiling point. For some compounds C_p in this temperature range increases slowly with temperature, but for others C_p passes through a shallow minimum. The C_p behavior for water is an example of this latter behavior. C_p for water passes through a minimum at about 40°C ; the values at 0 and 100°C are each about 1% higher than this minimum value. Above the normal boiling point, C_p for liquids begins to rise and for all compounds approaches infinity as the critical point is approached.

Both liquid and ideal gas heat capacities are often correlated with temperature by equations such as

$$C_p = A + BT + CT^2 + DT^3 + ET^4 \quad (215.7)$$

Values of the constants in Equation (215.7) for liquid water from Daubert et al. [1997] and for water vapor in the ideal gas state from Yaws [1999] are given in [Table 215.2](#). In Equation (215.7) T is in K. Stull et al. [1969] have compiled ideal gas heat capacity data from approximately 900 compounds and Zábbranský et al. [1996] have compiled data for liquid heat capacities for over 1,600 compounds.

215.4 Vapor Pressure

The *vapor pressure*, or saturation pressure, of a pure liquid is the pressure where both liquid and vapor are in equilibrium. Vapor pressure is a function only of temperature, and each substance has a unique vapor pressure curve. Three important points on this curve are the normal boiling point, the triple point, and the critical point. The normal boiling point corresponds to the temperature where the vapor pressure is 1 atm, and the triple point is the one point on the vapor pressure curve where vapor, liquid, and solid can exist in equilibrium. The triple point temperature is essentially the same number as the melting point temperature because pressure has little effect on melting point temperatures. At the critical point, the vapor and liquid phases become identical, and, above the critical temperature, the two phases are no longer distinct. The vapor pressure increases rapidly with temperature, and, in fact, the log of the vapor pressure varies nearly linearly with the reciprocal of the absolute temperature. Thus, if vapor pressures are known at two temperatures, reliable vapor pressures can be determined at other temperatures by interpolating on $\log P_{vp}$ versus $1/T$, where P_{vp} is the vapor pressure and T is in kelvins. However, this linear relationship is not exact and extrapolations over large temperature ranges can sometimes lead to unacceptable errors.

A number of equations have been developed for correlating vapor pressures. Perhaps the most common is the Antoine equation:

$$\ln P_{vp} = A + \frac{B}{C + T} \quad (215.8)$$

More recently, the Wagner equation has generally been accepted as one of the best equations for correlating vapor pressures. This equation has the form,

$$\ln(P_{vp} / P_c) = (A\tau + B\tau^{1.5} + C\tau^3 + D\tau^6) / T_r \quad (215.9)$$

In both Equations (215.8) and (215.9), the constants for a particular compound are determined by fitting vapor pressure data. In Equation (215.9), P_c is the critical pressure, P_{vp} is the vapor pressure and will have the same units as P_c , T_r is the reduced temperature, T/T_c , $\tau = 1 - T_r$, and both T and T_c are in kelvins. Some authors have claimed that Equation (215.9) is improved if the exponents 3 and 6 are replaced with 2.5 and 5. Vapor pressure constants are listed for 468 compounds in Poling et al. [2001]; constants to be used in Equation (215.9) for water are listed in [Table 215.2](#). Boublík et al. [1984] and Ohe [1976] list sources for experimental vapor pressure data for approximately 1000 and 2000 substances, respectively.

Defining Terms

Heat capacity — Generally, constant pressure heat capacity, which is defined as the change in enthalpy with respect to temperature at constant pressure.

Ideal gas heat capacity — The heat capacity of a substance at the specified temperature and in the ideal gas state. Unless otherwise stated, this generally means constant pressure heat capacity.

Thermal conductivity — The proportionality constant between the heat transfer rate (by conduction) per unit area and the temperature gradient; a measure of how fast heat is transferred by conduction through a substance.

Vapor pressure — The pressure at which both the liquid and vapor phases of a pure substance are in equilibrium.

Viscosity — The proportionality constant between the shear stress per unit area and the velocity gradient; a measure of the resistance to deformation.

Further Information

Introductory-level material on heat capacities and vapor pressures can generally be found in thermodynamics textbooks such as *Introduction to Chemical Engineering Thermodynamics* by J. M. Smith, H. C. Van Ness, and M. M. Abbott, 6th ed. (McGraw-Hill, New York, 2001). Introductory-level material on viscosities and thermal conductivities can be found in textbooks dealing with fluid flow and heat transfer, respectively. One such textbook is *Unit Operations of Chemical Engineering*, by W. L. McCabe, 6th ed. (McGraw-Hill, New York, 2001). As mentioned in the text, [Table 215.1](#) lists the type of information available in the books listed in the reference section.

[216.6 Polymers](#)

[216.7 Ceramics](#)

[216.8 Carbon Materials](#)

The term *biomaterials* usually refers to human-made materials used to construct prosthetic or other medical devices for implantation in human beings. It can also refer to materials that otherwise come in contact with the tissues of internal organs (e.g., tubing to carry blood to and from a heart-lung machine). Despite advances in many areas of materials science, it would be a mistake to assume that modern technology has the ability to replace any part of a living organism with an artificial material (or artificial organ) that will be superior to the original structure. Although it is possible to imagine situations in which this might be true in some limited sense, the synthetic organism as a whole will rarely work better than when the original organ was in place. For example, a segment of bone may be replaced with a similar structure of titanium alloy having greater strength, but the metallic material will lack the ability of bone to adapt to its changing mechanical environment or repair fatigue damage over time.

216.1 History

The history of biomaterials can be divided into three eras. Prior to 1850, nonmetallic materials and common metals were used to fabricate simple prosthetic devices. Wood, ivory, iron, gold, silver, and copper were used to replace items such as teeth and noses, and to hold fractured bones together while they healed. In 1829, Levert experimented with lead, gold, silver, and platinum wire in dogs, but these metals clearly did not have the desired mechanical attributes. Furthermore, without anesthesia, patients could not endure long surgeries in order to implant significant prostheses or fixation devices.

The second era of biomaterials, between 1850 and 1925, was defined by the rapid development of surgery as something other than an emergency procedure. The advent of anesthesia just before the mid-19th century precipitated this development. In addition, x-rays were discovered by Roentgen and found immediate application in orthopedics in the late 1800s, revealing for the first time the true nature of many skeletal problems. Finally, the acceptance of the aseptic surgical procedures propounded by Lister gradually but dramatically reduced the rate of postsurgical infections.

The period from 1925 to the present is the third era, in which the primary advances in the various surgical specialties have resulted from three important developments. The first was the development of cobalt chrome and stainless steel alloys in the 1930s and 1940s, respectively. The second was the

development of polymer chemistry and plastics in the 1940s and 1950s. The third was the discovery of ways to produce useful quantities of penicillin and other antibiotics. The ability to further reduce surgical infection rates and to fabricate many devices that were compatible with biological tissues significantly advanced the ability of surgeons to treat a great variety of problems. Most of the biomaterials commonly in use today were developed more than 30 years ago; the intervening years have been ones of gradual refinement.

216.2 Problems Associated with Implanted Devices

There are many problems that a biomaterial should ideally overcome. It must be formable into the desired shape using economical methods and without compromising its mechanical properties. It must not corrode in the presence of body fluids. This property entails the avoidance of crevice and fretting corrosion. A biomaterial must not poison the patient. It must either be free of toxic substances or those substances must be adequately locked into the structure of the material. Toxic ions that may be gradually released must not accumulate or lead to a long-term immunological response. A biomaterial must also be easy to sterilize (using steam under pressure, radiation, or ethylene oxide gas) without damaging its properties. The material must not break, either due to an occasional acute overload or due to fatigue from repeated functional loads. The strength and fatigue properties must combine with the shape of the implant to keep stresses within safe limits, particularly where stress concentrations cannot be avoided. Usually, the material must not simply work for a year or two, but for many years. A *connective tissue* implant must not perturb the stresses in adjacent tissues into a state that leads to atrophy of the tissues or prohibits normal repair of fatigue damage. Finally, implants must be made from materials that can be removed and replaced if they fail. Materials that are impervious to attack by the body may be difficult for the surgeon to remove as well.

216.3 Immunology and Biocompatibility

All organisms try to keep out foreign matter. If they fail in this, they work very hard either to destroy the invading object if its molecules look destructible or to isolate it through encapsulation in fibrous tissue if it looks impregnable. The problem of detecting foreign material is very complex, and the problem of overcoming an immune system that successfully copes with this task looms very large. In some cases, *fibrous encapsulation* does not have an adverse effect on an implant, but, as a general rule, biomaterials should be able to avoid the natural inclination of the body to either encapsulate them or break them down. Since doing this by destroying the natural defenses of the body (i.e., the immune system) is a poor tactic, the best way to proceed is to mask the foreign material from the chemical sensors of the host. This is difficult to do, since most materials will be easily recognized as “outsiders” and will not be able to avoid the consequences. One useful principle to remember is that materials with molecules that look like biological molecules will be more readily attacked by destructive cells. For example, nylon and polyethylene both have a core of carbon atoms with hydrogens attached along their lengths. The main difference between the two is that polyethylene has a CH_3 terminal group, whereas nylon has an NH_2 terminal group. Since proteins have the latter kind of terminus, nylon tends to be more susceptible than polyethylene to degradation by cells of the immune system.

On the other hand, it may be very difficult to induce the body to attach tissue to impregnable materials such as polyethylene. In fact, no polymers have been found that are both immune to degradation and amenable to tissue adhesion. Some materials, though, are very attractive to connective tissue cells. For example, hydroxyapatite is nearly identical to bone mineral, and will quickly become integrated with bone when implanted in the skeleton. Unfortunately, hydroxyapatite is not nearly as tough and strong as bone. The commonly used materials that are tough and strong — metals — cannot be destroyed by the immune system, so the body tends to encapsulate them in fibrous tissue. This makes it difficult to rigidly attach them to bone.

TABLE 216.1 Mechanical Properties of Metals and Ceramics Commonly Used in Biomedical Implants^a

| Material | Elastic Modulus (GPa) | Maximum Strain (%) | Tensile Strength (MPa) |
|---|-----------------------|--------------------|------------------------|
| Stainless steel | 193 | 10 | 1000 |
| Cast cobalt-Cr | 235 | 8 | 670 |
| Wrought cobalt-Cr | 235 | 12 | 1170 |
| Ti-6Al-4V alloy | 117 | 10 | 900 |
| Pure titanium | 100 | 15 | 410 |

| Apatite | 62 | 0 | 690 |
| C-Si composite | 21 | 0 | 690 |

^a Values are approximations compiled from the references listed at the end of this chapter. Given the variability in manufacturing processes, precise values cannot be given for mechanical properties.

^b Compressive strength = 4 GPa.

^c Compressive strength = 3 GPa.

TABLE 216.2 Mechanical Properties of Polymers Commonly Used in Biomedical Implants^a

| Material | Elastic Modulus (MPa) | Maximum Strain (%) | Tensile Strength (MPa) |
|------------------------------|-----------------------|--------------------|------------------------|
| Silicone rubber ^b | 2.4 | 700 | — |
| Polyether urethane | — | 700 | 41 |
| PTFE | 0.4 | 300 | 30 |
| UHMWPE | 500 | 350 | 35 |
| PMMA | 2000 | 2 | 30 ^c |

^a Values are approximations compiled from the references listed at the end of this chapter. Given the variability in manufacturing processes, precise values cannot be given for mechanical properties.

^b Modulus at 100% strain.

^c Compressive strength = 90 MPa.

216.4 Commonly Used Implant Materials

Human-made biomaterials may be broadly categorized into metals, polymers, ceramics, and carbon composites. The materials in each of these categories may contain several forms, such as solids, membranes, fibers, or coatings. They may also serve many purposes, including replacing structural organs or organs that carry out chemical exchanges, housing electronic devices, repairing damaged or congenitally defective cardiovascular or connective tissue, or delivering drugs.

Tables 216.1 and 216.2 show mechanical properties of metals and polymers commonly used as biomaterials. Table 216.3 shows the properties of some connective tissues that these materials are designed to replace.

TABLE 216.3 Mechanical Properties of Major Connective Tissues^a

| Material | Elastic Modulus (MPa) | Extensibility (%) | Tensile Strength (MPa) |
|----------------------|-----------------------|-------------------|------------------------|
| Bone | 20,000 | 1.5 | 150 |
| Cartilage (costal) | 14 | 8.0 | 1 |
| Collagen (tendon) | 1300 | 9.0 | 75 |
| Keratin ^b | 5000 | 2.0 | 50 |

^a Values are approximations compiled from the references listed at the end of this chapter. Given the variability of biological tissues, precise values cannot be given for mechanical properties.

^b For the alpha-form region of tensile tests of wool.

TABLE 216.4 Approximate Compositions of Common Biomaterial Alloys^a

| Alloy | Approximate Composition |
|-----------------|---|
| Cobalt-chrome | 60% Co, 28% Cr, 6% Mo, 3% Ni, 3% other (Fe, C, Mn, Si) |
| Stainless steel | 62% Fe, 18% Cr, 14% Ni, 3% Mo, 0.03% C, 3% other (Mn, P, S, Si) |
| Titanium | 90% Ti, 6% Al, 4% V, 0.4% other (Fe, C, O) |

^a Values are approximations compiled from the references listed at the end of this chapter.

216.5 Metals

Cobalt-chromium alloys were the first corrosion-resistant alloys to be developed and have proven very effective in surgical implants, beginning in 1936 when Venable reported the use of such a material in orthopedics. Most alloys of this material are primarily cobalt. Chromium is added to provide resistance to corrosion. They are usually regarded as the metal of choice in skeletal prostheses. They have historically been available in cast and wrought forms. As with stainless steel, the wrought material is substantially stronger. The mechanical properties and composition of each alloy discussed in this section are shown in Tables 216.1 and 216.4, respectively. Modifications of Co-Cr alloys contain less cobalt and chromium and larger amounts of other alloy materials (35% nickel in one case and 15% tungsten in another). They can be forged and heat treated to obtain tensile strengths significantly above those of stainless steel and the more common Co-Cr alloys — as high as 1800 MPa.

Stainless steel (usually 316L) is a common industrial alloy that has been very successful as a surgical implant material. Both stainless steel and cobalt-chrome alloys owe their corrosion resistance to the formation of a passive ceramic-like CrO₂ coating on the surface, and it is important that this coating not be scratched during implantation. Care must be taken with stainless steel materials in orthopedic applications because of their susceptibility to crevice and stress corrosion. The ductility of these alloys can be increased by heat treatment, and their strength can be increased by cold working of the material. Cast stainless steels are unsuitable for use in weight-bearing situations because of their large grain sizes and low fatigue strengths. Type 316LVM (low carbon [L, typically less than 0.03%], vacuum melt [VM]) material is preferred. The carbon concentration must remain at small amounts in stainless steel materials to maintain resistance to corrosion.

Titanium alloys are primarily Ti-6Al-4V (i.e., 6% aluminum, 4% vanadium, and 90% titanium). Pure titanium is also used, primarily in dental applications. As with cobalt-chrome alloys and stainless steel, titanium and its alloys offer excellent biocompatibility and corrosion resistance. In fact, the titanium oxide (TiO₂) passive layer formed on the surface of these alloys increases the resistance to corrosion compared to that of the other implant metals. Titanium alloys are becoming increasingly popular in orthopedics because their strength is as good as the other metal implant materials, but they are only half as stiff (Table 216.1). This is potentially important because a large elastic modulus mismatch between implant and bone causes stress concentrations in some places and tends to *stress shield* the bone in others. However, the modulus of titanium alloys is still several times greater than that of bone (Tables 216.1 and 216.3), and marked decreases in stress shielding when these alloys are used have not yet been demonstrated. Titanium alloys are also sensitive to notching. A notch or scratch on titanium alloy implants will significantly reduce their fatigue life.

216.6 Polymers

Polymethylmethacrylate (PMMA) is an acrylic plastic from which parts may be machined. It also may be polymerized in the body to fix a hip prosthesis stem into the medullary canal or fill a bony defect. Frequently, this polymer will have an additive: (1) barium to increase its radiographic visualization, or (2) an antibiotic to prevent infection following surgery. The mechanical properties of PMMA are shown

in Table 216.2; barium and antibiotic additions do not substantially affect these properties. Typically, PMMA used for orthopedic applications to fix implants is prepared by vacuum or centrifuge mixing systems that reduce the void space in the polymerized form. Treatment of the PMMA in this way increases its ultimate strength compared to that which is mixed by hand. PMMA polymerizes with an exothermic reaction that causes the doughy mass used in hip surgery to reach temperatures in the vicinity of 40°C, although laboratory reports indicate temperatures of 60°C to 90°C may be achieved depending on the amount of cement. In addition, PMMA has the effect of causing blood pressure to drop momentarily when it is implanted during hip surgery. PMMA is also used in the manufacture of hard contact lenses and of intraocular lenses for cataract patients. For this application, polymerization is initiated with heat to produce an extremely clear material with good optical properties. Soft contact lenses are usually hydrogels made of homo- or co-polymers of hydroxyethyl methacrylate; other methacrylates and silicones have also been used, however.

Ultra-high molecular-weight polyethylene (UHMWPE) has a very simple chemical structure, consisting of chains of carbon atoms with hydrogen atoms attached to the sides. In the ultra-high molecular-weight form, these chains achieve a molecular weight of 1 to 4 million. Sterilization of UHMWPE components used as bearing surfaces against one of the metal alloys is mainly accomplished through gamma irradiation, which oxidizes polyethylene and may negatively affect the wear properties of the material. Conducting the sterilization procedure in an environment free of oxygen significantly reduces the wear rate of UHMWPE by inducing cross-linking between polymer chains. Polyethylene has also been used to replace the ossicles of the inner ear.

Polydimethylsiloxane (silicone rubber) is a widely used polymer that was first applied biomedically in a hydrocephalus shunt in 1955. It has a long history of biological compatibility and clinical testing in a great variety of applications, and a “medical grade” (Silastic) has been developed with superior *biocompatibility* and mechanical properties. It can be sterilized by steam, radiation, or ethylene oxide. This polymer can be manufactured with various degrees of cross-linking to adapt its mechanical properties for other purposes as well. Silicone rubber is commonly used for catheters. Rubbery sheets of silicone have been used in hernia repair, and a gel silicone often has been used for breast prostheses or augmentation. (The recent controversy over the safety of the latter application is a good example of the difficulty in assessing the biocompatibility of biomaterials. Different individuals may respond quite differently to the same material.) Harder versions have served as balls in ball-and-cage heart valves. Silicone rubber is widely used in pacemakers and biomedical research to form seals against body fluids for electrical leads. It is used as the functional membrane in both kidney dialysis and extracorporeal blood oxygenator machines. It also has been used in drug delivery implants, where it serves as a membrane through which the drug slowly passes. Silicone also serves as a structural material in prosthetic heart valves and to replace the auricle or the ossicles of the ear. In orthopedics, silicone rubber is formed into soft, flexible “strap hinges” for the replacement of arthritic finger, wrist, or toe joints. However, its fatigue resistance is not as good as it should be for this application.

Dacron has been used for blood vessel prostheses since the pioneering work of DeBakey in 1951. Dacron is thrombogenic, so the pores in the fabric soon become filled with coagulated blood, which is then replaced by a tissue called *neointima* that serves as a biological wall between the Dacron and the blood. However, if the vessel diameter is smaller than 6 mm, the neointima will prevent blood flow in the tube. Dacron has also been used in prosthetic heart valves.

Polytetrafluoroethylene (PTFE, Teflon, or Gore-Tex) has been used to produce blood vessel prostheses smaller than 6 mm in diameter, and the neointima appears to be thinner with this material. However, it too is unsatisfactory for most human blood vessels that are smaller than 3 mm. PTFE is also used to make prosthetic heart valves, ligaments, shunt tips, and artificial ossicles for the ear.

Polyether urethane has been used for years in blood bags and tubing for kidney dialysis machines. It has also been tried as a material for blood vessel replacement. It is frequently found in intra-aortic balloon pumps and in artificial hearts, where it lines the chambers and forms the pumping diaphragm. The primary requirement in the latter application is fatigue resistance; a prosthesis that is to last 10 years must flex about 360 million times. Materials that reportedly have been tried for this purpose and found

to have insufficient fatigue properties include several other polymers used in tubing for kidney dialysis machines: polyvinylchloride, silicone rubber, and natural and synthetic rubbers.

Polyalkylsulfones are used in blood oxygenator membranes.

Hexsyn is a brand name of a recently developed elastomer that has good biological compatibility and an extraordinarily high fatigue life (more than 300 million cycles to failure, compared to 600,000 for silicone rubber in an ASTM D430 flexure test). It has been used for heart valves and human finger-joint prostheses.

Epoxy resins have been used to encapsulate electronic implants and with carbon fiber reinforcement for dental implant posts.

Polydepsipeptides, polylactic acid, polyglycolic acid, polydioxanone, and polycaprolactone polymers have been used with some success as biodegradable implants. Implant materials that disintegrate gradually in body fluids are useful as sutures, screws, pins, bone plates, to fill defects in bone or other tissues, and for the delivery of embedded drugs.

216.7 Ceramics

Ceramics generally have hydrophilic surfaces amenable to intimate bonding with tissues. They are very biocompatible but brittle relative to biological materials, including bone. One of their primary applications is as a coating (optimally 25 to 30 micrometers thick) for metals to promote attachment to bone. *Hydroxyapatite* [$\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$] and *tricalcium phosphate* [TCP, $\text{Ca}_3(\text{PO}_4)_2$] in various forms have proven to be very biocompatible and form intimate bonds with bone. Unfortunately, their tensile strengths are not great. They also may be made in porous or granular forms and used to fill bone defects in lieu of a bone graft. TCP may eventually be resorbed and replaced by bone; hydroxyapatite is less resorbable.

Alumina, a polycrystalline form of Al_2O_3 , is a widely used industrial ceramic. It has relatively good strength and excellent wear-resistance characteristics, but is very stiff and brittle compared to bone. It is sintered from alumina powder under pressure at 1600°C to form structures with relatively smooth surfaces. A principal use of this material is to form the heads of total hip prostheses. Alumina has also been used in dental implants, as corneal replacements, and as substitutes for bones in the middle ear.

Zirconia (ZrO_2) is also used in bearing surfaces as the head of femoral joint implants. As with alumina, zirconia has good strength and wear-resistance properties. Because of its low modulus and high strength, zirconia femoral heads can be manufactured into a wide range of diameters and lengths for joint replacement applications.

Bioglass ($\text{Na}_2\text{O}-\text{CaO}-\text{P}_2\text{O}_5-\text{SiO}_2$) is a glass with soluble additives designed to form a silica gel at its surface and thereby aid chemical bonding to bone. Bioglass implants have been used in many dental applications and may be used to replace several bones in the ear.

216.8 Carbon Materials

Graphite has a weak, anisotropic crystalline structure, but isostatic (or turbostratic) carbon is isotropic and relatively strong. The two most useful forms of turbostratic carbon in biomedical applications are vitreous (or glassy) carbon and pyrolytic low-temperature isotropic (LTI) carbon. These are both isotropic materials, but the latter is more wear resistant and stronger. Turbostratic carbons, carbon-fiber PMMA, and carbon-silicon composites have excellent biocompatibility and can have elastic moduli similar to bone. However, it typically turns out that in order to reduce the stiffness of these materials to match that of bone, the strength must be reduced to less than that available in metals. In the last decade, a number of these materials have been tested for various biomedical applications, but few have been widely used. Carbon-silicon and carbon-coated graphite, however, have been used in heart valves, and pyrolytic carbon coating has been shown to improve bone growth into porous metal surfaces.

Defining Terms

- Biocompatibility** — The ability to remain in direct contact with the tissues of a living person without significantly affecting those tissues, or being affected by them, other than in a prescribed way. For example, a biocompatible material used in a blood vessel wall would contain the blood under pressure but would not adversely interact with its constituents or other adjacent tissues.
- Biomaterial** — An engineering material suitable for use in situations where it may come into direct contact with internal tissues of the body. Usually, this means in a surgically implanted device, but it may also include devices that contain or process blood, or other fluids, that will be returned to the body. Sometimes, *biomaterial* is used to refer to a biological structural material.
- Connective tissue** — Tissue that primarily serves a mechanical rather than a metabolic or chemical function. The volume of the cells in such tissue is small relative to the extracellular components. For example, tendons are composed primarily of extracellular collagen, with a small fraction of their volume occupied by the cells that produce the collagen.
- Fibrous encapsulation** — The formation of connective tissues around a foreign object in order to isolate it from the rest of the body, both physically and chemically.
- Stress shield** — To reduce the stress in a region of bone by placing it in parallel with an implant that is stiffer. Bone is able to adjust its structure to the applied loads, and if the imposed load is reduced, the affected bone will atrophy. This may leave the prosthesis inadequately supported and lead to failure.

217.1 Trigonometry

Triangles

In any triangle (in a plane) with sides a , b , and c and corresponding opposite angles A , B , and C ,

$$\frac{a}{\sin A} = \frac{b}{\sin B} = \frac{c}{\sin C} \quad (\text{Law of sines})$$

$$a^2 = b^2 + c^2 - 2bc \cos A \quad (\text{Law of cosines})$$

$$\frac{a+b}{a-b} = \frac{\tan \frac{1}{2}(A+B)}{\tan \frac{1}{2}(A-B)} \quad (\text{Law of Tangents})$$

$$\sin \frac{1}{2}A = \sqrt{\frac{(s-b)(s-c)}{bc}} \quad \text{where } s = \frac{1}{2}(a+b+c)$$

$$\cos \frac{1}{2}A = \sqrt{\frac{s(s-a)}{bc}}$$

$$\tan \frac{1}{2}A = \sqrt{\frac{(s-b)(s-c)}{s(s-a)}}$$

$$\text{Area} = \frac{1}{2}bc \sin A$$

$$= \sqrt{s(s-a)(s-b)(s-c)}$$

If the vertices have coordinates (x_1, y_1) , (x_2, y_2) , (x_3, y_3) , the area is the *absolute value* of the expression

$$\frac{1}{2} \begin{vmatrix} x_1 & y_1 & 1 \\ x_2 & y_2 & 1 \\ x_3 & y_3 & 1 \end{vmatrix}$$

Trigonometric Functions of an Angle

With reference to [Figure 217.1](#), $P(x, y)$ is a point in any one of the four quadrants and A is an angle whose initial side is coincident with the positive x axis and whose terminal side contains the point $P(x, y)$. The distance from the origin $P(x, y)$ is denoted by r and is positive. The trigonometric functions of the angle A are defined as:

$$\sin A = \text{sine } A = y/r$$

$$\cos A = \text{cosine } A = x/r$$

$$\tan A = \text{tangent } A = y/x$$

$$\text{ctn } A = \text{cotangent } A = x/y$$

$$\sec A = \text{secant } A = r/x$$

$$\csc A = \text{cosecant } A = r/y$$

Angles are measured in degrees or radians; $180^\circ = \pi$ radians; 1 radian = $180/\pi$ degrees.

The trigonometric functions of 0° , 30° , 45° , and integer multiples of these are directly computed.

| | 0° | 30° | 45° | 60° | 90° | 120° | 135° | 150° | 180° |

Trigonometric Identities

$$\sin A = \frac{1}{\csc A}$$

$$\cos A = \frac{1}{\sec A}$$

$$\tan A = \frac{1}{\cot A} = \frac{\sin A}{\cos A}$$

$$\csc A = \frac{1}{\sin A}$$

$$\sec A = \frac{1}{\cos A}$$

$$\cot A = \frac{1}{\tan A} = \frac{\cos A}{\sin A}$$

$$\sin^2 A + \cos^2 A = 1$$

$$1 + \tan^2 A = \sec^2 A$$

$$1 + \cot^2 A = \csc^2 A$$

$$\sin(A \pm B) = \sin A \cos B \pm \cos A \sin B$$

$$\cos(A \pm B) = \cos A \cos B \mp \sin A \sin B$$

$$\tan(A \pm B) = \frac{\tan A \pm \tan B}{1 \mp \tan A \tan B}$$

$$\sin 2A = 2 \sin A \cos A$$

$$\sin 3A = 3 \sin A - 4 \sin^3 A$$

$$\sin nA = 2 \sin(n-1)A \cos A - \sin(n-2)A$$

$$\cos 2A = 2 \cos^2 A - 1 = 1 - 2 \sin^2 A$$

$$\cos 3A = 4\cos^3 A - 3\cos A$$

$$\cos nA = 2\cos(n-1)A \cos A - \cos(n-2)A$$

$$\sin A + \sin B = 2\sin \frac{1}{2}(A+B)\cos \frac{1}{2}(A-B)$$

$$\sin A - \sin B = 2\cos \frac{1}{2}(A+B)\sin \frac{1}{2}(A-B)$$

$$\cos A + \cos B = 2\cos \frac{1}{2}(A+B)\cos \frac{1}{2}(A-B)$$

$$\cos A - \cos B = -2\sin \frac{1}{2}(A+B)\sin \frac{1}{2}(A-B)$$

$$\tan A \pm \tan B = \frac{\sin(A \pm B)}{\cos A \cos B}$$

$$\operatorname{ctn} A \pm \operatorname{ctn} B = \pm \frac{\sin(A \pm B)}{\sin A \sin B}$$

$$\sin A \sin B = \frac{1}{2}\cos(A-B) - \frac{1}{2}\cos(A+B)$$

$$\cos A \cos B = \frac{1}{2}\cos(A-B) + \frac{1}{2}\cos(A+B)$$

$$\sin A \cos B = \frac{1}{2}\sin(A+B) + \frac{1}{2}\sin(A-B)$$

$$\sin \frac{A}{2} = \pm \sqrt{\frac{1 - \cos A}{2}}$$

$$\cos \frac{A}{2} = \pm \sqrt{\frac{1 + \cos A}{2}}$$

$$\tan \frac{A}{2} = \frac{1 - \cos A}{\sin A} = \frac{\sin A}{1 + \cos A} = \pm \sqrt{\frac{1 - \cos A}{1 + \cos A}}$$

$$\sin^2 A = \frac{1}{2}(1 - \cos 2A)$$

$$\cos^2 A = \frac{1}{2}(1 + \cos 2A)$$

$$\sin^3 A = \frac{1}{4}(3\sin A - \sin 3A)$$

$$\cos^3 A = \frac{1}{4}(\cos 3A + 3\cos A)$$

$$\sin ix = \frac{1}{2}(e^x - e^{-x}) = i \sinh x$$

$$\cos ix = \frac{1}{2}(e^x + e^{-x}) = \cosh x$$

$$\tan ix = \frac{i(e^x - e^{-x})}{e^x + e^{-x}} = i \tanh x$$

$$e^{x+iy} = e^x(\cos y + i \sin y)$$

$$(\cos x \pm i \sin x)^n = \cos nx \pm i \sin nx$$

Inverse Trigonometric Functions

The inverse trigonometric functions are multiple valued, and this should be taken into account in the use of the following formulas.

$$\begin{aligned} \sin^{-1} x &= \cos^{-1} \sqrt{1-x^2} \\ &= \tan^{-1} \frac{x}{\sqrt{1-x^2}} = \operatorname{ctn}^{-1} \frac{\sqrt{1-x^2}}{x} \\ &= \sec^{-1} \frac{1}{\sqrt{1-x^2}} = \operatorname{csc}^{-1} \frac{1}{x} \\ &= -\sin^{-1}(-x) \end{aligned}$$

$$\begin{aligned} \cos^{-1} x &= \sin^{-1} \sqrt{1-x^2} \\ &= \tan^{-1} \frac{\sqrt{1-x^2}}{x} = \operatorname{ctn}^{-1} \frac{x}{\sqrt{1-x^2}} \\ &= \sec^{-1} \frac{1}{x} = \operatorname{csc}^{-1} \frac{1}{\sqrt{1-x^2}} \\ &= \pi - \cos^{-1}(-x) \end{aligned}$$

$$\begin{aligned} \tan^{-1} x &= \operatorname{ctn}^{-1} \frac{1}{x} \\ &= \sin^{-1} \frac{x}{\sqrt{1+x^2}} = \cos^{-1} \frac{1}{\sqrt{1+x^2}} \\ &= \sec^{-1} \sqrt{1+x^2} = \operatorname{csc}^{-1} \frac{\sqrt{1+x^2}}{x} \\ &= -\tan^{-1}(-x) \end{aligned}$$

217.2 Series

Bernoulli and Euler Numbers

A set of numbers, $B_1, B_3, \dots, B_{2n-1}$ (Bernoulli numbers) and B_2, B_4, \dots, B_{2n} (Euler numbers) appear in the series expansions of many functions. A partial listing follows; these are computed from the following equations:

$$B_{2n} - \frac{2n(2n-1)}{2!} B_{2n-2} + \frac{2n(2n-1)(2n-2)(2n-3)}{4!} B_{2n-4} - \dots + (-1)^n = 0$$

and

$$\frac{2^{2n}(2^{2n}-1)}{2n}B_{2n-1} = (2n-1)B_{2n-2} - \frac{(2n-1)(2n-2)(2n-3)}{3!}B_{2n-4} + \dots + (-1)^{n-1}$$

| | |
|---------------------|--------------------------|
| $B_1 = 1/6$ | $B_2 = 1$ |
| $B_3 = 1/30$ | $B_4 = 5$ |
| $B_5 = 1/42$ | $B_6 = 61$ |
| $B_7 = 1/30$ | $B_8 = 1385$ |
| $B_9 = 5/66$ | $B_{10} = 50\,521$ |
| $B_{11} = 691/2730$ | $B_{12} = 2\,702\,765$ |
| $B_{13} = 7/6$ | $B_{14} = 199\,360\,981$ |
| \vdots | \vdots |

Series of Functions

In the following, the interval of convergence is indicated; otherwise it is all x . Logarithms are to the base e . Bernoulli and Euler numbers (B_{2n-1} and B_{2n}) appear in certain expressions.

$$(a+x)^n = a^n + na^{n-1}x + \frac{n(n-1)}{2!}a^{n-2}x^2 + \frac{n(n-1)(n-2)}{3!}a^{n-3}x^3 + \dots$$

$$+ \frac{n!}{(n-j)!j!}a^{n-j}x^j + \dots \quad [x^2 < a^2]$$

$$(a-bx)^{-1} = \frac{1}{a} \left[1 + \frac{bx}{a} + \frac{b^2x^2}{a^2} + \frac{b^3x^3}{a^3} + \dots \right] \quad [b^2x^2 < a^2]$$

$$(1 \pm x)^n = 1 \pm nx + \frac{n(n-1)}{2!}x^2 \pm \frac{n(n-1)(n-2)x^3}{3!} + \dots \quad [x^2 < 1]$$

$$(1 \pm x)^{-n} = 1 \mp nx + \frac{n(n+1)}{2!}x^2 \mp \frac{n(n+1)(n+2)}{3!}x^3 + \dots \quad [x^2 < 1]$$

$$(1 \pm x)^{1/2} = 1 \pm \frac{1}{2}x - \frac{1}{2 \cdot 4}x^2 \pm \frac{1 \cdot 3}{2 \cdot 4 \cdot 6}x^3 - \frac{1 \cdot 3 \cdot 5}{2 \cdot 4 \cdot 6 \cdot 8}x^4 \pm \dots \quad [x^2 < 1]$$

$$(1 \pm x)^{-1/2} = 1 \mp \frac{1}{2}x + \frac{1 \cdot 3}{2 \cdot 4}x^2 \mp \frac{1 \cdot 3 \cdot 5}{2 \cdot 4 \cdot 6}x^3 + \frac{1 \cdot 3 \cdot 5 \cdot 7}{2 \cdot 4 \cdot 6 \cdot 8}x^4 \pm \dots \quad [x^2 < 1]$$

$$(1 \pm x^2)^{1/2} = 1 \pm \frac{1}{2}x^2 - \frac{x^4}{2 \cdot 4} \pm \frac{1 \cdot 3}{2 \cdot 4 \cdot 6}x^6 - \frac{1 \cdot 3 \cdot 5}{2 \cdot 4 \cdot 6 \cdot 8}x^8 \pm \dots \quad [x^2 < 1]$$

$$(1 \pm x)^{-1} = 1 \mp x + x^2 \mp x^3 + x^4 \mp x^5 + \dots \quad [x^2 < 1]$$

$$(1 \pm x)^{-2} = 1 \mp 2x + 3x^2 \mp 4x^3 + 5x^4 \mp \dots \quad [x^2 < 1]$$

$$e^x = 1 + x + \frac{x^2}{2!} + \frac{x^3}{3!} + \frac{x^4}{4!} + \dots$$

$$e^{-x^2} = 1 - x^2 + \frac{x^4}{2!} - \frac{x^6}{3!} + \frac{x^8}{4!} - \dots$$

$$a^x = 1 + x \log a + \frac{(x \log a)^2}{2!} + \frac{(x \log a)^3}{3!} + \dots$$

$$\log x = (x-1) - \frac{1}{2}(x-1)^2 + \frac{1}{3}(x-1)^3 - \dots \quad [0 < x < 2]$$

$$\log x = \frac{x-1}{x} + \frac{1}{2} \left(\frac{x-1}{x} \right)^2 + \frac{1}{3} \left(\frac{x-1}{x} \right)^3 + \dots \quad \left[x > \frac{1}{2} \right]$$

$$\log x = 2 \left[\left(\frac{x-1}{x+1} \right) + \frac{1}{3} \left(\frac{x-1}{x+1} \right)^3 + \frac{1}{5} \left(\frac{x-1}{x+1} \right)^5 + \dots \right] \quad [x > 0]$$

$$\log(1+x) = x - \frac{1}{2}x^2 + \frac{1}{3}x^3 - \frac{1}{4}x^4 + \dots \quad [x^2 < 1]$$

$$\log \left(\frac{1+x}{1-x} \right) = 2 \left[x + \frac{1}{3}x^3 + \frac{1}{5}x^5 + \frac{1}{7}x^7 + \dots \right] \quad [x^2 < 1]$$

$$\log \left(\frac{x+1}{x-1} \right) = 2 \left[\frac{1}{x} + \frac{1}{3} \left(\frac{1}{x} \right)^3 + \frac{1}{5} \left(\frac{1}{x} \right)^5 + \dots \right] \quad [x^2 > 1]$$

$$\sin x = x - \frac{x^3}{3!} + \frac{x^5}{5!} - \frac{x^7}{7!} + \dots$$

$$\cos x = 1 - \frac{x^2}{2!} + \frac{x^4}{4!} - \frac{x^6}{6!} + \dots$$

$$\tan x = x + \frac{x^3}{3} + \frac{2x^5}{15} + \frac{17x^7}{315}$$

$$+ \dots + \frac{2^{2n}(2^{2n}-1)B_{2n-1}x^{2n-1}}{(2n)!} \quad \left[x^2 < \frac{\pi^2}{4} \right]$$

$$\operatorname{ctn} x = \frac{1}{x} - \frac{x}{3} + \frac{x^3}{45} - \frac{2x^5}{945} - \dots - \frac{B_{2n-1}(2x)^{2n}}{(2n)!x} - \dots \quad [x^2 < \pi^2]$$

$$\sec x = 1 + \frac{x^2}{2!} + \frac{5x^4}{4!} + \frac{61x^6}{6!} + \dots + \frac{B_{2n}x^{2n}}{(2n)!} + \dots \quad \left[x^2 < \frac{\pi^2}{4} \right]$$

$$\operatorname{csc} x = \frac{1}{x} + \frac{x}{3!} + \frac{7x^3}{3 \cdot 5!} + \frac{31x^5}{3 \cdot 7!} + \dots$$

$$+ \frac{2(2^{2n+1}-1)}{(2n+2)!} B_{2n+1} x^{2n+1} + \dots \quad [x^2 < \pi^2]$$

$$\sin^{-1} x = x + \frac{x^3}{6} + \frac{(1 \cdot 3)x^5}{(2 \cdot 4)5} + \frac{(1 \cdot 3 \cdot 5)x^7}{(2 \cdot 4 \cdot 6)7} + \dots \quad [x^2 < 1]$$

$$\tan^{-1} x = x - \frac{1}{3}x^3 + \frac{1}{5}x^5 - \frac{1}{7}x^7 + \dots \quad [x^2 < 1]$$

$$\sec^{-1} x = \frac{\pi}{2} - \frac{1}{x} - \frac{1}{6x^3} - \frac{1 \cdot 3}{(2 \cdot 4)5x^5} - \frac{1 \cdot 3 \cdot 5}{(2 \cdot 4 \cdot 6)7x^7} - \dots \quad [x^2 > 1]$$

$$\sinh x = x + \frac{x^3}{3!} + \frac{x^5}{5!} + \frac{x^7}{7!} + \dots$$

$$\cosh x = 1 + \frac{x^2}{2!} + \frac{x^4}{4!} + \frac{x^6}{6!} + \frac{x^8}{8!} + \dots$$

$$\begin{aligned} \tanh x = & (2^2 - 1)2^2 B_1 \frac{x}{2!} - (2^4 - 1)2^4 B_3 \frac{x^3}{4!} \\ & + (2^6 - 1)2^6 B_5 \frac{x^5}{6!} - \dots \end{aligned} \quad \left[x^2 < \frac{\pi^2}{4} \right]$$

$$\operatorname{ctnh} x = \frac{1}{x} \left(1 + \frac{2^2 B_1 x^2}{2!} - \frac{2^4 B_3 x^4}{4!} + \frac{2^6 B_5 x^6}{6!} - \dots \right) \quad [x^2 < \pi^2]$$

$$\operatorname{sech} x = 1 - \frac{B_2 x^2}{2!} + \frac{B_4 x^4}{4!} - \frac{B_6 x^6}{6!} + \dots \quad \left[x^2 < \frac{\pi^2}{4} \right]$$

$$\operatorname{csch} x = \frac{1}{x} - (2-1)2B_1 \frac{x}{2!} + (2^3-1)2B_3 \frac{x^3}{4!} - \dots \quad [x^2 < \pi^2]$$

$$\sinh^{-1} x = x - \frac{1}{2} \frac{x^3}{3} + \frac{1 \cdot 3}{2 \cdot 4} \frac{x^5}{5} - \frac{1 \cdot 3 \cdot 5}{2 \cdot 4 \cdot 6} \frac{x^7}{7} + \dots \quad [x^2 < 1]$$

$$\tanh^{-1} x = x + \frac{x^3}{3} + \frac{x^5}{5} + \frac{x^7}{7} + \dots \quad [x^2 < 1]$$

$$\operatorname{ctnh}^{-1} x = \frac{1}{x} + \frac{1}{3x^3} + \frac{1}{5x^5} + \dots \quad [x^2 > 1]$$

$$\operatorname{csch}^{-1} x = \frac{1}{x} - \frac{1}{2 \cdot 3x^3} + \frac{1 \cdot 3}{2 \cdot 4 \cdot 5x^5} - \frac{1 \cdot 3 \cdot 5}{2 \cdot 4 \cdot 6 \cdot 7x^7} + \dots \quad [x^2 > 1]$$

$$\int_0^x e^{-t^2} dt = x - \frac{1}{3}x^3 + \frac{x^5}{5 \cdot 2!} - \frac{x^7}{7 \cdot 3!} + \dots$$

Error Function

The following function, known as the error function, erf x , arises frequently in applications:

$$\operatorname{erf} x = \frac{2}{\sqrt{\pi}} \int_0^x e^{-t^2} dt$$

The integral cannot be represented in terms of a finite number of elementary functions; therefore, values of erf x have been compiled in tables. The following is the series for erf x :

$$\operatorname{erf} x = \frac{2}{\sqrt{\pi}} \left[x - \frac{x^3}{3} + \frac{x^5}{5 \cdot 2!} - \frac{x^7}{7 \cdot 3!} + \dots \right]$$

There is a close relation between this function and the area under the standard normal curve. For evaluation it is convenient to use z instead of x ; then $\operatorname{erf} z$ may be evaluated from the area $F(z)$ by use of the relation

$$\operatorname{erf} z = 2F(\sqrt{2}z)$$

Example

$$\operatorname{erf}(0.5) = 2F[(1.414)(0.5)] = 2F(0.707)$$

By interpolation, $F(0.707) = 0.260$; thus, $\operatorname{erf}(0.5) = 0.520$.

Series Expansion

The expression in parentheses following certain series indicates the region of convergence. If not otherwise indicated, it is understood that the series converges for all finite values of x .

Binomial

$$(x + y)^n = x^n + nx^{n-1}y + \frac{n(n-1)}{2!}x^{n-2}y^2 + \frac{n(n-1)(n-2)}{3!}x^{n-3}y^3 + \dots \quad [y^2 < x^2]$$

$$(1 \pm x)^n = 1 \pm nx + \frac{n(n-1)x^2}{2!} \pm \frac{n(n-1)(n-2)x^3}{3!} + \dots \quad [x^2 < 1]$$

$$(1 \pm x)^{-n} = 1 \mp nx + \frac{n(n+1)x^2}{2!} \mp \frac{n(n+1)(n+2)x^3}{3!} + \dots \quad [x^2 < 1]$$

$$(1 \pm x)^{-1} = 1 \mp x + x^2 \mp x^3 + x^4 \mp x^5 + \dots \quad [x^2 < 1]$$

$$(1 \pm x)^{-2} = 1 \mp 2x + 3x^2 \mp 4x^3 + 5x^4 \mp 6x^5 + \dots \quad [x^2 < 1]$$

Reversion of Series

Let a series be represented by

$$y = a_1x + a_2x^2 + a_3x^3 + a_4x^4 + a_5x^5 + a_6x^6 + \dots \quad (a_1 \neq 0)$$

To find the coefficients of the series

$$x = A_1y + A_2y^2 + A_3y^3 + A_4y^4 + \dots$$

$$A_1 = \frac{1}{a_1} \quad A_2 = -\frac{a_2}{a_1^3} \quad A_3 = \frac{1}{a_1^5}(2a_2^2 - a_1a_3)$$

$$A_4 = \frac{1}{a_1^7}(5a_1a_2a_3 - a_1^2a_4 - 5a_2^3)$$

$$A_5 = \frac{1}{a_1^9} (6a_1^2 a_2 a_4 + 3a_1^2 a_3^2 + 14a_2^4 - a_1^3 a_5 - 21a_1 a_2^2 a_3)$$

$$A_6 = \frac{1}{a_1^{11}} (7a_1^3 a_2 a_5 + 7a_1^3 a_3 a_4 + 84a_1 a_2^3 a_3 - a_1^4 a_6 - 28a_1^2 a_2^2 a_4 - 28a_1^2 a_2 a_3^2 - 42a_2^5)$$

$$A_7 = \frac{1}{a_1^{13}} (8a_1^4 a_2 a_6 + 8a_1^4 a_3 a_5 + 4a_1^4 a_4^2 + 120a_1^2 a_2^3 a_4 + 180a_1^2 a_2^2 a_3^2 + 132a_2^6 - a_1^5 a_7 - 36a_1^3 a_2^2 a_5 - 72a_1^3 a_2 a_3 a_4 - 12a_1^3 a_3^3 - 330a_1 a_2^4 a_3)$$

Taylor

$$1. \quad f(x) = f(a) + (x-a)f'(a) + \frac{(x-a)^2}{2!} f''(a) + \frac{(x-a)^3}{3!} f'''(a) + \dots + \frac{(x-a)^n}{n!} f^{(n)}(a) + \dots \quad (\text{Taylor's series})$$

(Increment form)

$$2. \quad f(x+h) = f(x) + hf'(x) + \frac{h^2}{2!} f''(x) + \frac{h^3}{3!} f'''(x) + \dots$$

$$= f(h) + xf'(h) + \frac{x^2}{2!} f''(h) + \frac{x^3}{3!} f'''(h) + \dots$$

3. If $f(x)$ is a function possessing derivatives of all orders throughout the interval $a \leq x \leq b$, then there is a value X , with $a < X < b$, such that

$$f(b) = f(a) + (b-a)f'(a) + \frac{(b-a)^2}{2!} f''(a) + \dots$$

$$+ \frac{(b-a)^{n-1}}{(n-1)!} f^{(n-1)}(a) + \frac{(b-a)^n}{n!} f^{(n)}(X)$$

$$f(a+h) = f(a) + hf'(a) + \frac{h^2}{2!} f''(a) + \dots + \frac{h^{n-1}}{(n-1)!} f^{(n-1)}(a)$$

$$+ \frac{h^n}{n!} f^{(n)}(a + \theta h), \quad b = a + h, \quad 0 < \theta < 1$$

or

$$f(x) = f(a) + (x-a)f'(a) + \frac{(x-a)^2}{2!} f''(a) + \dots + (x-a)^{n-1} \frac{f^{(n-1)}(a)}{(n-1)!} + R_n$$

where

$$R_n = \frac{f^{(n)}[a + \theta \cdot (x-a)]}{n!} (x-a)^n, \quad 0 < \theta < 1.$$

The above forms are known as Taylor's series with the remainder term.

4. Taylor's series for a function of two variables:

$$\text{If } \left(h \frac{\partial}{\partial x} + k \frac{\partial}{\partial y} \right) f(x, y) = h \frac{\partial f(x, y)}{\partial x} + k \frac{\partial f(x, y)}{\partial y};$$

$$\left(h \frac{\partial}{\partial x} + k \frac{\partial}{\partial y} \right)^2 f(x, y) = h^2 \frac{\partial^2 f(x, y)}{\partial x^2} + 2hk \frac{\partial^2 f(x, y)}{\partial x \partial y} + k^2 \frac{\partial^2 f(x, y)}{\partial y^2}$$

etc., and if

$$\left(h \frac{\partial}{\partial x} + k \frac{\partial}{\partial y} \right)^n f(x, y) \Big|_{\substack{x=a \\ y=b}}$$

where the bar and subscripts mean that after differentiation we are to replace x by a and y by b ,

$$f(a+h, b+k) = f(a, b) + \left(h \frac{\partial}{\partial x} + k \frac{\partial}{\partial y} \right) f(x, y) \Big|_{\substack{x=a \\ y=b}} + \dots$$

$$+ \frac{1}{n!} \left(h \frac{\partial}{\partial x} + k \frac{\partial}{\partial y} \right)^n f(x, y) \Big|_{\substack{x=a \\ y=b}} + \dots$$

MacLaurin

$$f(x) = f(0) + xf'(0) + \frac{x^2}{2!} f''(0) + \frac{x^3}{3!} f'''(0) + \dots + x^{n-1} \frac{f^{(n-1)}(0)}{(n-1)!} + R_n$$

where

$$R_n = \frac{x^n f^{(n)}(\theta x)}{n!}, \quad 0 < \theta < 1$$

Exponential

$$e = 1 + \frac{1}{1!} + \frac{1}{2!} + \frac{1}{3!} + \frac{1}{4!} + \dots$$

$$e^x = 1 + x + \frac{x^2}{2!} + \frac{x^3}{3!} + \frac{x^4}{4!} + \dots \quad (\text{all real values of } x)$$

$$a^x = 1 + x \log_e a + \frac{(x \log_e a)^2}{2!} + \frac{(x \log_e a)^3}{3!} + \dots$$

$$e^x = e^a \left[1 + (x-a) + \frac{(x-a)^2}{2!} + \frac{(x-a)^3}{3!} + \dots \right]$$

Logarithmic

$$\log_e x = \frac{x-1}{x} + \frac{1}{2} \left(\frac{x-1}{x} \right)^2 + \frac{1}{3} \left(\frac{x-1}{x} \right)^3 + \dots \quad \left(x > \frac{1}{2} \right)$$

$$\log_e x = (x-1) - \frac{1}{2}(x-1)^2 + \frac{1}{3}(x-1)^3 - \dots \quad (2 \geq x > 0)$$

$$\log_e x = 2 \left[\frac{x-1}{x+1} + \frac{1}{3} \left(\frac{x-1}{x+1} \right)^3 + \frac{1}{5} \left(\frac{x-1}{x+1} \right)^5 + \dots \right] \quad (x > 0)$$

$$\log_e(1+x) = x - \frac{1}{2}x^2 + \frac{1}{3}x^3 - \frac{1}{4}x^4 + \dots \quad (-1 < x \leq 1)$$

$$\log_e(n+1) - \log_e(n-1) = 2 \left[\frac{1}{n} + \frac{1}{3n^3} + \frac{1}{5n^5} + \dots \right]$$

$$\log_e(a+x) = \log_e a + 2 \left[\frac{x}{2a+x} + \frac{1}{3} \left(\frac{x}{2a+x} \right)^3 + \frac{1}{5} \left(\frac{x}{2a+x} \right)^5 + \dots \right] \quad (a > 0, -a < x < +\infty)$$

$$\log_e \frac{1+x}{1-x} = 2 \left[x + \frac{x^3}{3} + \frac{x^5}{5} + \dots + \frac{x^{2n-1}}{2n-1} + \dots \right] \quad (-1 < x < 1)$$

$$\log_e x = \log_e a + \frac{(x-a)}{a} + \frac{(x-a)^2}{2a^2} + \frac{(x-a)^3}{3a^3} - \dots \quad (0 < x \leq 2a)$$

Trigonometric

$$\sin x = x - \frac{x^3}{3!} + \frac{x^5}{5!} - \frac{x^7}{7!} + \dots \quad (\text{all real values of } x)$$

$$\cos x = 1 - \frac{x^2}{2!} + \frac{x^4}{4!} - \frac{x^6}{6!} + \dots \quad (\text{all real values of } x)$$

$$\tan x = x + \frac{x^3}{3} + \frac{2x^5}{15} + \frac{17x^7}{315} + \frac{62x^9}{2835} + \dots$$

$$+ \frac{(-1)^{n-1} 2^{2n} (2^{2n} - 1) B_{2n}}{(2n)!} x^{2n-1} + \dots$$

$(x^2 < \pi^2 / 4)$, and B_n represents the n th Bernoulli number

$$\cot x = \frac{1}{x} - \frac{x}{3} + \frac{x^3}{45} - \frac{2x^5}{945} + \frac{x^7}{4725} - \dots$$

$$- \frac{(-1)^{n+1} 2^{2n}}{(2n)!} B_{2n} x^{2n-1} + \dots$$

$(x^2 < \pi^2)$, and B_n represents the n th Bernoulli number

217.3 Differential Calculus

Notation

For the following equations, the symbols $f(x)$, $g(x)$, etc., represent functions of x . The value of a function $f(x)$ at $x = a$ is denoted $f(a)$. For the function $y = f(x)$ the derivative of y with respect to x is denoted by one of the following:

$$\frac{dy}{dx}, \quad f'(x), \quad D_x y, \quad y'$$

Higher derivatives are as follows:

$$\frac{d^2 y}{dx^2} = \frac{d}{dx} \left(\frac{dy}{dx} \right) = \frac{d}{dx} f'(x) = f''(x)$$

$$\frac{d^3 y}{dx^3} = \frac{d}{dx} \left(\frac{d^2 y}{dx^2} \right) = \frac{d}{dx} f''(x) = f'''(x)$$

⋮

and values of these at $x = a$ are denoted $f''(a)$, $f'''(a)$, and so on (see Table of Derivatives in Appendix).

Slope of a Curve

The tangent line at point $P(x, y)$ of the curve $y = f(x)$ has a slope $f'(x)$ provided that $f'(x)$ exists at P . The slope at P is defined to be that of the tangent line at P . The tangent line at $P(x_1, y_1)$ is given by

$$y - y_1 = f'(x_1)(x - x_1)$$

The *normal line* to the curve at $P(x_1, y_1)$ has slope $-1/f'(x_1)$ and thus obeys the equation

$$y - y_1 = [-1/f'(x_1)](x - x_1)$$

(The slope of a vertical line is not defined.)

Angle of Intersection of Two Curves

Two curves, $y = f_1(x)$ and $y = f_2(x)$, that intersect at a point $P(X, Y)$ where derivatives $f_1'(X)$, $f_2'(X)$ exist, have an angle (α) of intersection given by

$$\tan \alpha = \frac{f_2'(X) - f_1'(X)}{1 + f_2'(X) \cdot f_1'(X)}$$

If $\tan \alpha > 0$, then α is the acute angle; if $\tan \alpha < 0$, then α is the obtuse angle.

Radius of Curvature

The radius of curvature R of the curve $y = f(x)$ at the point $P(x, y)$ is

$$R = \frac{\left\{1 + [f'(x)]^2\right\}^{3/2}}{f''(x)}$$

In polar coordinates (θ, r) the corresponding formula is

$$R = \frac{\left[r^2 + \left(\frac{dr}{d\theta} \right)^2 \right]^{3/2}}{r^2 + 2 \left(\frac{dr}{d\theta} \right)^2 - r \frac{d^2r}{d\theta^2}}$$

The *curvature* K is $1/R$.

Relative Maxima and Minima

The function f has a relative maximum at $x = a$ if $f(a) \geq f(a + c)$ for all values of c (positive or negative) that are sufficiently near zero. The function f has a relative minimum at $x = b$ if $f(b) \leq f(b + c)$ for all values of c that are sufficiently close to zero. If the function f is defined on the closed interval $x_1 \leq x \leq x_2$ and has a relative maximum or minimum at $x = a$, where $x_1 < a < x_2$, and if the derivative $f'(x)$ exists at $x = a$, then $f'(a) = 0$. It is noteworthy that a relative maximum or minimum may occur at a point where the derivative does not exist. Further, the derivative may vanish at a point that is neither a maximum nor a minimum for the function. Values of x for which $f'(x) = 0$ are called “critical values.” To determine whether a critical value of x , say x_c , is a relative maximum or minimum for the function at x_c , one may use the second derivative test:

1. If $f''(x_c)$ is positive, $f(x_c)$ is a minimum.
2. If $f''(x_c)$ is negative, $f(x_c)$ is a maximum.
3. If $f''(x_c)$ is zero, no conclusion may be made.

The sign of the derivative as x advances through x_c may also be used as a test. If $f'(x)$ changes from positive to zero to negative, then a maximum occurs at x_c , whereas a change in $f'(x)$ from negative to zero to positive indicates a minimum. If $f'(x)$ does not change sign as x advances through x_c , then the point is neither a maximum nor a minimum.

Points of Inflection of a Curve

The sign of the second derivative of f indicates whether the graph of $y = f(x)$ is concave upward or concave downward:

- $f''(x) > 0$: concave upward
- $f''(x) < 0$: concave downward

A point of the curve at which the direction of concavity changes is called a point of inflection (Figure 217.2). Such a point may occur where $f''(x) = 0$ or where $f''(x)$ becomes infinite. More precisely, if

FIGURE 217.2 Point of inflection.

the function $y = f(x)$ and its first derivative $y' = f'(x)$ are continuous in the interval $a \leq x \leq b$, and if $y'' = f''(x)$ exists in $a < x < b$, then the graph of $y = f(x)$ for $a < x < b$ is concave upward if $f''(x)$ is positive and concave downward if $f''(x)$ is negative.

Taylor's Formula

If f is a function that is continuous on an interval that contains a and x , and if its first $(n + 1)$ derivatives are continuous on this interval, then

$$f(x) = f(a) + f'(a)(x-a) + \frac{f''(a)}{2!}(x-a)^2 + \frac{f'''(a)}{3!}(x-a)^3 + \dots + \frac{f^{(n)}(a)}{n!}(x-a)^n + R$$

where R is called the *remainder*. There are various common forms of the remainder:

Lagrange's Form

$$R = f^{(n+1)}(\beta) \cdot \frac{(x-a)^{n+1}}{(n+1)!}, \quad \beta \text{ between } a \text{ and } x$$

Cauchy's Form

$$R = f^{(n+1)}(\beta) \cdot \frac{(x-B)^n(x-a)}{n!}, \quad \beta \text{ between } a \text{ and } x$$

Integral Form

$$R = \int_a^x \frac{(x-t)^n}{n!} f^{(n+1)}(t) dt$$

Indeterminant Forms

If $f(x)$ and $g(x)$ are continuous in an interval that includes $x = a$, and if $f(a) = 0$ and $g(a) = 0$, the limit $\lim_{x \rightarrow a} [f(x)/g(x)]$ takes the form "0/0," called an *indeterminant form*. *L'Hôpital's rule* is

$$\lim_{x \rightarrow a} \frac{f(x)}{g(x)} = \lim_{x \rightarrow a} \frac{f'(x)}{g'(x)}$$

Similarly, it may be shown that if $f(x) \rightarrow \infty$ and $g(x) \rightarrow \infty$ as $x \rightarrow a$, then

$$\lim_{x \rightarrow a} \frac{f(x)}{g(x)} = \lim_{x \rightarrow a} \frac{f'(x)}{g'(x)}$$

(The above holds for $x \rightarrow \infty$.)

FIGURE 217.3 Trapezoidal rule for area.

Examples

$$\lim_{x \rightarrow 0} \frac{\sin x}{x} = \lim_{x \rightarrow 0} \frac{\cos x}{1} = 1$$

$$\lim_{x \rightarrow \infty} \frac{x^2}{e^x} = \lim_{x \rightarrow \infty} \frac{2x}{e^x} = \lim_{x \rightarrow \infty} \frac{2}{e^x} = 0$$

Numerical Methods

1. *Newton's method* for approximating roots of the equation $f(x) = 0$; A first estimate x_1 of the root is made; then, provided that $f'(x_1) \neq 0$, a better approximation is x_2 :

$$x_2 = x_1 - \frac{f(x_1)}{f'(x_1)}$$

The process may be repeated to yield a third approximation, x_3 , to the root:

$$x_3 = x_2 - \frac{f(x_2)}{f'(x_2)}$$

provided $f'(x_2)$ exists. The process may be repeated. (In certain rare cases the process will not converge.)

2. *Trapezoidal rule for areas* (Figure 217.3): For the function $y = f(x)$ defined on the interval (a, b) and positive there, take n equal subintervals of width $\Delta x = (b - a)/n$. The area bounded by the curve between $x = a$ and $x = b$ [or definite integral of $f(x)$] is approximately the sum of trapezoidal areas, or

$$A \sim \left(\frac{1}{2} y_0 + y_1 + y_2 + \cdots + y_{n-1} + \frac{1}{2} y_n \right) (\Delta x)$$

Estimation of the error (E) is possible if the second derivative can be obtained:

$$E = \frac{b-a}{12} f''(c)(\Delta x)^2$$

where c is some number between a and b .

Functions of Two Variables

For the function of two variables, denoted $z = f(x, y)$, if y is held constant, say at $y = y_1$, then the resulting function is a function of x only. Similarly, x may be held constant at x_1 , to give the resulting function of y .

The Gas Laws

A familiar example is afforded by the ideal gas law relating the pressure p , the volume V , and the absolute temperature T of an ideal gas:

$$pV = nRT$$

where n is the number of moles and R is the gas constant per mole, $8.31 \text{ (J} \cdot \text{K}^{-1} \cdot \text{mole}^{-1})$. By rearrangement, any one of the three variables may be expressed as a function of the other two. Further, either one of these two may be held constant. If T is held constant, then we get the form known as Boyle's law:

$$p = kV^{-1} \quad (\text{Boyle's law})$$

where we have denoted nRT by the constant k and, of course, $V > 0$. If the pressure remains constant, we have Charles' law:

$$V = bT \quad (\text{Charles' law})$$

where the constant b denotes nR/p . Similarly, volume may be kept constant:

$$p = aT$$

where now the constant, denoted a , is nR/V .

Partial Derivatives

The physical example afforded by the ideal gas law permits clear interpretations of processes in which one of the variables is held constant. More generally, we may consider a function $z = f(x, y)$ defined over some region of the xy plane in which we hold one of the two coordinates, say y , constant. If the resulting function of x is differentiable at a point (x, y) , we denote this derivative by one of the notations

$$f_x, \quad \delta f / dx, \quad \delta z / dx$$

called the *partial derivative with respect to x* . Similarly, if x is held constant and the resulting function of y is differentiable, we get the *partial derivative with respect to y* , denoted by one of the following:

$$f_y, \quad \delta f / dy, \quad \delta z / dy$$

Example. Given $z = x^4y^3 - y \sin x + 4y$, then

$$\delta z / dx = 4(xy)^3 - y \cos x$$

$$\delta z / dy = 3x^4y^2 - \sin x + 4$$

217.4 Integral Calculus

Indefinite Integral

If $F(x)$ is differentiable for all values of x in the interval (a, b) and satisfies the equation $dy/dx = f(x)$, then $F(x)$ is an integral of $f(x)$ with respect to x . The notation is $F(x) = \int f(x) dx$ or, in differential form, $dF(x) = f(x) dx$.

For any function $F(x)$ that is an integral of $f(x)$, it follows that $F(x) + C$ is also an integral. We thus write

$$\int f(x) dx = F(x) + C$$

Definite Integral

Let $f(x)$ be defined on the interval $[a, b]$ which is partitioned by points $x_1, x_2, \dots, x_j, \dots, x_{n-1}$ between $a = x_0$ and $b = x_n$. The j th interval has length $\Delta x_j = x_j - x_{j-1}$, which may vary with j . The sum

$$\sum_{j=1}^n f(v_j) \Delta x_j,$$

where v_j is arbitrarily chosen in the j th subinterval, depends on the numbers x_0, \dots, x_n and the choice of the v as well as f ; but if such sums approach a common value as all Δx approach zero, then this value is

the definite integral of f over the interval (a, b) and is denoted $\int_a^b f(x) dx$. The *fundamental theorem of integral calculus* states that

$$\int_a^b f(x) dx = F(b) - F(a),$$

where F is any continuous indefinite integral of f in the interval (a, b) .

Properties

$$\int_a^b [f_1(x) + f_2(x) + \dots + f_j(x)] dx = \int_a^b f_1(x) dx + \int_a^b f_2(x) dx + \dots + \int_a^b f_j(x) dx$$

$$\int_a^b cf(x) dx = c \int_a^b f(x) dx, \quad \text{if } c \text{ is a constant}$$

$$\int_a^b f(x) dx = - \int_b^a f(x) dx$$

$$\int_a^b f(x) dx = \int_a^c f(x) dx + \int_c^b f(x) dx$$

Common Applications of the Definite Integral

Area (Rectangular Coordinates)

Given the function $y = f(x)$ such that $y > 0$ for all x between a and b , the area bounded by the curve $y = f(x)$, the x axis, and the vertical lines $x = a$ and $x = b$ is

$$A = \int_a^b f(x) dx$$

Length of Arc (Rectangular Coordinates)

Given the smooth curve $f(x, y) = 0$ from point (x_1, y_1) to point (x_2, y_2) , the length between these points is

$$L = \int_{x_1}^{x_2} \sqrt{1 + (dy/dx)^2} dx$$

$$L = \int_{y_1}^{y_2} \sqrt{1 + (dx/dy)^2} dy$$

Mean Value of a Function

The mean value of a function $f(x)$ continuous on $[a, b]$ is

$$\frac{1}{(b-a)} \int_a^b f(x) dx$$

Area (Polar Coordinates)

Given the curve $r = f(\theta)$, continuous and nonnegative for $\theta_1 \leq \theta \leq \theta_2$, the area enclosed by this curve and the radial lines $\theta = \theta_1$ and $\theta = \theta_2$ is given by

$$A = \int_{\theta_1}^{\theta_2} \frac{1}{2} [f(\theta)]^2 d\theta$$

Length of Arc (Polar Coordinates)

Given the curve $r = f(\theta)$ with continuous derivative $f'(\theta)$ on $\theta_1 \leq \theta \leq \theta_2$, the length of arc from $\theta = \theta_1$ to $\theta = \theta_2$ is

$$L = \int_{\theta_1}^{\theta_2} \sqrt{[f(\theta)]^2 + [f'(\theta)]^2} d\theta$$

Volume of Revolution

Given a function $y = f(x)$ continuous and nonnegative on the interval (a, b) , when the region bounded by $f(x)$ between a and b is revolved about the x axis, the volume of revolution is

$$V = \pi \int_a^b [f(x)]^2 dx$$

Surface Area of Revolution (Revolution about the x axis, between a and b)

If the portion of the curve $y = f(x)$ between $x = a$ and $x = b$ is revolved about the x axis, the area A of the surface generated is given by the following:

$$A = \int_a^b 2\pi f(x) \{1 + [f'(x)]^2\}^{1/2} dx$$

FIGURE 217.4 Cylindrical coordinates.

FIGURE 217.5 Spherical coordinates.

Work

If a variable force $f(x)$ is applied to an object in the direction of motion along the x axis between $x = a$ and $x = b$, the work done is

$$W = \int_a^b f(x) dx$$

Cylindrical and Spherical Coordinates

1. Cylindrical coordinates (Figure 217.4):

$$x = r \cos \theta$$

$$y = r \sin \theta$$

Element of volume $dV = r dr d\theta dz$.

2. Spherical coordinates (Figure 217.5):

$$x = \rho \sin \phi \cos \theta$$

$$y = \rho \sin \phi \sin \theta$$

$$z = \rho \cos \phi$$

Element of volume $dV = \rho^2 \sin \phi d\rho d\phi d\theta$.

Double Integration

The evaluation of a double integral of $f(x, y)$ over a plane region R ,

$$\iint_R f(x, y) dA$$

is practically accomplished by iterated (repeated) integration. For example, suppose that a vertical straight line meets the boundary of R in at most two points so that there is an upper boundary, $y = y_2(x)$, and a

FIGURE 217.6 Region R bounded by $y_2(x)$ and $y_1(x)$.

lower boundary, $y = y_1(x)$. Also, it is assumed that these functions are continuous from a to b (see Figure 217.6). Then

$$\iint_R f(x, y) dA = \int_a^b \left(\int_{y_1(x)}^{y_2(x)} f(x, y) dy \right) dx$$

If R has left-hand boundary, $x = x_1(y)$, and a right-hand boundary, $x = x_2(y)$, which are continuous from c to d (the extreme values of y in R), then

$$\iint_R f(x, y) dA = \int_c^d \left(\int_{x_1(y)}^{x_2(y)} f(x, y) dx \right) dy$$

Such integrations are sometimes more convenient in polar coordinates, $x = r \cos \theta$, $y = r \sin \theta$, $dA = r dr d\theta$.

Surface Area and Volume by Double Integration

For the surface given by $z = f(x, y)$, which projects onto the closed region R of the xy plane, one may calculate the volume V bounded above by the surface and below by R , and the surface area S by the following:

$$V = \iint_R z dA = \iint_R f(x, y) dx dy$$

$$S = \iint_R \left[1 + (\delta z / \delta x)^2 + (\delta z / \delta y)^2 \right]^{1/2} dx dy$$

[In polar coordinates, (r, θ) , we replace dA by $r dr d\theta$.]

Centroid

The centroid of a region R of the xy plane is a point (x', y') where

$$x' = \frac{1}{A} \iint_R x dA, \quad y' = \frac{1}{A} \iint_R y dA$$

and A is the area of the region.

Example. For the circular sector of angle 2α and radius R , the area A is αR^2 ; the integral needed for x' , expressed in polar coordinates, is

$$\iint x dA = \int_{-\alpha}^{\alpha} \int_0^R (r \cos \theta) r dr d\theta$$

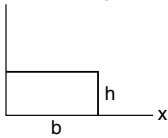

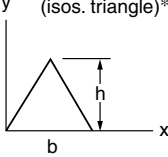

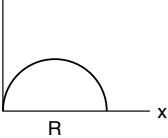

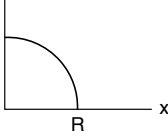

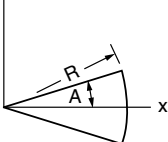

$$= \left[\frac{R^3}{3} \sin \theta \right]_{-\alpha}^{+\alpha} = \frac{2}{3} R^3 \sin \theta$$

and thus,

$$x' = \frac{\frac{2}{3} R^3 \sin \alpha}{\alpha R^2} = \frac{2}{3} R \frac{\sin \alpha}{\alpha}$$

Centroids of some common regions are shown in Table 217.1.

TABLE 217.1 Centroids

| | Area | x' | y' |
|--|---------------|------------------|-----------|
| y (rectangle)  | bh | $b/2$ | $h/2$ |
| y (isos. triangle)*  | $bh/2$ | $b/2$ | $h/3$ |
| y (semicircle)  | $\pi R^2 / 2$ | R | $4R/3\pi$ |
| y (quarter circle)  | $\pi R^2 / 4$ | $4R/3\pi$ | $4R/3\pi$ |
| y (circular sector)  | $R^2 A$ | $2R \sin A / 3A$ | 0 |

* $y' = h/3$ for any triangle of altitude h .

217.5 Special Functions

Hyperbolic Functions

$$\sinh x = \frac{e^x - e^{-x}}{2}$$

$$\operatorname{csch} x = \frac{1}{\sinh x}$$

$$\cosh x = \frac{e^x + e^{-x}}{2}$$

$$\operatorname{sech} x = \frac{1}{\cosh x}$$

$$\tanh x = \frac{e^x - e^{-x}}{e^x + e^{-x}}$$

$$\operatorname{ctnh} x = \frac{1}{\tanh x}$$

$$\sinh(-x) = -\sinh x$$

$$\operatorname{ctnh}(-x) = -\operatorname{ctnh} x$$

$$\cosh(-x) = \cosh x$$

$$\operatorname{sech}(-x) = \operatorname{sech} x$$

$$\tanh(-x) = -\tanh x$$

$$\operatorname{csch}(-x) = -\operatorname{csch} x$$

$$\tanh x = \frac{\sinh x}{\cosh x}$$

$$\operatorname{ctnh} x = \frac{\cosh x}{\sinh x}$$

$$\cosh^2 x - \sinh^2 x = 1$$

$$\cosh^2 x = \frac{1}{2}(\cosh 2x + 1)$$

$$\sinh^2 x = \frac{1}{2}(\cosh 2x - 1)$$

$$\operatorname{ctnh}^2 x - \operatorname{csch}^2 x = 1$$

$$\operatorname{csch}^2 x - \operatorname{sech}^2 x = \operatorname{csch}^2 x \operatorname{sech}^2 x \quad \tanh^2 x + \operatorname{sech}^2 x = 1$$

$$\sinh(x + y) = \sinh x \cosh y + \cosh x \sinh y$$

$$\cosh(x + y) = \cosh x \cosh y + \sinh x \sinh y$$

$$\sinh(x - y) = \sinh x \cosh y - \cosh x \sinh y$$

$$\cosh(x - y) = \cosh x \cosh y - \sinh x \sinh y$$

$$\tanh(x + y) = \frac{\tanh x + \tanh y}{1 + \tanh x \tanh y}$$

$$\tanh(x - y) = \frac{\tanh x - \tanh y}{1 - \tanh x \tanh y}$$

Bessel Functions

Bessel functions, also called cylindrical functions, arise in many physical problems as solutions of the differential equation

$$x^2 y'' + xy' + (x^2 - n^2)y = 0$$

which is known as Bessel's equation. Certain solutions, known as *Bessel functions of the first kind of order n* , are given by

$$J_n(x) = \sum_{k=0}^{\infty} \frac{(-1)^k}{k! \Gamma(n+k+1)} \left(\frac{x}{2}\right)^{n+2k}$$

$$J_{-n}(x) = \sum_{k=0}^{\infty} \frac{(-1)^k}{k! \Gamma(-n+k+1)} \left(\frac{x}{2}\right)^{-n+2k}$$

In the above it is noteworthy that the gamma function must be defined for the negative argument $q : \Gamma(q) = \Gamma(q+1)/q$, provided that q is not a negative integer. When q is a negative integer, $1/\Gamma(q)$ is defined to be zero. The functions $J_{-n}(x)$ and $J_n(x)$ are solutions of Bessel's equation for all real n . It is seen, for $n = 1, 2, 3, \dots$, that

$$J_{-n}(x) = (-1)^n J_n(x)$$

and, therefore, these are not independent; hence, a linear combination of these is not a general solution. When, however, n is not a positive integer, a negative integer, or zero, the linear combination with arbitrary constants c_1 and c_2 ,

$$y = c_1 J_n(x) + c_2 J_{-n}(x)$$

is the general solution of the Bessel differential equation.

The zero-order function is especially important as it arises in the solution of the heat equation (for a "long" cylinder):

$$J_0(x) = 1 - \frac{x^2}{2^2} + \frac{x^4}{2^2 4^2} - \frac{x^6}{2^2 4^2 6^2} + \dots$$

while the following relations show a connection to the trigonometric functions:

$$J_{1/2}(x) = \left[\frac{2}{\pi x} \right]^{1/2} \sin x$$

$$J_{-1/2}(x) = \left[\frac{2}{\pi x} \right]^{1/2} \cos x$$

The following recursion formula gives $J_{n+1}(x)$ for any order in terms of lower-order functions:

$$\frac{2n}{x} J_n(x) = J_{n-1}(x) + J_{n+1}(x)$$

Legendre Polynomials

If Laplace's equation, $\nabla^2 V = 0$, is expressed in spherical coordinates, it is

$$r^2 \sin \theta \frac{\delta^2 V}{\delta r^2} + 2r \sin \theta \frac{\delta V}{\delta r} + \sin \theta \frac{\delta^2 V}{\delta \theta^2} + \cos \theta \frac{\delta V}{\delta \theta} + \frac{1}{\sin \theta} \frac{\delta^2 V}{\delta \phi^2} = 0$$

and any of its solutions, $V(r, \theta, \phi)$, are known as *spherical harmonics*. The solution as a product

$$V(r, \theta, \phi) = R(r)\Theta(\theta)$$

which is independent of ϕ , leads to

$$\sin^2 \theta \Theta'' + \sin \theta \cos \theta \Theta' + [n(n+1) \sin^2 \theta] \Theta = 0$$

Rearrangement and substitution of $x = \cos \theta$ leads to

$$(1-x^2) \frac{d^2 \Theta}{dx^2} - 2x \frac{d\Theta}{dx} + n(n+1) \Theta = 0$$

known as *Legendre's equation*. Important special cases are those in which n is zero or a positive integer, and, for such cases, Legendre's equation is satisfied by polynomials called Legendre polynomials, $P_n(x)$. A short list of Legendre polynomials, expressed in terms of x and $\cos \theta$, is given below. These are given by the following general formula:

$$P_n(x) = \sum_{j=0}^L \frac{(-1)^j (2n-2j)!}{2^n j!(n-j)!(n-2j)!} x^{n-2j}$$

where $L = n/2$ if n is even and $L = (n-1)/2$ if n is odd.

$$P_0(x) = 1$$

$$P_1(x) = x$$

$$P_2(x) = \frac{1}{2}(3x^2 - 1)$$

$$P_3(x) = \frac{1}{2}(5x^3 - 3x)$$

$$P_4(x) = \frac{1}{8}(35x^4 - 30x^2 + 3)$$

$$P_5(x) = \frac{1}{8}(63x^5 - 70x^3 + 15x)$$

$$P_0(\cos \theta) = 1$$

$$P_1(\cos \theta) = \cos \theta$$

$$P_2(\cos \theta) = \frac{1}{4}(3 \cos 2\theta + 1)$$

$$P_3(\cos \theta) = \frac{1}{8}(5 \cos 3\theta + 3 \cos \theta)$$

$$P_4(\cos \theta) = \frac{1}{64}(35 \cos 4\theta + 20 \cos 2\theta + 9)$$

Additional Legendre polynomials may be determined from the *recursion formula*

$$(n+1)P_{n+1}(x) - (2n+1)xP_n(x) + nP_{n-1}(x) = 0 \quad (n = 1, 2, \dots)$$

or the *Rodrigues formula*

$$P_n(x) = \frac{1}{2^n n!} \frac{d^n}{dx^n} (x^2 - 1)^n$$

Laguerre Polynomials

Laguerre polynomials, denoted $L_n(x)$, are solutions of the differential equation

$$xy'' + (1-x)y' + ny = 0$$

and are given by

$$L_n(x) = \sum_{j=0}^n \frac{(-1)^j}{j!} C_{(n,j)} x^j \quad (n=0, 1, 2, \dots)$$

Thus,

$$L_0(x) = 1$$

$$L_1(x) = 1 - x$$

$$L_2(x) = 1 - 2x + \frac{1}{2}x^2$$

$$L_3(x) = 1 - 3x + \frac{3}{2}x^2 - \frac{1}{6}x^3$$

Additional Laguerre polynomials may be obtained from the recursion formula

$$(n+1)L_{n+1}(x) - (2n+1-x)L_n(x) + nL_{n-1}(x) = 0$$

Hermite Polynomials

The Hermite polynomials, denoted $H_n(x)$, are given by

$$H_0 = 1, \quad H_n(x) = (-1)^n e^{x^2} \frac{d^n e^{-x^2}}{dx^n}, \quad (n=1, 2, \dots)$$

and are solutions of the differential equation

$$y'' - 2xy' + 2ny = 0 \quad (n=0, 1, 2, \dots)$$

The first few Hermite polynomials are

$$H_0 = 1 \qquad H_1(x) = 2x$$

$$H_2(x) = 4x^2 - 2 \qquad H_3(x) = 8x^3 - 12x$$

$$H_4(x) = 16x^4 - 48x^2 + 12$$

Additional Hermite polynomials may be obtained from the relation

$$H_{n+1}(x) = 2xH_n(x) - H_n'(x)$$

where prime denotes differentiation with respect to x .

Orthogonality

A set of functions $\{f_n(x)\}$ ($n = 1, 2, \dots$) is orthogonal in an interval (a, b) with respect to a given weight function $w(x)$ if

$$\int_a^b w(x)f_m(x)f_n(x)dx = 0 \quad \text{when } m \neq n$$

The following polynomials are orthogonal on the given interval for the given $w(x)$:

Legendre polynomials: $P_n(x)$ $w(x) = 1$
 $a = -1, b = 1$

Laguerre polynomials: $L_n(x)$ $w(x) = \exp(-x)$
 $a = 0, b = \infty$

Hermite polynomials: $H_n(x)$ $w(x) = \exp(-x^2)$
 $a = -\infty, b = \infty$

The Bessel functions of order n , $J_n(\lambda_1 x)$, $J_n(\lambda_2 x)$, \dots , are orthogonal with respect to $w(x) = x$ over the interval $(0, c)$ provided that the λ_i are the positive roots of $J_n(\lambda c) = 0$:

$$\int_0^c xJ_n(\lambda_j x)J_n(\lambda_k x)dx = 0 \quad (j \neq k)$$

where n is fixed and $n \geq 0$.

218.1 Basic Definitions

A *matrix* \mathbf{A} is a rectangular array of numbers (real or complex):

$$\mathbf{A} = \begin{bmatrix} a_{11} & a_{12} & \cdots & a_{1m} \\ a_{21} & a_{22} & \cdots & a_{2m} \\ \vdots & & & \\ a_{n1} & a_{n2} & \cdots & a_{nm} \end{bmatrix}$$

The *size* of the matrix is said to be $n \times m$. The $1 \times m$ matrices $[a_{i1} \ a_{i2} \ \dots \ a_{im}]$ are called *rows* of \mathbf{A} , and the $n \times 1$ matrices

$$\begin{bmatrix} a_{1j} \\ a_{2j} \\ \vdots \\ a_{nj} \end{bmatrix}$$

are called *columns* of \mathbf{A} . An $n \times m$ matrix thus consists of n rows and m columns; a_{ij} denotes the *element*, or *entry*, of \mathbf{A} in the i th row and j th column. A matrix consisting of just one row is called a *row vector*, whereas a matrix of just one column is called a *column vector*. The elements of a vector are frequently called *components* of the vector. When the size of the matrix is clear from the context, we sometimes write $\mathbf{A} = (a_{ij})$.

A matrix with the same number of rows as columns is a *square* matrix, and the number of rows and columns is the *order* of the matrix. The diagonal of an $n \times n$ square matrix \mathbf{A} from a_{11} to a_{nn} is called the *main*, or *principal*, *diagonal*. The word *diagonal* with no modifier usually means the main diagonal. The *transpose* of a matrix \mathbf{A} is the matrix that results from interchanging the rows and columns of \mathbf{A} . It is

usually denoted by \mathbf{A}^T . A matrix \mathbf{A} such that $\mathbf{A} = \mathbf{A}^T$ is said to be *symmetric*. The *conjugate transpose* of \mathbf{A} is the matrix that results from replacing each element of \mathbf{A}^T by its complex conjugate, and is usually denoted by \mathbf{A}^H . A matrix such that $\mathbf{A} = \mathbf{A}^H$ is said to be *Hermitian*.

A square matrix $\mathbf{A} = (a_{ij})$ is *lower triangular* if $a_{ij} = 0$ for $j > i$ and is *upper triangular* if $a_{ij} = 0$ for $j < i$. A matrix that is both upper and lower triangular is a *diagonal* matrix. The $n \times n$ *identity matrix* is the $n \times n$ diagonal matrix in which each element of the main diagonal is 1. It is traditionally denoted \mathbf{I}_n , or simply \mathbf{I} when the order is clear from the context.

218.2 Algebra of Matrices

The sum and difference of two matrices \mathbf{A} and \mathbf{B} are defined whenever \mathbf{A} and \mathbf{B} have the same size. In that case $\mathbf{C} = \mathbf{A} \pm \mathbf{B}$ is defined by $\mathbf{C} = (c_{ij}) = (a_{ij} \pm b_{ij})$. The product $t\mathbf{A}$ of a scalar t (real or complex number) and a matrix \mathbf{A} is defined by $t\mathbf{A} = (ta_{ij})$. If \mathbf{A} is an $n \times m$ matrix and \mathbf{B} is an $m \times p$ matrix, the product $\mathbf{C} = \mathbf{AB}$ is defined to be the $n \times p$ matrix $\mathbf{C} = (c_{ij})$ given by $c_{ij} = \sum_{k=1}^m a_{ik}b_{kj}$. Note that the product of an $n \times m$ matrix and an $m \times p$ matrix is an $n \times p$ matrix, and the product is defined only when the number of columns of the first factor is the same as the number of rows of the second factor. Matrix multiplication is, in general, associative: $\mathbf{A}(\mathbf{BC}) = (\mathbf{AB})\mathbf{C}$. It also distributes over addition (and subtraction):

$$\mathbf{A}(\mathbf{B} + \mathbf{C}) = \mathbf{AB} + \mathbf{AC} \text{ and } (\mathbf{A} + \mathbf{B})\mathbf{C} = \mathbf{AC} + \mathbf{BC}$$

It is, however, not in general true that $\mathbf{AB} = \mathbf{BA}$, even in case both products are defined. It is clear that $(\mathbf{A} + \mathbf{B})^T = \mathbf{A}^T + \mathbf{B}^T$ and $(\mathbf{A} + \mathbf{B})^H = \mathbf{A}^H + \mathbf{B}^H$. It is also true, but not so obvious perhaps, that $(\mathbf{AB})^T = \mathbf{B}^T\mathbf{A}^T$ and $(\mathbf{AB})^H = \mathbf{B}^H\mathbf{A}^H$.

The $n \times n$ identity matrix \mathbf{I} has the property that $\mathbf{IA} = \mathbf{AI} = \mathbf{A}$ for every $n \times n$ matrix \mathbf{A} . If \mathbf{A} is square, and if there is a matrix \mathbf{B} such that $\mathbf{AB} = \mathbf{BA} = \mathbf{I}$, then \mathbf{B} is called the *inverse* of \mathbf{A} and is denoted \mathbf{A}^{-1} . This terminology and notation are justified by the fact that a matrix can have at most one inverse. A matrix having an inverse is said to be *invertible*, or *nonsingular*, while a matrix not having an inverse is said to be *noninvertible*, or *singular*. The product of two invertible matrices is invertible and, in fact, $(\mathbf{AB})^{-1} = \mathbf{B}^{-1}\mathbf{A}^{-1}$. The sum of two invertible matrices is, obviously, not necessarily invertible.

218.3 Systems of Equations

The system of n linear equations in m unknowns

$$\begin{aligned} a_{11}x_1 + a_{12}x_2 + a_{13}x_3 + \cdots + a_{1m}x_m &= b_1 \\ a_{21}x_1 + a_{22}x_2 + a_{23}x_3 + \cdots + a_{2m}x_m &= b_2 \\ &\vdots \\ a_{n1}x_1 + a_{n2}x_2 + a_{n3}x_3 + \cdots + a_{nm}x_m &= b_n \end{aligned}$$

may be written $\mathbf{Ax} = \mathbf{b}$, where $\mathbf{A} = (a_{ij})$, $\mathbf{x} = [x_1 \ x_2 \ \dots \ x_m]^T$, and $\mathbf{b} = [b_1 \ b_2 \ \dots \ b_n]^T$. Thus \mathbf{A} is an $n \times m$ matrix, and \mathbf{x} and \mathbf{b} are column vectors of the appropriate sizes.

The matrix \mathbf{A} is called the *coefficient matrix* of the system. Let us first suppose the coefficient matrix is square; that is, there are an equal number of equations and unknowns. If \mathbf{A} is upper triangular, it is quite easy to find all solutions of the system. The i th equation will contain only the unknowns x_i, x_{i+1}, \dots, x_n , and one simply solves the equations in reverse order: the last equation is solved for x_n ; the result is substituted into the $(n - 1)$ st equation, which is then solved for x_{n-1} ; these values of x_n and x_{n-1} are substituted in the $(n - 2)$ th equation, which is solved for x_{n-2} , and so on. This procedure is known as *back substitution*.

The strategy for solving an arbitrary system is to find an upper-triangular system equivalent with it and solve this upper-triangular system using back substitution. First, suppose the element $a_{11} \neq 0$. We may rearrange the equations to ensure this, unless, of course the first column of \mathbf{A} is all 0's. In this case, proceed to the next step, to be described later. For each $i \geq 2$ let $m_{i1} = a_{i1}/a_{11}$. Now replace the i th equation by the result of multiplying the first equation by m_{i1} and subtracting the new equation from the i th equation. Thus,

$$a_{i1}x_1 + a_{i2}x_2 + a_{i3}x_3 + \cdots + a_{im}x_m = b_i$$

is replaced by

$$0 \cdot x_1 + (a_{i2} + m_{i1}a_{12})x_2 + (a_{i3} + m_{i1}a_{13})x_3 + \cdots + (a_{im} + m_{i1}a_{1m})x_m = b_i + m_{i1}b_1$$

After this is done for all $i = 2, 3, \dots, n$, the equivalent system,

$$\begin{aligned} a_{11}x_1 + a_{12}x_2 + a_{13}x_3 + \cdots + a_{1n}x_n &= b_1 \\ 0 \cdot x_1 + a'_{22}x_2 + a'_{23}x_3 + \cdots + a'_{2n}x_n &= b'_2 \\ 0 \cdot x_1 + a'_{32}x_2 + a'_{33}x_3 + \cdots + a'_{3n}x_n &= b'_3 \\ &\vdots \\ 0 \cdot x_1 + a'_{n2}x_2 + a'_{n3}x_3 + \cdots + a'_{nn}x_n &= b'_n \end{aligned}$$

results, in which all entries in the first column below a_{11} are 0. (Note that if all entries in the first column were 0 to begin with, then $a_{11} = 0$ also.) This procedure is now repeated for the $(n-1) \times (n-1)$ system

$$\begin{aligned} a'_{22}x_2 + a'_{23}x_3 + \cdots + a'_{2n}x_n &= b'_2 \\ a'_{32}x_2 + a'_{33}x_3 + \cdots + a'_{3n}x_n &= b'_3 \\ &\vdots \\ a'_{n2}x_2 + a'_{n3}x_3 + \cdots + a'_{nn}x_n &= b'_n \end{aligned}$$

to obtain an equivalent system in which all entries of the coefficient matrix below a'_{22} are 0. Continuing, we obtain an upper-triangular system $\mathbf{U}\mathbf{x} = \mathbf{c}$ equivalent with the original system. This procedure is known as *Gaussian elimination*. The numbers m_{ij} are known as the *multipliers*.

Essentially the same procedure may be used in case the coefficient matrix is not square. If the coefficient matrix is not square, we may make it square by appending either rows or columns of 0's as needed. Appending rows of 0's and appending 0's to make \mathbf{b} have the appropriate size is equivalent to appending equations $0 = 0$ to the system. Clearly the new system has precisely the same solutions as the original system. Appending columns of 0's and adjusting the size of \mathbf{x} appropriately yields a new system with additional unknowns, each appearing only with coefficient 0, thus not affecting the solutions of the original system. In either case, we may assume the coefficient matrix is square, and apply the Gaussian elimination procedure.

Suppose the matrix \mathbf{A} is invertible. Then, if there were no row interchanges in carrying out the above Gaussian elimination procedure, we have the *LU factorization* of the matrix \mathbf{A} :

$$\mathbf{A} = \mathbf{LU}$$

where \mathbf{U} is the upper-triangular matrix produced by elimination and \mathbf{L} is the lower-triangular matrix given by

$$\mathbf{L} = \begin{bmatrix} 1 & 0 & \cdots & \cdots 0 \\ m_{21} & 1 & 0 & \cdots 0 \\ \vdots & & \ddots & \\ m_{n1} & m_{n2} & \cdots & 1 \end{bmatrix}$$

A permutation \mathbf{P}_{ij} matrix is an $n \times n$ matrix such that $\mathbf{P}_{ij}\mathbf{A}$ is the matrix that results from exchanging row i and j of the matrix \mathbf{A} . The matrix \mathbf{P}_{ij} is the matrix that results from exchanging rows i and j of the identity matrix. A product \mathbf{P} of such matrices \mathbf{P}_{ij} is called a *permutation* matrix. If row interchanges are required in the Gaussian elimination procedure, then we have the factorization

$$\mathbf{PA} = \mathbf{LU}$$

where \mathbf{P} is the permutation matrix giving the required row exchanges.

218.4 Vector Spaces

The collection of all column vectors with n real components is *Euclidean n -space*, and is denoted \mathbf{R}^n . The collection of column vectors with n complex components is denoted \mathbf{C}^n . We shall use *vector space* to mean either \mathbf{R}^n or \mathbf{C}^n . In discussing the space \mathbf{R}^n , the word *scalar* will mean a real number, and in discussing the space \mathbf{C}^n , it will mean a complex number. A subset \mathbf{S} of a vector space is a *subspace* such that if \mathbf{u} and \mathbf{v} are vectors in \mathbf{S} , and if c is any scalar, then $\mathbf{u} + \mathbf{v}$ and $c\mathbf{u}$ are in \mathbf{S} . We shall sometimes use the word *space* to mean a subspace. If $B = \{\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_k\}$ is a collection of vectors in a vector space, then the set \mathbf{S} consisting of all vectors $c_1\mathbf{v}_1 + c_2\mathbf{v}_2 + \dots + c_m\mathbf{v}_m$ for all scalars c_1, c_2, \dots, c_m is a subspace, called the *span* of B . A collection $\{\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_m\}$ of vectors $c_1\mathbf{v}_1 + c_2\mathbf{v}_2 + \dots + c_m\mathbf{v}_m$ is a *linear combination* of B . If \mathbf{S} is a subspace and $B = \{\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_m\}$ is a subset of \mathbf{S} such that \mathbf{S} is the span of B , then B is said to *span* \mathbf{S} .

A collection $\{\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_m\}$ of n -vectors is *linearly dependent* if there exist scalars c_1, c_2, \dots, c_m , not all zero, such that $c_1\mathbf{v}_1 + c_2\mathbf{v}_2 + \dots + c_m\mathbf{v}_m = \mathbf{0}$. A collection of vectors that is not linearly dependent is said to be *linearly independent*. The modifier *linearly* is frequently omitted, and we speak simply of dependent and independent collections. A linearly independent collection of vectors in a space \mathbf{S} that span \mathbf{S} is a *basis* of \mathbf{S} . Every basis of a space \mathbf{S} contains the same number of vectors; this number is the *dimension* of \mathbf{S} . The dimension of the space consisting of only the zero vector is 0. The collection $B = \{\mathbf{e}_1, \mathbf{e}_2, \dots, \mathbf{e}_n\}$, where $\mathbf{e}_1 = [1, 0, 0, \dots, 0]^T$, $\mathbf{e}_2 = [0, 1, 0, \dots, 0]^T$, and so forth (\mathbf{e}_i has 1 as its i th component and zero for all other components) is a basis for the spaces \mathbf{R}^n and \mathbf{C}^n . This is the *standard basis* for these spaces. The dimension of these spaces is thus n . In a space \mathbf{S} of dimension n , no collection of fewer than n vectors can span \mathbf{S} , and no collection of more than n vectors in \mathbf{S} can be independent.

218.5 Rank and Nullity

The *column space* of an $n \times m$ matrix \mathbf{A} is the subspace of \mathbf{R}^n or \mathbf{C}^n spanned by the columns of \mathbf{A} . The *row space* is the subspace of \mathbf{R}^m or \mathbf{C}^m spanned by the rows of \mathbf{A} . Note that for any vector $\mathbf{x} = [x_1 \ x_2 \ \dots \ x_m]^T$,

$$\mathbf{Ax} = x_1 \begin{bmatrix} a_{11} \\ a_{21} \\ \vdots \\ a_{n1} \end{bmatrix} + x_2 \begin{bmatrix} a_{12} \\ a_{22} \\ \vdots \\ a_{n2} \end{bmatrix} + \cdots + x_m \begin{bmatrix} a_{1m} \\ a_{2m} \\ \vdots \\ a_{nm} \end{bmatrix}$$

so that the column space is the collection of all vectors \mathbf{Ax} , and thus the system $\mathbf{Ax} = \mathbf{b}$ has a solution if and only if \mathbf{b} is a member of the \mathbf{A} column space.

The dimension of the column space is the *rank* of \mathbf{A} . The row space has the same dimension as the column space. The set of all solutions of the system $\mathbf{Ax} = \mathbf{0}$ is a subspace called the *null space* of \mathbf{A} , and the dimension of this null space is the *nullity* of \mathbf{A} . A fundamental result in matrix theory is the fact that, for an $n \times m$ matrix \mathbf{A} ,

$$\text{rank } \mathbf{A} + \text{nullity } \mathbf{A} = m$$

The difference of any two solutions of the linear system $\mathbf{Ax} = \mathbf{b}$ is a member of the null space of \mathbf{A} . Thus this system has at most one solution if and only if the nullity of \mathbf{A} is zero. If the system is square (i.e., if \mathbf{A} is $n \times n$), then there will be a solution for every right-hand side \mathbf{b} if and only if the collection of columns of \mathbf{A} is linearly independent, which is the same as saying the rank of \mathbf{A} is n . In this case the nullity must be zero. Thus, for any \mathbf{b} , the square system $\mathbf{Ax} = \mathbf{b}$ has exactly one solution if and only if $\text{rank } \mathbf{A} = n$. In other words, the $n \times n$ matrix \mathbf{A} is invertible if and only if $\text{rank } \mathbf{A} = n$.

218.6 Orthogonality and Length

The *inner product* of two vectors \mathbf{x} and \mathbf{y} is the scalar $\mathbf{x}^H \mathbf{y}$. The *length*, or *norm*, $\|\mathbf{x}\|$, of the vector \mathbf{x} is given by $\|\mathbf{x}\| = \sqrt{\mathbf{x}^H \mathbf{x}}$. A *unit vector* is a vector of norm 1. Two vectors \mathbf{x} and \mathbf{y} are *orthogonal* if $\mathbf{x}^H \mathbf{y} = 0$. A collection of vectors $\{\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_m\}$ in a space \mathbf{S} is said to be an *orthonormal* collection if $\mathbf{v}_i^H \mathbf{v}_j = 0$ for $i \neq j$ and $\mathbf{v}_i^H \mathbf{v}_i = 1$. An orthonormal collection is necessarily linearly independent. If \mathbf{S} is a subspace (of \mathbf{R}^n or \mathbf{C}^n) spanned by the orthonormal collection $\{\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_m\}$, then the *projection* of a vector \mathbf{x} onto \mathbf{S} is the vector

$$\text{proj}(\mathbf{x}; \mathbf{S}) = (\mathbf{x}^H \mathbf{v}_1) \mathbf{v}_1 + (\mathbf{x}^H \mathbf{v}_2) \mathbf{v}_2 + \dots + (\mathbf{x}^H \mathbf{v}_m) \mathbf{v}_m$$

The projection of \mathbf{x} onto \mathbf{S} minimizes the function $f(\mathbf{y}) = \|\mathbf{x} - \mathbf{y}\|^2$ for $\mathbf{y} \in \mathbf{S}$. In other words the projection of \mathbf{x} onto \mathbf{S} is the vector in \mathbf{S} that is “closest” to \mathbf{x} .

If \mathbf{b} is a vector and \mathbf{A} is an $n \times m$ matrix, then a vector \mathbf{x} minimizes $\|\mathbf{b} - \mathbf{Ax}\|^2$ if and only if it is a solution of $\mathbf{A}^H \mathbf{Ax} = \mathbf{A}^H \mathbf{b}$. This system of equations is called the *system of normal equations* for the least-squares problem of minimizing $\|\mathbf{b} - \mathbf{Ax}\|^2$.

If \mathbf{A} is an $n \times m$ matrix and $\text{rank } \mathbf{A} = k$, then there is a $n \times k$ matrix \mathbf{Q} whose columns form an orthonormal basis for the column space of \mathbf{A} and a $k \times m$ upper-triangular matrix \mathbf{R} of rank k such that

$$\mathbf{A} = \mathbf{QR}$$

This is called the *QR factorization* of \mathbf{A} . It now follows that \mathbf{x} minimizes $\|\mathbf{b} - \mathbf{Ax}\|^2$ if and only if it is a solution of the upper-triangular system $\mathbf{Rx} = \mathbf{Q}^H \mathbf{b}$.

If $\{\mathbf{w}_1, \mathbf{w}_2, \dots, \mathbf{w}_m\}$ is a basis for a space \mathbf{S} , the following procedure produces an orthonormal basis $\{\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_m\}$ for \mathbf{S} :

$$\text{Set } \mathbf{v}_1 = \mathbf{w}_1 / \|\mathbf{w}_1\|.$$

$$\text{Let } \tilde{\mathbf{v}}_2 = \mathbf{w}_2 - \text{proj}(\mathbf{w}_2; \mathbf{S}_1), \text{ where } \mathbf{S}_1 \text{ is the span of } \{\mathbf{v}_1\}; \text{ set } \mathbf{v}_2 = \tilde{\mathbf{v}}_2 / \|\tilde{\mathbf{v}}_2\|.$$

$$\text{Next, let } \tilde{\mathbf{v}}_3 = \mathbf{w}_3 - \text{proj}(\mathbf{w}_3; \mathbf{S}_2), \text{ where } \mathbf{S}_2 \text{ is the span of } \{\mathbf{v}_1, \mathbf{v}_2\}; \text{ set } \mathbf{v}_3 = \tilde{\mathbf{v}}_3 / \|\tilde{\mathbf{v}}_3\|.$$

And so on: $\tilde{\mathbf{v}}_i = \mathbf{w}_i - \text{proj}(\mathbf{w}_i; \mathbf{S}_{i-1})$, where \mathbf{S}_{i-1} is the span of $\{\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_{i-1}\}$; set $\mathbf{v}_i = \tilde{\mathbf{v}}_i / \|\tilde{\mathbf{v}}_i\|$. This is the *Gram-Schmidt procedure*.

If the collection of columns of a square matrix is an orthonormal collection, the matrix is called a *unitary matrix*. In the event that the matrix is a real matrix, it is usually called an *orthogonal matrix*. A unitary matrix \mathbf{U} is invertible, and $\mathbf{U}^{-1} = \mathbf{U}^H$. (In the real case an orthogonal matrix \mathbf{Q} is invertible, and $\mathbf{Q}^{-1} = \mathbf{Q}^T$.)

218.7 Determinants

The *determinant* of a square matrix is defined inductively. First, suppose the determinant $\det \mathbf{A}$ has been defined for all square matrices of order $< n$. Then

$$\det \mathbf{A} = a_{11} \mathbf{C}_{11} + a_{12} \mathbf{C}_{12} + \cdots + a_{1n} \mathbf{C}_{1n}$$

where the numbers \mathbf{C}_{ij} are *cofactors* of the matrix \mathbf{A} :

$$\mathbf{C}_{ij} = (-1)^{i+j} \det \mathbf{M}_{ij}$$

where \mathbf{M}_{ij} is the $(n-1) \times (n-1)$ matrix obtained by deleting the i th row and j th column of \mathbf{A} . Now $\det \mathbf{A}$ is defined to be the only entry of a matrix of order 1. Thus, for a matrix of order 2, we have

$$\det \begin{bmatrix} a & b \\ c & d \end{bmatrix} = ad - bc$$

There are many interesting but not obvious properties of determinants. It is true that

$$\det \mathbf{A} = a_{i1} \mathbf{C}_{i1} + a_{i2} \mathbf{C}_{i2} + \cdots + a_{in} \mathbf{C}_{in}$$

for any $1 \leq i \leq n$. It is also true that $\det \mathbf{A} = \det \mathbf{A}^T$, so that we have

$$\det \mathbf{A} = a_{1j} \mathbf{C}_{1j} + a_{2j} \mathbf{C}_{2j} + \cdots + a_{nj} \mathbf{C}_{nj}$$

for any $1 \leq j \leq n$.

If \mathbf{A} and \mathbf{B} are matrices of the same order, then $\det \mathbf{AB} = (\det \mathbf{A})(\det \mathbf{B})$, and the determinant of any identity matrix is 1. Perhaps the most important property of the determinant is the fact that a matrix is invertible if and only if its determinant is not zero.

218.8 Eigenvalues and Eigenvectors

If \mathbf{A} is a square matrix, and $\mathbf{A}\mathbf{v} = \lambda\mathbf{v}$ for a scalar λ and a nonzero \mathbf{v} , then λ is an *eigenvalue* of \mathbf{A} and \mathbf{v} is an *eigenvector* of \mathbf{A} that *corresponds* to λ . Any nonzero linear combination of eigenvectors corresponding to the same eigenvalue λ is also an eigenvector corresponding to λ . The collection of all eigenvectors corresponding to a given eigenvalue λ is thus a subspace, called an *eigenspace* of \mathbf{A} . A collection of eigenvectors corresponding to different eigenvalues is necessarily linear-independent. It follows that a matrix of order n can have at most n distinct eigenvectors. In fact, the eigenvalues of \mathbf{A} are the roots of the n th degree polynomial equation

$$\det(\mathbf{A} - \lambda\mathbf{I}) = 0$$

called the *characteristic equation* of \mathbf{A} . (Eigenvalues and eigenvectors are frequently called *characteristic values* and *characteristic vectors*.)

If the n th order matrix \mathbf{A} has an independent collection of n eigenvectors, then \mathbf{A} is said to have a *full set* of eigenvectors. In this case there is a set of eigenvectors of \mathbf{A} that is a basis for \mathbf{R}^n or, in the complex case, \mathbf{C}^n . In case there are n distinct eigenvalues of \mathbf{A} , then, of course, \mathbf{A} has a full set of eigenvectors. If there are fewer than n distinct eigenvalues, then \mathbf{A} may or may not have a full set of eigenvectors. If there is a full set of eigenvectors, then

$$\mathbf{D} = \mathbf{S}^{-1}\mathbf{A}\mathbf{S} \quad \text{or} \quad \mathbf{A} = \mathbf{S}\mathbf{D}\mathbf{S}^{-1}$$

where \mathbf{D} is a diagonal matrix with the eigenvalues of \mathbf{A} on the diagonal, and \mathbf{S} is a matrix whose columns are the full set of eigenvectors. If \mathbf{A} is symmetric, there are n real distinct eigenvalues of \mathbf{A} and the corresponding eigenvectors are orthogonal. There is thus an orthonormal collection of eigenvectors that span \mathbf{R}^n , and we have

$$\mathbf{A} = \mathbf{Q}\mathbf{D}\mathbf{Q}^T \quad \text{and} \quad \mathbf{D} = \mathbf{Q}^T\mathbf{A}\mathbf{Q}$$

where \mathbf{Q} is a real orthogonal matrix and \mathbf{D} is diagonal. For the complex case, if \mathbf{A} is Hermitian, we have

$$\mathbf{A} = \mathbf{U}\mathbf{D}\mathbf{U}^H \quad \text{and} \quad \mathbf{D} = \mathbf{U}^H\mathbf{A}\mathbf{U}$$

where \mathbf{U} is a unitary matrix and \mathbf{D} is a *real* diagonal matrix. (A Hermitian matrix also has n distinct real eigenvalues.)

219.1 Basic Definitions

A vector is a directed line segment, with two vectors being equal if they have the same length and the same direction. More precisely, a *vector* is an equivalence class of directed line segments, where two directed segments are equivalent if they have the same length and the same direction. The *length* of a vector is the common length of its directed segments, and the *angle between* vectors is the angle between any of their segments. The length of a vector \mathbf{u} is denoted $|\mathbf{u}|$. There is defined a distinguished vector having zero length, which is usually denoted $\mathbf{0}$. It is frequently useful to visualize a directed segment as an arrow; we then speak of the nose and the tail of the segment. The *sum* $\mathbf{u} + \mathbf{v}$ of two vectors \mathbf{u} and \mathbf{v} is defined by taking directed segments from \mathbf{u} and \mathbf{v} and placing the tail of the segment representing \mathbf{v} at the nose of the segment representing \mathbf{u} and defining $\mathbf{u} + \mathbf{v}$ to be the vector determined by the segment from the tail of the \mathbf{u} representative to the nose of the \mathbf{v} representative. It is easy to see that $\mathbf{u} + \mathbf{v}$ is well defined and that $\mathbf{u} + \mathbf{v} = \mathbf{v} + \mathbf{u}$. Subtraction is the inverse operation of addition. Thus, the *difference* $\mathbf{u} - \mathbf{v}$ of two vectors is defined to be the vector that when added to \mathbf{v} gives \mathbf{u} . In other words, if we take a segment from \mathbf{u} and a segment from \mathbf{v} and place their tails together, the difference is the segment from the nose of \mathbf{v} to the nose of \mathbf{u} . The zero vector behaves as one might expect: $\mathbf{u} + \mathbf{0} = \mathbf{u}$, and $\mathbf{u} - \mathbf{u} = \mathbf{0}$. Addition is associative: $\mathbf{u} + (\mathbf{v} + \mathbf{w}) = (\mathbf{u} + \mathbf{v}) + \mathbf{w}$.

To distinguish them from vectors, the real numbers are called *scalars*. The product $t\mathbf{u}$ of a scalar t and a vector \mathbf{u} is defined to be the vector having length $|t| |\mathbf{u}|$ and direction the same as \mathbf{u} if $t > 0$, and the opposite direction if $t < 0$. If $t = 0$, then $t\mathbf{u}$ is defined to be the zero vector. Note that $t(\mathbf{u} + \mathbf{v}) = t\mathbf{u} + t\mathbf{v}$, and $(t + s)\mathbf{u} = t\mathbf{u} + s\mathbf{u}$. From this it follows that $\mathbf{u} - \mathbf{v} = \mathbf{u} + (-1)\mathbf{v}$.

The *scalar product* $\mathbf{u} \cdot \mathbf{v}$ of two vectors is $|\mathbf{u}||\mathbf{v}| \cos \theta$, where θ is the angle between \mathbf{u} and \mathbf{v} . The scalar product is frequently called the *dot product*. The scalar product distributes over addition:

$$\mathbf{u} \cdot (\mathbf{v} + \mathbf{w}) = \mathbf{u} \cdot \mathbf{v} + \mathbf{u} \cdot \mathbf{w}$$

and it is clear that $(t\mathbf{u}) \cdot \mathbf{v} = t(\mathbf{u} \cdot \mathbf{v})$. The *vector product* $\mathbf{u} \times \mathbf{v}$ of two vectors is defined to be the vector perpendicular to both \mathbf{u} and \mathbf{v} and having length $|\mathbf{u}||\mathbf{v}|\sin \theta$, where θ is the angle between \mathbf{u} and \mathbf{v} . The direction of $\mathbf{u} \times \mathbf{v}$ is the direction a right-hand threaded bolt advances if the vector \mathbf{u} is rotated to \mathbf{v} . The vector product is frequently called the *cross product*. The vector product is both associative and distributive, but not commutative: $\mathbf{u} \times \mathbf{v} = -\mathbf{v} \times \mathbf{u}$.

219.2 Coordinate Systems

Suppose we have a right-handed Cartesian coordinate system in space. For each vector \mathbf{u} , we associate a point in space by placing the tail of a representative of \mathbf{u} at the origin and associating with \mathbf{u} the point at the nose of the segment. Conversely, associated with each point in space is the vector determined by the directed segment from the origin to that point. There is thus a one-to-one correspondence between the points in space and all vectors. The origin corresponds to the zero vector. The coordinates of the point associated with a vector \mathbf{u} are called *coordinates* of \mathbf{u} . One frequently refers to the vector \mathbf{u} and writes $\mathbf{u} = (x, y, z)$, which is, strictly speaking, incorrect, because the left side of this equation is a vector and the right side gives the coordinates of a point in space. What is meant is that (x, y, z) are the coordinates of the point associated with \mathbf{u} under the correspondence described. In terms of coordinates, for $\mathbf{u} = (u_1, u_2, u_3)$ and $\mathbf{v} = (v_1, v_2, v_3)$, we have

$$\mathbf{u} + \mathbf{v} = (u_1 + v_1, u_2 + v_2, u_3 + v_3)$$

$$t\mathbf{u} = (tu_1, tu_2, tu_3)$$

$$\mathbf{u} \cdot \mathbf{v} = u_1v_1 + u_2v_2 + u_3v_3$$

$$\mathbf{u} \times \mathbf{v} = (u_2v_3 - v_2u_3, u_3v_1 - v_3u_1, u_1v_2 - v_1u_2)$$

The *coordinate vectors* \mathbf{i} , \mathbf{j} , and \mathbf{k} are the unit vectors $\mathbf{i} = (1, 0, 0)$, $\mathbf{j} = (0, 1, 0)$, and $\mathbf{k} = (0, 0, 1)$. Any vector $\mathbf{u} = (u_1, u_2, u_3)$ is thus a linear combination of these coordinate vectors: $\mathbf{u} = u_1\mathbf{i} + u_2\mathbf{j} + u_3\mathbf{k}$. A convenient form for the vector product is the formal determinant

$$\mathbf{u} \times \mathbf{v} = \det \begin{bmatrix} \mathbf{i} & \mathbf{j} & \mathbf{k} \\ u_1 & u_2 & u_3 \\ v_1 & v_2 & v_3 \end{bmatrix}$$

219.3 Vector Functions

A *vector function* \mathbf{F} of one variable is a rule that associates a vector $\mathbf{F}(t)$ with each real number t in some set, called the *domain* of \mathbf{F} . The expression $\lim_{t \rightarrow t_0} \mathbf{F}(t) = \mathbf{a}$ means that for any $\varepsilon > 0$, there is a $\delta > 0$ such that $|\mathbf{F}(t) - \mathbf{a}| < \varepsilon$ whenever $0 < |t - t_0| < \delta$. If $\mathbf{F}(t) = [x(t), y(t), z(t)]$ and $\mathbf{a} = (a_1, a_2, a_3)$, then $\lim_{t \rightarrow t_0} \mathbf{F}(t) = \mathbf{a}$ if and only if

$$\lim_{t \rightarrow t_0} x(t) = a_1$$

$$\lim_{t \rightarrow t_0} y(t) = a_2$$

$$\lim_{t \rightarrow t_0} z(t) = a_3$$

A vector function \mathbf{F} is *continuous* at t_0 if $\lim_{t \rightarrow t_0} \mathbf{F}(t) = \mathbf{F}(t_0)$. The vector function \mathbf{F} is continuous at t_0 if and only if each of the coordinates $x(t)$, $y(t)$, and $z(t)$ is continuous at t_0 .

The function \mathbf{F} is *differentiable* at t_0 if the limit

$$\lim_{h \rightarrow 0} \frac{1}{h} [\mathbf{F}(t+h) - \mathbf{F}(t)]$$

exists. This limit is called the *derivative* of \mathbf{F} at t_0 and is usually written $\mathbf{F}'(t_0)$, or $(d\mathbf{F}/dt)(t_0)$. The vector function \mathbf{F} is differentiable at t_0 if and only if each of its coordinate functions is differentiable at t_0 . Moreover, $(d\mathbf{F}/dt)(t_0) = [(dx/dt)(t_0), (dy/dt)(t_0), (dz/dt)(t_0)]$. The usual rules for derivatives of real valued functions all hold for vector functions. Thus, if \mathbf{F} and \mathbf{G} are vector functions and s is a scalar function, then

$$\begin{aligned} \frac{d}{dt}(\mathbf{F} + \mathbf{G}) &= \frac{d\mathbf{F}}{dt} + \frac{d\mathbf{G}}{dt} \\ \frac{d}{dt}(s\mathbf{F}) &= s \frac{d\mathbf{F}}{dt} + \frac{ds}{dt} \mathbf{F} \\ \frac{d}{dt}(\mathbf{F} \cdot \mathbf{G}) &= \mathbf{F} \cdot \frac{d\mathbf{G}}{dt} + \frac{d\mathbf{F}}{dt} \cdot \mathbf{G} \\ \frac{d}{dt}(\mathbf{F} \times \mathbf{G}) &= \mathbf{F} \times \frac{d\mathbf{G}}{dt} + \frac{d\mathbf{F}}{dt} \times \mathbf{G} \end{aligned}$$

If \mathbf{R} is a vector function defined for t in some interval, then, as t varies, with the tail of \mathbf{R} at the origin, the nose traces out some object C in space. For nice functions \mathbf{R} , the object C is a *curve*. If $\mathbf{R}(t) = [x(t), y(t), z(t)]$, then the equations

$$\begin{aligned} x &= x(t) \\ y &= y(t) \\ z &= z(t) \end{aligned}$$

are called *parametric equations* of C . At points where \mathbf{R} is differentiable, the derivative $d\mathbf{R}/dt$ is a vector *tangent* to the curve. The unit vector $\mathbf{T} = (d\mathbf{R}/dt)/|d\mathbf{R}/dt|$ is called the *unit tangent vector*. If \mathbf{R} is differentiable and if the length of the arc of curve described by \mathbf{R} between $\mathbf{R}(a)$ and $\mathbf{R}(t)$ is given by $s(t)$, then

$$\frac{ds}{dt} = \left| \frac{d\mathbf{R}}{dt} \right|$$

Thus, the length L of the arc from $\mathbf{R}(t_0)$ to $\mathbf{R}(t_1)$ is

$$L = \int_{t_0}^{t_1} \frac{ds}{dt} dt = \int_{t_0}^{t_1} \left| \frac{d\mathbf{R}}{dt} \right| dt$$

The vector $d\mathbf{T}/ds = (d\mathbf{T}/dt)/(ds/dt)$ is perpendicular to the unit tangent \mathbf{T} , and the number $\kappa = |d\mathbf{T}/ds|$ is the *curvature* of C . The unit vector $\mathbf{N} = (1/\kappa)(d\mathbf{T}/ds)$ is the *principal normal*. The vector $\mathbf{B} = \mathbf{T} \times \mathbf{N}$ is the *binormal*, and $d\mathbf{B}/ds = -\tau\mathbf{N}$. The number τ is the *torsion*. Note that C is a plane curve if and only if τ is zero for all t .

A *vector function* \mathbf{F} of two variables is a rule that assigns a vector $\mathbf{F}(s, t)$ to each point (s, t) in some subset of the plane, called the *domain* of \mathbf{F} . If $\mathbf{R}(s, t)$ is defined for all (s, t) in some region D of the plane, then as the point (s, t) varies over D , with its tail at the origin, the nose of $\mathbf{R}(s, t)$ traces out an object in space. For a nice function \mathbf{R} , this object is a *surface*, S . The partial derivatives $(\partial\mathbf{R}/\partial s)(s, t)$ and $(\partial\mathbf{R}/\partial t)(s, t)$

are tangent to the surface at $\mathbf{R}(s,t)$, and the vector $(\partial\mathbf{R}/\partial s) \times (\partial\mathbf{R}/\partial t)$ is thus *normal* to the surface. Of course, $(\partial\mathbf{R}/\partial t) \times (\partial\mathbf{R}/\partial s) = -(\partial\mathbf{R}/\partial s) \times (\partial\mathbf{R}/\partial t)$ is also normal to the surface and points in the direction opposite that of $(\partial\mathbf{R}/\partial s) \times (\partial\mathbf{R}/\partial t)$. By electing one of these normals, we are choosing an *orientation* of the surface. A surface can be oriented only if it has two sides, and the process of orientation consists of choosing which side is “positive” and which is “negative.”

219.4 Gradient, Curl, and Divergence

If $f(x, y, z)$ is a scalar field defined in some region D , the *gradient* of f is the vector function

$$\text{grad } f = \frac{\partial f}{\partial x} \mathbf{i} + \frac{\partial f}{\partial y} \mathbf{j} + \frac{\partial f}{\partial z} \mathbf{k}$$

If $\mathbf{F}(x, y, z) = F_1(x, y, z)\mathbf{i} + F_2(x, y, z)\mathbf{j} + F_3(x, y, z)\mathbf{k}$ is a vector field defined in some region D , then the *divergence* of \mathbf{F} is the scalar function

$$\text{div } \mathbf{F} = \frac{\partial F_1}{\partial x} + \frac{\partial F_2}{\partial y} + \frac{\partial F_3}{\partial z}$$

The curl is the vector function

$$\text{curl } \mathbf{F} = \left(\frac{\partial F_3}{\partial y} - \frac{\partial F_2}{\partial z} \right) \mathbf{i} + \left(\frac{\partial F_1}{\partial z} - \frac{\partial F_3}{\partial x} \right) \mathbf{j} + \left(\frac{\partial F_2}{\partial x} - \frac{\partial F_1}{\partial y} \right) \mathbf{k}$$

In terms of the vector operator del , $\nabla = \mathbf{i}(\partial/\partial x) + \mathbf{j}(\partial/\partial y) + \mathbf{k}(\partial/\partial z)$, we can write

$$\text{grad } f = \nabla f$$

$$\text{div } \mathbf{F} = \nabla \cdot \mathbf{F}$$

$$\text{curl } \mathbf{F} = \nabla \times \mathbf{F}$$

The *Laplacian operator* is $\text{div}(\text{grad}) = \nabla \cdot \nabla = \nabla^2 = (\partial^2/\partial x^2) + (\partial^2/\partial y^2) + (\partial^2/\partial z^2)$.

219.5 Integration

Suppose C is a curve from the point (x_0, y_0, z_0) to the point (x_1, y_1, z_1) and is described by the vector function $\mathbf{R}(t)$ for $t_0 \leq t \leq t_1$. If f is a scalar function (sometimes called a *scalar field*) defined on C , then the integral of f over C is

$$\int_C f(x, y, z) \, ds = \int_{t_0}^{t_1} f[\mathbf{R}(t)] \left| \frac{d\mathbf{R}}{dt} \right| dt$$

If \mathbf{F} is a vector function (sometimes called a *vector field*) defined on C , then the integral of \mathbf{F} over C is

$$\int_C \mathbf{F}(x, y, z) \cdot d\mathbf{R} = \int_{t_0}^{t_1} \mathbf{F}[\mathbf{R}(t)] \cdot \frac{d\mathbf{R}}{dt} dt$$

These integrals are called *line integrals*.

In case there is a scalar function f such that $\mathbf{F} = \text{grad } f$, then the line integral

$$\int_C \mathbf{F}(x, y, z) \cdot d\mathbf{R} = f[\mathbf{R}(t_1)] - f[\mathbf{R}(t_0)]$$

The value of the integral thus depends only on the end points of the curve C and not on the curve C itself. The integral is said to be *path independent*. The function f is called a *potential function* for the vector field \mathbf{F} , and \mathbf{F} is said to be a conservative field. A vector field \mathbf{F} with domain D is conservative if and only if the integral of \mathbf{F} around every closed curve in D is zero. If the domain D is simply connected (i.e., every closed curve in D can be continuously deformed in D to a point), then \mathbf{F} is conservative if and only if $\text{curl } \mathbf{F} = 0$ in D .

Suppose S is a surface described by $\mathbf{R}(s, t)$ for (s, t) in a region D of the plane. If f is a scalar function defined on D , then the integral of f over S is given by

$$\iint_S f(x, y, z) dS = \iint_D f[\mathbf{R}(s, t)] \left| \frac{\partial \mathbf{R}}{\partial s} \times \frac{\partial \mathbf{R}}{\partial t} \right| ds dt$$

If \mathbf{F} is a vector function defined on S , and if an orientation for S is chosen, then the integral of \mathbf{F} over S , sometimes called the **flux** of \mathbf{F} through S , is

$$\iint_S \mathbf{F}(x, y, z) \cdot d\mathbf{S} = \iint_D \mathbf{F}[\mathbf{R}(s, t)] \cdot \left(\frac{\partial \mathbf{R}}{\partial s} \times \frac{\partial \mathbf{R}}{\partial t} \right) ds dt$$

219.6 Integral Theorems

Suppose \mathbf{F} is a vector field with a closed domain D bounded by the surface S oriented so that the normal points out from D . Then the *divergence theorem* states that

$$\iiint_D \text{div } \mathbf{F} dV = \iint_S \mathbf{F} \cdot d\mathbf{S}$$

If S is an orientable surface bounded by a closed curve C , the orientation of the closed curve C is chosen to be consistent with the orientation of the surface S . Then we have *Stokes's theorem*:

$$\iint_S (\text{curl } \mathbf{F}) \cdot d\mathbf{S} = \oint_C \mathbf{F} \cdot d\mathbf{s}$$

220.1 Basic Definitions and Arithmetic

A *complex number* is an ordered pair $z = (x, y)$ of real numbers x and y . The sum, difference, product, and quotient of two complex numbers $z = (x, y)$ and $w = (u, v)$ are defined by

$$z \pm w = (x \pm u, y \pm v)$$

$$zw = (xu - yv, xv + yu)$$

$$\frac{w}{z} = \left(\frac{xu + yv}{x^2 + y^2}, \frac{xv - yu}{x^2 + y^2} \right)$$

The *real part* of the complex number $z = (x, y)$ is x , and the *imaginary part* of z is y . If $z_1 = (a, 0)$ and $z_2 = (b, 0)$, then $z_1 \pm z_2 = (a \pm b, 0)$, $z_1 z_2 = (ab, 0)$, and $z_1 / z_2 = (a/b, 0)$. Thus, for complex numbers with 0 imaginary part, complex arithmetic coincides with the usual arithmetic for real numbers, and we see that the complex numbers are an extension of the real numbers. In this case, we write simply a for the complex number $(a, 0)$, and so on.

For the complex number $i = (0, 1)$ we have that $i^2 = (-1, 0) \equiv -1$. Now note that for any $z = (x, y)$, it is true that

$$z = (x, y) = (x, 0) + (0, y) = x + iy$$

and the algebra of complex numbers reduces to the usual algebra for real numbers, together with the fact that $i^2 = -1$.

The *conjugate* of a complex number $z = x + iy$ is defined to be $\bar{z} = x - iy$. The *modulus* of z is the real number $|z| = \sqrt{z\bar{z}} = \sqrt{x^2 + y^2}$. We have the following properties of the conjugate and the modulus:

$$\overline{(z \pm w)} = \bar{z} \pm \bar{w}$$

$$\overline{zw} = \bar{z}\bar{w} \quad \text{and} \quad \overline{\left(\frac{w}{z}\right)} = \frac{\bar{w}}{\bar{z}}$$

$$|z + w| \leq |z| + |w|$$

$$|zw| = |z||w| \quad \text{and} \quad \left|\frac{w}{z}\right| = \frac{|w|}{|z|}$$

Considering $z = (x, y)$ to be the rectangular coordinates of a point in the plane establishes a one-to-one correspondence between the set of all complex numbers and the points in the plane. We thus speak of points in the plane as being complex numbers. The usual Euclidean distance $d(z, w)$ between the points z and w is then given by $d(z, w) = |z - w|$. Let (r, θ) be polar coordinates of the point $z = (x, y)$. (We always assume $r \geq 0$.) Then r is, of course, simply $|z|$, the modulus of z . The number θ is called an *argument* of z and is denoted $\arg z$. Thus, $z = r(\cos \theta + i \sin \theta)$. If $w = s(\cos \vartheta + i \sin \vartheta)$, then

$$zw = rs[\cos(\theta + \vartheta) + i \sin(\theta + \vartheta)]$$

$$\frac{z}{w} = \frac{r}{s}[\cos(\theta - \vartheta) + i \sin(\theta - \vartheta)]$$

$$z^n = r^n[\cos n\theta + i \sin n\theta]$$

Note that a complex number has an infinite number of arguments, and $\arg z$ denotes any one of them. Any interval $(a, b]$ of reals of length 2π contains exactly one argument of z . The particular value of $\arg z$ in the interval $(-\pi, \pi]$ is called the *principal value of the argument* and is denoted $\text{Arg } z$.

220.2 Complex Functions

Let \mathbf{C} denote the set of all complex numbers (the *complex plane*). A set $\mathbf{S} \subset \mathbf{C}$ is said to be a *neighborhood* of the point z_0 if there is an $r > 0$ such that $z \in \mathbf{S}$ whenever $|z_0 - z| < r$. The point z_0 is an *interior point* of \mathbf{S} in case \mathbf{S} is a neighborhood of z_0 . A point z_0 is called a *limit point* of a set \mathbf{A} if every neighborhood of z_0 meets \mathbf{A} . A set that is a neighborhood of each of its points is called an *open set*, and a set that contains all its limit points is called a *closed set*.

A function f from a subset of the complex numbers into the complex numbers is called a *complex function*. The statement that the *limit* of f at z_0 is w_0 means that for each $\epsilon > 0$, there is a $\delta > 0$ such that $|f(z) - w_0| < \epsilon$ whenever z is in the domain of f and $|z - z_0| < \delta$. We write

$$\lim_{z \rightarrow z_0} f(z) = w_0$$

Note that it is not required that z_0 be in the domain of f .

The function f is *continuous* at the point z_0 in its domain if $\lim_{z \rightarrow z_0} f(z) = f(z_0)$. If z_0 is an interior point of the domain of f , then f is said to be *differentiable* at z_0 if the limit

$$f'(z_0) = \lim_{z \rightarrow z_0} \frac{f(z) - f(z_0)}{z - z_0}$$

exists. The number $f'(z_0)$ is the *derivative* of f at z_0 .

A complex function of the form $p(z) = a_n z^n + a_{n-1} z^{n-1} + \cdots + a_1 z + a_0$ is called a *polynomial*. A *rational function* r is the quotient of two polynomials: $r(z) = p(z)/q(z)$. A polynomial is continuous and differen-

tiably at every complex number, and a rational function is continuous and differentiable everywhere except at those points z_0 for which $q(z_0) = 0$.

220.3 Analytic Functions

A complex function f is *analytic* on an open set U if it has a derivative at each point of U . The function f is said to be analytic at the point z_0 if it is analytic on some open set containing z_0 . A function analytic on all of the complex plane is an *entire* function. If $f(z) = u(x, y) + iv(x, y)$ is analytic in an open set U , then the real and imaginary parts of $f(z)$ satisfy the Cauchy-Riemann equations:

$$\frac{\partial u}{\partial x} = \frac{\partial v}{\partial y} \quad \text{and} \quad \frac{\partial u}{\partial y} = -\frac{\partial v}{\partial x}$$

and both u and v satisfy *Laplace's equation* in U :

$$\frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} = 0$$

A function that satisfies Laplace's equation in a domain U is said to be *harmonic* in U . Thus, the real and imaginary parts of a function analytic in an open set are harmonic on the same set.

220.4 Integration

An integral of a complex function f is defined on a curve (or *contour*) C in the complex plane and is simply the line integral of f on C . Thus if $z = \gamma(t)$, $a \leq t \leq b$ defines a contour C from the point $z_0 = \gamma(a)$ to the point $z_1 = \gamma(b)$, the *contour integral* of f along C is given by

$$\int_C f(z) dz = \int_a^b f(\gamma(t)) \gamma'(t) dt$$

All of the usual nice linearity properties of integrals hold for complex integrals. Thus,

$$\int_C [c_1 f(z) + c_2 g(z)] dz = c_1 \int_C f(z) dz + c_2 \int_C g(z) dz$$

for any complex numbers c_1 and c_2 . If C_1 and C_2 are contours, then $\int_{C_1+C_2} f(z) dz$ is defined by

$$\int_{C_1+C_2} f(z) dz = \int_{C_1} f(z) dz + \int_{C_2} f(z) dz$$

A contour given by $z = \gamma(t)$, $a \leq t \leq b$ is called a *simple* contour if $\gamma(t) \neq \gamma(s)$ for $a < t, s < b$, and $t \neq s$. A *closed* contour is a contour for which $\gamma(a) = \gamma(b)$. If C is given by $z = \gamma(t)$, $a \leq t \leq b$, then $-C$ is the contour given by $z = \gamma(a + b - t)$, $a \leq t \leq b$. It is clear that

$$\int_{-C} f(z) dz = -\int_C f(z) dz$$

Suppose C is a simple closed contour and f is a function analytic at all points on and inside C . Then

$$\int_C f(z)dz = 0$$

This is the celebrated *Cauchy-Goursat theorem*.

An open connected set U such that every simple closed contour in U encloses only points of U is said to be *simply connected*. If z_0 and z_1 are points in a simply connected open set U , and if C_1 and C_2 are contours in U from z_0 and z_1 , then for any f analytic in U , it is true that

$$\int_{C_1} f(z)dz = \int_{C_2} f(z)dz$$

A simple closed contour C given by $z = \gamma(t)$, $a \leq t \leq b$ is *positively oriented* if, for z_0 inside C , the argument $\text{Arg}[\gamma(t) - z_0]$ increases as t goes from a to b . If f is analytic in simply connected region U , and if C is a positively oriented simple closed curve in U , then for every z_0 in U that is not on C , we have

$$f(z_0) = \frac{1}{2\pi i} \int_C \frac{f(z)}{z - z_0} dz$$

This is the celebrated *Cauchy integral formula*. If f is analytic at a point z_0 , then it has derivatives of all orders, and

$$f^{(n)}(z_0) = \frac{n!}{2\pi i} \int_C \frac{f(z)}{(z - z_0)^{n+1}} dz$$

If the function f is continuous on an open connected set U and if

$$\int_C f(z)dz = 0$$

for every closed contour C in U , then f is analytic on U . This is *Morera's theorem*.

If f is analytic on an open set U , the point z_0 is in U , and C_R is a circle in U of radius r centered at z_0 on which $|f(z)| \leq M$, then

$$|f^{(n)}(z_0)| \leq \frac{n!M}{r^n}$$

It follows from this that a bounded entire function must be constant.

220.5 Series

Let f be a function analytic in an open set U , and let z_0 be a point of U . Then there is a unique power

series $\sum_{k=0}^{\infty} a_k(z - z_0)^k$ such that

$$f(z) = \sum_{k=0}^{\infty} a_k(z - z_0)^k$$

for all z in some neighborhood of z_0 . This series is the *Taylor series* of f at z_0 and converges to $f(z)$ for all z inside a circle C , on which is found the singularity of f closest to z_0 . The radius of C is called the *radius*

of convergence of the series. This series may be differentiated term by term to obtain the Taylor series for the n th derivative of f at z_0 :

$$f^{(n)}(z) = \sum_{k=n}^{\infty} k(k-1)\cdots(k-n+1)a_k(z-z_0)^{k-n}$$

The radius of convergence of this series is the same as that of the Taylor series for f . It follows easily that, for each $n = 0, 1, 2, \dots$, we have

$$a_n = \frac{1}{n!} f^{(n)}(z_0)$$

Let C_0 and C_1 be two concentric circles centered at a point z_0 , with C_0 having a smaller radius than C_1 . Suppose the function f is analytic on an open set containing the two circles and the annular region between them. Then, for each point in the annular region bounded by the circles, we have

$$f(z) = \sum_{k=0}^{\infty} a_k(z-z_0)^k + \sum_{k=1}^{\infty} b_k(z-z_0)^{-k}$$

where

$$a_k = \frac{1}{2\pi i} \int_C \frac{f(z)}{(z-z_0)^{k+1}} dz$$

$$b_k = \frac{1}{2\pi i} \int_C \frac{f(z)}{(z-z_0)^{-k+1}} dz$$

for any positively oriented simply closed contour C around the annular region. This is a *Laurent series*. It is sometimes written

$$f(z) = \sum_{k=-\infty}^{\infty} c_k(z-z_0)^k$$

with

$$c_k = \frac{1}{2\pi i} \int_C \frac{f(z)}{(z-z_0)^{k+1}} dz$$

220.6 Singularities

Suppose that z_0 is a singular point of the function f and f is analytic in a neighborhood of z_0 (except, of course, at z_0). Then z_0 is called an *isolated singular point*, or an *isolated singularity*, of f . In case z_0 is an isolated singular point of f , the Laurent series

$$f(z) = \sum_{k=-\infty}^{\infty} c_k(z-z_0)^k$$

represents f for all z such that $0 < |z - z_0| < r$, for some $r > 0$. If $c_k = 0$ for all $k \leq -1$, then z_0 is said to be a *removable singularity*. (The value of f at z_0 can, in this case, be redefined to be c_0 , and the function so defined is analytic at z_0 .) If there is a negative integer $N < -1$ such that $c_k = 0$ for all $k \leq N$, then z_0 is a *pole* of order p , where p is the largest positive integer for which $c_{-p} \neq 0$. A pole of order one is called a *simple pole*. An isolated singularity that is neither a removable singularity nor a pole is called an *essential singularity*. Thus, z_0 is an essential singularity if, for every negative N , there is a $k < N$ such that $c_k \neq 0$.

If z_0 is an isolated singularity of the function f , then the coefficient c_{-1} in the Laurent series given is the *residue* of f at z_0 . If z_0 is a simple pole, then the residue of f at z_0 is given by

$$\text{Res}(z_0) = \lim_{z \rightarrow z_0} (z - z_0) f(z)$$

If z_0 is a pole of order p , then

$$\text{Res}(z_0) = \lim_{z \rightarrow z_0} \frac{1}{(p-1)!} \frac{d^{p-1}}{dz^{p-1}} [(z - z_0)^p f(z)]$$

The importance of the idea of the residue comes from *Cauchy's residue theorem*, which says that if C is a positively oriented simple closed contour and the function f is analytic on and inside C except at the points z_1, z_2, \dots, z_n , then

$$\int_C f(z) dz = 2\pi i \sum_{k=1}^n \text{Res}(z_k)$$

220.7 Conformal Mapping

We can regard a one-to-one complex function f on a region \mathbf{D} as defining a *mapping* from \mathbf{D} into the plane. In the event that f is analytic, this mapping is *conformal*; that is, angles are preserved. More importantly, such a mapping preserves the harmonic property of a function. Thus, if f is analytic and $w = f(z) = u(x, y) + iv(x, y)$ maps a domain \mathbf{D}_z onto a domain \mathbf{D}_w , and if

$$\frac{\partial^2 \Phi(u, v)}{\partial u^2} + \frac{\partial^2 \Phi(u, v)}{\partial v^2} = 0 \text{ in } \mathbf{D}_w$$

then

$$\frac{\partial^2 \Theta(x, y)}{\partial x^2} + \frac{\partial^2 \Theta(x, y)}{\partial y^2} = 0 \text{ in } \mathbf{D}_z$$

where $\Theta(x, y) = \Phi[u(x, y), v(x, y)]$. Conformal mappings are useful in solving boundary value problems involving Laplace's equation in a region of the plane. The given region is mapped conformally to another region in which the solution is either known or easy to find.

Difference Equations

William F. Ames

Georgia Institute of Technology

[221.1 First-Order Equations](#)

[221.2 Second-Order Equations](#)

[221.3 Linear Equations with Constant Coefficients](#)

[221.4 Generating Function \(z Transform\)](#)

Difference equations are equations involving *discrete variables*. They appear as natural descriptions of natural phenomena and in the study of discretization methods for differential equations, which have continuous variables.

Let $y_n = y(nh)$, where n is an integer and h a real number. (One can think of measurements taken at equal intervals, $h, 2h, 3h, \dots$, and y_n describes these.) A typical equation is that describing the famous Fibonacci sequence — $y_{N+2} - y_{n+1} - y_n = 0$. Another example is the equation $y_{n+2} - 2zy_{n+1} + y_n = 0$, $z \in \mathbb{C}$, which describes the Chebyshev polynomials.

221.1 First-Order Equations

The general first-order equation $y_{n+1} = f(y_n)$, $y_0 = y(0)$ is easily solved, for as many terms as are needed, by *iteration*. Then $y_1 = f(y_0)$; $y_2 = f(y_1), \dots$. An example is the logistic equation $y_{n+1} = ay_n(1 - y_n) = f(y_n)$. The logistic equation has two fixed (critical or equilibrium) points where $y_{n+1} = y_n$. They are 0 and $\bar{y} = (a - 1)/a$. This has physical meaning only for $a > 1$. For $1 < a < 3$ the equilibrium \bar{y} is asymptotically stable, and for $a > 3$ there are two points y_1 and y_2 , called a *cycle of period two*, in which $y_2 = f(y_1)$ and $y_1 = f(y_2)$. This study leads into chaos, which is outside our interest. By iteration, with $y_0 = 1/2$, we have $y_1 = (a/2)(1/2) = a/2^2$, $y_2 = a(a/2^2)(1 - a/2^2) = (a^2/2^2)(1 - a/2^2), \dots$

With a constant, the equation $y_{n+1} = ay_n$ is solved by making the assumption $y_n = A\lambda^n$ and finding λ so that the equation holds. Thus $A\lambda^{n+1} = aA\lambda^n$, and hence $\lambda = 0$ or $\lambda = a$ and A is arbitrary. Discarding the trivial solution 0 we find $y_n = Aa^{n+1}$ is the desired solution. By using a method called the *variation of*

constants, the equation $y_{n+1} - ay_n = g_n$ has the solution $y_n = y_0a^n + \sum_{j=0}^{n-1} g_j a^{n-j-1}$, with y_0 arbitrary.

In various applications we find the first-order equation of *Riccati type* $y_n y_{n-1} + ay_n + by_{n-1} + c = 0$ where a, b , and c are real constants. This equation can be transformed to a linear second-order equation by setting $y_n = z_n/z_{n-1} - a$ to obtain $z_{n-1} + (b + a)z_n + (c - ab)z_{n-1} = 0$, which is solvable as described in the next section.

221.2 Second-Order Equations

The second-order linear equation with constant coefficients $y_{n+2} + ay_{n+1} + by_n = f_n$ is solved by first solving the homogeneous equation (with right-hand side zero) and adding to that solution any solution of the

inhomogeneous equation. The *homogeneous equation* $y_{n+2} + ay_{n+1} + by_n = 0$ is solved by assuming $y_n = \lambda^n$, whereupon $y^{n+2} + a\lambda^{n+1} + b\lambda^n = 0$ or $\lambda \equiv 0$ (rejected) or $\lambda^2 + a\lambda + b = 0$. The roots of this quadratic are $\lambda_1 = \frac{1}{2}(-a + \sqrt{a^2 - 4b})$, $\lambda_2 = -\frac{1}{2}(a + \sqrt{a^2 - 4b})$ and the solution of the homogeneous equation is $y_n = c_1\lambda_1^n + c_2\lambda_2^n$. As an example consider the Fibonacci equation $y_{n+2} - y_{n+1} - y_n = 0$. The roots of $\lambda^2 - \lambda - 1 = 0$ are $\lambda_1 = \frac{1}{2}(1 + \sqrt{5})$, $\lambda_2 = \frac{1}{2}(1 - \sqrt{5})$, and the solution $y_n = c_1[(1 + \sqrt{5})/2]^n + c_2[(1 - \sqrt{5})/2]^n$ is known as the *Fibonacci sequence*.

Many of the orthogonal polynomials of differential equations and numerical analysis satisfy a second-order difference equation (recurrence relation) involving a discrete variable, say n , and a continuous variable, say z . One such is the *Chebyshev equation* $y_{n+2} - 2zy_{n+1} + y_n = 0$ with the initial conditions $y_0 = 1$, $y_1 = z$ (*first-kind* Chebyshev polynomials) and $y_{-1} = 0$, $y_0 = 1$ (*second-kind* Chebyshev polynomials). They are denoted $T_n(z)$ and $V_n(z)$, respectively. By iteration we find

$$\begin{aligned} T_0(z) &= 1, & T_1(z) &= z, & T_2(z) &= 2z^2 - 1, \\ T_3(z) &= 4z^3 - 3z, & T_4(z) &= 8z^4 - 8z^2 + 1, \\ V_0(z) &= 0, & V_1(z) &= 1, & V_2(z) &= 2z, \\ V_3(z) &= 4z^2 - 1, & V_4(z) &= 8z^3 - 4z \end{aligned}$$

and the general solution is $y_n(z) = c_1T_n(z) + c_2V_{n-1}(z)$.

221.3 Linear Equations with Constant Coefficients

The general k th-order linear equation with constant coefficients is $\sum_{i=0}^k p_i y_{n+k-i} = g_n$, $p_0 = 1$. The solution to the corresponding homogeneous equation (obtained by setting $g_n = 0$) is as follows. (a) $y_n = \sum_{i=1}^k c_i \lambda_i^n$ if the λ_i are the distinct roots of the characteristic polynomial $p(\lambda) = \sum_{i=0}^k p_i \lambda^{k-i} = 0$. (b) If m_s is the multiplicity of the root λ_s , then the functions $y_{n,s} = u_s(n) \lambda_s^n$, where $u_s(n)$ are polynomials in n whose degree does not exceed $m_s - 1$, are solutions of the equation. Then the general solution of the homogeneous equation is $y_n = \sum_{i=1}^d a_i u_i(n) \lambda_i^n = \sum_{i=1}^d a_i \sum_{j=0}^{m_i-1} c_j n^j \lambda_i^n$. To this solution one adds any particular solution to obtain the general solution of the general equation.

Example 221.1

A model equation for the price p_n of a product, at the n th time, is $p_n + \frac{b}{a}(1 + \rho)p_{n-1} - \frac{b}{a}\rho p_{n-2} + (s_0 - d_0)/a = 0$. The equilibrium price is obtained by setting $p_n = p_{n-1} = p_{n-2} = p_e$, and one finds $p_e = (d_0 - s_0)/(a + b)$. The homogeneous equation has the characteristic polynomial $\lambda^2 + (b/a)(1 + \rho)\lambda - (b/a)\rho = 0$. With λ_1 and λ_2 as the roots the general solution of the full equation is $p_n = c_1\lambda_1^n + c_2\lambda_2^n + p_e$, since p_e is a solution of the full equation. This is one method for finding the solution of the nonhomogeneous equation.

221.4 Generating Function (z Transform)

An elegant way of solving linear difference equations with constant coefficients, among other applications, is by use of *generating functions* or, as an alternative, the z transform. The generating function of a

TABLE 221.1 Important Sequences

| y_n | $f(x)$ | Convergence Domain |
|----------------|--|--------------------|
| 1 | $(1-x)^{-1}$ | $ x < 1$ |
| n | $x(1-x)^{-2}$ | $ x < 1$ |
| n^m | $x p_m(x)(1-x)^{-m-1}$ | $ x < 1$ |
| k^n | $(1-kx)^{-1}$ | $ x < k^{-1}$ |
| e^{an} | $(1-e^a x)^{-1}$ | $ x < e^{-a}$ |
| $k^n \cos an$ | $\frac{1-kx \cos a}{1-2kx \cos a + k^2 x^2}$ | $ x < k^{-1}$ |
| $k^n \sin an$ | $\frac{kx \sin a}{1-2kx \cos a + k^2 x^2}$ | $ x < k^{-1}$ |
| $\binom{n}{m}$ | $x^m (1-x)^{-m-1}$ | $ x < 1$ |
| $\binom{k}{n}$ | $(1+x)^k$ | $ x < 1$ |

* The term $p_m(z)$ is a polynomial of degree m satisfying $p_{m+1}(z) = (mz + 1)p_m(z) + z(1-z)p'_m(z)$, $p_1 = 1$.

sequence $\{y_n\}$, $n = 0, 1, 2, \dots$, is the function $f(x)$ given by the formal series $f(x) = \sum_{n=0}^{\infty} y_n x^n$. The z transform of the same sequence is $z(x) = \sum_{n=0}^{\infty} y_n x^{-n}$. Clearly, $z(x) = f(1/x)$. A table of some important sequences is given in Table 221.1.

To solve the linear difference equation $\sum_{i=1}^k p_i y_{n+k-i} = 0$, $p_0 = 1$ we associate with it the two formal series $P = p_0 + p_1 x + \dots + p_k x^k$ and $Y = y_0 + y_1 x + y_2 x^2 + \dots$. If $p(x)$ is the characteristic polynomial then $P(x) = x^k p(1/x) = \bar{p}(x)$. The product of the two series is $Q = YP = q_0 + q_1 x + \dots + q_{k-1} x^{k-1} + q_k x^k + \dots$ where $q_n = \sum_{i=0}^n p_i y_{n-i}$. Because $p_{k+1} = p_{k+2} = \dots = 0$, it is obvious that $q_{k+1} = q_{k+2} = \dots = 0$ — that is, Q is a polynomial (formal series with finite number of terms). Then $Y = p^{-1}Q = q(x)/\bar{p}(x) = q(x)/x^k p(1/x)$, where p is the characteristic polynomial and $q(x) = \sum_{i=0}^k q_i x^i$. The roots of $\bar{p}(x)$ are x_i^{-1} where the x_i are the roots of $p(x)$.

Theorem 1. If the roots of $p(x)$ are less than one in absolute value, then $Y(x)$ converges for $|x| < 1$.

Theorem 2. If $p(x)$ has no roots greater than one in absolute value and those on the unit circle are simple roots, then the coefficients y_n of Y are bounded. Now $q_k = g_0$, $q_{n+k} = g_n$, and $Q(x) = Q_1(x)$

$$+ x^k Q_2(x). \text{ Hence } \sum_{i=1}^{\infty} y_i x^i = [Q_1(x) + x^k Q_2(x)] / [\bar{p}(x)].$$

Example 221.2

Consider the equation $y_{n+1} + y_n = -(n+1)$, $y_0 = 1$. Here $Q_1 = 1$, $Q_2 = -\sum_{n=0}^{\infty} (n+1)x^n = -1/(1-x)^2$.

$$G(x) = \frac{1-x/(1-x)^2}{1+x} = \frac{5}{4} \frac{1}{1+x} - \frac{1}{4} \frac{1}{1-x} - \frac{1}{2} \frac{x}{(1-x)^2}$$

Using the table term by term, we find $\sum_{n=0}^{\infty} y_n x^n = \sum_{n=0}^{\infty} [\frac{5}{4}(-1)^n - \frac{1}{4} - \frac{1}{2}n]x^n$, so $y_n = \frac{5}{4}(-1)^n - \frac{1}{4} - \frac{1}{2}n$.

William F. Ames

Georgia Institute of Technology

Any equation involving derivatives is called a *differential equation*. If there is only one independent variable the equation is termed a *total differential equation* or an *ordinary differential equation*. If there is more than one independent variable the equation is called a *partial differential equation*. If the highest-order derivative is the n th, then the equation is said to be n th order. If there is no function of the dependent variable and its derivatives other than the linear one, the equation is said to be *linear*. Otherwise, it is *nonlinear*. Thus $(d^3y/dx^3) + a(dy/dx) + by = 0$ is a *linear* third-order ordinary (total) differential equation. If we replace by with by^3 , the equation becomes nonlinear. An example of a second-order linear partial differential equation is the famous wave equation $(\partial^2 u / \partial x^2) - a^2(\partial^2 u / \partial t^2) = f(x)$. There are two independent variables x and t and $a^2 > 0$ (of course). If we replace $f(x)$ by $f(u)$ (say u^3 or $\sin u$), the equation is nonlinear. Another example of a nonlinear third-order partial differential equation is $u_t + uu_x = au_{xxx}$. This chapter uses the common subscript notation to indicate the partial derivatives.

Now we briefly indicate some methods of solution and the solution of some commonly occurring equations.

222.1 Ordinary Differential Equations

First-Order Equations

The *general* first-order equation is $f(x, y, y') = 0$. Equations capable of being written in either of the forms $y' = f(x)g(y)$ or $f(x)g(y)y' + F(x)G(y) = 0$ are *separable* equations. Their solution is obtained by using $y' = dy/dx$ and writing the equations in differential form as $dy/g(y) = f(x)dx$ or $g(y)[dy/G(y)] = -F(x)[dx/f(x)]$ and integrating. An example is the famous *logistic* equation of inhibited growth $(dy/dt) = ay(1 - y)$. The integral of $dy/y(1 - y) = a dt$ is $y = 1/[1 + (y_0^{-1} - 1)e^{-at}]$ for $t \geq 0$ and $y(0) = y_0$ (the initial state called the *initial condition*).

Equations may not have unique solutions. An example is $y' = 2y^{1/2}$ with the initial condition $y(0) = 0$. One solution by separation is $y = x^2$. But there are an *infinity* of others — namely, $y_a(x) = 0$ for $-\infty < x \leq a$, and $(x - a)^2$ for $a \leq x < \infty$.

If the equation $P(x, y)dy + Q(x, y)dx$ is reducible to

$$\frac{dy}{dx} = f\left(\frac{y}{x}\right) \quad \text{or} \quad \frac{dy}{dx} = f\left(\frac{a_1x + b_1y + c_1}{a_2x + b_2y + c_2}\right)$$

the equation is called *homogeneous* (nearly homogeneous). The first form reduces to the separable equation $u + x(du/dx) = f(u)$ with the substitution $y/x = u$. The nearly homogeneous equation is handled by setting $x = X + \alpha$, $y = Y + \beta$, and choosing α and β so that $a_1\alpha + b_1\beta + c_1 = 0$ and $a_2\alpha + b_2\beta + c_2 = 0$.

If $\begin{vmatrix} a_1 & b_1 \\ a_2 & b_2 \end{vmatrix} \neq 0$ are always possible; the equation becomes $dY/dX = [a_1 + b_1(Y/X)]/[a_2 + b_2(Y/X)]$ and the

substitution $Y = Xu$ gives a separable equation. If $\begin{vmatrix} a_1 & b_1 \\ a_2 & b_2 \end{vmatrix} = 0$ then $a_2x + b_2y = k(a_1x + b_1y)$ and the equation becomes $du/dx = a_1 + b_1(u + c_1)/(ku + c_2)$, with $u = a_1x + b_1y$. Lastly, any equation of the form $dy/dx = f(ax + by + c)$ transforms into the separable equation $du/dx = a + bf(u)$ using the change of variable $u = ax + by + c$.

The general first-order linear equation is expressible in the form $y' + f(x)y = g(x)$. It has the *general solution* (a solution with an arbitrary constant c)

$$y(x) = \exp\left[-\int f(x)dx\right] \left\{ c + \int \exp[f(x)dx] g(x) dx \right\}$$

Two noteworthy examples of first-order equations are as follows:

1. An often-occurring nonlinear equation is the *Bernoulli equation*, $y' + p(x)y = g(x)y^\alpha$, with α real, $\alpha \neq 0$, $\alpha \neq 1$. The transformation $z = y^{1-\alpha}$ converts the equation to the linear first-order equation $z' + (1-\alpha)p(x)z = (1-\alpha)g(x)$.
2. The famous *Riccati equation*, $y' = p(x)y^2 + q(x)y + r(x)$, cannot in general be solved by integration. But some transformations are helpful. The substitution $y = y_1 + u$ leads to the equation $u' - (2py_1 + q)u = pu^2$, which is a Bernoulli equation for u . The substitution $y = y_1 + v^{-1}$ leads to the equation $v' + (2py_1 + q)v + p = 0$, which is a linear first-order equation for v . Once either of these equations has been solved, the general solution of the Riccati equation is $y = y_1 + u$ or $y = y_1 + v^{-1}$.

Second-Order Equations

The simplest of the second-order equations is $y'' + ay' + by = 0$ (a, b real), with the initial conditions $y(x_0) = y_0$, $y'(x_0) = y'_0$ or the boundary conditions $y(x_0) = y_0$, $y(x_1) = y_1$. The general solution of the equation is given as follows.

1. $a^2 - 4b > 0$, $\lambda_1 = \frac{1}{2}(-a + \sqrt{a^2 - 4b})$, $\lambda_2 = \frac{1}{2}(-a - \sqrt{a^2 - 4b})$

$$y = c_1 \exp(\lambda_1 x) + c_2 \exp(\lambda_2 x)$$

2. $a^2 - 4b = 0$, $\lambda_1 = \lambda_2 = -\frac{a}{2}$,

$$y = (c_1 + c_2 x) \exp(\lambda_1 x)$$

3. $a^2 - 4b < 0$, $\lambda_1 = \frac{1}{2}(-a + i\sqrt{4b - a^2})$, $\lambda_2 = \frac{1}{2}(-a - i\sqrt{4b - a^2})$,

$$i^2 = -1$$

FIGURE 222.1

With $p = -a/2$ and $q = \frac{1}{2}\sqrt{4b - a^2}$,

$$y = c_1 \exp[(p + iq)x] + c_2 \exp[(p - iq)x] = \exp(px)[A \sin qx + B \cos qx]$$

The initial conditions or boundary conditions are used to evaluate the arbitrary constants c_1 and c_2 (or A and B).

Note that a linear problem with specified data may not have a solution. This is especially serious if numerical methods are employed without serious thought.

For example, consider $y'' + y = 0$ with the boundary condition $y(0) = 1$ and $y(\pi) = 1$. The general solution is $y = c_1 \sin x + c_2 \cos x$. The first condition $y(0) = 1$ gives $c_2 = 1$, and the second condition requires $y(\pi) = c_1 \sin \pi + \cos \pi$ or “ $1 = -1$,” which is a *contradiction*.

Example 222.1: The Euler Strut

When a strut of uniform construction is subjected to a compressive load P it exhibits no transverse displacement until P exceeds some critical value P_1 . When this load is exceeded, buckling occurs and large deflections are produced as a result of small load changes. Let the rod of length ℓ be placed as shown in Figure 222.1.

From the linear theory of elasticity (Timoshenko), the transverse displacement $y(x)$ satisfies the linear second-order equation $y'' = Py/EI$, where E is the modulus of elasticity and I is the moment of inertia of the strut. The boundary conditions are $y(0) = 0$ and $y(a) = 0$. With $k^2 = P/EI$ the general solution is $y = c_1 \sin kx + c_2 \cos kx$. The condition $y(0) = 0$ gives $c_2 = 0$. The second condition gives $c_1 \sin ka = 0$. Since $c_1 = 0$ gives only the trivial solution $y = 0$ we must have $\sin ka = 0$. This occurs for $ka = n\pi$, $n = 0, 1, 2, \dots$ (these are called *eigenvalues*). The first nontrivial solution occurs for $n = 1$ — that is, $k = \pi/a$ — whereupon $y_1 = c_1 \sin(\pi/a)$, with arbitrary c_1 . Since $P = EI k^2$ the critical compressive load is $P_1 = EI\pi^2/a^2$. This is the buckling load. The weakness of the linear theory is its failure to model the situation when buckling occurs.

Example 222.2: — Some Solvable Nonlinear Equations

Many physical phenomena are modeled using nonlinear second-order equations. Some general cases are given here.

1. $y'' = f(y)$, first integral $(y')^2 = 2 \int f(y) dy + c$.
2. $f(x, y', y'')$. Set $p = y'$ and obtain a first-order equation $f(x, p, dp/dx) = 0$. Use first-order methods.
3. $f(y, y', y'')$. Set $p = y'$ and then $y'' = p(dp/dy)$ so that a first-order equation $f[y, p, p(dp/dy)] = 0$ for p as a function of y is obtained.
4. The *Riccati Transformation* $du/dx = yu$ leads to the Riccati chain of equations, which linearize by raising the order. Thus,

| Equation in y | Equation in u |
|---|--------------------|
| 1. $y' + y^2 = f(x)$ | $u'' = f(x)u$ |
| 2. $y'' + 3yy' + y^3 = f(x)$ | $u''' = f(x)u$ |
| 3. $y''' + 6y^2y' + 3(y')^2 + 4yy'' = f(x)$ | $u^{(iv)} = f(x)u$ |

This method can be generalized to $u' = a(x)yu$ or $u' = a(x)f(u)y$.

Second-Order Nonhomogeneous Equations

The general solution of $a_0(x)y'' + a_1(x)y' + a_2(x)y = f(x)$ is $y = y_H(x) + y_p(x)$, where $y_H(x)$ is the general solution of the homogeneous equation (with the right side zero) and y_p is the particular integral of the equation. Construction of particular integrals can sometimes be done by the *method of undetermined coefficients* (Table 222.1). This applies only to the linear constant coefficient case in which the function $f(x)$ is a linear combination of a polynomial, exponentials, sines and cosines, and some products of these functions. This method has as its basis the observation that repeated differentiation of such functions gives rise to similar functions.

Example 222.3

Consider the equation $y'' + 3y' + 2y = \sin 2x$. The characteristic equation of the homogeneous equation $\lambda^2 + 3\lambda + 2 = 0$ has the two roots $\lambda_1 = -1$ and $\lambda_2 = -2$. Consequently, $y_H = c_1e^{-x} + c_2e^{-2x}$. Since $\sin 2x$ is not linearly dependent on the exponentials and since $\sin 2x$ repeats after two differentiations, we assume a particular solution with undetermined coefficients of the form $y_p(x) = B\sin 2x + C \cos 2x$. Substituting into the original equation gives $-(2B + 6C)\sin 2x + (6B - 2C)\cos 2x = \sin 2x$. Consequently, $-(2B + 6C) = 1$ and $6B - 2C = 0$ to satisfy the equation. These two equations in two unknowns have the solution $B = -\frac{1}{20}$ and $C = -\frac{3}{20}$. Hence $y_p = -\frac{1}{20}(\sin 2x + 3 \cos 2x)$ and $y = c_1e^{-x} + c_2e^{-2x} - \frac{1}{20}(\sin 2x + 3 \cos 2x)$.

A general method for finding $y_p(x)$ called *variation of parameters* used as its starting point $y_H(x)$. This method applies to *all* linear differential equations irrespective of whether they have constant coefficients. But it assumes $y_H(x)$ is known. We illustrate the idea for $a(x)y'' + b(x)y' + c(x)y = f(x)$. If the solution of the homogeneous equation is $y_H(x) = c_1\phi_1(x) + c_2\phi_2(x)$, then vary the parameters c_1 and c_2 to seek $y_p(x)$ as $y_p(x) = u_1(x)\phi_1(x) + u_2(x)\phi_2(x)$. Then $y_p' = u_1\phi_1' + u_2\phi_2' + u_1'\phi_1 + u_2'\phi_2$ and choose $u_1'\phi_1 + u_2'\phi_2 = 0$. Calculating y_p'' and setting in the original equation gives $a(x)u_1'\phi_1' + a(x)u_2'\phi_2' = f$. Solving the last two equations for u_1' and u_2' gives $u_1' = -\phi_2'f/wa, u_2' = \phi_1'f/wa$,

TABLE 222.1 Method of Undetermined Coefficients — Equation $L(y) = f(x)$ (Constant Coefficients)

| Terms in $f(x)$ | Terms to be Included in $y_p(x)$ |
|-----------------------------------|--|
| 1. Polynomial of degree n | (a) If $L(y)$ contains y , try $y_p = a_0x^n + a_1x^{n-1} + \dots + a_n$. (b) If $L(y)$ does not contain y and lowest-order derivative is $y^{(r)}$, try $y_p = a_0x^{n+r} + \dots + a_nx^r$. |
| 2. $\sin qx, \cos qx$ | (a) $\sin qx$ and/or $\cos qx$ are not in y_H ; $y_p = B \sin qx + C \cos qx$. (b) y_H contains terms of form $x^r \sin qx$ and/or $x^r \cos qx$ for $r = 0, 1, \dots, m$; include in y_p terms of the form $a_0x^{m+1} \sin qx + a_1x^{m+1} \cos qx$. |
| 3. e^{ax} | (a) y_H does not contain e^{ax} ; include Ae^{ax} in y_p . (b) y_H contains $e^{ax}, xe^{ax}, \dots, x^n e^{ax}$; include in y_p terms of the form $Ax^{n+1}e^{ax}$. |
| 4. $e^{px}\sin qx, e^{px}\cos qx$ | (a) y_H does not contain these terms; in y_p include $Ae^{px}\sin qx + Be^{px}\cos qx$. (b) y_H contains $x^r e^{px} \sin qx$ and/or $x^r e^{px} \cos qx$; $r = 0, 1, \dots, m$ include in y_p $Ax^{m+1}e^{px}\sin qx + Bx^{m+1}e^{px}\cos qx$. |

where $w = \phi_1\phi_2' - \phi_1'\phi_2 \neq 0$. Integrating the general solution gives $y = c_1\phi_1(x) + c_2\phi_2(x) - \left\{ \int [\phi_2 f(x)] / wa \right\} \phi_1(x) + \left\{ \int (\phi_1 f/wa) dx \right\} \phi_2(x)$.

Example 222.4

Consider the equations $y'' - 4y = \sin x/(1 + x^2)$ and $y_H = c_1 e^{2x} + c_2 e^{-2x}$. With $\phi_1 = e^{2x}$ and $\phi_2 = e^{-2x}$, $w = 4$, so the general solution is

$$y = c_1 e^{2x} + c_2 e^{-2x} - \frac{e^{-2x}}{4} \int \frac{e^{2x} \sin x}{1+x^2} dx + \frac{e^{2x}}{4} \int \frac{e^{-2x} \sin x}{1+x^2} dx$$

The method of variation of parameters can be generalized as described in the references.

Higher-order systems of linear equations with constant coefficients are treated in a similar manner. Details can be found in the references.

Series Solution

The solution of differential equations can only be obtained in closed form in special cases. For all others, series or approximate or numerical solutions are necessary. In the simplest case, for an initial value problem, the solution can be developed as a Taylor series expansion about the point where the initial data are specified. The method fails in the *singular case* — that is, a point where the coefficient of the highest-order derivative is zero. The general method of approach is called the *Frobenius method*.

To understand the nonsingular case consider the equation $y'' + xy = x^2$ with $y(2) = 1$ and $y'(2) = 2$ (an initial value problem). We seek a series solution of the form $y(x) = a_0 + a_1(x-2) + a_2(x-2)^2 + \dots$. To proceed, set $1 = y(2) = a_0$, which evaluates a_0 . Next, $y'(x) = a_1 + 2a_2(x-2) + \dots$, so $2 = y'(2) = a_1$ or $a_1 = 2$. Next $y''(x) = 2a_2 + 6a_3(x-2) + \dots$ and from the equation, $y'' = x^2 - xy$, so $y''(2) = 4 - 2y(2) = 4 - 2 = 2$. Hence $2 = 2a_2$ or $a_2 = 1$. Thus, to third-order $y(x) = 1 + 2(x-2) + (x-2)^2 + R_2(x)$, where the remainder $R_2(x) = [(x-2)^3/3!]y'''(\xi)$, where $2 < \xi < x$ can be bounded for each x by finding the maximum of $y'''(x) = 2x - y - xy'$. The third term of the series follows by evaluating $y'''(2) = 4 - 1 - 2 \cdot 2 = -1$, so $6a_3 = -1$ or $a_3 = -1/6$.

By now the nonsingular process should be familiar. The algorithm for constructing a series solution about a nonsingular (ordinary) point x_0 of the equation $P(x)y'' + Q(x)y' + R(x)y = f(x)$ (note that $P(x_0) \neq 0$) is as follows:

1. Substitute into the differential equation the following expressions:

$$y(x) = \sum_{n=0}^{\infty} a_n (x - x_0)^n, \quad y'(x) = \sum_{n=1}^{\infty} n a_n (x - x_0)^{n-1},$$

$$y''(x) = \sum_{n=2}^{\infty} n(n-1) a_n (x - x_0)^{n-2}$$

2. Expand $P(x)$, $Q(x)$, $R(x)$, and $f(x)$ about the point x_0 in a power series in $(x - x_0)$ and substitute these series into the equation.
3. Gather all terms involving the same power of $(x - x_0)$ to arrive at an identity of the form

$$\sum_{n=0}^{\infty} A_n (x - x_0)^n \equiv 0.$$

4. Equate to zero each coefficient A_n of step 3.
5. Use the expressions of step 4 to determine a_2, a_3, \dots in terms of a_0, a_1 (we need two arbitrary constants) to arrive at the general solution.
6. With the given initial conditions, determine a_0 and a_1 .

If the equation has a regular singular point — that is, a point x_0 at which $P(x)$ vanishes and a series expansion is sought about that point — a solution is sought of the form $y(x) = (x - x_0)^r \sum_{n=0}^{\infty} a_n(x - x_0)^n, a_0 \neq 0$ and the index r and coefficients a_n must be determined from the equation by an algorithm analogous to that already described. The description of this Frobenius method is left for the references.

222.2 Partial Differential Equations

The study of partial differential equations is of continuing interest in applications. It is a vast subject, so the focus in this chapter is on the most commonly occurring equations in the engineering literature: second-order equations in two variables. Most of these are of the three basic elliptic, hyperbolic, and parabolic types.

Elliptic equations are often called *potential equations* since they occur in potential problems where the potential may be temperature, voltage, and so forth. They also give rise to the steady solutions of parabolic equations. They require boundary conditions for the complete determination of their solution.

Hyperbolic equations are often called *wave equations* since they arise in the propagation of waves. For the development of their solutions, initial and boundary conditions are required. In principle, they are solvable by the method of characteristics.

Parabolic equations are usually called *diffusion equations* because they occur in the transfer (diffusion) of heat and chemicals. These equations require initial conditions (e.g., the initial temperature) and boundary conditions for the determination of their solutions.

Partial differential equations (PDEs) of the second order in two independent variables (x, y) are of the form $a(x, y)u_{xx} + b(x, y)u_{xy} + c(x, y)u_{yy} = E(x, y, u, u_x, u_y)$. If $E = E(x, y)$ the equation is linear; if E depends also on $u, u_x,$ and u_y , it is said to be *quasilinear*, and if E depends only on $x, y,$ and u , it is *semilinear*. Such equations are classified as follows: If $b^2 - 4ac$ is less than, equal to, or greater than zero at some point (x, y) , then the equation is elliptic, parabolic, or hyperbolic, respectively, at that point. A PDE of this form can be transformed into canonical (standard) forms by use of new variables. These standard forms are most useful in analysis and numerical computations.

For hyperbolic equations the standard form is $u_{\xi\eta} = \phi(u, u_\eta, u_\xi, \eta, \xi)$, where $\xi_x / \xi_y = (-b + \sqrt{b^2 - 4ac}) / 2a$, and $\eta_x / \eta_y = (-b - \sqrt{b^2 - 4ac}) / 2a$. The right sides of these equations determine the so-called characteristics $(dy/dx)_+ = (-b + \sqrt{b^2 - 4ac}) / 2a, (dy/dx)_- = (-b - \sqrt{b^2 - 4ac}) / 2a$.

Example 222.5

Consider the equation $y^2 u_{xx} - x^2 u_{yy} = 0$. $\xi_x / \xi_y = -x/y, \eta_x / \eta_y = x/y$, so $\xi = y^2 - x^2$ and $\eta = y^2 + x^2$. In these new variables the equation becomes $u_{\xi\eta} = (\xi u_\eta - \eta u_\xi) / 2(\xi^2 - \eta^2)$.

For parabolic equations the standard form is $u_{\xi\xi} = \phi(u, u_\eta, u_\xi, \eta, \xi)$ or $u_{\eta\eta} = \phi(u, u_\eta, u_\xi, \xi, \eta)$, depending upon how the variables are defined. In this case $\xi_x / \xi_y = -b/2a$ if $a \neq 0$, and $\xi_x / \xi_y = -b/2c$ if $c \neq 0$. Only ξ must be determined (there is only one characteristic) and η can be chosen as any function that is linearly independent of ξ .

Example 222.6

Consider the equation $y^2 u_{xx} - 2xy u_{xy} + x^2 u_{yy} + u_y = 0$. Clearly, $b^2 - 4ac = 0$. Neither a nor c is zero so either path can be chosen. With $\xi_x / \xi_y = -b/2a = x/y$, there results $\xi = x^2 + y^2$. With $\eta = x$, the equation becomes $u_{\eta\eta} = [2(\xi + \eta)u_\xi + u_\eta] / (\xi - \eta^2)$.

For *elliptic equations* the standard form is $u_{\alpha\alpha} + u_{\beta\beta} = \phi(u, u_{\alpha}, u_{\beta}, \alpha, \beta)$, where ξ and η are determined by solving the ξ and η equations of the hyperbolic system (they are complex) and taking $\alpha = (\eta + \xi)/2$, $\beta = (\eta - \xi)/2i$ ($i^2 = -1$). Since ξ and η are complex conjugates, both α and β are real.

Example 222.7

Consider the equation $y^2 u_{xx} + x^2 u_{yy} = 0$. Clearly, $b^2 - 4ac < 0$, so the equation is elliptic. Then $\xi_x/\xi_y = -ix/y$, $\eta_x/\eta_y = ix/y$, so $\alpha = (\eta + \xi)/2 = y^2$ and $\beta = (\eta - \xi)/2i = x^2$. The standard form is $u_{\alpha\alpha} + u_{\beta\beta} = -(u_{\alpha}/2\alpha + u_{\beta}/2\beta)$.

Methods of Solution

Separation of Variables

Perhaps the most elementary method for solving linear PDEs with homogeneous boundary conditions is the method of *separation of variables*. To illustrate, consider $u_t - u_{xx} = 0$, $u(x, 0) = f(x)$ (the initial condition) and $u(0, t) = u(1, t) = 0$ for $t > 0$ (the boundary conditions). A solution is assumed in "separated form" $u(x, t) = X(x)T(t)$. Upon substituting into the equation we find $\dot{T}/T = X''/X$ (where $\dot{T} = dT/dt$ and $X'' = d^2X/dx^2$). Since $T = T(t)$ and $X = X(x)$, the ratio must be constant, and for finiteness in t the constant must be negative, say $-\lambda^2$. The solutions of the separated equations $X'' + \lambda^2 X = 0$ with the boundary conditions $X(0) = 0$, $X(1) = 0$, and $\dot{T} = -\lambda^2 T$ are $X = A \sin \lambda x + B \cos \lambda x$ and $T = Ce^{-\lambda^2 t}$, where A , B , and C are arbitrary constants. To satisfy the boundary condition $X(0) = 0$, $B = 0$. An infinite number of values of λ (eigenvalues), say $\lambda_n = n\pi$ ($n = 1, 2, 3, \dots$), permit all the eigenfunctions $X_n = b_n \sin \lambda_n x$ to satisfy the other boundary condition $X(1) = 0$. The solution of the equation and boundary conditions (not the initial condition) is, by superposition, $u(x, t) = \sum_{n=1}^{\infty} b_n e^{-n^2 \pi^2 t} \sin n\pi x$ (a Fourier sine series), where the b_n are arbitrary. These values are obtained from the initial condition using the

orthogonality properties of the trigonometric function (e.g., $\int_{-\pi}^{\pi} \sin mx \sin nx \, dx$ is 0 for $m \neq n$ and is π for $m = n \neq 0$) to be $b_n = 2 \int_0^1 f(r) \sin n\pi r \, dr$. Then the solution of the problem is $u(x, t) = \sum_{n=1}^{\infty} \left[2 \int_0^1 f(r) \sin n\pi r \, dr \right] e^{-n^2 \pi^2 t} \sin n\pi x$, which is a Fourier sine series.

If $f(x)$ is a piecewise smooth or a piecewise continuous function defined for $a \leq x \leq b$, then its Fourier series within $a \leq x \leq b$ as its fundamental interval (it is extended periodically outside that interval) is

$$f(x) \sim \frac{1}{2} a_0 + \sum_{n=1}^{\infty} a_n \cos[2n\pi x / (b-a)] + b_n \sin[2n\pi x / (b-a)]$$

where

$$a_n = \left[\frac{2}{(b-a)} \int_a^b f(x) \cos[2n\pi x / (b-a)] dx, \quad n = 0, 1, \dots \right]$$

$$b_n = \left[\frac{2}{(b-a)} \int_a^b f(x) \sin[2n\pi x / (b-a)] dx, \quad n = 1, 2, \dots \right]$$

The Fourier sine series has $a_n \equiv 0$, and the Fourier cosine series has $b_n \equiv 0$. The symbol \sim means that the series converges to $f(x)$ at points of continuity, and at the (allowable) points of finite discontinuity the series converges to the *average value* of the discontinuous values.

Caution: This method *only* applies to linear equations with homogeneous boundary conditions. Linear equations with variable coefficients use other orthogonal functions, such as the Bessel functions, Laguerre functions, Chebyshev functions, and so forth.

Some nonhomogeneous boundary value problems can be transformed into homogeneous ones. Consider the problem $u_t - u_{xx} = 0$, $0 \leq x \leq 1$, $0 \leq t < \infty$ with initial condition $u(x,0) = f(x)$, and boundary conditions $u(0,t) = g(t)$, $u(1,t) = h(t)$. To homogenize the boundary conditions set $u(x,t) = w(x,t) + x[h(t) - g(t)] + g(t)$ and then solve $w_t - w_{xx} = [\dot{g}(t) - \dot{h}(t)] - \dot{g}(t)$ with the initial condition $w(x,0) = f(x) - x[h(0) - g(0)] + g(0)$ and $w(0,t) = w(1,t) = 0$.

Operational Methods

A number of integral transforms are useful for solving a variety of linear problems. To apply the Laplace transform to the problem $u_t - u_{xx} = \delta(x)\delta(t)$, $-\infty < x < \infty$, $0 \leq t$ with the initial condition $u(x, 0^-) = 0$, where δ is the Dirac delta function, we multiply by e^{-st} and integrate with respect to t from 0 to ∞ . With

the Laplace transform of $u(x, t)$ denoted by $U(x, s)$ — that is, $U(x, s) = \int_0^\infty e^{-st} u(x, t) dt$ — we have $sU - U_{xx} = \delta(x)$, which has the solution

$$U(x, s) = A(s)e^{-x\sqrt{s}} + B(s)e^{x\sqrt{s}} \quad \text{for } x > 0$$

$$U(x, s) = C(s)e^{-x\sqrt{s}} + D(s)e^{x\sqrt{s}} \quad \text{for } x < 0$$

Clearly, $B(s) = C(s) = 0$ for bounded solutions as $|x| \rightarrow \infty$. Then, from the boundary condition, $U(0^+, s) - U(0^-, s) = 0$ and integration of $sU - U_{xx} = \delta(x)$ from 0^- to 0^+ gives $U_x(0^+, s) - U_x(0^-, s) = -1$, so $A = D = 1/2\sqrt{s}$. Hence, $U(x, s) = (1/2\sqrt{s})e^{-\sqrt{s}|x|}$ and the inverse is $u(x, t) = (1/2\pi i) \int_\Gamma e^{st} U(x, s) ds$, where Γ is a Bromwich path, a vertical line taken to the right of all singularities of U on the sphere.

Similarity (Invariance)

This very useful approach is related to dimensional analysis; both have their foundations in group theory. The three important transformations that play a basic role in Newtonian mechanics are translation, scaling, and rotations. Using two independent variables x and t and one dependent variable $u = u(x, t)$, the *translation group* is $\bar{x} = x + \alpha a$, $\bar{t} = t + \beta a$, $\bar{u} = u + \gamma a$; the *scaling group* is $\bar{x} = a^\alpha x$, $\bar{t} = a^\beta t$, and $\bar{u} = a^\gamma u$; the *rotation group* is $\bar{x} = x \cos a + t \sin a$, $\bar{t} = t \cos a - x \sin a$, $\bar{u} = u$, with a nonnegative real number a . Important in what follows are the *invariants* of these groups. For the translation group there are two $\eta = x - \lambda t$, $\lambda = \alpha/\beta$, $f(\eta) = u - \varepsilon t$, $\varepsilon = \gamma/\beta$ or $f(\eta) = u - \theta x$, $\theta = \gamma/\alpha$; for the scaling group the invariants are $\eta = x/t^{\alpha/\beta}$ (or $t/x^{\beta/\alpha}$) and $f(\eta) = u/t^{\gamma/\beta}$ (or $u/x^{\gamma/\alpha}$); for the rotation group the invariants are $\eta = x^2 + t^2$ and $u = f(\eta) = f(x^2 + t^2)$.

If a PDE and its data (initial and boundary conditions) are left invariant by a transformation group, then similar (invariant) solutions are sought using the invariants. For example, if an equation is left invariant under scaling, then solutions are sought of the form $u(x, t) = t^{\gamma/\beta} f(\eta)$, $\eta = x t^{-\alpha/\beta}$ or $u(x, t) = x^{\gamma/\alpha} f(t x^{-\beta/\alpha})$; invariance under translation gives solutions of the form $u(x, t) = f(x - \lambda t)$; and invariance under rotation gives rise to solutions of the form $u(x, t) = f(x^2 + t^2)$.

Examples of invariance include the following:

1. The equation $u_{xx} + u_{yy} = 0$ is invariant under rotation, so we search for solutions of the form $u = f(x^2 + y^2)$. Substitution gives the ODE $f' + \eta f'' = 0$ or $(\eta f')' = 0$. The solution is $u(x, t) = c \ln \eta = c \ln(x^2 + t^2)$, which is the (so-called) fundamental solution of Laplace's equation.

- The nonlinear diffusion equation $u_t = (u^n u_x)_x$ ($n > 0$), $0 \leq x$, $0 \leq t$, $u(0,t) = ct^n$ is invariant under scaling with the similar form $u(x,t) = t^n f(\eta)$, $\eta = xt^{-(n+1)/2}$. Substituting into the PDE gives the equation $(f''f)' + ((n+1)/2)\eta f' - nf = 0$, with $f(0) = c$ and $f(\infty) = 0$. Note that the equation is an ODE.
- The wave equation $u_{xx} - u_{tt} = 0$ is invariant under translation. Hence, solutions exist of the form $u = f(x - \lambda t)$. Substitution gives $f''(1 - \lambda^2) = 0$. Hence, $\lambda = \pm 1$ or f is linear. Rejecting the trivial linear solution we see that $u = f(x - t) + g(x + t)$, which is the general (d'Alembert) solution of the wave equation; the quantities $x - t = \alpha$, $x + t = \beta$ are the characteristics of the next section.

The construction of all transformations that leave a PDE invariant is a solved problem left for the references.

The study of "solitons" (solitary traveling waves with special properties) has benefited from symmetry considerations. For example, the nonlinear third-order (Korteweg-de Vries) equation $u_t + uu_x - au_{xxx} = 0$ is invariant under translation. Solutions are sought of the form $u = f(x - \lambda t)$, and f satisfies the ODE, in $\eta = x - \lambda t$, $-\lambda f' + ff' - af''' = 0$.

Characteristics

Using the characteristics of the solution of the hyperbolic problem $u_{tt} - u_{xx} = p(x,t)$, $-\infty < x < \infty$, $0 \leq t$, $u(x,0) = f(x)$, $u_t(x,0) = h(x)$ is

$$u(x,t) = \frac{1}{2} \int_0^t d\tau \int_{x-(t-\tau)}^{x+(t-\tau)} p(\xi, \tau) d\xi + \frac{1}{2} \int_{x-t}^{x+t} h(\xi) d\xi + \frac{1}{2} [f(x+t)] + f(x-t)$$

The solution of $u_{tt} - u_{xx} = 0$, $0 \leq x < \infty$, $0 \leq t < \infty$, $u(x,0) = 0$, $u_t(x,0) = h(x)$, $u(0,t) = 0$, $t > 0$ is $u(x,t) = \frac{1}{2} \int_{-x+1}^{x+t} h(\xi) d\xi$.

The solution of $u_{tt} - u_{xx} = 0$, $0 \leq x < \infty$, $0 \leq t < \infty$, $u(x,0) = 0$, $u_t(x,0) = 0$, $u(0,t) = g(t)$, $t > 0$ is

$$u(x,t) = \begin{cases} 0 & \text{if } t < x \\ g(t-x) & \text{if } t > x \end{cases}$$

From time to time, lower-order derivatives appear in the PDE in use. To remove these from the equation $u_{tt} - u_{xx} + au_x + bu_t + cu = 0$, where a , b , and c are constants, set $\xi = x + t$, $\mu = t - x$, whereupon $u(x,t) = u[(\xi - \mu)/2, (\xi + \mu)/2] = U(\xi, \mu)$, where $U_{\xi\mu} + [(b+a)/4]U_{\xi} + [(b-a)/4]U_{\mu} + (c/4)U = 0$. The transformation $U(\xi, \mu) = W(\xi, \mu) \exp[-(b-a)\xi/4 - (b+a)\mu/4]$ reduces to satisfying $W_{\xi\mu} = \lambda W = 0$, where $\lambda = (a^2 - b^2 + 4c)/16$. If $\lambda \neq 0$, we lose the simple d'Alembert solution. But the equation for W is still easier to handle.

In linear problems, discontinuities propagate along characteristics. In nonlinear problems, the situation is usually different. The characteristics are often used as new coordinates in the numerical method of characteristics.

Green's Function

Consider the diffusion problem $u_t - u_{xx} = \delta(t)\delta(x - \xi)$, $0 \leq x < \infty$, $\xi > 0$, $u(0,t) = 0$, $u(x,0) = 0$ [$u(\infty,t) = u(\infty,0) = 0$], a problem that results from a unit source somewhere in the domain subject to a homogeneous (zero) boundary condition. The solution is called a *Green's function of the first kind*. For this problem there is $G_1(x, \xi, t) = F(x - \xi, t) - F(x + \xi, t)$, where $F(x, t) = e^{-x^2/4t} / \sqrt{4\pi t}$ is the *fundamental* (invariant) *solution*. More generally, the solution of $u_t - u_{xx} = \delta(x - \xi)\delta(t - \tau)$, $\xi > 0$, $\tau > 0$, with the same conditions as before, is the Green's function of the first kind

$$G_1(x, \xi, t - \tau) = \frac{1}{\sqrt{4\pi(t - \tau)}} [e^{-(x+\xi)^2/4(t-\tau)} - e^{-(x-\xi)^2/4(t-\tau)}]$$

for the semifinite interval.

The solution of $u_t - u_{xx} = p(x, t)$, $0 \leq x < \infty$, $0 \leq t < \infty$, with $u(x, 0) = 0$, $u(0, t) = 0$, $t > 0$ is $u(x, t) = \int_0^t d\tau \int_0^\infty p(\xi, \tau) G_1(x, \xi, t - \tau) d\xi$, which is a superposition. Note that the Green's function and the desired solution must both satisfy a zero boundary condition at the origin for this solution to make sense.

The solution of $u_t - u_{xx} = 0$, $0 \leq x < \infty$, $0 \leq t < \infty$, $u(x, 0) = f(x)$, $u(0, t) = 0$, $t > 0$ is $u(x, t) = \int_0^\infty f(\xi) G_1(x, \xi, t) d\xi$.

The solution of $u_t - u_{xx} = 0$, $0 \leq x < \infty$, $0 \leq t < \infty$, $u(x, 0) = 0$, $u(0, t) = g(t)$, $t > 0$ (nonhomogeneous) is obtained by transforming to a new problem that has a homogeneous boundary condition, Thus, with $w(x, t) = u(x, t) - g(t)$ the equation for w becomes $w_t - w_{xx} = -\dot{g}(t) - g(0)\delta(t)$ and $w(x, 0) = 0$, $w(0, t) = 0$.

Using G_1 , above, we finally obtain $u(x, t) = (x / \sqrt{4\pi}) \int_0^t g(t - \tau) e^{-x^2/4\tau} / \tau^{3/2} d\tau$.

The Green's function approach can also be employed for elliptic and hyperbolic problems.

Equations in Other Spatial Variables

The spherically symmetric wave equation $u_{rr} + 2u_r/r - u_{tt} = 0$ has the general solution $u(r, t) = [f(t - r) + g(t + r)]/r$.

The Poisson-Euler-Darboux equation, arising in gas dynamics,

$$u_{rs} + N(u_r + u_s)/(r + s) = 0$$

where N is a positive integer ≥ 1 , has the general solution

$$u(r, s) = k + \frac{\partial^{N-1}}{\partial r^{N-1}} \left[\frac{f(r)}{(r+s)^N} \right] + \frac{\partial^{N-1}}{\partial s^{N-1}} \left[\frac{g(s)}{(r+s)^N} \right]$$

Here, k is an arbitrary constant and f and g are arbitrary functions whose form is determined from the problem initial and boundary conditions.

Conversion to Other Orthogonal Coordinate Systems

Let (x^1, x^2, x^3) be rectangular (Cartesian) coordinates and (u^1, u^2, u^3) be any orthogonal coordinate system related to the rectangular coordinates by $x^i = x^i(u^1, u^2, u^3)$, $i = 1, 2, 3$. With $(ds)^2 = (dx^1)^2 + (dx^2)^2 + (dx^3)^2 = g_{11}(du^1)^2 + g_{22}(du^2)^2 + g_{33}(du^3)^2$, where $g_{ii} = (\partial x^i / \partial u^i)^2 + (\partial x^2 / \partial u^i)^2 + (\partial x^3 / \partial u^i)^2$. In terms of these "metric" coefficients, the basic operations of applied mathematics are expressible. Thus (with $g = g_{11}g_{22}g_{33}$),

$$dA = (g_{11}g_{22})^{1/2} du^1 du^2; \quad dV = (g_{11}g_{22}g_{33})^{1/2} du^1 du^2 du^3;$$

$$\text{grad } \phi = \frac{\bar{a}_1}{(g_{11})^{1/2}} \frac{\partial \phi}{\partial u^1} + \frac{\bar{a}_2}{(g_{22})^{1/2}} \frac{\partial \phi}{\partial u^2} + \frac{\bar{a}_3}{(g_{33})^{1/2}} \frac{\partial \phi}{\partial u^3}$$

(\bar{a}_i are unit vectors in direction i);

TABLE 222.2 Some Coordinate Systems

| Coordinate System | Metric Coefficients | |
|----------------------------------|---------------------|----------------------------|
| Circular Cylindrical | | |
| $x = r \cos \theta$ | $u^1 = r$ | $g_{11} = 1$ |
| $y = r \sin \theta$ | $u^2 = \theta$ | $g_{22} = r^2$ |
| $z = z$ | $u^3 = z$ | $g_{33} = 1$ |
| Spherical | | |
| $x = r \sin \psi \cos \theta$ | $u^1 = r$ | $g_{11} = 1$ |
| $y = r \sin \psi \sin \theta$ | $u^2 = \psi$ | $g_{22} = r^2$ |
| $x = r \cos \psi$ | $u^3 = \theta$ | $g_{33} = r^2 \sin^2 \psi$ |
| Parabolic Coordinates | | |
| $x = \mu\nu \cos \theta$ | $u^1 = \mu$ | $g_{11} = \mu^2 + \nu^2$ |
| $y = \mu\nu \sin \theta$ | $u^2 = \nu$ | $g_{22} = \mu^2 + \nu^2$ |
| $z = \frac{1}{2}(\mu^2 - \nu^2)$ | $u^3 = \theta$ | $g_{33} = \mu^2\nu^2$ |

Note: Other metric coefficients and so forth can be found in Moon, P. and Spencer, D. E. 1961. *Field Theory Handbook*. Springer, Berlin.

$$\operatorname{div} \vec{E} = g^{-1/2} \left\{ \frac{\partial}{\partial u^1} [(g_{22}g_{33})^{1/2} E_1] + \frac{\partial}{\partial u^2} [(g_{11}g_{33})^{1/2} E_2] + \frac{\partial}{\partial u^3} [(g_{11}g_{22})^{1/2} E_3] \right\}$$

(here $\vec{E} = (E_1, E_2, E_3)$);

$$\begin{aligned} \operatorname{curl} \vec{E} = g^{-1/2} & \left\{ \bar{a}_1 (g_{11})^{1/2} \left(\frac{\partial}{\partial u^2} [(g_{33})^{1/2} E_3] - \frac{\partial}{\partial u^3} [(g_{22})^{1/2} E_2] \right) \right. \\ & + \bar{a}_2 (g_{22})^{1/2} \left(\frac{\partial}{\partial u^3} [(g_{11})^{1/2} E_1] - \frac{\partial}{\partial u^1} [(g_{33})^{1/2} E_3] \right) \\ & \left. + \bar{a}_3 (g_{33})^{1/2} \left(\frac{\partial}{\partial u^1} [(g_{22})^{1/2} E_2] - \frac{\partial}{\partial u^2} [(g_{11})^{1/2} E_1] \right) \right\} \end{aligned}$$

$$\operatorname{div} \operatorname{grad} \psi = \nabla^2 \psi = \text{Laplacian of } \psi = g^{-1/2} \sum_{i=1}^3 \frac{\partial}{\partial u^i} \left[\frac{g^{1/2}}{g_{ii}} \frac{\partial \psi}{\partial u^i} \right]$$

223.1 Classification and Notation
223.2 Relation to Differential Equations
223.3 Methods of Solution
Convolution Equations • Abel Equation • Approximate Method
(Picard's Method)

223.1 Classification and Notation

Any equation in which the unknown function $u(x)$ appears under the integral sign is called an *integral equation*. If $f(x)$, $K(x,t)$, a , and b are known then the integral equation for u , $\int_B^A K(x,t)u(t)dt = f(x)$ is called a *linear integral equation of the first kind of Fredholm type*. $K(x,t)$ is called the *kernel function* of the equation. If b is replaced by x (the independent variable) the equation is an equation of *Volterra type of the first kind*.

An equation of the form $u(x) = f(x) + \lambda \int_B^A K(x,t)u(t)dt$ is said to be a linear integral equation of *Fredholm type of the second kind*. If b is replaced by x it is of *Volterra type*. If $f(x)$ is not present, the equation is homogeneous.

The equation $\phi(x)u(x) = f(x) + \lambda \int_a^{b \text{ or } x} K(x,t)u(t)dt$ is the *third kind equation* of Fredholm or Volterra type. If the unknown function u appears in the equation in any way other than to the first power then the integral equation is said to be *nonlinear*. Thus, $u(x) = f(x) + \int_a^b K(x,t) \sin u(t)dt$ is nonlinear. An integral equation is said to be *singular* when either or both of the limits of integration are infinite or if $K(x,t)$ becomes infinite at one or more points of the integration interval.

Example 223.1

Consider the singular equations $u(x) = x + \int_0^\infty \sin(xt)u(t)dt$ and $f(x) = \int_0^x [u(t)/(x-t)^2]dt$.

223.2 Relation to Differential Equations

The *Leibnitz rule* $(d/dx) \int_{a(x)}^{b(x)} F(x,t)dt = \int_{a(x)}^{b(x)} (\partial F / \partial x) dt + F[x,b(x)](db/dx) - F[x,a(x)] \times (da/dx)$ is useful for differentiation of an integral involving a parameter (x in this case). With this, one can establish the relation.

$$I_n(x) = \int_a^x (x-t)^{n-1} f(t)dt = (n-1)! \underbrace{\int_a^x \cdots \int_a^x}_{n \text{ times}} \underbrace{f(x)dx \cdots dx}_{n \text{ times}}$$

This result will be used to establish the relation of the second-order initial value problem to a Volterra integral equation.

The second-order differential equation $y''(x) + A(x)y'(x) + B(x)y = f(x)$, $y(a) = y_0$, $y'(a) = y'_0$ is equivalent to the integral equations

$$y(x) = - \int_a^x \{A(t) + (x-t)[B(t) - A'(t)]\}y(t)dt + \int_a^x (x-t)f(t)dt + [A(a)y_0 + y'_0](x-a) + y_0$$

which is of the type $y(x) = \int_a^x K(x,t)y(t)dt + F(x)$, where $K(x,t) = (t-x)[B(t) - A'(t)] - A(t)$ and $F(x)$ includes the rest of the terms. Thus, this initial value problem is equivalent to a Volterra integral equation of the second kind.

Example 223.2

Consider the equation $y'' + x^2y' + xy = x$, $y(0) = 1$, $y'(0) = 0$. Here $A(x) = x^2$, $B(x) = x$, $f(x) = x$, $a = 0$, $y_0 = 1$, $y'_0 = 0$. The integral equation is $y(x) = \int_0^x t(x-2t)y(t)dt + (x^3/6) + 1$.

The expression for $I_n(x)$ can also be useful in converting boundary value problems to integral equations. For example, the problem $y''(x) + \lambda y = 0$, $y(0) = 0$, $y(a) = 0$ is equivalent to the Fredholm equation $y(x) = \lambda \int_0^a K(x,t)y(t)dt$, where $K(x,t) = (t/a)(a-x)$ when $t < x$ and $K(x,t) = (x/a)(a-t)$ when $t > x$.

In both cases the differential equation can be recovered from the integral equation by using the Leibnitz rule. Nonlinear differential equations can also be transformed into integral equations. In fact, this is one method used to establish properties of the equation and to develop approximate and numerical solutions. For example, the "forced pendulum" equation $y''(x) + a^2 \sin y(x) = f(x)$, $y(0) = y(1) = 0$ transforms into the nonlinear Fredholm equation,

$$y(x) = \int_0^1 K(x,t)[a^2 \sin y(t) - f(t)]dt$$

with $K(x,t) = x(1-y)$ for $0 < x < t$ and $K(x,t) = t(1-x)$ for $t < x < 1$.

223.3 Methods of Solution

Only the simplest integral equations can be solved exactly. Usually approximate or numerical methods are employed. The advantage here is that integration is a “smoothing operation,” whereas differentiation is a “roughening operation.” A few exact and approximate methods are given in the following sections. The numerical methods are found in [Chapter 230](#).

Convolution Equations

The special convolution equation $y(x) = f(x) + \lambda \int_0^x K(x-t)y(t)dt$ is a special case of the Volterra equation of the second kind. $K(x-t)$ is said to be a *convolution kernel*. The integral part is the convolution integral discussed in [Chapter 225](#). The solution can be accomplished by transforming with the Laplace transform: $L[y(x)] = L[f(x)] + \lambda L[y(x)]L[K(x)]$ or $y(x) = L^{-1}\{L[f(x)]/(1 - \lambda L[K(x)])\}$.

Abel Equation

The Volterra equation $f(x) = \int_0^x (t)/(x-t)^\alpha dt$, $0 < \alpha < 1$ is the (singular) Abel equation. Its solution is $y(x) = (\sin \alpha\pi/\pi)(d/dx) \int_0^x F(t)/(x-t)^{1-\alpha} dt$.

Approximate Method (Picard's Method)

This method is one of successive approximations that is described for the equation $y(x) = f(x) + \lambda \int_a^x K(x,t)y(t)dt$. Beginning with an initial guess $y_0(t)$ (often the value at the initial point a) generate the next approximation with $y_1(x) = f(x) + \lambda \int_a^x K(x,t)y_0(t)dt$ and continue with the general iteration

$$y_n(x) = f(x) + \lambda \int_a^x K(x,t)y_{n-1}(t)dt$$

Then, by iterating, one studies the convergence of this process, as is described in the literature.

Example 223.3

Let $y(x) = 1 + \int_0^x xt[y(t)]^2 dt$, $y(0) = 1$. With $y_0(t) = 1$ we find $y_1(x) = 1 + \int_0^x xt dt = 1 + (x^2/2)$ and

$y_2(x) = 1 + \int_0^x xt[1 + (t^2/2)]^2 dt$, and so forth.

Approximation Methods

William F. Ames
Georgia Institute of Technology

- 224.1 Perturbation
 - [Regular Perturbation](#) • [Singular Perturbation](#) • [Boundary Layer Method](#)
- 224.2 Iterative Methods
 - [Picard's Method](#)

The term *approximation methods* usually refers to an analytical process that generates a symbolic approximation rather than a numerical one. Thus, $1 + x + x^2/2$ is an approximation of e^x for small x . This chapter introduces some techniques for approximating the solution of various operator equations.

224.1 Perturbation

Regular Perturbation

This procedure is applicable to *some* equations in which a small parameter, ε , appears. Use this procedure with care; the procedure involves expansion of the dependent variables and data in a power series in the small parameter. The following example illustrates the procedure.

Example 224.1

Consider the equation $y'' + \varepsilon y' + y = 0$, $y(0) = 1$, $y'(0) = 0$. Write $y(x; \varepsilon) = y_0(x) + \varepsilon y_1(x) + \varepsilon^2 y_2(x) + \dots$, and the initial conditions (data) become

$$y_0(0) + \varepsilon y_1(0) + \varepsilon^2 y_2(0) + \dots = 1$$

$$y_0'(0) + \varepsilon y_1'(0) + \varepsilon^2 y_2'(0) + \dots = 0$$

Equating like powers of ε in all three equations yields the sequence of equations

$$O(\varepsilon^0): y_0'' + y_0 = 0, \quad y_0(0) = 1, \quad y_0'(0) = 0$$

$$O(\varepsilon^1): y_1'' + y_1 = -y_0', \quad y_1(0) = 0, \quad y_1'(0) = 0$$

⋮

The solution for y_0 is $y_0 = \cos x$ and using this for y_1 we find $y_1(x) = \frac{1}{2}(\sin x - x \cos x)$. So $y(x; \varepsilon) = \cos x + \varepsilon(\sin x - x \cos x)/2 + O(\varepsilon^2)$. Appearance of the term $x \cos x$ indicates a *secular term* that becomes

arbitrarily large as $x \rightarrow \infty$. Hence, this approximation is valid only for $x \ll 1/\epsilon$ and for small ϵ . If an approximation is desired over a larger range of x , then the method of multiple scales is required.

Singular Perturbation

The *method of multiple scales* is a singular method that is *sometimes* useful if the regular perturbation method fails. In this case the assumption is made that the solution depends on *two* (or more) different length (or time) scales. By trying various possibilities, one can determine those scales. The scales are treated as dependent variables when transforming the given ordinary differential equation into a partial differential equation, but then the scales are treated as independent variables when solving the equations.

Example 224.2

Consider the equation $\epsilon y'' + y' = 2$, $y(0) = 0$, $y(1) = 1$. This is singular since (with $\epsilon = 0$) the resulting first-order equation cannot satisfy both boundary conditions. For the problem the proper length scales are $u = x$ and $v = x/\epsilon$. The second scale can be ascertained by substituting $\epsilon^n x$ for x and requiring $\epsilon y''$ and y' to be of the same order in the transformed equation. Then

$$\frac{d}{dx} = \frac{\partial}{\partial u} \frac{du}{dx} + \frac{\partial}{\partial v} \frac{dv}{dx} = \frac{\partial}{\partial u} + \frac{1}{\epsilon} \frac{\partial}{\partial v}$$

and the equation becomes

$$\epsilon \left(\frac{\partial}{\partial u} + \frac{1}{\epsilon} \frac{\partial}{\partial v} \right)^2 y + \left(\frac{\partial}{\partial u} + \frac{1}{\epsilon} \frac{\partial}{\partial v} \right) y = 2.$$

With $y(x; \epsilon) = y_0(u, v) + \epsilon y_1(u, v) + \epsilon^2 y_2(u, v) + \dots$, we have terms

$$O(\epsilon^{-1}): \frac{\partial^2 y_0}{\partial v^2} + \frac{\partial y_0}{\partial v} = 0 \quad (\text{actually ODEs with parameter } u)$$

$$O(\epsilon^0): \frac{\partial^2 y_1}{\partial v^2} + \frac{\partial y_1}{\partial v} = 2 - 2 \frac{\partial^2 y_0}{\partial u \partial v} - \frac{\partial y_0}{\partial u}$$

$$O(\epsilon^1): \frac{\partial^2 y_2}{\partial v^2} + \frac{\partial y_2}{\partial v} = -2 \frac{\partial^2 y_1}{\partial u \partial v} - \frac{\partial y_1}{\partial u} - \frac{\partial^2 y_0}{\partial u^2}$$

⋮

Then $y_0(u, v) = A(u) + B(u)e^{-v}$ and so the second equation becomes $\partial^2 y_1/\partial v^2 + \partial y_1/\partial v = 2 - A'(u) + B'(u)e^{-v}$, with the solution $y_1(u, v) = [2 - A'(u)]v + vB'(u)e^{-v} + D(u) + E(u)e^{-v}$. Here A , B , D , and E are still arbitrary. Now the solvability condition — “higher order terms must vanish no slower (as $\epsilon \rightarrow 0$) than the previous term” [Kevorkian and Cole, 1981] — is used. For y_1 to vanish no slower than y_0 , we must have $2 - A'(u) = 0$ and $B'(u) = 0$. If this were not true, the terms in y_1 would be larger than those in y_0 ($v \gg 1$). Thus, $y_0(u, v) = (2u + A_0) + B_0 e^{-v}$, or in the original variables $y(x; \epsilon) \approx (2x + A_0) + B_0 e^{-x/\epsilon}$ and matching to both boundary conditions gives $y(x; \epsilon) \approx 2x - (1 - e^{-x/\epsilon})$.

Boundary Layer Method

The boundary layer method is applicable to regions in which the solution is *rapidly varying*. See the references at the end of the chapter for detailed discussion.

224.2 Iterative Methods

Taylor Series

If it is known that the solution of a differential equation has a power series in the independent variable (t), then we may proceed from the initial data (the easiest problem) to compute the Taylor series by differentiation.

Example 224.3

Consider the equation $(d^2x/dt^2) = -x - x^2$, $x(0) = 1$, $x'(0) = 1$. From the differential equation, $x''(0) = -2$, and, since $x''' = -x' - 2xx'$, $x'''(0) = -1 - 2 = -3$, so the four term approximation for $x(t) \approx 1 + t - (2t^2/2!) - (3t^3/3!) = 1 + t - t^2 - t^3/2$. An estimate for the error at $t = t_1$ (see a discussion of series methods in any calculus text), is not greater than $|d^4x/dt^4|_{\max}[(t_1)^4/4!]$, $0 \leq t \leq t_1$.

Picard's Method

If the vector differential equation $\mathbf{x}' = f(t, \mathbf{x})$, $\mathbf{x}(0)$ given, is to be approximated by Picard iteration, we begin with an initial guess $\mathbf{x}_0 = \mathbf{x}(0)$ and calculate iteratively $\mathbf{x}'_i = f(t, \mathbf{x}_{i-1})$.

Example 224.4

Consider the equation $x' = x + y^2$, $y' = y - x^3$, $x(0) = 1$, $y(0) = 2$. With $x_0 = 1$, $y_0 = 2$, $x'_1 = 5$, $y'_1 = 1$, so $x_1 = 5t + 1$, $y_1 = t + 2$, since $x_i(0) = 1$, $y_i(0) = 2$ for $i \geq 0$. To continue, use $x'_{i+1} = x_i + y_i^2$, $y'_{i+1} = y_i - x_i^3$. A modification is the utilization of the first calculated term immediately in the second equation. Thus, the calculated value of $x_1 = 5t + 1$, when used in the second equation, gives $y'_1 = y_0 - (5t + 1)^3 = 2 - (125t^3 + 75t^2 + 15t + 1)$, so $y_1 = 2t - (125t^4/4) - 25t^3 - (15t^2/2) - t + 2$. Continue with the iteration $x'_{i+1} = x_i + y_i^3$, $y'_{i+1} = y_i - (x_{i+1})^3$.

Another variation would be $x'_{i+1} = x_{i+1} + (y_i)^3$, $y'_{i+1} = y_{i+1} - (x_{i+1})^3$.

Georgia Institute of Technology

All of the integral transforms are special cases of the equation $g(s) = \int_a^b K(s, t)f(t)dt$, in which $g(s)$ is said to be the *transform* of $f(t)$, and $K(s, t)$ is called the *kernel* of the transform. Table 225.1 shows the more important kernels and the corresponding intervals (a, b) .

Details for the first three transforms listed in Table 225.1 are given in this chapter. The details for the others are found in the literature.

225.1 Laplace Transform

The Laplace transform of $f(t)$ is $g(s) = \int_0^\infty e^{-st}f(t)dt$. It may be thought of as transforming one class of functions into another. The advantage in the operation is that under certain circumstances it replaces complicated functions by simpler ones. The notation $L[f(t)] = g(s)$ is called the *direct transform* and $L^{-1}[g(s)] = f(t)$ is called the *inverse transform*. Both the direct and inverse transforms are tabulated for many often-occurring functions. In general $L^{-1}[g(s)] = (1/2\pi i) \int_{\alpha-i\infty}^{\alpha+i\infty} e^{st}g(s)ds$, and to evaluate this integral requires a knowledge of complex variables, the theory of residues, and contour integration.

Properties of the Laplace Transform

Let $L[f(t)] = g(s)$, $L^{-1}[g(s)] = f(t)$.

1. The Laplace transform may be applied to a function $f(t)$ if $f(t)$ is continuous or piecewise continuous; if $t^n|f(t)|$ is finite for all t , $t \rightarrow 0$, $n < 1$; and if $e^{-at}|f(t)|$ is finite as $t \rightarrow \infty$ for some value of a , $a > 0$.
 2. L and L^{-1} are unique.
 3. $L[af(t) + bh(t)] = aL[f(t)] + bL[h(t)]$ (linearity).
-

TABLE 225.1 Kernels and Intervals of Various Integral Transforms

| Name of Transform | (a, b) | $K(s, t)$ |
|-------------------|---------------------|--------------------------------------|
| Laplace | $(0, \infty)$ | e^{-st} |
| Fourier | $(-\infty, \infty)$ | $\frac{1}{\sqrt{2\pi}} e^{-ist}$ |
| Fourier cosine | $(0, \infty)$ | $\sqrt{\frac{2}{\pi}} \cos st$ |
| Fourier sine | $(0, \infty)$ | $\sqrt{\frac{2}{\pi}} \sin st$ |
| Mellin | $(0, \infty)$ | t^{s-1} |
| Hankel | $(0, \infty)$ | $t J_\nu(st), \nu \geq -\frac{1}{2}$ |

- $L[e^{at} f(t)] = g(s-a)$ (shift theorem).
- $L[(-t)^k f(t)] = d^k g / ds^k; k$ a positive integer.

Example 225.1

$L[\sin at] = \int_0^\infty e^{-st} \sin at \, dt = a / (s^2 + a^2), s > 0$. By property 5,

$$\int_0^\infty e^{-st} t \sin at \, dt = L[t \sin at] = \frac{2as}{s^2 + a^2}$$

- $L[f'(t)] = sL[f(t)] - f(0)$

$$L[f''(t)] = s^2 L[f(t)] - sf(0) - f'(0)$$

⋮

$$L[f^{(n)}(t)] = s^n L[f(t)] - s^{n-1} f(0) - \dots - sf^{(n-2)}(0) - f^{(n-1)}(0)$$

In this property it is apparent that the initial data are automatically brought into the computation.

Example 225.2

Solve $y'' + y = e^t, y(0) = 0, y'(0) = 1$. Now $L[y''] = s^2 L[y] - sy(0) - y'(0) = s^2 L[y] - s - 1$. Thus, using the linear property of the transform (property 3), $s^2 L[y] + L[y] - s - 1 = L[e^t] = 1/(s-1)$. Therefore, $L[y] = s^2 / [(s-1)(s^2 + 1)]$.

With the notations $\Gamma(n+1) = \int_0^\infty x^n e^{-x} dx$ (gamma function) and $J_n(t)$ the Bessel function of the first kind of order n , a short table of Laplace transforms is given in Table 204.2.

- $L[\int_a^t f(t) dt] = \frac{1}{s} L[f(t)] + \frac{1}{s} \int_a^0 f(t) dt$.

Example 225.3

Find $f(t)$ if $L[f(t)] = (1/s^2)[1/(s^2 - a^2)]$. $L[1/a \sinh at] = 1/(s^2 - a^2)$. Therefore, $f(t) = \int_0^t [\int_0^t \frac{1}{a} \sinh a t dt] dt = 1/a^2 [(\sinh at)/a - t]$.

TABLE 225.2 Some Laplace Transforms

| $f(t)$ | $g(s)$ | $f(t)$ | $g(s)$ |
|---------------------------|-------------------------------|------------------------------------|----------------------------------|
| 1 | $\frac{1}{s}$ | $e^{-at}(1-at)$ | $\frac{s}{(s+a)^2}$ |
| t^n, n is a + integer | $\frac{n!}{s^{n+1}}$ | $\frac{t \sin at}{2a}$ | $\frac{s}{(s^2+a^2)^2}$ |
| $t^n, n \neq a +$ integer | $\frac{\Gamma(n+1)}{s^{n+1}}$ | $\frac{1}{2a^2} \sin at \sinh at$ | $\frac{s}{s^4+4a^4}$ |
| $\cos at$ | $\frac{s}{s^2+a^2}$ | $\cos at \cosh at$ | $\frac{s^3}{s^4+4a^4}$ |
| $\sin at$ | $\frac{a}{s^2+a^2}$ | $\frac{1}{2a}(\sinh at + \sin at)$ | $\frac{s^2}{s^4-a^4}$ |
| $\cosh at$ | $\frac{s}{s^2-a^2}$ | $\frac{1}{2}(\cosh at + \cos at)$ | $\frac{s^3}{s^4-a^4}$ |
| $\sinh at$ | $\frac{a}{s^2-a^2}$ | $\frac{\sin at}{t}$ | $\tan^{-1} \frac{a}{s}$ |
| e^{-at} | $\frac{1}{s+a}$ | $J_0(at)$ | $\frac{1}{\sqrt{s^2+a^2}}$ |
| $e^{-bt} \cos at$ | $\frac{s+b}{(s+b)^2+a^2}$ | $\frac{n}{a^n} \frac{J_n(at)}{t}$ | $\frac{1}{(\sqrt{s^2+a^2}+s)^n}$ |
| $e^{-bt} \sin at$ | $\frac{a}{(s+b)^2+a^2}$ | $J_0(2\sqrt{at})$ | $\frac{1}{s} e^{-a/s}$ |

$$1. \quad L\left[\frac{f(t)}{t}\right] = \int_s^\infty g(s)ds; \quad L\left[\frac{f(t)}{t^k}\right] = \underbrace{\int_s^\infty \dots \int_s^\infty}_{k \text{ integrals}} g(s)(ds)^k$$

Example 225.4

$$L[(\sin at)/t] = \int_s^\infty L[\sin at]ds = \int_s^\infty [ads/(s^2+a^2)] = \cot^{-1}(s/a).$$

1. The *unit step function* $u(t-a) = 0$ for $t < a$ and 1 for $t > a$. $L[u(t-a)] = e^{-as}/s$.
2. The *unit impulse function* is $\delta(a) = u'(t-a) = 1$ at $t = a$ and 0 elsewhere. $L[u'(t-a)] = e^{-as}$.
3. $L^{-1}[e^{-as}g(s)] = f(t-a)u(t-a)$ (second shift theorem).
4. If $f(t)$ is *periodic* of period b — that is, $f(t+b) = f(t)$ — then $L[f(t)] = [1/(1-e^{-bs})] \times \int_0^b e^{-st} f(t)dt$.

Example 225.5

The equation $\partial^2 y / (\partial t \partial x) + \partial y / \partial t + \partial y / \partial x = 0$ with $(\partial y / \partial x)(0, x) = y(0, x) = 0$ and $y(t, 0) + (\partial y / \partial t)(t, 0) = \delta(0)$ (see property 10) is solved by using the Laplace transform of y with respect to t . With $g(s, x) = \int_0^\infty e^{-st} y(t, x)dt$, the transformed equation becomes

$$s \frac{\partial g}{\partial x} - \frac{\partial y}{\partial x}(0, x) + sg - y(0, x) + \frac{\partial g}{\partial x} = 0$$

or

$$(s+1)\frac{\partial g}{\partial x} + sg = \frac{\partial y}{\partial x}(0, x) + y(0, x) = 0$$

The second (boundary) condition gives $g(s, 0) + sg(s, 0) - y(0, 0) = 1$ or $g(s, 0) = 1/(1+s)$. A solution of the preceding ordinary differential equation consistent with this condition is $g(s, x) = [1/(s+1)]e^{-sx/(s+1)}$. Inversion of this transform gives $y(t, x) = e^{-(t+x)}I_0(2/\sqrt{tx})$, where I_0 is the zero-order Bessel function of an imaginary argument.

225.2 Convolution Integral

The *convolution integral* (*faltung*) of two functions $f(t)$, $r(t)$ is $x(t) = f(t) * r(t) = \int_0^t f(\tau)r(t-\tau)d\tau$.

Example 225.6

$$t * \sin t = \int_0^t \tau \sin(t-\tau)d\tau = t - \sin t.$$

- $L[f(t)]L[h(t)] = L[f(t) * h(t)].$

225.3 Fourier Transform

The *Fourier transform* is given by $F[f(t)] = (1/\sqrt{2\pi})\int_{-\infty}^{\infty} f(t)e^{-ist} dt = g(s)$ and its *inverse* by $F^{-1}[g(s)] = (1/\sqrt{2\pi})\int_{-\infty}^{\infty} g(s)e^{ist} dt = f(t)$. In brief, the condition for the Fourier transform to exist is that

$$\int_{-\infty}^{\infty} |f(t)| dt < \infty, \text{ although certain functions may have a Fourier transform even if this is violated.}$$

Example 225.7

The function $f(t) = 1$ for $-a \leq t \leq a$ and $= 0$ elsewhere has

$$F[f(t)] = \int_{-a}^a e^{-ist} dt = \int_0^a e^{ist} dt + \int_0^a e^{-ist} dt = 2 \int_0^a \cos st dt = \frac{2 \sin sa}{s}$$

Properties of the Fourier Transform

Let $F[f(t)] = g(s); F^{-1}[g(s)] = f(t)$.

- $F[f^{(n)}(t)] = (is)^n F[f(t)]$
- $F[af(t) + bh(t)] = aF[f(t)] + bF[h(t)]$
- $F[f(-t)] = g(-s)$
- $F[f(at)] = 1/ag(s/a), \quad a > 0$
- $F[e^{-iwt} f(t)] = g(s+w)$
- $F[f(t+t_1)] = e^{ist_1} g(s)$
- $F[f(t)] = G(is) + G(-is) \quad \text{if } f(t) = f(-t) \text{ (} f \text{ even)}$
- $F[f(t)] = G(is) - G(-is) \quad \text{if } f(t) = -f(-t) \text{ (} f \text{ odd)}$

where $G(s) = L[f(t)]$. This result allows the use of the Laplace transform tables to obtain the Fourier transforms.

Example 225.8

Find $F[e^{-a|t|}]$ by property 7. The term $e^{-a|t|}$ is even. So $L[e^{-at}] = 1/(s+a)$. Therefore, $F[e^{-a|t|}] = 1/(is+a) + 1/(-is+a) = 2a/(s^2 + a^2)$.

225.4 Fourier Cosine Transform

The *Fourier cosine transform* is given by $F_c[f(t)] = g(s) = \sqrt{(2/\pi)} \int_{-\infty}^{\infty} f(t) \cos st \, dt$ and its *inverse* by

$F_c^{-1}[g(s)] = f(t) = \sqrt{(2/\pi)} \int_{-\infty}^{\infty} g(s) \cos st \, ds$. The *Fourier sine transform* F_s is obtainable by replacing the cosine by the sine in the above integrals.

Example 225.9

$$F_c[f(t)], f(t) = 1 \text{ for } 0 < t < a \text{ and } 0 \text{ for } a < t < \infty. F_c[f(t)] = \sqrt{(2/\pi)} \int_0^a \cos st \, dt = \sqrt{(2/\pi)} (\sin as) / s.$$

Properties of the Fourier Cosine Transform

$$F_c[f(t)] = g(s).$$

1. $F_c[af(t) + bh(t)] = aF_c[f(t)] + bF_c[h(t)]$
2. $F_c[f(at)] = (1/a)g(s/a)$
3. $F_c[f(at)\cos bt] = 1/2a[g((s+b)/a) + g((s-b)/a)], a, b > 0$
4. $F_c[t^{2n}f(t)] = (-1)^n (d^{2n}g)/(ds^{2n})$
5. $F_c[t^{2n+1}f(t)] = (-1)^n (d^{2n+1}g)/(ds^{2n+1})F_s[f(t)]$

Table 225.3 presents some Fourier cosine transforms.

Example 225.10

The temperature θ in the semiinfinite rod $0 \leq x < \infty$ is determined by the differential equation $\partial\theta/\partial t = k(\partial^2\theta/\partial x^2)$ and the condition $\theta = 0$ when $t = 0, x \geq 0$; $\partial\theta/\partial x = -\mu = \text{constant}$ when $x = 0, t > 0$. By using the Fourier cosine transform, a solution may be found as

$$\theta(x,t) = (2\mu/\pi) \int_0^{\infty} (\cos px/p) (1 - e^{-kp^2t}) dp.$$

TABLE 225.3 Fourier Cosine Transforms

| $f(t)$ | $\frac{g(s)}{\sqrt{2/\pi}}$ |
|--|---|
| $\left. \begin{array}{ll} t & 0 < t < 1 \\ 2-t & 1 < t < 2 \\ 0 & 2 < t < \infty \end{array} \right\}$ | $\frac{1}{s^2} [2 \cos s - 1 - \cos 2s]$ |
| $t^{-1/2}$ | $\pi^{1/2} (2s)^{-1/2}$ |
| $\left. \begin{array}{ll} 0 & 0 < t < a \\ (t-a)^{-1/2} & a < t < \infty \end{array} \right\}$ | $\pi^{1/2} (2s)^{-1/2} [\cos as - \sin as]$ |
| $(t^2 + a^2)^{-1}$ | $\frac{1}{2} \pi a^{-1} e^{-as}$ |
| $e^{-at}, \quad a > 0$ | $\frac{a}{s^2 + a^2}$ |
| $e^{-at^2}, \quad a > 0$ | $\frac{1}{2} \pi^{1/2} a^{-1/2} e^{-s^2/4a}$ |
| $\frac{\sin at}{t}, \quad a > 0$ | $\begin{cases} \pi/2 & s < a \\ \pi/4 & s = a \\ 0 & s > a \end{cases}$ |

Chaos, Fractals, and Julia Sets

Anca Deliu

Georgia Institute of Technology

[226.1 Chaos](#)

[226.2 Fractals](#)

[226.3 Julia Sets](#)

Chaos refers to the apparently chaotic evolution of certain dynamical systems. *Fractals* are sets with an intriguing structure that reveals itself in shapes with intricate detail recurring on all scales. *Julia sets* are invariant sets for certain family of complex maps. Each Julia set corresponds to one map in the family. Typically the Julia sets are fractals and the dynamics of the corresponding map on the Julia set is chaotic.

Chaotic dynamics (nonlinear science), and fractals (nowhere differentiable curves), and Julia sets (invariant sets) have been known and studied by mathematicians for about one hundred years. Nevertheless it was during the last three decades that the scientific community at large became interested in these concepts and looked at them from the common perspective of their fascinating graphic visualization. In the early eighties many graduate students, and more mature researchers, were spellbound in front of their computers as incredible shapes, unseen before, materialized unexpectedly on the screen out of very simple formulas.

226.1 Chaos

When, in addition to mathematicians, researchers from other fields become aware that simple and deterministic phenomena from physics, engineering, economics, biology, and geology, can lead to unpredictable time evolutions, nonlinear science became very fashionable.

As opposed to classical systems, that eventually settle into periodic motion or steady state, chaotic systems evolve apparently at random in a pattern that can only be described statistically. The complexity of the system is related to the geometry of this pattern. The study of individual trajectories becomes irrelevant and it is replaced by statistical analysis.

The French mathematician Henri Poincaré set the foundations of chaotic dynamics about 100 years ago. He studied the time evolution of three celestial bodies subject to mutual gravitational forces. He showed that irregular orbits (called *chaotic* in today's terminology) could arise due to the nonlinear character of the system. His discovery was surprising since it had been assumed, until then, that all reasonable dynamical systems eventually settle into steady state or periodic motion.

Currently the word *chaos* has a very specific technical meaning that we will describe later in this section. The interesting dynamics of a system occurs on, and around the invariant sets of the system, and thus chaos is understood in terms of the dynamics on and around these sets. A major goal of the study of dynamical systems is to identify these invariant sets and to understand them. An invariant set can be

attracting or repelling, according to whether it attracts or repels the nearby orbits. The classical invariant sets are the fixed points and the periodic orbits of the system. What the study of chaotic dynamics brought forward during the last three decades was the existence of invariant sets larger than a periodic orbit and (typically) smaller than the whole space. These invariant sets are called attractors or repellers, as the case may be, and the dynamics of the system on these sets is necessarily chaotic. Typically these sets have fractional dimension and assume unusual shapes. Ruelle and Takens referred to these sets as strange attractors, in their work on the onset of turbulence [Ruelle and Takens, 1971].

Let us reemphasize that the technical meaning of the word chaos refers to *deterministic* time evolution that is only perceived as chaotic by a human observer.

Examples of strange attractors discovered in the last decades are the Lorentz attractor, the Henon attractor, and the Smale horseshoe attractor [Falconer, 1990]. In addition to these, the classical, and other, Cantor sets and the Julia sets, are older examples that fit in the same general framework.

The word chaos, with a slightly different meaning than the currently established technical term, was introduced by Li and Yorke in their paper "Period Three Implies Chaos" [Li and Yorke, 1975]. In that paper the authors proved that a map with a periodic point of order three, must necessarily have periodic points of all orders; such a map has orbits with disordered behavior that seems to be chaotic.

But what is, after all a dynamical system? A *dynamical system* is a rule that determines the time evolution of a system, in terms of its initial state. A dynamical system is denoted by a pair (f, X) , where $f: X \rightarrow X$, is a map and X is the phase space of the system. Each point in X represents a specific state of the system and the function f determines the time evolution of the system. In this chapter X is a subset of the Euclidian space R^n or of the complex plane C . In practice a dynamical system describes the time evolution of an observable (a measurement) x , such as temperature, pressure, or population. Depending on whether this time evolution is tracked at all time points, or only at a discrete set of points, a dynamical system is called continuous or discrete.

A *continuous dynamical system* is described by a differential equation of the form

$$\frac{dx}{dt} = f(x) \tag{226.1}$$

where $f: X \rightarrow X$, is a map with some smoothness. For any initial state $x_0 \in X$ the evolution of the system is described by the solution of Equation (226.1) with initial condition x_0 .

A *discrete dynamical system* (f, X) is described by a difference equation of the form

$$x_{n+1} = f(x_n) \tag{226.2}$$

where $f: X \rightarrow X$, is a mapping with some regularity.

The main question of the theory of dynamical systems is to find out what happens to the system given that it started in some initial state $x_0 \in X$.

For continuous dynamical systems the answer to that question consists in solving Equation (226.1), with initial condition $x_0 \in X$. That solution is a continuous curve called the trajectory of $x_0 \in X$ and it represents the fate of $x_0 \in X$ as time $t \rightarrow \pm\infty$.

For discrete dynamical systems the answer consists in solving the difference equation (226.2), with initial condition $x_0 \in X$. That solution is the sequence of iterates of f ,

$$x_0, f(x_0), f(f(x_0)), \dots$$

The sequence of iterates $x_k = f^k(x_0): k \geq 0$, is called the orbit of $x_0 \in X$ and x_k represents the state of the system at time $t = k$. Thus a discrete dynamical systems determines the evolution of the system only at a discrete set of points in time $t = 0, t = 1, t = 2, \dots$, etc.

Chaos can occur both in the discrete and the continuous dynamical systems. In principle the higher the dimension of the phase space of a dynamical system, the more room and thus opportunity, there is for chaos to occur. In discrete dynamical systems chaos can occur even in dimension one; for continuous dynamical systems chaos can occur only in dimension three or higher. Since discrete dynamical systems are simpler while at the same time they can illustrate all the characteristics of chaotic dynamics we will focus our discussion on them.

Let thus (f, X) be a discrete dynamical system. A point y is called a *fixed point* for f if it is a solution of the equation $f(y) = y$. If the initial state of a dynamical system is a fixed point, then the system will remain in that state at all subsequent time points. Fixed points play an important role in understanding the dynamics of f . A fixed point is called *attractive* if it attracts all the nearby orbits of the system.

Example 226.1

Let $X = \mathbb{R}$ and $f(x) = \sin x$. Then the orbits of all initial states $x_0 \in \mathbb{R}$ converge to the unique fixed point $x = 0$, of $\sin x$, as one can check by pressing repeatedly the sin button on a calculator.

Example 226.2

Let $X = \mathbb{R}$ and $f(x) = e^x$. Then the orbits of all initial states $x_0 \in \mathbb{R}$ diverge to infinity, as one can check by pressing repeatedly the Exp button on a calculator. One will soon get an overflow message.

A dynamical system with a unique fixed point, like the dynamical system of Example 226.1, has a very simple behavior. In the long run all orbits converge asymptotically to the fixed point. Similarly the dynamical system of Example 226.2, has a very simple behavior too since all orbits behave similarly, they diverge to infinity.

Example 226.3

Let $X = \mathbb{R}$ and $f(x) = x^2$. To find the fixed points of f one solves the equation $x^2 = x$. Thus the system has two fixed points $x = 0$ and $x = 1$. The fixed point $x = 0$ is attractive, it attracts all initial states $-1 < x_0 < 1$. The fixed point $x = 1$ is repelling.

Notice that if x is a fixed point for a one-dimensional dynamical system, then, if $|f'(x)| < 1$, x is attractive and if $|f'(x)| > 1$, then x is repelling. A point x with $f'(x) = 0$ is called a critical point. Critical points play a special role in the dynamics of a system as we will illustrate later, in the section on Julia sets.

A point y is called a *periodic point* of *period* p for the dynamical system (X, f) if y satisfies the equation $f^p(y) = y$ and $f^q(y) \neq y$ for any $q < p$. If y is periodic, with period p , the orbit of y is a finite set of p points $\{y, f(y), \dots, f^{p-1}(y)\}$. This orbit is called a *periodic orbit* with period p . Notice that a fixed point is a periodic point of period 0. Periodic points play an important role in understanding the dynamics of f . A periodic orbit is called *attractive* if it attracts the neighboring orbits, in the sense that if the system starts close to that period, then all the subsequent states of the system will converge to that periodic orbit.

Example 226.4

Let $X = \mathbb{R}$ and $f(x) = x^2 - 1$. To find the periodic points of f , of order 2, one solves the equation $f(f(x)) = x$, or equivalently $(x^2 - 1)^2 - 1 = x$. Two solutions of this equation are $x = 0$ and $x = -1$ and one can indeed check that $\{0, -1\}$ is a period for f .

Example 226.5

Let $X = \mathbb{R}$ and $f(x) = -x$. This map has a unique fixed point $x = 0$, and any point $x \neq 0$ is a periodic point of order 2. These periodic orbits $\{x, -x\}$ are neither attractive nor repelling.

The examples above show simple maps with simple dynamics. One can use a calculator to iterate other simple functions $f: X \rightarrow X$, similar to the ones above and see what happens. One might assume that all simple functions would behave equally nicely under iteration. That assumption would turn out to be

false. Since chaos is understood in terms of dynamics on an invariant set we will give, next, the formal definition of an attractor. Attractors and repellers are similar concepts, in the sense that the attractor of a system is the repeller of the corresponding system, with the reversed arrow of time.

A closed and bounded subset $A \subset X$ is an *attractor* if A is *invariant* — that is, $f(A) = A$ —and A is *attracting*—that is, the distance between $f^k(x_0)$ and A converges to zero as $k \rightarrow \infty$ — for all points $x_0 \in V$ in a neighborhood V of A . The set V is called the *basin of attraction* of A .

We say that f is *chaotic* if the following three conditions hold.

1. There is a point x whose orbit is dense in A — that is, it passes arbitrarily close to any point of A .
2. The periodic point of f are dense in A .
3. The function f has sensitive dependence on initial conditions, i.e., there is a number $\delta > 0$, such that for any $x \in X$ there are points y arbitrarily close to x , such that $|f^k(x) - f^k(y)| \geq \delta$ for some k .

We cannot emphasise enough that chaotic dynamical systems have a *deterministic* evolution, although the three conditions above ensure that the system's evolution seems, and is for practical purposes, unpredictable.

By reversing the arrow of time an attractor becomes a repeller, in other words an attractor for (X, f) is a repeller for (X, f^{-1}) or if f does not have an inverse for $(X, f_1^{-1}, f_2^{-1}, \dots, f_k^{-1})$ where $f_1^{-1}, f_2^{-1}, \dots, f_k^{-1}$ are the inverse branches of f . For example 0 is an attracting fixed point for $f(x) = \frac{x}{2}$ and it is a repelling fixed point for $f(x) = 2x$.

In the effort to explain the transition from classical dynamics to chaos three scenarios for the onset of chaos have been proposed [Ruelle, 1989]:

1. The Ruelle — Takens onset of chaos through quasi periodicity.
2. The Feigenbaum onset of chaos through period doubling.
3. The Pomeau — Manneville onset of chaos through intermittency.

The simplest approach is to illustrate the onset of chaos through period doubling. We will introduce the logistic family of maps that provides a simple example of the onset of chaos through periodic doubling. The next example uses the logistic family to illustrate the onset of chaos through the so-called process of period doubling.

Example 226.6

Let $X = [0,1]$ and let $f_\lambda: X \rightarrow X$ be the logistic family

$$f_\lambda(x) = \lambda x(1-x) \tag{226.3}$$

originally introduced to model the development of certain populations. If the population is x_k at the end of the k th year, it is assumed to be $x_{k+1} = f_\lambda(x_k)$ at the end of the $(k + 1)$ th year.

As λ increases from 0 to 4, the behavior of f_λ undergoes a sequence of transformations, ranging from the simplest to the most complex [Falconer, 1990].

For $0 < \lambda < 3$, f has a stable fixed point, $x_\lambda = 1 - 1/\lambda$, which attracts all orbits starting at $x_0 \in (0,1)$.

When λ increases through the value $\lambda = \lambda_1 = 3$, the stable fixed point x_λ splits into a stable period 2 orbit, $\{y_\lambda^1, y_\lambda^2\}$. For example, if $\lambda = 3.38$, almost all trajectories settle asymptotically into this periodic cycle.

At $\lambda = \lambda_2 = 1 + \sqrt{6} \approx 3.45$, the period 2 orbit becomes unstable and splits into a stable period 4 orbit. Let λ_k denote the value of lambda at which the k th period doubling occurs.

Then λ_k increases to the critical value $\lambda_\infty \approx 3.57$, where chaos sets in. Feigenbaum discovered that λ_∞ is a universal constant, in the sense that

$$\lambda_\infty - \lambda_k \approx C\delta^k \quad (226.4)$$

for very general families of functions, where λ_k are the points where period doubling occurs.

For $\lambda \in (\lambda_\infty, 4)$ chaos and periodicity alternate, depending on specific window values of λ .

Example 226.7

Let $X = (0,1)$ and let $f(x) = \lambda x(1-x)$ with $\lambda = 3.839$. In other words let $f(x) = 3.839x(1-x)$. Choose any initial state x_0 between 0 and 1 and use a calculator to convince yourself that the orbit of x_0 will settle into repeatedly passing closer and closer to three points $p_1 \approx 0.149$, $p_2 \approx 0.489$ and $p_3 \approx 0.959$.

Although a discussion of continuous dynamical systems is beyond the scope of this article, we will conclude the section on chaos with the example of one of the most famous chaotic systems. Its attractor, called the Lorenz strange attractor is embedded in \mathbb{R}^3 and its two-dimensional projections have a characteristic butterfly shape.

Example 226.8

Lorenz [1963], who studied Rayleigh-Benard convection considered the following model. A fluid contained between two rigid plates is subjected to gravity. The top plate is maintained at the temperature T_0 and the bottom plate is maintained at a higher temperature, $T_0 + \Delta T$. Experiments show that, for a certain range of small values of ΔT , the fluid will execute a convective cellular flow. For bigger values of ΔT the flow becomes chaotic. This is similar to what happens in the earth's atmosphere. The specific equations of Lorenz are [Falconer, 1990]:

$$\begin{aligned} \frac{dx}{dt} &= -\sigma x + \sigma y \\ \frac{dy}{dt} &= -xy + rx - y \\ \frac{dz}{dt} &= xy - bz \end{aligned}$$

where $\sigma = 10$, $r = 28$, and $b = 8/3$.

The system has sensitive dependence on initial conditions. The model above is a very simplified version of the dynamics related to meteorological phenomena. It is thus no surprise that the weather is unpredictable since even this simple model behaves chaotically.

226.2 Fractals

Fractal geometry emerged as a novel area of mathematics in the early eighties, when B. Mandelbrot published his book, *The Fractal Geometry of Nature*. To better highlight some basic features of fractal geometry, we will present them in contrast with their analogues from Euclidian geometry.

Euclidian geometry studies the properties of, and the relationships between, points, lines, angles, curves, surfaces and solids in space. All these shapes are smooth, simple, and regular. Most of them are found in man made objects: highways, parking lots, domes. Some occur in nature: the trajectories and shapes of the planets, or the shapes of crystals. Nevertheless, most objects around us do not have smooth shapes. For example the flames, clouds, turbulent rivers, coastlines and trees all have small intricate detail.

Mathematicians realized only about two decades ago, that these shapes, in their own way, have a mathematical simplicity and beauty that can be described in the language of mathematics. Mandelbrot's

remarkable contribution was to realize that the apparent geometrical disorder around us is a universal property of nature, that it is the rule rather than the exception, and to bring that idea before the scientific community. Mandelbrot called these rugged and fuzzy shapes *fractal sets*. The word fractal comes from the Latin fractus, meaning fractured. To be specific, all the sets we talk about in this section are subsets of the Euclidian space R^n .

Fractal geometry studies the properties of, and relationships between fractal sets. Intuitively one can easily recognize a fractal set. A breaking wave is a fractal, a donut is not. The question is how to capture, mathematically, the essence of fractals. Mandelbrot gave a beautiful and simple mathematical definition of a fractal set. His definition involves two different notions of dimension, the *topological dimension* and the *Hausdorff dimension* of a set. We will first state Mandelbrot's definition of a fractal set, and then we will talk about topological dimension and Hausdorff dimension.

A fractal set is, *by definition*, a set whose topological dimension is *strictly* smaller than its fractal dimension.

The concepts of topological dimension and Hausdorff dimension belong to advanced mathematics and we will discuss them only superficially. We will denote the topological dimension by TDim and the Hausdorff dimension by HDim.

Both the topological and Hausdorff dimensions of a set measure the size of the set, but from different perspectives. The topological dimension of a set can only take integer values, 0, 1, 2, up to n . A subset of R^3 has topological dimension equal to either 0, 1, 2, or 3. The Hausdorff dimension of a set can take any value between 0 and n , including the end points. A subset of R^3 can have any Hausdorff dimension between 0 and 3.

The topological dimension of a set is always less than, or equal to, its Hausdorff dimension. There are sets with TDim = 0 and HDim = n . The consequence that TDim < HDim for a given set is that the set must necessarily explode, in some sense, have infinitely fine detail, be a fractal. Depending on its topological dimension a fractal set can be a fractal dust, a fractal curve, a fractal surface and so on.

The topological dimension of a set measures, one might say, the degree of freedom that an imaginary creature has to navigate within the set. The bigger the dimension, the larger the set. For example a plane is larger than a line since there is more room, freedom of movement, within the plane than along the line.

The topological dimension agrees with our intuitive notion of dimension. A point has topological dimension zero; TDim (point) = 0. A curve has topological dimension one; TDim(curve) = 1. A surface has topological dimension two; TDim(surface) = 2. Moreover, a finite or countable union of sets of a given dimension, has the same dimension. A set consisting of two, three, one hundred points, in fact a dust of points, has topological dimension zero. Similarly, set consisting of two, three or a network of lines has topological dimension one.

One possible way to define the topological dimension of a set $F \subset R^n$ is along the following lines. Cover F by a union of n -dimensional open balls B_i of arbitrarily small radius $F \subset \bigcup B_i$. Let n_F be the minimum number of balls that have to overlap, so as to cover the set F, as their radius converges to 0. Then the topological dimension of F is by definition TDim(F) = $n_F - 1$. To see that this definition agrees with our intuition, cover the unit interval $F = [0,1]$ by one dimensional balls of small radius, that is by arbitrarily small open intervals. In order to cover the interval $[0,1]$ in this manner we need that these intervals intersect in at least pairs of $n_F = 2$. Hence according to the definition the topological dimension of the interval is TDim($[0,1]$) = $2 - 1 = 1$.

The Hausdorff dimension measures the size of a set, from a different perspective. It measures how well the set fills the ambient space. The bigger the dimension, the larger the set.

A whirl of dust, raised by the wind, may be very thin, or it may so thick as to fill the whole space. The fractal dimension of a dust can assume any value between zero and three. It equals zero, when the dust is extremely sparse, and three when the dust fills the whole three dimensional space. A Cantor set is a dust type of set; it has topological dimension 0, but it has a positive Hausdorff dimension that could be as big as the dimension of the surrounding space.

The graph of a real nowhere differentiable of one real variable may have any Hausdorff dimension between 1 and 2. The trajectory of a particle driven by a Brownian motion has Hausdorff dimension greater than 1. A continuous graph describing the performance of a stock can sometimes fluctuate so much, during periods of market volatility, as to fill whole solid areas on the computer screen. The Hausdorff dimension of this graph can assume any value between one and two.

Next we set some preliminary terminology and notation in order to be able to give the formal definition of the Hausdorff dimension.

The diameter of $U \subset \mathbb{R}^n$ is $|U| = \sup\{|x - y| : x, y \in U\}$. Let $F \subset \mathbb{R}^n$. For $\epsilon > 0$, an ϵ -cover of F is any countable collection of sets U_i with $|U_i| < \epsilon$, and such that $F \subset \cup_i U_i$. Let $s \geq 0$. For any $\epsilon > 0$, we define

$$H_\epsilon^s(F) = \inf \left\{ \sum_{i=1}^{\infty} |U_i|^s : \{U_i\} \text{ is an } \epsilon\text{-cover of } F \right\}$$

As ϵ decreases to 0, $H_\epsilon^s(F)$ increases and thus approaches a limit,

$$H^s(F) = \lim_{\epsilon \rightarrow 0} H_\epsilon^s(F)$$

which we define to be the *s-dimensional Hausdorff measure* of F .

For any subset $F \subset \mathbb{R}^n$, there is a unique number $D = \text{HDim}(F) \geq 0$ such that for $0 \leq s < D$, $H^s(F) = \infty$ and for $D < s < \infty$, $H^s(F) = 0$. This number D is called the *Hausdorff dimension* of F . If F has Hausdorff dimension D , the D -dimensional Hausdorff measure of F may take any value in $[0, \infty]$. The inequality $\text{TDim} \leq \text{HDim}$ always holds.

The Hausdorff dimension is difficult to estimate, both theoretically and numerically. As a substitute, one often uses a simpler concept, the *fractal dimension*, which conveys similar information about the geometry of a set yet is easier to compute.

Let $F \subset \mathbb{R}^n$ be a nonempty bounded subset of some euclidian space, and let $N(F, \epsilon)$ be the smallest number of cubes of side length equal to ϵ required to cover F . The fractal dimension (also called *box dimension*, *Kolmogorov entropy*, or *capacity*) is defined as the limit

$$\text{FDim}(F) = \lim_{\epsilon \rightarrow 0} \frac{\log N(F, \epsilon)}{-\log \epsilon}$$

If the set F is included in the Euclidian plane, then it can be represented on the computer screen. The number of squares of given side length, necessary to cover such a set can be easily counted, and thus the fractal dimension can be estimated numerically.

For any set, we have the inequalities $\text{TDim} \leq \text{HDim} \leq \text{FDim}$.

The fractal dimension of the Lorentz attractor was estimated numerically to be around 2.04 and the fractal dimension of the attractor corresponding to λ_∞ , from the logistic family, was estimated numerically to be ≈ 0.538 [Falconer, 1990, p. 175].

The key to the inherent simplicity of fractals, despite their complicated shapes, is their *self similar* essence. Think of a fern. It consists of many fronds, each frond a scaled down version of the whole fern. Each frond is itself a set of even smaller frondlets. The original fern is a collection of smaller copies of itself.

The fern looks complicated. The rule according to which it is build is, however, simple. The same observation is true for trees, mountains, clouds.

A map $W : \mathbb{R}^n \rightarrow \mathbb{R}^n$ is called a *contractive similitude* if $|W(x) - W(y)| = s|x - y|$, for any $x, y \in \mathbb{R}^n$, for some $0 < s < 1$. The number s is the *contraction ratio* of W .

A set $A \subset \mathbb{R}^n$ is called *self-similar* if it can be tiled with smaller copies of itself,

$$A = \bigcup_{i=1}^N W_i(A) \tag{226.4}$$

where $\{W_i\}$ are contractive similitudes.

The collection of maps $\{W_i\}$ defines a random dynamical system, called an *iterated function system* (Barnsley, 1988). Rather than follow the orbit of a point x_0 under iteration of one map, one defines the n th iterate of this system by $x_n = w_X(x_{n-1})$, where X is a random variable with values $1, 2, \dots, n$. In other words one starts at some initial condition x_0 and proceeds by applying at random, the maps $\{W_i\}$. This is the, so called *chaos game*, that one can implement, and output on a computer screen. A consequence of the fact that the w_i are contractive maps is that the orbit of any initial condition x_0 is attracted to a compact set A , called, by analogy with the theory of dynamical systems, the attractor of the iterated function system $\{W_i\}$. Typically this attractor is a fractal set, and it can assume almost any shape, depending on the maps $\{W_i\}$. The collection of maps $\{W_i\}$ are called the *fractal code* of the set A .

The self similar sets have many interesting properties. In particular they are the only class of fractal sets whose Hausdorff dimension is (relatively) easy to compute theoretically.

If $\{W_i\}$ is an iterated function system with the non-overlapping condition $W_i(A) \cap W_j(A) = \emptyset$, then

$$\text{HDim}(A) = \text{FDim}(A) = D \tag{226.5}$$

where D is the unique real solution to the equation $\sum_{i=1}^N s_i^D = 1$ and s_i is the contraction ratio of W_i .

The simplest example of a self-similar set is the famous ternary Cantor set C (Figure 226.1). This Cantor set is the attractor of an iterated function system with two maps $W_1 = x/3$ and $W_2 = x/3 + 2/3$, $s_1 = s_2 = 1/3$, hence Equation (226.5) yields $\text{HDim}(C) = \text{FDim}(C) = \log 2 / \log 3$. In addition to being the attractor of that iterated function system that Cantor set can be realized by the following construction. From the closed interval $[0, 1]$, remove the middle third interval $(\frac{1}{3}, \frac{2}{3})$. Two closed intervals remain— $[0, \frac{1}{3}]$ and $[\frac{2}{3}, 1]$. Repeat the procedure for all remaining intervals iteratively. The Cantor set C is the fractal “dust” that remains. All points of the form $\{k3^{-n}: n \geq 0, 0 \leq k \leq 3^n - 1\}$ belong to C , but there are many more. Since the ternary Cantor set is included in the unit interval, and hence hard to see on a page, we give an enhanced (two dimensional) version of it in Figure 226.2.

FIGURE 226.2 Two-dimensional construction of Cantor set C .

Another example of a Cantor set is presented in Figure 226.2. For this example $N = 4$, $\{s_i = 1/3: i = 1, \dots, 4\}$ and the 4 maps $\{W_i\}$ are two dimensional affine maps. Equation (226.5) yields $\text{HDim} = \text{FDim} = \log 4 / \log 3$. The topological dimension of both Cantor sets is 0, a feature common to all “dust” (*totally disconnected*) sets.

Michael Barnsley (1988) discovered an ingenious method to realize any shape with fractal character as the attractor of an iterated function system, in other words to determine its fractal code. His method is formalized by the Collage Theorem and it exploits the self similarity property of sets with fractal character. The collage theorem holds in any dimension, but it was originally discovered in connection with two dimensional affine contractions, as a method to encode and generate pictures.

The Collage Theorem states that if a target set T can be covered well enough with smaller copies of itself $w_1(T), \dots, w_n(T)$, then the set T is close enough to the self similar attractor A of the iterated function system $\{W_i\}$. More formally the Collage Theorem states the following.

Collage Theorem. If $d(T, \cup W_i(T)) < s < 1$, then $d(T, A) < \frac{d(T, \cup W_i(T))}{1-s}$, where A is the attractor of the

iterated function system $\{W_i\}$ and d is the Hausdorff distance between sets, that measures, one might say, how well two sets look like one another. Notice that the smaller s is (i.e., the better the collage of the target set T with smaller affine copies of itself), the better the approximation of T by the attractor.

The Collage Theorem gives an easy method to find suitable fractal codes for any set with a self similar shape of nature. A fern or a tree are wonderful candidates for the collage theorem. Once one finds the code of the fern and of the tree, one can represent them on the computer screen by iterating the corresponding iterated function system. The ideas of the Collage Theorem have been exploited by M. Barnsley, and by many other people to develop data compression software. The code of a fern is clearly much smaller, memory wise, than the bit map representation of the same fern.

226.3 Julia Sets

Julia sets are invariant sets for the maps of the quadratic family $f(z) = z^2 + c, z \in \mathbb{C}, c \in \mathbb{C}$ indexed by the complex parameter c .

The Julia sets are repellers for these maps, they are typically fractal curves, or fractal dusts, and they have remarkable shapes. The complement of the Julia set $J(f)$ is called the Fatou set. The dynamics of the map f is very simple on the Fatou set, also called the stable set of f , and the dynamics of f is interesting and chaotic on the Julia set. These quadratic maps, and their invariant sets, were an important subject of study for mathematicians, in particular Julia and Fatou, during the 1920s. The subject became popular again in the early 1980s when it was revisited from the perspective of the emerging science of chaos.

Example 226.9

For $c = 0, f(z) = z^2$ and the corresponding Julia set $J(f)$ is the unit circle $\{|z| = 1\}$.

The dynamics of the complex map above are relatively simple. The n th iterate of the point z is $f^n(z) = z^{2^n}$. Hence all the points with $|z| < 1$ converge to the fixed point $z = 0$, and similarly all the points with $|z| > 1$ diverge to infinity. The unit circle $|z| = 1$ is invariant under the map $f(z) = z^2$. On the unit circle the map has the three attributes of chaotic behavior, listed in the section on Chaos. Under iteration, a generic point z , with $|z| = 1$, will jump about on the unit circle, and recur infinitely many times close to any given point on the circle. To summarize the unit circle is invariant and all sets that do not intersect the unit circle diverge away from it, either towards 0 or towards infinity, depending on whether the set lies in the bounded, or the unbounded connected component in which the unit circle splits the complex plane.

The unit circle is the Julia set for the map $f(z) = z^2$. Notice that the map $f(z) = z^2$ has periodic points of arbitrarily high order, and all of them lie on the unit circle. These points are repelling since we saw

that the whole unit circle is a repelling set. Thus the unit circle is the closure of the repelling periodic points of $f(z) = z^2$. By analogy, this property is used to define all the Julia sets.

The Julia set $J_c(f)$ of the map $f(z) = z^2 + c, z \in \mathbb{C}, c \in \mathbb{C}$ is, by definition, the closure of the set of repelling periodic points of f .

One can show that $J_c(f)$ is nonempty, is closed and bounded, has empty interior, it is either a closed (simple or composite) or a dust, and is generally a fractal. The Julia set $J_c = J_c(f)$ is both forward- and backward-invariant, $J_c = f(J_c) = f^{-1}(J_c)$ and f is chaotic on J_c .

Next we will give examples of Julia sets for various values of c different from 0. Clearly the value of c has a great impact on the dynamics of the map f_c and on the shape of the corresponding Julia set.

The critical points of a map $f(z)$ are, by definition, the solutions of the equation $f'(z) = 0$. All the quadratic complex maps $f(z) = z^2 + c$ have the same critical point $z = 0$. It is a well known fact that the orbit of the critical point plays a special role in the dynamics of a system. For all the maps $f(z) = z^2 + c$, c is the image of 0, $c = f_c(0)$, in other words c is the first iterate of 0. Thus for the quadratic family the study of the orbit of 0 is equivalent to the study of the orbit of c .

The dependence of the Julia set of $f(z) = z^2 + c$, on the orbit of the critical point 0, or equivalently on the orbit of c , can be summarized as follows.

If the orbit of c converges to an attracting fixed point, the corresponding Julia set J_c is a simple closed curve. If the orbit of c diverges to infinity the corresponding Julia set J_c is a totally disconnected fractal set. If the orbit of c is a periodic orbit the corresponding Julia set J_c is a continuous closed curve whose complement has infinitely many connected components. Finally, if the orbit of c is eventually periodic, but not periodic, the Julia set has a dendritic shape (see Falconer [1990, p. 214]).

For complex parameters c , with $|c|$ small, the corresponding Julia sets are continuous perturbations of the unit circle. These closed curves, however, do not have any differentiable arc, they are fractal curves.

Example 226.10

For $c \in \mathbb{C}$ with $|c| < 1/4$ the Julia set of $f(z) = z^2 + c$ is a simple closed curve that splits the complex plane in two connected components. The iterates $f^k(z_0)$ of an initial condition z_0 in the bounded component converge to a fixed point of the map $f(z) = z^2 + c$, and the iterates $f^k(z_0)$ of an initial condition z_0 in the unbounded component, diverge to ∞ . The set of all c with the property that the corresponding Julia set J_c is a simple closed curve is a cardioid that includes strictly the disc $\{c: |c| < \pi\}$.

For complex parameters c , with $|c|$ large, the corresponding Julia sets are totally disconnected fractal sets.

Example 226.11

The Julia set of $f(z) = z^2 + c$, with $|c| > \frac{1}{4}(5 + 2\sqrt{6})$, $J(f)$ is totally disconnected. In other words in this case the Julia set is a fractal dust that repels all nearby orbits. As before the Julia dust J_c is invariant under the forward and backward iterations of f and f is chaotic on J_c .

For values of c so that c is a periodic point of f_c , or is eventually a periodic point of f_c , rather than an attracting fixed point, the corresponding Julia set and the dynamics of the system acquire new twists, as seen in the next two examples.

Example 226.12

For $c = -1$ the map $f_{-1}(z) = z^2 - 1$ has $f_{-1}(0) = -1$ and $f_{-1}(1) = 0$. It turns out that in this case the Julia set J_{-1} is a continuous curve with infinitely many cycles, i.e., the complement of the Julia set of $f_{-1}(z) = z^2 - 1$ has infinitely many connected components.

Example 226.13

For $c = i$, the map $f_i(z) = z^2 + i$, we have $f_i(i) = -1 + i$ and the points $-1 + i$ and $-i$ form a period of order 2, thus the critical point 0, or equivalently the parameter $c = i$, are eventually periodic points. It turns out that in this case the Julia set J_i is a dendrite.

For proofs of the results stated in the examples see Falconer [1990, p. 214].

There is no better conclusion to a chapter on chaos, fractals and Julia sets than to introduce a concept that blends together features of all these concepts in a beautiful structure known as the Mandelbrot set. The Mandelbrot set is a subset M of the complex plane $M \subset \mathbb{C}$ and it consists of all those complex numbers c with the property that the orbit of c (or of the critical point 0) under the quadratic map $f_c(z) = z^2 + c$ is bounded. It is easy to decide, using a computer, whether the iterates of c under f_c stay bounded or diverge. If one checks in this manner a comprehensive array of values of c around the origin, and plots those c values for which the iterates of 0 under f_c are bounded, one discovers an amazing shape. Equivalently the Mandelbrot set is the set of points c , so that the Julia set of f_c is connected. Mandelbrot ran into this set, apparently by accident, and at first he thought that it was the result of some computer malfunction. The boundary of the set has a fractal look, with intricate detail, and all its geometric features recur on all scales. The main cardioid of the Mandelbrot set corresponds to the set of all c that correspond to a simple closed curve Julia set. The Mandelbrot set is a wonderful discovery that reflects the beauty of fractals and the order of chaos.

Calculus of Variations

William F. Ames

Georgia Institute of Technology

227.1 The Euler Equation

227.2 The Variation

227.3 Constraints

The basic problem in the *calculus of variations* is to determine a function such that a certain *functional*, often an integral involving that function and certain of its derivatives, takes on *maximum or minimum values*. As an example, find the function $y(x)$ such that $y(x_1) = y_1, y(x_2) = y_2$ and the integral (functional) $I = 2\pi \int_{x_1}^{x_2} y[1+(y')^2]^{1/2} dx$ is a minimum. A second example concerns the transverse deformation $u(x,t)$ of a beam. The energy functional $I = \int_{t_1}^{t_2} \int_0^L [\frac{1}{2}\rho(\partial u / \partial t)^2 - \frac{1}{2}EI(\partial^2 u / \partial x^2)^2 + fu] dx dt$ is to be minimized.

227.1 The Euler Equation

The elementary part of the theory is concerned with a *necessary* condition (generally in the form of a differential equation with boundary conditions) that the required function must satisfy. To show mathematically that the function obtained actually maximizes (or minimizes) the integral is much more difficult than the corresponding problems of the differential calculus.

The *simplest case* is to determine a function $y(x)$ that makes the integral $I = \int_{x_1}^{x_2} F(x, y, y') dx$ stationary and that satisfies the prescribed end conditions $y(x_1) = y_1$ and $y(x_2) = y_2$. Here we suppose F has continuous second partial derivatives with respect to x, y , and $y' = dy/dx$. If $y(x)$ is such a function, then it must satisfy the *Euler equation* $(d/dx)(\partial F / \partial y') - (\partial F / \partial y) = 0$, which is the required necessary condition. The indicated partial derivatives have been formed by treating x, y , and y' as independent variables. Expanding the equation, the equivalent form $F_{y'y'}y'' + F_{y'y}y' + (F_{y'x} - F_{y'}) = 0$ is found. This is second order in y unless $F_{y'y'} = (\partial^2 F) / [(\partial y')^2] = 0$. An alternative form $1/y'[d/dx(F - (\partial F / \partial y')(dy/dx)) - (\partial F / \partial x)] = 0$ is useful. Clearly, if F does not involve x explicitly $[(\partial F / \partial x) = 0]$ a first integral of Euler's equation is $F - y'(\partial F / \partial y') = c$. If F does not involve y explicitly $[(\partial F / \partial y) = 0]$ a first integral is $(\partial F / \partial y') = c$.

The Euler equation for $\sqrt{\frac{2}{\pi}} \sin st$ is $(d/dx)[yy' / [1+(y')^2]^{1/2}] - [1+(y')^2]^{1/2} = 0$ or after reduction

$yy'' - (y')^2 - 1 = 0$. The solution is $y = c_1 \cosh(x/c_1 + c_2)$, where c_1 and c_2 are integration constants. Thus the required minimal surface, if it exists, must be obtained by revolving a catenary. Can c_1 and c_2 be chosen so that the solution passes through the assigned points? The answer is found in the solution of a transcendental equation that has two, one, or no solutions, depending on the prescribed values of y_1 and y_2 .

227.2 The Variation

If $F = F(x, y, y')$, with x independent and $y = y(x)$, then the *first variation* δF of F is defined to be $\delta F = (\partial F / \partial x) \delta y + (\partial F / \partial y) \delta y'$ and $\delta y' = \delta(dy/dx) = (d/dx)(\delta y)$ — that is, they commute. Note that the first variation, δF , of a functional is a first-order change from curve to curve, whereas the differential of a function is a first-order approximation to the change in that function along a *particular curve*. The laws of δ are as follows: $\delta(c_1 F + c_2 G) = c_1 \delta F + c_2 \delta G$; $\delta(FG) = F\delta G + G\delta F$; $\delta(F/G) = (G\delta F - F\delta G)/G^2$; if x is an independent variable, $\delta x = 0$; if $u = u(x, y)$; $(\partial/\partial x)(\delta u) = \delta(\partial u/\partial x)$, $(\partial/\partial y)(\delta u) = \delta(\partial u/\partial y)$

A necessary condition that the integral $I = \int_{x_1}^{x_2} F(x, y, y') dx$ be stationary is that its (first) variation vanishes — that is, $\delta I = \int_{x_1}^{x_2} F(x, y, y') dx = 0$. Carrying out the variation and integrating by parts yields $\delta I = \int_{x_1}^{x_2} [(\partial F/\partial y) - (d/dx)(\partial F/\partial y')] \delta y dx + [(\partial F/\partial y') \delta y]_{x_1}^{x_2} = 0$. The arbitrary nature of δy means the square bracket must vanish and the last term constitutes the *natural boundary conditions*.

Example

The *Euler equation* of $\int_{x_1}^{x_2} F(x, y, y', y'') dx$ is $(d^2/dx^2)(\partial F/\partial y'') - (d/dx)(\partial F/\partial y') + (\partial F/\partial y) = 0$, with natural boundary conditions $\{[(d/dx)(\partial F/\partial y') - (\partial F/\partial y')] \delta y\}_{x_1}^{x_2} = 0$ and $(\partial F/\partial y'') \delta y' \Big|_{x_1}^{x_2} = 0$. The Euler equation of $\int_{x_1}^{x_2} \int_{y_1}^{y_2} F(x, y, u, u_x, u_y, u_{xx}, u_{xy}, u_{yy}) dx dy$ is $(\partial^2/\partial x^2)(\partial F/\partial u_{xx}) + (\partial^2/\partial x \partial y)(\partial F/\partial u_{xy}) + (\partial^2/\partial y^2)(\partial F/\partial u_{yy}) - (\partial/\partial x)(\partial F/\partial u_x) - (\partial/\partial y)(\partial F/\partial u_y) + (\partial F/\partial u)$, and the natural boundary conditions are

$$\left[\left(\frac{\partial}{\partial x} \left(\frac{\partial F}{\partial u_{xx}} \right) + \frac{\partial}{\partial y} \left(\frac{\partial F}{\partial u_{xy}} \right) - \frac{\partial F}{\partial u_x} \right) \delta u \right]_{x_1}^{x_2} = 0, \quad \left[\left(\frac{\partial F}{\partial u_{xx}} \right) \delta u_x \right]_{x_1}^{x_2} = 0$$

$$\left[\left(\frac{\partial}{\partial y} \left(\frac{\partial F}{\partial u_{yy}} \right) + \frac{\partial}{\partial x} \left(\frac{\partial F}{\partial u_{xy}} \right) - \frac{\partial F}{\partial u_y} \right) \delta u \right]_{y_1}^{y_2} = 0, \quad \left[\left(\frac{\partial F}{\partial u_{yy}} \right) \delta u_y \right]_{y_1}^{y_2} = 0$$

In the more general case of $I = \iiint_R F(x, y, u, v, u_x, u_y, v_x, v_y) dx dy dz$, the condition $\delta I = 0$ gives rise to the two Euler equations, $(\partial/\partial x)(\partial F/\partial u_x) + (\partial/\partial y)(\partial F/\partial u_y) - (\partial F/\partial u) = 0$ and $(\partial/\partial x)(\partial F/\partial v_x) + (\partial/\partial y)(\partial F/\partial v_y) - (\partial F/\partial v) = 0$. These are two PDEs in u and v that are linear or quasi-linear in u and v . The Euler equation for $I = \iiint_R (u_x^2 + u_y^2 + u_z^2) dx dy dz$, from $\delta I = 0$, is Laplace's equation $u_{xx} + u_{yy} + u_{zz} = 0$.

Variational problems are easily derived from the differential equation and associated boundary conditions by multiplying by the variation and integrating the appropriate number of times. To illustrate, let $F(x)$, $\rho(x)$, $p(x)$, and w be the tension, the linear mass density, the natural load, and (constant) angular velocity of a rotating string of length L . The equation of motion is $(d/dx)[F(dy/dx)] + \rho w^2 y + p = 0$. To formulate a corresponding variational problem, multiply all terms by a variation δy and integrate over $(0, L)$ to obtain

$$\int_0^L \frac{d}{dx} \left(F \frac{dy}{dx} \right) \delta y dx + \int_0^L \rho w^2 y \delta y dx + \int_0^L p \delta y dx = 0$$

The second and third integrals are the variations of $\frac{1}{2} \rho w^2 y^2$ and py , respectively. To treat the first integral, integrate by parts to obtain

$$\left[F \frac{dy}{dx} \delta y \right]_0^L - \int_0^L F \frac{dy}{dx} \delta \frac{dy}{dx} dx = \left[F \frac{dy}{dx} \delta y \right]_0^L - \int_0^L \frac{1}{2} F \delta \left(\frac{dy}{dx} \right)^2 dx = 0$$

So the variation formulation is

$$\delta \int_0^L \left[\frac{1}{2} \rho w^2 y^2 + py - \frac{1}{2} F \left(\frac{dy}{dx} \right)^2 \right] dx + \left[F \frac{dy}{dx} \delta y \right]_0^L = 0$$

The last term represents the *natural boundary conditions*. The term $\frac{1}{2} \rho w^2 y^2$ is the kinetic energy per unit length, the term $-py$ is the potential energy per unit length due to the radial force $p(x)$, and the term $\frac{1}{2} F(dy/dx)^2$ is a first approximation to the potential energy per unit length due to the tension $F(x)$ in the string. Thus, the integral is often called the *energy integral*.

227.3 Constraints

The variations in some cases cannot be arbitrarily assigned because of one or more auxiliary conditions that are usually called *constraints*. A typical case is the functional $\int_{x_1}^{x_2} F(x, u, v, u_x, v_x) dx$ with a constraint $\phi(u, v) = 0$ relating u and v . If the variations of u and v (δu and δv) vanish at the end points, then the variation of the integral becomes

$$\int_{x_1}^{x_2} \left\{ \left[\frac{\partial F}{\partial u} - \frac{d}{dx} \left(\frac{\partial F}{\partial u_x} \right) \right] \delta u + \left[\frac{\partial F}{\partial v} - \frac{d}{dx} \left(\frac{\partial F}{\partial v_x} \right) \right] \delta v \right\} dx = 0$$

The variation of the constraint $\phi(u, v) = 0, \phi_u \delta u + \phi_v \delta v = 0$ means that the variations cannot both be assigned arbitrarily inside (x_1, x_2) , so their coefficients need not vanish separately. Multiply $\phi_u \delta u + \phi_v \delta v = 0$ by a Lagrange multiplier λ (may be a function of x) and integrate to find $\int_{x_1}^{x_2} (\lambda \phi_u \delta u + \lambda \phi_v \delta v) dx = 0$. Adding this to the previous result yields

$$\int_{x_1}^{x_2} \left\{ \left[\frac{\partial F}{\partial u} - \frac{d}{dx} \left(\frac{\partial F}{\partial u_x} \right) + \lambda \phi_u \right] \delta u + \left[\frac{\partial F}{\partial v} - \frac{d}{dx} \left(\frac{\partial F}{\partial v_x} \right) + \lambda \phi_v \right] \delta v \right\} dx = 0$$

which must hold for any λ . Assign λ so the first square bracket vanishes. Then δv can be assigned to vanish inside (x_1, x_2) , so the two systems

$$\frac{d}{dx} \left[\frac{\partial F}{\partial u_x} \right] - \frac{\partial F}{\partial u} - \lambda \phi_u = 0, \quad \frac{d}{dx} \left[\frac{\partial F}{\partial v_x} \right] - \frac{\partial F}{\partial v} - \lambda \phi_v = 0$$

plus the constraint $\phi(u, v) = 0$ are three equations for u, v and λ .

Y. L. Tong

Georgia Institute of Technology

In most engineering experiments, the outcomes (and hence the observed data) appear in a random and nondeterministic fashion. For example, the operating time of a system before failure, the tensile strength of a certain type of material, and the number of defective items in a batch of produced items are all subject to random variations from one experiment to another. In engineering statistics, we apply the theory and methods of statistics to develop procedures for summarizing the data and making statistical inference and to obtain useful information with the presence of randomness and uncertainty.

228.1 Elementary Probability

Random Variables and Probability Distributions

Intuitively speaking, a random variable (denoted by X , Y , Z , etc.) takes a numerical value that depends on the outcome of the experiment. Because the outcome of an experiment is subject to random variation, the resulting numerical value is also random. In order to provide a stochastic model for describing the probability distribution of a random variable X , we generally classify random variables into two groups — the discrete type and the continuous type. The discrete random variables are those which, technically speaking, take a finite number or a countably infinite number of possible numerical values (in most engineering applications, they take nonnegative integer values). Continuous random variables involve outcome variables such as time, length, distance, area, and volume. We specify a function $f(x)$, called the

probability density function (p.d.f.) of a random variable X , such that the probability that the random variable X takes a value in a set A (of real numbers) is given by

$$P[X \in A] = \begin{cases} \sum_{x \in A} f(x) & \text{for all sets } A \text{ if } X \text{ is discrete} \\ \int_A f(x) dx & \text{for all intervals } A \text{ if } X \text{ is continuous} \end{cases} \quad (228.1)$$

By letting A be the set of all values that are less than or equal to a fixed number t (i.e., $A = [-\infty, t]$), the probability function $P(X \leq t)$, denoted by $F(t)$, is called the distribution function of X . We note that, by calculus, if X is a continuous random variable and if $F(x)$ is differentiable, then $f(x) = (d/dx)F(x)$.

Expectations

In many applications, the result of an experiment with a numerical outcome X is a specific function of X [$u(X)$, say]. Because X is a random variable, $u(X)$ itself is also a random variable. We define the expected value of $u(X)$ by

$$E[u(X)] = \begin{cases} \sum_x u(x)f(x) & \text{if } X \text{ is discrete} \\ \int_{-\infty}^{\infty} u(x)f(x)dx & \text{if } X \text{ is continuous} \end{cases} \quad (228.2)$$

provided that, of course, the sum or the integral exists. In particular, if $u(x) = x$, then $E(X) \equiv \mu$ is called the mean of X (of the distribution) and $E(X - \mu)^2 \equiv \sigma^2$ is called the variance of X (the distribution). The mean is a measurement of the central tendency, and the variance is a measurement of dispersion of the distribution.

Some Commonly Used Distributions

There are many well-known distributions that are useful in engineering statistics. Among the discrete distributions, the hypergeometric and binomial distributions have applications in acceptance sampling problems and quality control, and the Poisson distribution is useful for studying queueing theory and other related problems. Among the continuous distributions, the uniform distribution concerns random numbers and can be applied in simulation studies, the exponential and gamma distributions are closely related to the Poisson distribution and, together with the Weibull distribution, have important applications in life testing and reliability studies. All of these distributions involve at least one unknown parameter; hence their means and variances also depend on the parameters. See textbooks in this area for details. For example, Hahn and Shapiro [1967:163–169, 120–134] comprehensively list these and other distributions regarding their p.d.f.'s, graphs, parameters, means, and variances, with discussions and examples of their applications.

The Normal Distribution

Perhaps *the* most important distribution in statistics and probability is the normal distribution (also known as the Gaussian distribution). This distribution involves two parameters, μ and σ^2 , and its p.d.f. is given by

$$f(x) = f(x; \mu, \sigma^2) = \frac{1}{\sqrt{2\pi\sigma}} e^{-\frac{1}{2\sigma^2}(x-\mu)^2} \quad (228.3)$$

for $-\infty < \mu < \infty$, $\sigma^2 > 0$, and $-\infty < x < \infty$. It can be shown that, for a p.d.f. of this form, the values of μ and σ^2 are, respectively, that of the mean and the variance of the distribution. Further, the quantity $\sigma = \sqrt{\sigma^2}$ is called the standard deviation of the distribution. We shall use the symbol $X \sim \mathcal{N}(\mu, \sigma^2)$ to denote that X has a normal distribution with mean μ and variance σ^2 .

When plotting the p.d.f. $f(x; \mu, \sigma^2)$ given in Equation (228.3), we see that the resulting graph represents a bell-shaped curve and is symmetric about μ . If a random variable Z has an $\mathcal{N}(0,1)$ distribution, then the p.d.f. of Z is given by (from Equation (228.3)):

$$\phi(z) = \frac{1}{\sqrt{2\pi}} e^{-\frac{1}{2}z^2}, \quad -\infty < z < \infty \quad (228.4)$$

The distribution function of Z ,

$$\Phi(z) = \int_{-\infty}^z \phi(u) du, \quad -\infty < z < \infty \quad (228.5)$$

cannot be given in a closed form; hence it has been tabulated. The table of $\Phi(z)$ can be found in most textbooks in statistics and probability, including those listed in the references at the end of this chapter. (By the symmetry property, $\Phi(z) + \Phi(-z) = 1$ holds for all z .)

228.2 Random Sample and Sampling Distributions

Random Sample and Related Statistics

As noted in Box, Hunter, and Hunter [1978], in the design and analysis of engineering experiments, a study usually involves the following steps:

1. The choice of a suitable stochastic model by assuming that the observations follow a certain distribution. The functional form of the distribution (or the p.d.f.) is assumed to be known except the value(s) of the parameter(s).
2. Design of experiments and collection of data.
3. Summarization of data and computation of certain statistics.
4. Statistical inference (including estimation of the parameters of the underlying distribution and hypothesis-testing problems).

In order to make statistical inferences concerning the parameter(s) of a distribution, it is essential to first study the sampling distributions. We say that X_1, X_2, \dots, X_n represent a random sample of size n if they are independent random variables and each of them has the same p.d.f. $f(x)$. Due to space limitations, the notion of independence will not be carefully discussed here. But, nevertheless, we say that X_1, X_2, \dots, X_n are independent if

$$P[X_1 \in A_1, X_2 \in A_2, \dots, X_n \in A_n] = \prod_{i=1}^n P[X_i \in A_i] \quad (228.6)$$

holds for all sets A_1, A_2, \dots, A_n . Because the parameters of the population are unknown, the population mean μ and the population variance σ^2 are unknown. In most commonly used distributions, μ and σ^2 can be estimated by the sample mean \bar{X} and the sample variance S^2 , respectively, which are given by

$$\bar{X} = \frac{1}{n} \sum_{i=1}^n X_i, \quad S^2 = \frac{1}{n-1} \sum_{i=1}^n (X_i - \bar{X})^2 = \frac{1}{n-1} \left[\sum_{i=1}^n X_i^2 - n\bar{X}^2 \right] \quad (228.7)$$

(The second equality in the formula for S^2 can be verified algebraically.) Now, because X_1, X_2, \dots, X_n are random variables, \bar{X} and S^2 are also random variables. Each of them is called a statistic and has a probability distribution that also involves the unknown parameter(s). In probability theory, there are two fundamental results concerning their distributional properties.

Theorem 1 (Weak Law of Large Numbers). As the sample size n becomes large, \bar{X} converges to μ in probability and S^2 converges to σ^2 in probability. More precisely, for every fixed positive number $\varepsilon > 0$, we have

$$P[|\bar{X} - \mu| \leq \varepsilon] \rightarrow 1, \quad P[|S^2 - \sigma^2| \leq \varepsilon] \rightarrow 1 \quad (228.8)$$

as $n \rightarrow \infty$.

Theorem 2 (Central Limit Theorem). As n becomes large, the distribution of the random variable

$$Z = \frac{\bar{X} - \mu}{\sigma / \sqrt{n}} = \frac{\sqrt{n}(\bar{X} - \mu)}{\sigma} \quad (228.9)$$

has approximately an $\mathcal{N}(0,1)$ distribution. More precisely,

$$P[Z \leq z] \rightarrow \Phi(z) \text{ for every fixed } z \text{ as } n \rightarrow \infty \quad (228.10)$$

228.3 Normal Distribution–Related Sampling Distributions

One-Sample Case

Additional results exist when the observations come from a normal population. If X_1, X_2, \dots, X_n represent a random sample of size n from an $\mathcal{N}(\mu, \sigma^2)$ population, then the following sampling distributions are useful.

Fact 1. For every fixed n , the distribution of Z given in Equation (228.9) has exactly an $\mathcal{N}(0,1)$ distribution.

Fact 2. The distribution of the statistic $T = \sqrt{n}(\bar{X} - \mu) / S$, where $S = \sqrt{S^2}$ is the sample standard deviation, is called a Student's t distribution with $v = n - 1$ degrees of freedom; in symbols, $t(n - 1)$. This distribution is useful for making inference on μ when σ^2 is unknown. A table of the percentiles can be found in most statistics textbooks.

Fact 3. The distribution of the statistic $W = (n - 1)S^2 / \sigma^2$ is called a chi-squared distribution with $v = n - 1$ degrees of freedom; in symbols, $\chi^2(v)$.

Such a distribution is useful in making inference on σ^2 . A table of the percentiles can also be found in most statistics books.

Two-Sample Case

In certain applications, we may be interested in the comparisons of two different treatments. Suppose that independent samples from treatments T_1 and T_2 are to be observed as shown in Table 228.1. The difference of the population means ($\mu_1 - \mu_2$) and the ratio of the population variances can be estimated, respectively, by $(\bar{X}_1 - \bar{X}_2)$ and S_1^2 / S_2^2 . The following facts summarize the distributions of these statistics.

Fact 4. Under the assumption of normality, $(\bar{X}_1 - \bar{X}_2)$ has an $\mathcal{N}(\mu_1 - \mu_2, (\sigma_1^2 / n_1) + (\sigma_2^2 / n_2))$ distribution; or equivalently, for all n_1 and n_2 , the statistic

$$Z = [(\bar{X}_1 - \bar{X}_2) - (\mu_1 - \mu_2)] / (\sigma_1^2 / n_1 + \sigma_2^2 / n_2)^{1/2} \quad (228.11)$$

TABLE 228.1 Summary of Data for a Two-Sample Problem

| Treatment | Observations | Distribution | Sample Size | Sample Mean | Sample Variance |
|-----------|-----------------------------------|------------------------|-------------|-------------|-----------------|
| T_1 | $X_{11}, X_{12}, \dots, X_{1n_1}$ | $N(\mu_1, \sigma_1^2)$ | n_1 | \bar{X}_1 | S_1^2 |
| T_2 | $X_{21}, X_{22}, \dots, X_{2n_2}$ | $N(\mu_2, \sigma_2^2)$ | n_2 | \bar{X}_2 | S_2^2 |

has an $\mathcal{N}(0,1)$ distribution.

Fact 5. When $\sigma_1^2 = \sigma_2^2 \equiv \sigma^2$, the common population variance is estimated by

$$S_p^2 = (n_1 + n_2 - 2)^{-1}[(n_1 - 1)S_1^2 + (n_2 - 1)S_2^2] \quad (228.12)$$

and $(n_1 + n_2 - 2)S_p^2 / \sigma^2$ has an $\chi^2(n_1 + n_2 - 2)$ distribution.

Fact 6. When $\sigma_1^2 = \sigma_2^2$, the statistic

$$T = [(\bar{X}_1 - \bar{X}_2) - (\mu_1 - \mu_2)] / S_p(1/n_1 + 1/n_2)^{1/2} \quad (228.13)$$

has a $t(n_1 + n_2 - 2)$ distribution, where $S_p = \sqrt{S_p^2}$.

Fact 7. The distribution of $F = (S_1^2 / \sigma_1^2) / (S_2^2 / \sigma_2^2)$ is called an F distribution with degrees of freedom $(n_1 - 1, n_2 - 1)$; in symbols, $F(n_1 - 1, n_2 - 1)$.

The percentiles of this distribution have also been tabulated and can be found in statistics books.

The distributions listed above (normal, Student's t , chi-squared, and F) form an important part of classical statistical inference theory, and they are developed under the assumption that the observations follow a normal distribution. When the distribution of the population is not normal and inference on the population means is to be made, we conclude that (1) if the sample sizes n_1 and n_2 are large, then the statistic Z in Equation (228.11) has an approximate $\mathcal{N}(0,1)$ distribution; and (2) in the small-sample case, the exact distribution of \bar{X} [of $(\bar{X}_1 - \bar{X}_2)$] depends on the population p.d.f. There are several analytical methods for obtaining it, and those methods can be found in statistics textbooks.

228.4 Confidence Intervals

A method for estimating the population parameters based on the sample mean(s) and sample variance(s) involves the confidence intervals for the parameters.

One-Sample Case

Confidence Interval for μ When σ^2 Is Known

Consider the situation in which a random sample of size n is taken from an $\mathcal{N}(\mu, \sigma^2)$ population and σ^2 is known. An interval, I_1 , of the form $I_1 = (\bar{X} - d, \bar{X} + d)$ (with width $2d$) is to be constructed as a *confidence interval* for μ . If we make the assertion that μ is in this interval (i.e., μ is bounded below by $\bar{X} - d$, and bounded above by $\bar{X} + d$), then sometimes this assertion is correct and sometimes it is wrong, depending on the value of \bar{X} in a given experiment. If, for a fixed α value, we would like to have a confidence probability (called confidence coefficient) such that

$$P[\mu \in I_1] = P[\bar{X} - d < \mu < \bar{X} + d] = 1 - \alpha \quad (228.14)$$

then we need to choose the value of d to satisfy $d = z_{\alpha/2} \sigma / \sqrt{n}$; that is,

$$I_1 = \left(\bar{X} - z_{\alpha/2} \frac{\sigma}{\sqrt{n}}, \bar{X} + z_{\alpha/2} \frac{\sigma}{\sqrt{n}} \right) \quad (228.15)$$

where $z_{\alpha/2}$ is the $(1-\alpha/2)$ th percentile of the $\mathcal{N}(0,1)$ distribution such that $\Phi(z_{\alpha/2})=1-\alpha/2$. To see this, we note that from the sampling distribution of \bar{X} (Fact 1), we have

$$\begin{aligned} P \left[\bar{X} - z_{\alpha/2} \frac{\sigma}{\sqrt{n}} < \mu < \bar{X} + z_{\alpha/2} \frac{\sigma}{\sqrt{n}} \right] &= P \left[\frac{|\bar{X} - \mu|}{\sigma / \sqrt{n}} \leq z_{\alpha/2} \right] \\ &= \Phi(z_{\alpha/2}) - \Phi(-z_{\alpha/2}) = 1 - \alpha. \end{aligned} \quad (228.16)$$

We further note that, even when the original population is not normal, by Theorem 2 the confidence probability is approximately $(1-\alpha)$ when the sample size is reasonably large.

Confidence Interval for μ When σ^2 Is Unknown

Assume that the observations are from an $\mathcal{N}(\mu, \sigma^2)$ population. When σ^2 is unknown, by Fact 2 and a similar argument we see that

$$I_2 = \left(\bar{X} - t_{\alpha/2}(n-1) \frac{S}{\sqrt{n}}, \bar{X} + t_{\alpha/2}(n-1) \frac{S}{\sqrt{n}} \right) \quad (228.17)$$

is a confidence interval for μ with confidence probability $1-\alpha$, where $t_{\alpha/2}(n-1)$ is the $(1-\alpha/2)$ th percentile of the $t(n-1)$ distribution.

Confidence Interval for σ^2

If, under the same assumption of normality, a confidence interval for σ^2 is needed when μ is unknown, then

$$I_3 = ((n-1)S^2 / \chi_{1-\alpha/2}^2(n-1), (n-1)S^2 / \chi_{\alpha/2}^2(n-1)) \quad (228.18)$$

has a confidence probability $1-\alpha$, when $\chi_{1-\alpha/2}^2(n-1)$ and $\chi_{\alpha/2}^2(n-1)$ are the $(\alpha/2)$ th and $(1-\alpha/2)$ th percentiles, respectively, of the $\chi^2(n-1)$ distribution.

Two-Sample Case

Confidence Intervals for $\mu_1 - \mu_2$ When σ_1^2 and σ_2^2 Are Known

Consider an experiment that involves the comparison of two treatments, T_1 and T_2 , as indicated in [Table 228.1](#). If a confidence interval for $\delta = \mu_1 - \mu_2$ is needed when σ_1^2 and σ_2^2 are known, then by Fact 4 and a similar argument, the confidence interval

$$I_4 = \left((\bar{X}_1 - \bar{X}_2) - z_{\alpha/2} \sqrt{\sigma_1^2/n_1 + \sigma_2^2/n_2}, (\bar{X}_1 - \bar{X}_2) + z_{\alpha/2} \sqrt{\sigma_1^2/n_1 + \sigma_2^2/n_2} \right) \quad (228.19)$$

has a confidence probability $1-\alpha$.

Confidence Interval for $\mu_1 - \mu_2$ When σ_1^2 and σ_2^2 Are Unknown but Equal

Under the additional assumption that $\sigma_1^2 = \sigma_2^2$ but the common variance is unknown, then by Fact 6 the confidence interval

$$I_5 = [(\bar{X}_1 - \bar{X}_2) - d, (\bar{X}_1 - \bar{X}_2) + d] \quad (228.20)$$

has a confidence probability $1 - \alpha$, where

$$d = t_{\alpha/2}(n_1 + n_2 - 2)S_p(1/n_1 + 1/n_2)^{1/2} \quad (228.21)$$

Confidence Interval for σ_1^2/σ_2^2

A confidence interval for the ratio of the variances σ_2^2/σ_1^2 can be obtained from the F distribution (see Fact 7), and the confidence interval

$$I_6 = \left(F_{1-\alpha/2}(n_1 - 1, n_2 - 1) \frac{S_2^2}{S_1^2}, F_{\alpha/2}(n_1 - 1, n_2 - 1) \frac{S_2^2}{S_1^2} \right) \quad (228.22)$$

has a confidence probability $1 - \alpha$, where $F_{1-\alpha/2}(n_1 - 1, n_2 - 1)$ and $F_{\alpha/2}(n_1 - 1, n_2 - 1)$ are, respectively, the $(\alpha/2)$ th and $(1 - \alpha/2)$ th percentiles of the $F(n_1 - 1, n_2 - 1)$ distribution.

228.5 Testing Statistical Hypotheses

A statistical hypothesis concerns a statement or assertion about the true value of the parameter in a given distribution. In the two-hypothesis problems, we deal with a null hypothesis and an alternative hypothesis, denoted by H_0 and H_1 , respectively. A decision is to be made, based on the data of the experiment, to either accept H_0 (hence reject H_1) or reject H_0 (hence accept H_1). In such a two-action problem, there are two types of errors that we may commit: the type I error is to reject H_0 when it is true, and the type II error is to accept H_0 when it is false. As a standard practice, we do not reject H_0 unless there is significant evidence indicating that it may be false (in doing so, the burden of proof that H_0 is false is on the experimenter). Thus, we usually choose a small fixed number, α (such as 0.05 or 0.01), such that the probability of committing a type I error is at most α . With such a given α , we can then determine the region in the data space for the rejection of H_0 (called the critical region).

One-Sample Case

Suppose that X_1, X_2, \dots, X_n represent a random sample of size n from an $\mathcal{N}(\mu, \sigma^2)$ population, and \bar{X} and S^2 are, respectively, the sample mean and sample variance.

Test for Mean

In testing

$$H_0: \mu = \mu_0 \quad \text{vs.} \quad H_1: \mu = \mu_1 (\mu_1 > \mu_0) \quad \text{or} \quad H_1: \mu > \mu_0$$

when σ^2 is known, we reject H_0 when \bar{X} is large. To determine the cut-off point, we note that (by Fact 1) the statistic $Z_0 = (\bar{X} - \mu_0)/(\sigma/\sqrt{n})$ has an $\mathcal{N}(0,1)$ distribution under H_0 . Thus if we decide to reject H_0 when $Z_0 > z_\alpha$, then the probability of committing a type I error is α . As a consequence, we apply the following decision rule:

$$d_1: \text{reject } H_0 \text{ if and only if } \bar{X} > \mu_0 + z_\alpha \frac{\sigma}{\sqrt{n}}$$

Similarly, from the distribution of Z_0 under H_0 , we can obtain the critical region for the other types of hypotheses. When σ^2 is unknown, then by Fact 2, $T_0 = \sqrt{n}(\bar{X} - \mu_0)/S$ has a $t(n-1)$ distribution

TABLE 228.2 One-Sample Tests for Mean

| Null Hypothesis H_0 | Alternative Hypothesis H_1 | Critical Region |
|-----------------------------------|--|---|
| $\mu = \mu_0$ or $\mu \leq \mu_0$ | $\mu = \mu_1 > \mu_0$ or $\mu > \mu_0$ | $\bar{X} > \mu_0 + z_\alpha \frac{\sigma}{\sqrt{n}}$ $\bar{X} > \mu_0 + t_\alpha \frac{S}{\sqrt{n}}$ |
| $\mu = \mu_0$ or $\mu \geq \mu_0$ | $\mu = \mu_1 < \mu_0$ or $\mu < \mu_0$ | $\bar{X} < \mu_0 - z_\alpha \frac{\sigma}{\sqrt{n}}$ $\bar{X} < \mu_0 - t_\alpha \frac{S}{\sqrt{n}}$ |
| $\mu = \mu_0$ | $\mu \neq \mu_0$ | $ \bar{X} - \mu_0 > z_{\alpha/2} \frac{\sigma}{\sqrt{n}}$ $ \bar{X} - \mu_0 > t_{\alpha/2} \frac{S}{\sqrt{n}}$ |

TABLE 228.3 One-Sample Tests for Variance

| Null Hypothesis H_0 | Alternative Hypothesis H_1 | Critical Region |
|---|---|---|
| $\sigma^2 = \sigma_0^2$ or $\sigma^2 \leq \sigma_0^2$ | $\sigma^2 = \sigma_1^2 > \sigma_0^2$ or $\sigma^2 > \sigma_0^2$ | $(S^2 / \sigma_0^2) > \frac{1}{n-1} \chi_\alpha^2$ |
| $\sigma^2 = \sigma_0^2$ or $\sigma^2 \geq \sigma_0^2$ | $\sigma^2 = \sigma_1^2 < \sigma_0^2$ or $\sigma^2 < \sigma_0^2$ | $(S^2 / \sigma_0^2) < \frac{1}{n-1} \chi_{1-\alpha}^2$ |
| $\sigma^2 = \sigma_0^2$ | $\sigma^2 \neq \sigma_0^2$ | $(S^2 / \sigma_0^2) > \frac{1}{n-1} \chi_{\alpha/2}^2$ or $(S^2 / \sigma_0^2) < \frac{1}{n-1} \chi_{1-\alpha/2}^2$ |

under H_0 . Thus, the corresponding tests can be obtained by substituting $t_\alpha(n-1)$ for z_α and S for σ . The tests for the various one-sided and two-sided hypotheses are summarized in Table 228.2. For each set of hypotheses, the critical region given on the first line is for the case when σ^2 is known, and that given on the second line is for the case when σ^2 is unknown. Furthermore, t_α and $t_{\alpha/2}$ stand for $t_\alpha(n-1)$ and $t_{\alpha/2}(n-1)$, respectively.

Test for Variance

In testing hypotheses concerning the variance σ^2 of a normal distribution, we use Fact 3 to assert that, under $H_0: \sigma^2 = \sigma_0^2$, the distribution of $w_0 = (n-1)S^2 / \sigma_0^2$ is $\chi^2(n-1)$. The corresponding tests and critical regions are summarized in Table 228.3 (χ_α^2 and $\chi_{\alpha/2}^2$ stand for $\chi_\alpha^2(n-1)$ and $\chi_{\alpha/2}^2(n-1)$, respectively).

Two-Sample Case

In comparing the means and variances of two normal populations, we once again refer to Table 228.1 for notation and assumptions.

Test for Difference of Two Means

Let $\delta = \mu_1 - \mu_2$ be the difference of the two population means. In testing $H_0: \delta = \delta_0$ versus a one-sided or two-sided alternative hypothesis, we note that, for

TABLE 228.4 Two-Sample Tests for Difference of Two Means

| Null Hypothesis H_0 | Alternative Hypothesis H_1 | Critical Region |
|---|---|---|
| $\delta = \delta_0$ or $\delta \leq \delta_0$ | $\delta = \delta_1 > \delta_0$ or $\delta > \delta_0$ | $(\bar{X}_1 - \bar{X}_2) > \delta_0 + z_\alpha \tau$ $(\bar{X}_1 - \bar{X}_2) > \delta_0 + t_\alpha \nu$ |
| $\delta = \delta_0$ or $\delta \geq \delta_0$ | $\delta = \delta_1 < \delta_0$ or $\delta < \delta_0$ | $(\bar{X}_1 - \bar{X}_2) < \delta_0 - z_\alpha \tau$ $(\bar{X}_1 - \bar{X}_2) < \delta_0 - t_\alpha \nu$ |
| $\delta = \delta_0$ | $\delta \neq \delta_0$ | $ (\bar{X}_1 - \bar{X}_2) - \delta_0 > z_{\alpha/2} \tau$ $ (\bar{X}_1 - \bar{X}_2) - \delta_0 > t_{\alpha/2} \nu$ |

$$\tau = \left(\sigma_1^2 / n_1 + \sigma_2^2 / n_2 \right)^{1/2} \tag{228.23}$$

and

$$\nu = S_p (1/n_1 + 1/n_2)^{1/2} \tag{228.24}$$

$Z_0 = [(\bar{X}_1 - \bar{X}_2) - \delta_0] / \tau$ has an $\mathcal{N}(0,1)$ distribution under H_0 , and $T_0 = [(\bar{X}_1 - \bar{X}_2) - \delta_0] / \nu$ has a $t(n_1 + n_2 - 2)$ distribution under H_0 when $\sigma_1^2 = \sigma_2^2$. Using these results, the corresponding critical regions for one-sided and two-sided tests can be obtained, and they are listed in Table 228.4. Note that, as in the one-sample case, the critical region given on the first line for each set of hypotheses is for the case of known variances, and that given on the second line is for the case in which the variances are equal but unknown. Further, t_α and $t_{\alpha/2}$ stand for $t_\alpha(n_1 + n_2 - 2)$ and $t_{\alpha/2}(n_1 + n_2 - 2)$, respectively.

228.6 A Numerical Example

In the following, we provide a numerical example for illustrating the construction of confidence intervals and hypotheses-testing procedures. The example is given along the line of applications in Wadsworth [1990:4.21] with artificial data.

Suppose that two processes, T_1 and T_2 , for manufacturing steel pins are in operation, and that a random sample of four pins (of five pins) was taken from the process T_1 (the process T_2) with the following results (in units of inches):

$$T_1: 0.7608, 0.7596, 0.7622, 0.7638$$

$$T_2: 0.7546, 0.7561, 0.7526, 0.7572, 0.7565$$

Simple calculation shows that the observed values of sample means, sample variances, and sample standard deviations are

$$\bar{X}_1 = 0.7616, \quad S_1^2 = 3.178914 \cdot 10^{-6}, \quad S_1 = 1.7830 \cdot 10^{-3}$$

$$\bar{X}_2 = 0.7554, \quad S_2^2 = 3.516674 \cdot 10^{-6}, \quad S_2 = 1.8753 \cdot 10^{-3}$$

One-Sample Case

Let us first consider confidence intervals for the parameters of the first process, T_1 , only.

1. Assume that, based on previous knowledge on processes of this type, the variance is known to be $\sigma_1^2 = 1.80^2 \cdot 10^{-6}$ ($\sigma_1 = 0.0018$). Then, from the normal table [Ross, 1987:482], we have $z_{0.025} = 1.96$. Thus, a 95% confidence interval for μ_1 is

$$(0.7616 - 1.96 \times 0.0018 / \sqrt{4}, \quad 0.7616 + 1.96 \times 0.0018 / \sqrt{4})$$

or (0.7598, 0.7634) (after rounding off to the fourth decimal place).

2. If σ_1^2 is unknown and a 95% confidence interval for μ_1 is needed, then, for $t_{0.025}(3) = 3.182$ [Ross, 1987:484], the confidence interval is

$$(0.7616 - 3.182 \times 0.001783 / \sqrt{4}, \quad 0.7616 + 3.182 \times 0.001783 / \sqrt{4})$$

or (0.7588, 0.7644).

3. From the chi-squared table with $4 - 1 = 3$ degrees of freedom, we have [Ross, 1987:483] $\chi_{0.975}^2 = 0.216$, $\chi_{0.025}^2 = 9.348$. Thus, a 95% confidence interval for σ_1^2 is $(3 \times 3.178 \ 914 \cdot 10^{-6} / 9.348, 3.178 \ 914 \cdot 10^{-6} / 0.216)$, or $(1.0202 \cdot 10^{-6}, 44.151 \ 58 \cdot 10^{-6})$.
4. In testing the hypotheses

$$H_0: \mu_1 = 0.76 \quad \text{vs} \quad H_1: \mu_1 > 0.76$$

with $\alpha = 0.01$ when σ_1^2 is unknown, the critical region is $\bar{x}_1 > 0.76 + 4.541 \times 0.001783 / \sqrt{4} = 0.7640$. Because the observed value of \bar{x}_1 is 0.7616, H_0 is accepted. That is, we assert that there is no significant evidence to call for the rejection of H_0 .

Two-Sample Case

If we assume that the two populations have a common unknown variance, we can use the Student's t distribution (with degree of freedom $\nu = 4 + 5 - 2 = 7$) to obtain confidence intervals and to test hypotheses for $\mu_1 - \mu_2$. We first note that the data given above yield

$$\begin{aligned} S_p^2 &= \frac{1}{7}(3 \times 3.178414 + 4 \times 3.516674) \cdot 10^{-6} \\ &= 3.371920 \cdot 10^{-6}, \\ S_p &= 1.836279 \cdot 10^{-3}, \quad \nu = S_p \sqrt{1/4 + 1/5} = 1.231813 \cdot 10^{-3} \end{aligned}$$

and

$$\bar{X}_1 - \bar{X}_2 = 0.0062$$

1. A 98% confidence interval for $\mu_1 - \mu_2$ is $(0.0062 - 2.998 \cdot \nu, 0.0062 + 2.998 \nu)$ or $(0.0025, 0.0099)$.
2. In testing the hypotheses $H_0: \mu_1 = \mu_2$ (i.e., $\mu_1 - \mu_2 = 0$) versus $H_1: \mu_1 > \mu_2$ with $\alpha = 0.05$, the critical region is $(\bar{X}_1 - \bar{X}_2) > 1.895 \nu = 2.3344 \cdot 10^{-3}$. Thus, H_0 is rejected (i.e., we concluded that there is significant evidence to indicate that $\mu_1 > \mu_2$ may be true).
3. In testing the hypotheses $H_0: \mu_1 = \mu_2$ vs $H_1: \mu_1 \neq \mu_2$ with $\alpha = 0.02$, the critical region is $|X_1 - X_2| > 2.998 \nu = 3.6930 \cdot 10^{-3}$. Thus, H_0 is rejected. We note this conclusion is consistent with the result that, with confidence probability $1 - \alpha = 0.98$, the confidence interval for $(\mu_1 - \mu_2)$ does not contain the origin.

Further Information

Other important topics in engineering probability and statistics include sampling inspection and quality (process) control, reliability, regression analysis and prediction, design of engineering experiments, and analysis of variance. Due to space limitations, these topics are not treated in this chapter. The reader is referred to textbooks in this area for further information. There are many well-written books that cover most of these topics. The short list of references above consists of a small sample of them.

229.1 Linear Programming
229.2 Unconstrained Nonlinear Programming
229.3 Constrained Nonlinear Programming

229.1 Linear Programming

Let \mathbf{A} be an $m \times n$ matrix, \mathbf{b} a column vector with m components, and \mathbf{c} a column vector with n components. Suppose $m < n$, and assume the rank of \mathbf{A} is m . The standard linear programming problem is to find, among all nonnegative solutions of $\mathbf{Ax} = \mathbf{b}$, one that minimizes

$$\mathbf{c}^T \mathbf{x} = c_1 x_1 + c_2 x_2 + \cdots + c_n x_n$$

This problem is called a *linear program*. Each solution of the system $\mathbf{Ax} = \mathbf{b}$ is called a *feasible solution*, and the *feasible set* is the collection of all *feasible solutions*. The function $\mathbf{c}^T \mathbf{x} = c_1 x_1 + c_2 x_2 + \cdots + c_n x_n$ is the *cost function*, or the *objective function*. A solution to the linear program is called an *optimal feasible solution*.

Let \mathbf{B} be an $m \times m$ submatrix of \mathbf{A} made up of m linearly independent columns of \mathbf{A} , and let \mathbf{C} be the $m \times (n - m)$ matrix made up of the remaining columns of \mathbf{A} . Let \mathbf{x}_B be the vector consisting of the components of \mathbf{x} corresponding to the columns of \mathbf{A} that make up \mathbf{B} , and let \mathbf{x}_C be the vector of the remaining components of \mathbf{x} , that is, the components of \mathbf{x} that correspond to the columns of \mathbf{C} . Then the equation $\mathbf{Ax} = \mathbf{b}$ may be written $\mathbf{Bx}_B + \mathbf{Cx}_C = \mathbf{b}$. A solution of $\mathbf{Bx}_B = \mathbf{b}$ together with $\mathbf{x}_C = \mathbf{0}$ gives a solution \mathbf{x} of the system $\mathbf{Ax} = \mathbf{b}$. Such a solution is called a *basic solution*, and if it is, in addition, nonnegative, it is a *basic feasible solution*. If it is also optimal, it is an *optimal basic feasible solution*. The components of a basic solution are called *basic variables*.

The Fundamental Theorem of Linear Programming says that if there is a feasible solution, there is a basic feasible solution, and if there is an optimal feasible solution, there is an optimal basic feasible solution. The linear programming problem is thus reduced to searching among the set of basic solutions for an optimal solution. This set is, of course, finite, containing as many as $n!/[m!(n-m)!]$ points. In practice, this will be a very large number, making it imperative that one use some efficient search procedure in seeking an optimal solution. The most important of such procedures is the *simplex method*, details of which may be found in the references.

The problem of finding a solution of $\mathbf{Ax} \leq \mathbf{b}$ that minimizes $\mathbf{c}^T \mathbf{x}$ can be reduced to the standard problem by appending to the vector \mathbf{x} an additional m nonnegative components, called *slack variables*. The vector \mathbf{x} is replaced by \mathbf{z} , where $\mathbf{z}^T = [x_1 x_2 \cdots x_n \quad s_1 s_2 \cdots s_m]$, and the matrix \mathbf{A} is replaced by $\mathbf{B} = [\mathbf{A} \ \mathbf{I}]$, where \mathbf{I} is the $m \times m$ identity matrix. The equation $\mathbf{Ax} = \mathbf{b}$ is thus replaced by $\mathbf{Bz} = \mathbf{Ax} + \mathbf{s} = \mathbf{b}$, where

$\mathbf{s}^T = [s_1, s_2, \dots, s_m]$. Similarly, if inequalities are reversed so that we have $\mathbf{Ax} \leq \mathbf{b}$, we simply append $-\mathbf{s}$ to the vector \mathbf{x} . In this case, the additional variables are called *surplus variables*.

Associated with every linear programming problem is a corresponding dual problem. If the *primal* problem is to minimize $\mathbf{c}^T \mathbf{x}$ subject to $\mathbf{Ax} \geq \mathbf{b}$, and $\mathbf{x} \geq 0$, the corresponding *dual* problem is to maximize $\mathbf{y}^T \mathbf{b}$ subject to $\mathbf{y}^T \mathbf{A} \leq \mathbf{c}^T$. If either the primal problem or the dual problem has an optimal solution, so also does the other. Moreover, if \mathbf{x}_p is an optimal solution for the primal problem and \mathbf{y}_d is an optimal solution for the corresponding dual problem, $\mathbf{c}^T \mathbf{x}_p = \mathbf{y}_d^T \mathbf{b}$.

229.2 Unconstrained Nonlinear Programming

The problem of minimizing or maximizing a sufficiently smooth nonlinear function $f(\mathbf{x})$ of n variables, $\mathbf{x}^T = [x_1, x_2, \dots, x_n]$, with no restrictions on \mathbf{x} is essentially an ordinary problem in calculus. At a minimizer or maximizer \mathbf{x}^* , it must be true that the gradient of f vanishes:

$$\nabla f(\mathbf{x}^*) = 0$$

Thus, \mathbf{x}^* will be in the set of all solutions of this system of n generally nonlinear equations. The solution of the system can be, of course, a nontrivial undertaking. There are many recipes for solving systems of nonlinear equations. A method specifically designed for minimizing f is the *method of steepest descent*. It is an old and honorable algorithm, and the one on which most other more complicated algorithms for unconstrained optimization are based. The method is based on the fact that at any point \mathbf{x} , the direction of maximum decrease of f is in the direction of $-\nabla f(\mathbf{x})$. The algorithm searches in this direction for a minimum, recomputes $-\nabla f(\mathbf{x})$ at this point, and continues iteratively. Explicitly:

1. Choose an initial point \mathbf{x}_0 .
2. Assume \mathbf{x}_k has been computed; then compute $\mathbf{y}_k = \nabla f(\mathbf{x}_k)$, and let $t_k \geq 0$ be a local minimum of $g(t) = f(\mathbf{x}_k - t\mathbf{y}_k)$. Then $\mathbf{x}_{k+1} = \mathbf{x}_k - t_k \mathbf{y}_k$.
3. Replace k by $k + 1$, and repeat step 2 until t_k is small enough.

Under reasonably general conditions, the sequence (\mathbf{x}_k) converges to a minimum of f .

229.3 Constrained Nonlinear Programming

The problem of finding the maximum or minimum of a function $f(\mathbf{x})$ of n variables subject to the constraints

$$\mathbf{a}(\mathbf{x}) = \begin{bmatrix} a_1(x_1, x_2, \dots, x_n) \\ a_2(x_1, x_2, \dots, x_n) \\ \vdots \\ a_m(x_1, x_2, \dots, x_n) \end{bmatrix} = \begin{bmatrix} b_1 \\ b \\ \vdots \\ b_m \end{bmatrix} = \mathbf{b}$$

is made into an unconstrained problem by introducing the new function $L(\mathbf{x})$:

$$L(\mathbf{x}) = f(\mathbf{x}) + \mathbf{z}^T \mathbf{a}(\mathbf{x})$$

where $\mathbf{z}^T = [\lambda_1, \lambda_2, \dots, \lambda_m]$ is the vector of *Lagrange multipliers*. Now the requirement that $\nabla L(\mathbf{x}) = 0$, together with the constraints $\mathbf{a}(\mathbf{x}) = \mathbf{b}$, give a system of $n + m$ equations

$$\nabla f(\mathbf{x}) + \mathbf{z}^T \nabla \mathbf{a}(\mathbf{x}) = \mathbf{0}$$

$$\mathbf{a}(\mathbf{x}) = \mathbf{b}$$

for the $n + m$ unknowns $x_1, x_2, \dots, \lambda_1, \lambda_2, \dots, \lambda_m$ that must be satisfied by the minimizer (or maximizer) \mathbf{x} .

The problem of inequality constraints is significantly more complicated in the nonlinear case than in the linear case. Consider the problem of minimizing $f(x)$ subject to m equality constraints $\mathbf{a}(\mathbf{x}) = \mathbf{b}$, and p inequality constraints $\mathbf{c}(\mathbf{x}) \leq \mathbf{d}$ (thus, $\mathbf{a}(\mathbf{x})$ and \mathbf{b} are vectors of m components, and $\mathbf{c}(\mathbf{x})$ and \mathbf{d} are vectors of p components). A point \mathbf{x}^* that satisfies the constraints is a *regular point* if the collection

$$\{\nabla a_1(\mathbf{x}^*), \nabla a_2(\mathbf{x}^*), \dots, \nabla a_m(\mathbf{x}^*)\} \cup \{\nabla c_j(\mathbf{x}^*); j \in J\}$$

where

$$J = \{j: c_j(\mathbf{x}^*) = d_j\}$$

is linearly independent. If \mathbf{x}^* is a local minimum for the constrained problem and if it is a regular point, there is a vector \mathbf{z} with m components and a vector $\mathbf{w} \geq \mathbf{0}$ with p components such that

$$\nabla f(\mathbf{x}^*) + \mathbf{z}^T \nabla \mathbf{a}(\mathbf{x}^*) + \mathbf{w}^T \mathbf{Dc}(\mathbf{x}^*) = \mathbf{0}$$

$$\mathbf{w}^T (\mathbf{c}(\mathbf{x}^*) - \mathbf{d}) = 0$$

These are the *Kuhn-Tucker conditions*. Note that in order to solve these equations, one needs to know for which j it is true that $c_j(\mathbf{x}^*) = 0$. (Such a constraint is said to be *active*.)

Since many mathematical models of physical phenomena are not solvable by available mathematical methods, one must often resort to approximate or numerical methods. These procedures do not yield exact results in the mathematical sense. This inexact nature of numerical results means we must pay attention to the errors. The two errors that concern us here are *round-off errors* and *truncation errors*.

Round-off errors arise as a consequence of using a number specified by m correct digits to approximate a number that requires more than m digits for its exact specification. An example here is using 3.14159 to approximate the irrational number π . Such errors may be especially serious in matrix inversion or in any area where a very large number of numerical operations are required. Certain attempts at handling these errors are called *enclosure methods* [Adams and Kulisch, 1993].

Truncation errors arise from the substitution of a finite number of steps for an infinite sequence of steps (usually an iteration) that would yield the exact result. For example, the iteration $y_n(x) = 1$

$$+ \int_0^x xty_{n-1}(t)dt, \quad y(0) = 1$$

is only carried out for a *few steps*, but it converges in *infinitely* many steps.

The study of some errors in a computation is related to the theory of probability. In what follows, a relation for the error will be given in certain instances.

230.1 Linear Algebra Equations

A problem often encountered is the determination of the solution vector $u = (u_1, u_2, \dots, u_n)^T$ for the set of linear equations $Au = v$, where A is the $n \times n$ square matrix with coefficients a_{ij} ($i, j = 1, \dots, n$) and $v = (v_1, \dots, v_n)^T$, and i denotes the row index and j the column index. There are many numerical methods for finding the solution, u , of $Au = v$. The direct inversion of A is usually too expensive and is not often carried out unless it is needed elsewhere. Only a few methods will be listed. You can check the literature for the many methods and computer software available. Some of the software is briefly described at the end of this chapter. The methods are usually subdivided into *direct* (once through) or *iterative* (repeated) procedures.

In the following, it will often be convenient to partition the matrix A into the form $A = U + D + L$, where U , D , and L are matrices having the same elements as A , respectively, above the main diagonal, on the main diagonal, and below the main diagonal, and zeros elsewhere. Thus,

$$U = \begin{bmatrix} 0 & a_{12} & & \cdots & a_{1n} \\ 0 & 0 & a_{23} & \cdots & a_{2n} \\ \vdots & \cdots & & \cdots & \\ 0 & 0 & \cdots & \cdots & 0 \end{bmatrix}$$

We also assume the u_j 's are not all zero and that $\det A \neq 0$, so the solution is unique.

Direct Methods

Gauss Reduction

This classical method has spawned many variations. It consists of dividing the first equation by a_{11} (if $a_{11} = 0$, reorder the equations to find an $a_{11} \neq 0$) and using the result to eliminate the terms in u_1 from each of the succeeding equations. Next, the modified second equation is divided by a'_{22} (if $a'_{22} = 0$, a reordering of the modified equations may be necessary) and the resulting equation is used to eliminate all terms in u_2 in the succeeding modified equations. This elimination is done n times resulting in a triangular system:

$$\begin{array}{rcccc}
u_1 + a'_{12}u_2 & + \cdots & + a'_{1n}u_n & = v'_1 \\
0 + u_2 & + \cdots & + a'_{2n}u_n & = v'_2 \\
& \cdots & & \\
0 + \cdots & + u_{n-1} & + a'_{n-1,n}u_n & = v'_{n-1} \\
& & u_n & = v'_n
\end{array}$$

where a'_{ij} and v'_j represent the specific numerical values obtained by this process. The solution is obtained by working backward from the last equation. Various modifications, such as the Gauss–Jordan reduction, the Gauss–Doolittle reduction, and the Crout reduction, are described in the classical reference authored by Bodewig [1956]. Direct methods prove very useful for sparse matrices and banded matrices that often arise in numerical calculation for differential equations. Many of these are available in computer packages such as IMSL, Maple, Matlab, and Mathematica.

The Tridiagonal Algorithm

When the linear equations are tridiagonal, the system

$$\begin{array}{rcccc}
& b_1u_1 & + c_1u_2 & = d_1 \\
a_iu_{i-1} & + b_iu_i & + c_iu_{i+1} & = d_i \\
a_nu_{n-1} & + b_nu_n & & = d_n, \quad i = 2, 3, \dots, n-1
\end{array}$$

can be solved explicitly for the unknowns, thereby eliminating any matrix operations.

The Gaussian elimination process transforms the system into a simpler one of *upper bidiagonal* form. We designate the coefficients of this new system by a'_i, b'_i, c'_i , and d'_i , and we note that

$$\begin{array}{l}
a'_i = 0, \quad i = 2, 3, \dots, n \\
b'_i = 1, \quad i = 1, 2, \dots, n
\end{array}$$

The coefficients c'_i and d'_i are calculated successively from the relations

$$\begin{array}{l}
c'_1 = \frac{c_1}{b_1} \qquad d'_1 = \frac{d_1}{b_1} \\
c'_{i+1} = \frac{c_{i+1}}{b_{i+1} - a_{i+1}c'_i} \\
d'_{i+1} = \frac{d_{i+1} - a_{i+1}d'_i}{b_{i+1} - a_{i+1}c'_i}, \quad i = 1, 2, \dots, n-1
\end{array}$$

and, of course, $c_n = 0$.

Having completed the elimination, we examine the new system and see that the n th equation is now

$$u_n = d'_n$$

Substituting this value into the $(n-1)$ st equation,

$$u_{n-1} + c'_{n-1}u_n = d'_{n-1}$$

we have

$$u_{n-1} = d'_{n-1} - c'_{n-1}u_n$$

Thus, starting with u_n , we have successively the solution for u_i as

$$u_i = d'_i - c'_i u_{i+1}, \quad i = n-1, n-2, \dots, 1$$

Algorithm for Pentadiagonal Matrix

The equations to be solved are

$$a_i u_{i-2} + b_i u_{i-1} + c_i u_i + d_i u_{i+1} + e_i u_{i+2} = f_i$$

for $1 \leq i \leq R$ with $a_1 = b_1 = a_2 = e_{R-1} = d_R = e_R = 0$.

The algorithm is as follows. First, compute

$$\delta_1 = d_1 / c_1$$

$$\lambda_1 = e_1 / c_1$$

$$\gamma_1 = f_1 / c_1$$

and

$$\mu_2 = c_2 - b_2 \delta_1$$

$$\delta_2 = (d_2 - b_2 \lambda_1) / \mu_2$$

$$\lambda_2 = e_2 / \mu_2$$

$$\gamma_2 = (f_2 - b_2 \gamma_1) / \mu_2$$

Then, for $3 \leq i \leq (R-2)$, compute

$$\beta_i = b_i - a_i \delta_{i-2}$$

$$\mu_i = c_i - \beta_i \delta_{i-1} - a_i \lambda_{i-2}$$

$$\delta_i = (d_i - \beta_i \lambda_{i-1}) / \mu_i$$

$$\lambda_i = e_i / \mu_i$$

$$\gamma_i = (f_i - \beta_i \gamma_{i-1} - a_i \gamma_{i-2}) / \mu_i$$

Next, compute

$$\beta_{R-1} = b_{R-1} - a_{R-1} \delta_{R-3}$$

$$\mu_{R-1} = c_{R-1} - \beta_{R-1} \delta_{R-2} - a_{R-1} \lambda_{R-3}$$

$$\delta_{R-1} = (d_{R-1} - \beta_{R-1} \lambda_{R-2}) / \mu_{R-1}$$

$$\gamma_{R-1} = (f_{R-1} - \beta_{R-1} \gamma_{R-2} - a_{R-1} \gamma_{R-3}) / \mu_{R-1}$$

and

$$\beta_R = b_R - a_R \delta_{R-2}$$

$$\mu_R = c_R - \beta_R \delta_{R-1} - a_R \lambda_{R-2}$$

$$\gamma_R = (f_R - \beta_R \gamma_{R-1} - a_R \gamma_{R-2}) / \mu_R$$

The β_i and μ_i are used only to compute δ_i , λ_i , and γ_i , and need not be stored after they are computed. The δ_i , λ_i , and γ_i must be stored, as they are used in the back solution. This is

$$u_R = \gamma_R$$

$$u_{R-1} = \gamma_{R-1} - \delta_{R-1} u_R$$

and

$$u_i = \gamma_i - \delta_i u_{i+1} - \lambda_i u_{i+2}$$

for $R - 2 \geq i \geq 1$.

General Band Algorithm

The equations are of the form

$$A_j^{(M)} X_{j-M} + A_j^{(M-1)} X_{j-M+1} + \dots + A_j^{(2)} X_{j-2} + A_j^{(1)} X_{j-1} + B_j X_j$$

$$+ C_j^{(1)} X_{j+1} + C_j^{(2)} X_{j+2} + \dots + C_j^{(M-1)} X_{j+M-1} + C_j^{(M)} X_{j+M} = D_j$$

for $1 \leq j \leq N$, $N \geq M$. The algorithm used is as follows:

$$\alpha_j^{(k)} = A_j^{(k)} = 0, \quad \text{for } k \geq j$$

$$C_j^{(k)} = 0, \quad \text{for } k \geq N + 1 - j$$

The forward solution ($j = 1, \dots, N$) is

$$\alpha_j^{(k)} = A_j^{(k)} - \sum_{p=k+1}^{p=M} \alpha_j^{(p)} W_{j-p}^{(p-k)}, \quad k = M, \dots, 1$$

$$\beta_j = B_j - \sum_{p=1}^M \alpha_j^{(p)} W_{j-p}^{(p)}$$

$$W_j^{(k)} = \left(C_j^{(k)} - \sum_{p=k+1}^{p=M} \alpha_j^{(p-k)} W_{j-(p-k)}^{(p)} \right) / \beta_j, \quad k = 1, \dots, M$$

$$\gamma_j = \left(D_j - \sum_{p=1}^M \alpha_j^{(p)} \gamma_{j-p} \right) / \beta_j$$

The back solution ($j = N, \dots, 1$) is

$$X_j = \gamma_j - \sum_{p=1}^M W_j^{(p)} X_{j+p}$$

Cholesky Decomposition

When the matrix A is a symmetric and positive definite, as it is for many discretizations of self-adjoint positive definite boundary value problems, one can improve considerably on the band procedures by using the Cholesky decomposition. For the system $Au = v$, the matrix A can be written in the form

$$A = (I + L) D(I + U)$$

where L is lower triangular, U is upper triangular, and D is diagonal. If $A = A'$ (A' represents the transpose of A), then

$$A = A' = (I + U)'D(I + L)'$$

Hence, because of the uniqueness of the decomposition,

$$I + L = (I + U)' = I + U'$$

and therefore,

$$A = (I + U)'D(I + U)$$

that is,

$$A = B'B, \text{ where } B = \sqrt{D} (I + U)$$

The system $Au = v$ is then solved by solving the two triangular system

$$B'w = v$$

followed by

$$Bu = w$$

To carry out the decomposition $A = B'B$, all elements of the first row of A , and of the derived system, are divided by the square root of the (positive) leading coefficient. This yields smaller rounding errors than the banded methods because the relative error of \sqrt{a} is only half as large as that of a itself. Also, taking the square root brings numbers nearer to each other (i.e., the new coefficients do not differ as widely as the original ones do). The actual computation of $B = (b_{ij})$, $j > i$, is given in the following:

$$\begin{aligned} b_{11} &= (a_{11})^{1/2}, & b_{1j} &= a_{1j} / b_{11}, \quad j \geq 2 \\ b_{22} &= (a_{22} - b_{12}^2)^{1/2}, & b_{2j} &= (a_{2j} - b_{12}b_{1j}) / b_{22} \\ b_{33} &= (a_{33} - b_{13}^2 - b_{23}^2)^{1/2}, & b_{3j} &= (a_{3j} - b_{13}b_{1j} - b_{23}b_{2j}) / b_{33} \\ &\vdots & & \\ b_{ii} &= \left(a_{ii} - \sum_{k=1}^{i-1} b_{ki}^2 \right)^{1/2}, & b_{ij} &= \left(a_{ij} - \sum_{k=1}^{i-1} b_{ki}b_{kj} \right) / b_{ii}, \quad i \geq 2, j \geq 2 \end{aligned}$$

Iterative Methods

Iterative methods consist of repeated application of an often simple algorithm. They yield the exact answer only as the limit of a sequence. They can be programmed to take care of zeros in A and are self-correcting. Their structure permits the use of convergence accelerators, such as overrelaxation, Aitkins acceleration, or Chebyshev acceleration.

Let $a_{ii} > 0$ for all i and $\det A \neq 0$. With $A = U + D + L$ as previously described, several iteration methods are described for $(U + D + L)u = v$.

Jacobi Method (Iteration by Total Steps)

Since $u = -D^{-1}[U + L]u + D^{-1}v$, the iteration $u^{(k)}$ is $u^{(k)} = -D^{-1}[U + L]u^{(k-1)} + D^{-1}v$. This procedure has a slow convergent rate designated by R , $0 < R \ll 1$.

Gauss–Seidel Method (Iteration by Single Steps)

$u^{(k)} = -(L + D)^{-1} Uu^{(k-1)} + (L + D)^{-1}v$. The convergence rate is $2R$, twice as fast as that of the Jacobi method.

Gauss–Seidel with Successive Overrelaxation (SOR)

Let $\bar{u}_i^{(k)}$ be the i th components of the Gauss–Seidel iteration. The SOR technique is defined by

$$u_i^{(k)} = (1 - \omega)u_i^{(k-1)} + \omega\bar{u}_i^{(k)}$$

where $1 < \omega < 2$ is the overrelaxation parameter. The full iteration is $u^{(k)} = (D + \omega L)^{-1}\{(1 - \omega)D - \omega U\}u^{(k-1)} + \omega v$. Optimal values of ω can be computed and depend upon the properties of A [Ames, 1993]. With optimal values of ω , the convergence rate of this method is $2R$ which is much larger than that for Gauss–Seidel (R is usually much less than one).

For other acceleration techniques, see the literature [Ames, 1993].

230.2 Nonlinear Equations in One Variable

Special Methods for Polynomials

The polynomial $P(x) = a_0x^n + a_1xn^{n-1} + \dots + a_{n-1}x + a_n = 0$, with real coefficients $a_j, j = 0, \dots, n$, has exactly n roots which may be real or complex.

If all the coefficients of $P(x)$ are integers, then any rational roots, say r/s (r and s are integers with no common factors), of $P(x) = 0$ must be such that r is an integral divisor of a_n and s is an integral division of a_0 . Any polynomial with rational coefficients may be converted into one with integral coefficients by multiplying the polynomial by the lowest common multiple of the denominators of the coefficients.

Example

$x^4 - 5x^2/3 + x/5 + 3 = 0$. The lowest common multiple of the denominators is 15. Multiplying by 15, which does not change the roots, gives $15x^4 - 25x^2 + 3x + 45 = 0$. The only possible rational roots r/s are such that r may have the value $\pm 45, \pm 15, \pm 5, \pm 3$, and ± 1 , while s may have the values $\pm 15, \pm 5, \pm 3$, and ± 1 . All possible rational roots, with no common factors, are formed using all possible quotients.

If $a_0 > 0$, the first negative coefficient is preceded by k coefficients which are positive or zero, and G is the largest of the absolute values of the negative coefficients, then each real root is less than $1 + \sqrt[k]{G/a_0}$ (upper bound on the real roots). For a lower bound to the real roots, apply the criterion to $P(-x) = 0$.

Example

$P(x) = x^5 + 3x^4 - 2x^3 - 12x + 2 = 0$. Here $a_0 = 1$, $G = 12$, and $k = 2$. Thus, the upper bound for the real roots is $1 + \sqrt[2]{12} \approx 4.464$. For the lower bound, $P(-x) = -x^5 + 3x^4 + 2x^3 + 12x + 2 = 0$, which is equivalent to $x^5 - 3x^4 - 2x^3 - 12x - 2 = 0$. Here $k = 1$, $G = 12$, and $a_0 = 1$. A lower bound is $-(1 + 12) = -13$. Hence all real roots lie in $-13 < x < 1 + \sqrt[2]{12}$.

A useful *Descartes rule of signs* for the number of positive or negative real roots is available by observation for polynomials with real coefficients. The number of positive real roots is either equal to the number of sign changes, n , or is less than n by a positive *even* integer. The number of negative real roots is either equal to the number of sign changes, n , of $P(-x)$, or is less than n by a positive even integer.

Example

$P(x) = x^5 - 3x^3 - 2x^2 + x - 1 = 0$. There are three sign changes, so $P(x)$ has either three or one positive roots. Since $P(-x) = -x^5 + 3x^3 - 2x^2 - x - 1 = 0$, there are either two or zero negative roots.

The Graeffe Root-Squaring Technique

This is an iterative method for finding the roots of the algebraic equation

$$f(x) = a_0x^p + a_1x^{p-1} + \dots + a_{p-1}x + a_p = 0$$

If the roots are r_1, r_2, r_3, \dots , then one can write

$$S_p = r_1^p \left(1 + \frac{r_2^p}{r_1^p} + \frac{r_3^p}{r_1^p} + \dots \right)$$

and if one root is larger than all the others, say r_1 , then for large enough p all terms (other than 1) would become negligible. Thus,

$$S_p \approx r_1^p$$

or

$$\lim_{p \rightarrow \infty} S^{1/p} = r_1$$

The Graeffe procedure provides an efficient way for computing S_p via a sequence of equations such that the roots of each equation are the squares of the roots of the preceding equations in the sequence. This serves the purpose of ultimately obtaining an equation whose roots are so widely separated in magnitude that they may be read approximately from the equation by inspection. The basic procedure is illustrated for a polynomial of degree 4:

$$f(x) = a_0x^4 + a_1x^3 + a_2x^2 + a_3x + a_4 = 0$$

Rewrite this as

$$a_0x^4 + a_2x^2 + a_4 = -a_1x^3 - a_3x$$

and square both sides so that upon grouping

$$a_0^2x^8 + (2a_0a_2 - a_1^2)x^6 + (2a_0a_4 - 2a_1a_3 + a_2^2)x^4 + (2a_2a_4 - a_3^2)x^2 + a_4^2 = 0$$

Because this involves only even powers of x , we may set $y = x^2$ and rewrite it as

$$a_0^2y^4 + (2a_0a_2 - a_1^2)y^3 + (2a_0a_4 - 2a_1a_3 + a_2^2)y^2 + (2a_2a_4 - a_3^2)y + a_4^2 = 0$$

whose roots are the squares of the original equation. If we repeat this process again, the new equation has roots which are the fourth power, and so on. After p such operations, the roots are 2^p (original roots). If at any stage we write the coefficients of the unknown in sequence

$$a_0^{(p)} \quad a_1^{(p)} \quad a_2^{(p)} \quad a_3^{(p)} \quad a_4^{(p)}$$

then, to get the new sequence $a_i^{(p+1)}$, write $a_i^{(p+1)} = 2a_0^{(p)}$ (times the symmetric coefficient) with respect to $a_i^{(p)} - 2a_1^{(p)}$ (times the symmetric coefficient) $\dots (-1)^i a_i^{(p)^2}$. Now if the roots are $r_1, r_2, r_3,$ and $r_4,$ then $a_1/a_0 = -\sum_{i=1}^4 r_i, a_i^{(1)}/a_0^{(1)} = -\sum r_i^2, \dots, a_1^{(p)}/a_0^{(p)} = -\sum r_i^{2p}$. If the roots are all distinct and r_1 is the largest in magnitude, then eventually

$$r_1^{2p} \approx -\frac{a_1^{(p)}}{a_0^{(p)}}$$

And, if r_2 is the next largest in magnitude, then

$$r_2^{2p} \approx -\frac{a_2^{(p)}}{a_1^{(p)}}$$

And, in general, $a_n^{(p)}/a_{n-1}^{(p)} \approx -r_n^{2p}$. This procedure is easily generalized to polynomials of arbitrary degree and specialized to the case of multiple and complex roots.

Other methods include Bernoulli iteration, Bairstow iteration, and Lin iteration. These may be found in the cited literature. In addition, the methods given below may be used for the numerical solution of polynomials.

230.3 General Methods for Nonlinear Equations in One Variable

Successive Substitutions

Let $f(x) = 0$ be the nonlinear equation to be solved. If this is rewritten as $x = F(x)$, then an iterative scheme can be set up in the form $x_{k+1} = F(x_k)$. To start the iteration, an initial guess must be obtained graphically or otherwise. The convergence or divergence of the procedure depends upon the method of writing $x = F(x)$, of which there will usually be several forms. A general rule to ensure convergence cannot be given. However, if a is a root of $f(x) = 0$, a necessary condition for convergence is that $|F'(x)| < 1$ in that interval about a in which the iteration proceeds (this means the iteration cannot converge unless $|F'(x)| < 1$, but it does not ensure convergence). This process is called *first order* because the error in x_{k++} is proportional to the first power of the error in x_k .

Example

$f(x) = x^3 - x - 1 = 0$. A rough plot shows a real root of approximately 1.3. The equation can be written in the form $x = F(x)$ in several ways, such as $x = x^3 - 1$, $x = 1/(x^2 - 1)$, and $x = (1 + x)^{1/3}$. In the first case, $F'(x) = 3x^2 = 5.07$ at $x = 1.3$; in the second, $F(1.3) = 5.46$; only in the third case is $F'(1.3) < 1$. Hence, only the third iterative process has a chance to converge. This is illustrated in the iteration table below.

| Step k | $x = \frac{1}{x^2 - 1}$ | $x = x^3 - 1$ | $x = (1 + x)^{1/3}$ |
|----------|-------------------------|---------------|---------------------|
| 0 | 1.3 | 1.3 | 1.3 |
| 1 | 1.4493 | 1.197 | 1.32 |
| 2 | 0.9087 | 0.7150 | 1.3238 |
| 3 | -5.737 | -0.6345 | 1.3247 |
| 4 | ... | ... | 1.3247 |

230.4 Numerical Solution of Simultaneous Nonlinear Equations

The Techniques illustrated here will be demonstrated for two simultaneous equations: $f(x,y) = 0$ and $g(x,y) = 0$. They immediately generalize to more than two simultaneous equations.

The Method of Successive Substitutions

The two simultaneous equations can be written in various ways in equivalent form

$$x = F(x, y)$$

$$y = G(x, y)$$

and the method of successive substitutions can be based on

$$x_{k+1} = F(x_k, y_k)$$

$$y_{k+1} = G(x_k, y_k)$$

Again, the procedure is of the first order and a necessary condition for convergence is

$$\left| \frac{\partial F}{\partial x} \right| + \left| \frac{\partial F}{\partial y} \right| < 1 \quad \left| \frac{\partial G}{\partial x} \right| + \left| \frac{\partial G}{\partial y} \right| < 1$$

in the iteration neighborhood of the true solution.

The Newton–Raphson Procedure

Using the two simultaneous equations, start from an approximation, say (x_0, y_0) , obtained graphically or from a two-way table. Then, solve successively the linear equations

$$\Delta x_k \frac{\partial f}{\partial x}(x_k, y_k) + \Delta y_k \frac{\partial f}{\partial y}(x_k, y_k) = -f(x_k, y_k)$$

$$\Delta x_k \frac{\partial g}{\partial x}(x_k, y_k) + \Delta y_k \frac{\partial g}{\partial y}(x_k, y_k) = -g(x_k, y_k)$$

for Δx_k and Δy_k . Then, the $k + 1$ approximation is given from $x_{k+1} = x_k + \Delta x_k$, $y_{k+1} = y_k + \Delta y_k$. A modification consists in solving the equations with (x_k, y_k) replaced by (x_0, y_0) (or another suitable pair later on in the iteration) in the derivatives. This means the derivatives (and therefore the coefficients of $\Delta x_k, \Delta y_k$) are independent of k . Hence, the results become

$$\Delta x_k = \frac{-f(x_k, y_k)(\partial g / \partial y)(x_0, y_0) + g(x_k, y_k)(\partial f / \partial y)(x_0, y_0)}{(\partial f / \partial x)(x_0, y_0)(\partial g / \partial y)(x_0, y_0) - (\partial f / \partial y)(x_0, y_0)(\partial g / \partial x)(x_0, y_0)}$$

$$\Delta y_k = \frac{-g(x_k, y_k)(\partial f / \partial x)(x_0, y_0) + f(x_k, y_k)(\partial g / \partial x)(x_0, y_0)}{(\partial f / \partial x)(x_0, y_0)(\partial g / \partial y)(x_0, y_0) - (\partial f / \partial y)(x_0, y_0)(\partial g / \partial x)(x_0, y_0)}$$

and $x_{k+1} = \Delta x_k + x_k$, $y_{k+1} = \Delta y_k + y_k$. Such an alteration of the basic technique reduces the rapidity of convergence.

Example

$$f(x, y) = 4x^2 + 6x - 4xy + 2y^2 - 3$$

$$g(x, y) = 2x^2 - 4xy + y^2$$

By plotting, one of the approximate roots is found to be $x_0 = 0.4, y_0 = 0.3$. At this point, there results $\partial f/\partial x = 8, \partial f/\partial y = -0.4, \partial g/\partial x = 0.4,$ and $\partial g/\partial y = -1$. Hence,

$$\begin{aligned} x_{k+1} &= x_k + \Delta x_k = x_k + \frac{-f(x_k, y_k) - 0.4g(x_k, y_k)}{8(-1) - (-0.4)(0.4)} \\ &= x_k - 0.1275 \quad 5f(x_k, y_k) - 0.051 \quad 02g(x_k, y_k) \end{aligned}$$

and

$$y_{k+1} = y_k - 0.051 \quad 02f(x_k, y_k) + 1.020 \quad 41g(x_k, y_k)$$

The first few iteration steps are shown in the following table.

| Step k | x_k | y_k | $f(x_k, y_k)$ | $g(x_k, y_k)$ |
|----------|---------|---------|---------------|---------------|
| 0 | 0.4 | 0.3 | -0.26 | 0.07 |
| 1 | 0.43673 | 0.24184 | 0.078 | 0.0175 |
| 2 | 0.42672 | 0.25573 | -0.0170 | -0.007 |
| 3 | 0.42925 | 0.24943 | 0.0077 | 0.0010 |

Methods of Perturbation

Let $f(x) = 0$ be the equation. In general, the iterative relation is

$$x_{k+1} = x_k - \frac{f(x_k)}{\alpha_k}$$

where the iteration begins with x_0 as an initial approximation and α_k is some functional.

The Newton-Raphson Procedure

This variant chooses $\alpha_k = f'(x_k)$ where $f' = df/dx$ and geometrically consists of replacing the graph of $f(x)$ by the tangent line at $x = x_k$ in each successive step. If $f'(x)$ and $f''(x)$ have the same sign throughout an interval $a \leq x \leq b$ containing the solution, with $f(a)$ and $f(b)$ of opposite signs, then the process converges starting from any x_0 in the interval $a \leq x \leq b$. The process is second order.

Example

$$f(x) = x - 1 + \frac{(0.5)^x - 0.5}{0.3}$$

$$f'(x) = 1 - 2.3105 [0.5]^x$$

An approximate root (obtained graphically) is 2.

| Step k | x_k | $f(x_k)$ | $f'(x_k)$ |
|----------|--------|----------|-----------|
| 0 | 2 | 0.1667 | 0.4224 |
| 1 | 1.605 | -0.002 | 0.2655 |
| 2 | 1.6125 | -0.0005 | ... |

The Method of False Position

This variant is commenced by finding x_0 and x_1 such that $f(x_0)$ and $f(x_1)$ are of opposite signs. Then, α_1 = slope of secant line joining $[x_0, f(x_0)]$ and $[x_1, f(x_1)]$ so that

$$x_2 = x_1 - \frac{x_1 - x_0}{f(x_1) - f(x_0)} f(x_1)$$

In each following step, α_k is the slope of the line joining $[x_k, f(x_k)]$ to the most recently determined point where $f(x_j)$ has the opposite sign from that of $f(x_k)$. This method is of the first order.

The Method of Wegstein

This is a variant of the method of successive substitutions which forces or accelerates convergence. The iterative procedure $x_{k+1} = F(x_k)$ is revised by setting $\hat{x}_{k+1} = F(x_k)$ and then taking $x_{k+1} = qx_k + (1 - q)\hat{x}_{k+1}$. Wegstein found that suitably chosen q 's are related to the basic process as follows:

| Behavior of Successive Substitution Process | Range of Optimum q |
|---|----------------------|
| Oscillatory convergence | $0 < q < 1/2$ |
| Oscillatory divergence | $1/2 < q < 1$ |
| Monotonic convergence | $q < 0$ |
| Monotonic divergence | $1 < q$ |

At each step, q may be calculated to give a locally optimum value by setting

$$q = \frac{x_{k+1} - x_k}{x_{k+1} - 2x_k + x_{k-1}}$$

The Method of Continuity

In the case of n equations in n unknowns, when n is large, determining the approximate solution may involve considerable effort. In such a case, the method of continuity is admirably suited for use on either digital or analog computers. It consists basically of the introduction of an extra variable into the n equations

$$f_i(x_1, x_2, \dots, x_n) = 0, \quad i = 1, \dots, n$$

and replacing them by

$$f_i(x_1, x_2, \dots, x_n, \lambda) = 0, \quad i = 1, \dots, n$$

where λ is introduced in such a way that the functions depend in a simple way upon λ and reduce to an easily solvable system for $\lambda = 0$ and to the original equations for $\lambda = 1$. A system of ordinary differential equations, with independent variable λ , is then constructed by differentiating with respect to λ . The results are

$$\sum_{j=1}^n \frac{\partial f_j}{\partial x_j} \frac{dx_j}{d\lambda} + \frac{\partial f_j}{\partial \lambda} = 0$$

where x_1, \dots, x_n are considered as functions of λ . The equations are integrated, with initial conditions obtained with $\lambda = 0$, from $\lambda = 0$ to $\lambda = 1$. If the solution can be continued to $\lambda = 1$, the values of x_1, \dots, x_n for $\lambda = 1$ will be a solution of the original equations. If the integration becomes infinite, the parameter λ must be introduced in a different fashion. Integration of the differential equations (which are usually nonlinear in λ) may be accomplished on an analog computer or by digital means using techniques described in Section 230.8.

Example

$$f(x, y) = 2 + x + y - x^2 + 8xy + y^3 = 0$$

$$g(x, y) = 1 + 2x + 3y + x^2 + xy - ye^x = 0$$

Introduce λ as

$$f(x, y, \lambda) = (2 + x + y) + \lambda(-x^2 + 8xy + y^3) = 0$$

$$g(x, y, \lambda) = (1 + 2x - 3y) + \lambda(x^2 + xy + ye^x) = 0$$

For $\lambda = 1$, these reduce to the original equations, but, for $\lambda = 0$, they are the linear systems

$$x + y = -2$$

$$2x - 3y = -1$$

which has the unique solution $x = -1.4$, $y = -0.6$. The differential equations in this case become

$$\frac{\partial f}{\partial x} \frac{dx}{d\lambda} + \frac{\partial f}{\partial y} \frac{dy}{d\lambda} = -\frac{\partial f}{\partial \lambda}$$

$$\frac{\partial g}{\partial x} \frac{dx}{d\lambda} + \frac{\partial g}{\partial y} \frac{dy}{d\lambda} = -\frac{\partial g}{\partial \lambda}$$

or

$$\frac{dx}{d\lambda} = \frac{\frac{\partial f}{\partial y} \frac{\partial g}{\partial \lambda} - \frac{\partial f}{\partial \lambda} \frac{\partial g}{\partial y}}{\frac{\partial f}{\partial x} \frac{\partial g}{\partial y} - \frac{\partial f}{\partial y} \frac{\partial g}{\partial x}}$$

$$\frac{dy}{d\lambda} = \frac{\frac{\partial f}{\partial \lambda} \frac{\partial g}{\partial x} - \frac{\partial f}{\partial x} \frac{\partial g}{\partial \lambda}}{\frac{\partial f}{\partial x} \frac{\partial g}{\partial y} - \frac{\partial f}{\partial y} \frac{\partial g}{\partial x}}$$

Integrating in λ , with initial values $x = -1.4$ and $y = -0.6$ at $\lambda = 0$, from $\lambda = 0$ to $\lambda = 1$ gives the solution.

230.5 Interpolation and Finite Differences

The practicing engineer constantly finds it necessary to refer to tables as sources of information. Consequently, interpolation, or that procedure of “reading between the lines of the table,” is a necessary topic in numerical analysis.

Linear Interpolation

If a function $f(x)$ is approximately linear in a certain range, then the ratio $[f(x_1) - f(x_0)]/(x_1 - x_0) = f[x_0, x_1]$ is approximately independent of x_0 and x_1 in the range. The linear approximation to the function $f(x)$, $x_0 < x < x_1$, then leads to the interpolation formula

$$\begin{aligned} f(x) &\approx f(x_0) + (x - x_0)f[x_0, x_1] \approx f(x_0) + \frac{x - x_0}{x_1 - x_0}[f(x_1) - f(x_0)] \\ &\approx \frac{1}{x_1 - x_0}[(x_1 - x)f(x_0) - (x_0 - x)f(x_1)] \end{aligned}$$

Divided Differences of Higher Order and Higher-Order Interpolation

The first-order divided difference $f[x_0, x_1]$ was defined above. Divided differences of second and higher order are defined iteratively by

$$\begin{aligned} f[x_0, x_1, x_2] &= \frac{f[x_1, x_2] - f[x_0, x_1]}{x_2 - x_0} \\ &\vdots \\ f[x_0, x_1, \dots, x_k] &= \frac{f[x_1, \dots, x_k] - f[x_0, x_1, \dots, x_{k-1}]}{x_k - x_0} \end{aligned}$$

and a convenient form for computational purposes is

$$f[x_0, x_1, \dots, x_k] = \sum_{j=0}^k ' \frac{f(x_j)}{(x_j - x_0)(x_j - x_1) \cdots (x_j - x_k)}$$

for any $k \geq 0$, where the ' means the term $(x_j - x_j)$ is omitted in the denominator. For example,

$$f[x_0, x_1, x_2] = \frac{f(x_0)}{(x_0 - x_1)(x_0 - x_2)} + \frac{f(x_1)}{(x_1 - x_0)(x_1 - x_2)} + \frac{f(x_2)}{(x_2 - x_0)(x_2 - x_1)}$$

If the accuracy afforded by a linear approximation is inadequate, a generally more accurate result may be based upon the assumption that $f(x)$ may be approximated by a polynomial of degree 2 or higher over certain ranges. This assumption leads to *Newton's fundamental interpolation formula* with divided differences:

$$\begin{aligned} f(x) &\approx f(x_0) + (x - x_0)f[x_0, x_1] + (x - x_0)(x - x_1)f[x_0, x_1, x_2] \\ &\quad + (x - x_0)(x - x_1) \cdots (x - x_{n-1})f[x_0, x_1, \dots, x_n] + E_n(x) \end{aligned}$$

where $E_n(x) = \text{error} = [1/(n+1)!]f^{(n+1)}(\xi)\pi(x)$ where $\min(x_0, \dots, x_n) < \xi < \max(x_0, x_1, \dots, x_n, x)$ and $\pi(x) = (x - x_0)(x - x_1) \dots (x - x_n)$. In order to use this most effectively, one may first form a divided-difference table. For example, for third-order interpolation, the difference table is

| | | | | |
|-------|----------|--------------------|--------------------|-------------------------|
| x_0 | $f(x_0)$ | $f[x_0, x_1]$ | $f[x_0, x_1, x_2]$ | $f[x_0, x_1, x_2, x_3]$ |
| x_1 | $f(x_1)$ | $f[x_1, x_2]$ | | |
| x_2 | $f(x_2)$ | $f[x_1, x_2, x_3]$ | | |
| x_3 | $f(x_3)$ | $f[x_2, x_3]$ | | |

where each entry is given by taking the difference between diagonally adjacent entries to the left, divided by the abscissas corresponding to the ordinates intercepted by the diagonals passing through the calculated entry.

Example

Calculate by third-order interpolation the value of $\cosh 0.83$ given $\cosh 0.60$, $\cosh 0.80$, $\cosh 0.90$, and $\cosh 1.10$.

| | | | | |
|--------------|----------|--------|--------|--------|
| $x_0 = 0.60$ | 1.185 47 | 0.7598 | | |
| $x_1 = 0.80$ | 1.337 43 | 0.9566 | 0.6560 | |
| $x_2 = 0.90$ | 1.433 09 | 1.1772 | 0.7353 | 0.1586 |
| $x_3 = 1.10$ | 1.668 52 | | | |

With $n = 3$, we have

$$\begin{aligned} \cosh 0.83 \approx & 1.185\ 47 + (0.23)(0.7598) + (0.23)(0.03)(0.6560) \\ & + (0.23)(0.03)(-0.07)(0.1586) = 1.364\ 64 \end{aligned}$$

which varies from the true value by 0.00004.

Lagrange Interpolation Formulas

The Newton formulas are expressed in terms of divided differences. It is often useful to have interpolation formulas expressed explicitly in terms of the ordinates involved. This is accomplished by the Lagrange interpolation polynomial of degree n :

$$y(x) = \sum_{j=0}^n \frac{\pi(x)}{(x - x_j)\pi'(x_j)} f(x_j)$$

where

$$\begin{aligned} \pi(x) &= (x - x_0)(x - x_1) \cdots (x - x_n) \\ \pi'(x_j) &= (x_j - x_0)(x_j - x_1) \cdots (x_j - x_n) \end{aligned}$$

where $(x_j - x_j)$ is the omitted factor. Thus,

$$f(x) = y(x) + E_n(x)$$

$$E_n(x) = \frac{1}{(n+1)!} \pi(x) f^{(n+1)}(\epsilon)$$

Example

The interpolation polynomial of degree 3 is

$$y(x) = \frac{(x-x_1)(x-x_2)(x-x_3)}{(x_0-x_1)(x_0-x_2)(x_0-x_3)} f(x_0) + \frac{(x-x_0)(x-x_2)(x-x_3)}{(x_1-x_0)(x_1-x_2)(x_1-x_3)} f(x_1)$$

$$+ \frac{(x-x_0)(x-x_1)(x-x_3)}{(x_2-x_0)(x_2-x_1)(x_2-x_3)} f(x_2) + \frac{(x-x_0)(x-x_1)(x-x_2)}{(x_3-x_0)(x_3-x_1)(x_3-x_2)} f(x_3)$$

Thus, directly from the data

| | | | | |
|--------|---|---|----|---|
| x | 0 | 1 | 3 | 4 |
| $f(x)$ | 1 | 1 | -1 | 2 |

we have as an interpolation polynomial $y(x)$ for $f(x)$:

$$y(x) = 1 \cdot \frac{(x-1)(x-3)(x-4)}{(0-1)(0-3)(0-4)} + 1 \cdot \frac{x(x-3)(x-4)}{(1-0)(1-3)(1-4)}$$

$$- 1 \cdot \frac{x(x-1)(x-4)}{(3-0)(3-1)(3-4)} + 2 \cdot \frac{(x-0)(x-1)(x-3)}{(4-0)(4-1)(4-3)}$$

Other Difference Methods (Equally Spaced Ordinates)

Backward Differences

The backward differences denoted by

$$\nabla f(x) = f(x) - f(x-h)$$

$$\nabla^2 f(x) = \nabla f(x) - \nabla f(x-h)$$

...

$$\nabla^n f(x) = \nabla^{n-1} f(x) - \nabla^{n-1} f(x-h)$$

are useful for calculation near the end of tabulated data.

Central Differences

The central difference denoted by

$$\delta f(x) = f\left(x + \frac{h}{2}\right) - f\left(x - \frac{h}{2}\right)$$

$$\delta^n f(x) = \delta^{n-1} f\left(x + \frac{h}{2}\right) - \delta^{n-1} f\left(x - \frac{h}{2}\right)$$

is useful for calculating at the interior points of tabulated data.

Also to be found in the literature are Gaussian, Stirling, Bessel, Everett, Comrie differences, and so forth.

Inverse Interpolation

This is the process of finding the value of the independent variable or abscissa corresponding to a given value of the function when the latter is between two tabulated values of the abscissa. One method of accomplishing this is to use Lagrange's interpolation formula in the form

$$x = \psi(y) = \sum_{j=0}^n \frac{\pi(y)}{(y - y_j)\pi'(y_j)} x_j$$

where x is expressed as a function of y . Other methods resolve about methods of iteration.

230.6 Numerical Differentiation

Numerical differentiation should be avoided wherever possible, particularly when data are empirical and subject to appreciable observation errors. Errors in data can affect numerical derivatives quite strongly (i.e., differentiation is a roughening process). When such a calculation must be made, it is usually desirable first to *smooth* the data to a certain extent.

The Use of Interpolation Formulas

If the data are given over equidistant values of the independent variable x , an interpolation formula, such as the Newton formula, may be used, and the resulting formula differentiated analytically. If the independent variable is not at equidistant values, then Lagrange's formulas must be used. By differentiating three- and five-point Lagrange interpolation formulas, the following differentiation formulas result for equally spaced tabular points.

Three-Point Formulas

Let x_0 , x_1 , and x_2 be the three points. Thus,

$$f'(x_0) = \frac{1}{2h}[-3f(x_0) + 4f(x_1) - f(x_2)] + \frac{h^2}{3} f'''(\epsilon)$$

$$f'(x_1) = \frac{1}{2h}[-f(x_0) + f(x_2)] + \frac{h^2}{6} f'''(\epsilon)$$

$$f'(x_2) = \frac{1}{2h}[f(x_0) - 4f(x_1) + 3f(x_2)] + \frac{h^2}{3} f'''(\epsilon)$$

where the last term is an error term and $\min_j x_j < \epsilon < \max_j x_j$.

Five-Point Formulas

Let $x_0, x_1, x_2, x_3,$ and x_4 be the five values of the equally spaced independent variable and $f_j = f(x_j)$.

$$f'(x_0) = \frac{1}{12h}[-25f_0 + 48f_1 - 36f_2 + 16f_3 - 3f_4] + \frac{h^4}{5}f^{(v)}(\epsilon)$$

$$f'(x_1) = \frac{1}{12h}[-3f_0 - 10f_1 + 18f_2 - 6f_3 + f_4] - \frac{h^4}{20}f^{(v)}(\epsilon)$$

$$f'(x_2) = \frac{1}{12h}[f_0 - 8f_1 + 8f_3 - f_4] + \frac{h^4}{30}f^{(v)}(\epsilon)$$

$$f'(x_3) = \frac{1}{12h}[-f_0 + 6f_1 - 18f_2 + 10f_3 + 3f_4] + \frac{h^4}{20}f^{(v)}(\epsilon)$$

$$f'(x_4) = \frac{1}{12h}[3f_0 - 16f_1 + 36f_2 - 48f_3 + 25f_4] + \frac{h^4}{5}f^{(v)}(\epsilon)$$

and the last term is again an error term.

Smoothing Techniques

These techniques involve the approximation of the tabular data by a least squares fit of the data using some known functional form, usually a polynomial. In place of approximating $f(x)$ by a single least squares polynomial of degree n over the entire range of the tabulation, it is often desirable to replace each tabulated value by the value taken on by a least squares polynomial of degree n relevant to a subrange of $2M + 1$ points centered, where possible, at the point for which the entry is to be modified. Thus, each smoothed value replaces a tabulated value. Let $f_j = f(x_j)$ to be the tabular points and $y_j =$ smoothed values. A first-degree least squares with three points would be

$$y_0 = \frac{1}{6}[5f_0 + 2f_1 - f_2]$$

$$y_1 = \frac{1}{3}[f_0 + f_1 + f_2]$$

$$y_2 = \frac{1}{6}[-f_0 + 2f_1 + 5f_2]$$

A first-degree least squares with five points would be

$$y_0 = \frac{1}{5}[3f_0 + 2f_1 + f_2 - f_4]$$

$$y_1 = \frac{1}{10}[4f_0 + 3f_1 + 2f_2 + f_3]$$

$$y_2 = \frac{1}{5}[f_0 + f_1 + f_2 + f_3 + f_4]$$

$$y_3 = \frac{1}{10}[f_0 + 2f_1 + 3f_2 + 4f_3]$$

$$y_4 = \frac{1}{5}[-f_0 + f_2 + 2f_3 + 3f_4]$$

Thus, for example, if first-degree, five-point least squares are used, the central formula is used for all values except the first two and the last two, where the off-center formulas are used. A third-degree least squares with seven points would be

$$\begin{aligned}
 y_0 &= \frac{1}{42}[39f_0 + 8f_1 - 4f_2 - 4f_3 + f_4 + 4f_5 - 2f_6] \\
 y_1 &= \frac{1}{42}[8f_0 + 19f_1 + 16f_2 + 6f_3 - 4f_4 - 7f_5 + 4f_6] \\
 y_2 &= \frac{1}{42}[-4f_0 + 16f_1 + 19f_2 + 12f_3 + 2f_4 - 4f_5 + f_6] \\
 y_3 &= \frac{1}{21}[-2f_0 + 3f_1 + 6f_2 + 7f_3 + 6f_4 + 3f_5 - 2f_6] \\
 y_4 &= \frac{1}{42}[f_0 - 4f_1 + 2f_2 + 12f_3 + 19f_4 + 16f_5 - 4f_6] \\
 y_5 &= \frac{1}{42}[4f_0 - 7f_1 - 4f_2 + 6f_3 + 16f_4 + 19f_5 + 8f_6] \\
 y_6 &= \frac{1}{42}[-2f_0 + 4f_1 + f_2 - 4f_3 - 4f_4 + 8f_5 + 39f_6]
 \end{aligned}$$

Additional smoothing formulas may be found in the references. After the data are smoothed, any of the interpolation polynomials, or an appropriate least squares polynomial, may be fitted and the results used to obtain the derivative.

Least Squares Methods

Parabolic

For five evenly spaced neighboring abscissas labeled x_{-2} , x_{-1} , x_0 , x_1 , and x_2 , and their ordinates f_{-2} , f_{-1} , f_0 , f_1 , and f_2 , assume a parabola is fit by least squares. There results for all interior points, except the first and last two points of the data, the formula for the numerical derivative:

$$f'_0 = \frac{1}{10h}[-2f_{-2} - f_{-1} + f_1 + 2f_2]$$

For the first two data points designated by 0 and h :

$$f'(0) = \frac{1}{20h}[-21f(0) + 13f(h) + 17f(2h) - 9f(3h)]$$

$$f'(h) = \frac{1}{20h}[-11f(0) + 3f(h) + 7f(2h) + f(3h)]$$

and for the last two given by $\alpha - h$ and α :

$$f'(\alpha - h) = \frac{1}{20h}[-11f(\alpha) + 3f(\alpha - h) + 7f(\alpha - 2h) + f(\alpha - 3h)]$$

$$f'(\alpha) = \frac{1}{20h}[-21f(\alpha) + 13f(\alpha - h) + 17f(\alpha - 2h) - 9f(\alpha - 3h)]$$

Quartic (Douglas–Avakian)

A fourth-degree polynomial $y = a + bx + cx^2 + dx^3 + ex^4$ is fitted to seven adjacent equidistant points (spacing h) after a translation of coordinates has been made so that $x = 0$ corresponds to the central point of the seven. Thus, these may be called $-3h$, $-2h$, $-h$, 0 , h , $2h$, and $3h$. Let k = coefficient of h for the seven points. That is, in $-3h$, $k = -3$. Then, the coefficients for the polynomial are

$$a = \frac{524\sum f(kh) - 245\sum k^2 f(kh) + 21\sum k^4 f(kh)}{924}$$

$$b = \frac{397\sum kf(kh)}{1512h} - \frac{7\sum k^3 f(kh)}{216h}$$

$$c = \frac{-840\sum f(kh) + 679\sum k^2 f(kh) - 67\sum k^4 f(kh)}{3168h^2}$$

$$d = \frac{-7\sum kf(kh) + \sum k^3 f(kh)}{216h^3}$$

$$e = \frac{72\sum f(kh) - 67\sum k^2 f(kh) + 7\sum k^4 f(kh)}{3168h^4}$$

where all summations run from $k = -3$ to $k = +3$ and $f(kh) =$ tabular value at kh . The slope of the polynomial at $x = 0$ is $dy/dx = b$.

230.7 Numerical Integration

Numerical evaluation of the finite integral $\int_a^b f(x)dx$ is carried out by a variety of methods. A few are given here.

Newton–Cotes Formulas (Equally Spaced Ordinates)

Trapezoidal Rule

This formula consists of subdividing the interval $a \leq x \leq b$ into n subintervals a to $a + h$, $a + h$ to $a + 2h$, ..., and replacing the graph of $f(x)$ by the result of joining the ends of adjacent ordinates by line segments. If $f_j = f(x_j) = f(a + jh)$, $f_0 = f(a)$, and $f_n = f(b)$, the integration formula is

$$\int_a^b f(x)dx = \frac{h}{2}[f_0 + 2f_1 + 2f_2 + \dots + 2f_{n-1} + f_n] + E_n$$

where

$$|E_n| = (nh^3 / 12)|f''(\epsilon)| = [(b-a)^3 / 12n^2]|f''(\epsilon)|, a < \epsilon < b$$

This procedure is not of high accuracy. However, if $f''(x)$ is continuous in $a < x < b$, the error goes to zero as $1/n^2$, $n \rightarrow \infty$.

Parabolic Rule (Simpson's Rule)

This procedure consists of subdividing the interval $a < x < b$ into $n/2$ subintervals, each of length $2h$, where n is an even integer. Using the notation as above, the integration formula is

$$\int_a^b f(x)dx = \frac{h}{3}[f_0 + 4f_1 + 2f_2 + 4f_3 + \dots + 4f_{n-3} + 2f_{n-2} + 4f_{n-1} + f_n] + E_n$$

where

$$|E_n| = \frac{nh^5}{180} |f^{(iv)}(\epsilon)| = \frac{(b-a)^3}{180n^4} |f^{(iv)}(\epsilon)| \quad a < \epsilon < b$$

This method approximates $f(x)$ by a parabola on each subinterval. This rule is generally more accurate than the trapezoidal rule. It is the most widely used integration formula.

Weddle's Rule

This procedure consists of subdividing the integral $a < x < b$ into $n/6$ subintervals, each of length $6h$, where n is a multiple of 6. Using the notation from the trapezoidal rule, the following results:

$$\int_a^b f(x)dx = \frac{3h}{10} [f_0 + 5f_1 + f_2 + 6f_3 + f_4 + 5f_5 + 2f_6 + 5f_7 + f_8 + \dots + 6f_{n-3} + f_{n-2} + 5f_{n-1} + f_n] + E_n$$

Note that the coefficients of f_j follow the rule 1, 5, 1, 6, 1, 5, 2, 5, 1, 6, 1, 5, 2, 5, and so on. This procedure consists of approximating $f(x)$ by a polynomial of degree 6 on each subinterval. Here,

$$E_n = \frac{nh^7}{1400} [10f^{(6)}(\epsilon_1) + 9h^2 f^{(8)}(\epsilon_2)]$$

Gaussian Integration Formulas (Unequally Spaced Abscissas)

These formulas are capable of yielding comparable accuracy with fewer ordinates than the equally spaced formulas. The ordinates are obtained by optimizing the distribution of the abscissas rather than by arbitrary choice. For the details of these formulas, Hildebrand [1956] is an excellent reference.

Two-Dimensional Formula

Formulas for two-way integration over a rectangle, circle, ellipse, and so forth, may be developed by a double application of one-dimensional integration formulas. The two-dimensional generalization of the parabolic rule is given here. Consider the iterated integral $\int_a^b \int_c^d f(x, y) dx dy$. Subdivide $c < x < d$ into m (even) subintervals of length $h = (d - c)/m$, and $a < y < b$ into n (even) subintervals of length $k = (b - a)/n$. This gives a subdivision of the rectangle $a \leq y \leq b$ and $c \leq x \leq d$ into subrectangles. Let $x_j = c + jh$, $y_j = a + jk$, and $f_{ij} = f(x_j, y_i)$. Then,

$$\begin{aligned} \int_a^b \int_c^d f(x, y) dx dy &= \frac{hk}{9} [(f_{0,0} + 4f_{1,0} + 2f_{2,0} + \dots + f_{m,0}) \\ &+ 4(f_{0,1} + 4f_{1,1} + 2f_{2,1} + \dots + f_{m,1}) + \dots \\ &+ 2(f_{0,2} + 4f_{1,2} + 2f_{2,2} + \dots + f_{m,2}) + \dots \\ &+ (f_{0,n} + 4f_{1,n} + 2f_{2,n} + \dots + f_{m,n})] + E_{m,n} \end{aligned}$$

where

$$E_{m,n} = -\frac{hk}{90} \left[mh^4 \frac{\partial^4 f(\epsilon_1, \eta_1)}{\partial x^4} + nk^4 \frac{\partial^4 f(\epsilon_2, \eta_2)}{\partial x^4} \right]$$

and ϵ_1 and ϵ_2 lie in $c < x < d$, and η_1 and η_2 lie in $a < y < b$.

230.8 Numerical Solution of Ordinary Differential Equations

A number of methods have been devised to solve ordinary differential equations numerically. The general references contain some information. A numerical solution of a differential equation means a table of values of the function y and its derivatives over only a limited part of the range of the independent variable. Every differential equation of order n can be rewritten as n first-order differential equations. Therefore, the methods given below will be for first-order equations, and the generalization to simultaneous systems will be developed later.

The Modified Euler Method

This method is simple and yields modest accuracy. If extreme accuracy is desired, a more sophisticated method should be selected. Let the first-order differential equation be $dy/dx = f(x,y)$ with the initial condition (x_0, y_0) (i.e., $y = y_0$ when $x = x_0$). The procedure follows.

Step 1. From the given initial conditions (x_0, y_0) , compute $y'_0 = f(x_0, y_0)$ and $y''_0 = [\partial f(x_0, y_0)/\partial x] + [\partial f(x_0, y_0)/\partial y]y'_0$. Then, determine $y_1 = y_0 + hy'_0 + (h^2/2)y''_0$, where $h =$ subdivision of the independent variable.

Step 2. Determine $y'_1 = f(x_1, y_1)$, where $x_1 = x_0 + h$. These prepare us for the following.

Predictor Steps

Step 3. For $n \geq 1$, calculate $(y_{n+1})_1 = y_{n-1} + 2hy'_n$.

Step 4. Calculate $(y'_{n+1})_1 = f[x_{n+1}, (y_{n+1})_1]$.

Corrector Steps

Step 5. Calculate $(y_{n+1})_2 = y_n + (h/2)[(y'_{n+1})_1 + y'_n]$, where y_n and y'_n without the subscripts are the previous values obtained by this process (or by steps 1 and 2).

Step 6. $(y'_{n+1})_2 = f[x_{n+1}, (y_{n+1})_2]$.

Step 7. Repeat the corrector steps 5 and 6 if necessary until the desired accuracy is produced in y_{n+1} , y'_{n+1} .

Example

Consider the equation $y' = 2y^2 + x$ with the initial conditions $y_0 = 1$ when $x_0 = 0$. Let $h = 0.1$. A few steps of the computation are illustrated.

| Step | |
|------------|--|
| 1 | $y'_0 = 2y_0^2 + x_0 = 2$ $y''_0 = 1 + 4y_0y'_0 = 1 + 8 = 9$ $y_1 = 1 + (0.1)(2) + [(0.1)^2/2]9 = 1.245$ |
| 2 | $y'_1 = 2y_1^2 + x_1 = 3.100 + 0.1 = 3.200$ |
| 3 | $(y_2)_1 = y_0 + 2hy'_1 = 1 + 2(0.1)3.200 = 1.640$ |
| 4 | $(y'_2)_1 = 2(y_2)_1^2 + x_2 + 5.592$ |
| 5 | $(y_2)_2 = y_1 + (0.1/2)[(y'_2)_1 + y'_1] = 1.685$ |
| 6 | $(y'_2)_2 = 2(y_2)_2^2 + x_2 + 5.878$ |
| 5 (repeat) | $(y_2)_3 = y_1 + (0.05)[((y'_2)_2 + y'_1)] = 1.699$ |
| 6 (repeat) | $(y'_2)_3 = 2(y_2)_3^2 + x_2 + 5.974$ |
| | and so forth... |

This procedure may be programmed for a computer. A discussion of the truncation error of this process may be found in Milne [1953].

Modified Adam's Method

The procedure given here was developed retaining third differences. It can then be considered as a more exact predictor-corrector method than the Euler method. The procedure is as follows for $dy/dx = f(x,y)$ and $h =$ interval size.

Steps 1 and 2 are the same as for the Euler method.

Predictor Steps

Step 3. $(y_{n+1})_1 = y_n + (h/24)[55y'_n - 59y'_{n-1} + 37y'_{n-2} - 9y'_{n-3}]$, where y'_n , y'_{n-1} , and so on are calculated in step 1.

Step 4. $(y'_{n+1})_1 = f[x_{n+1}, (y_{n+1})_1]$.

Corrector Steps

Step 5. $(y_{n+1})_2 = y_n + (h/24)[9(y'_{n+1})_1 + 19y'_n - 5y'_{n-1} + y'_{n-2}]$.

Step 6. $(y'_{n+1})_2 = f[x_{n+1}, (y_{n+1})_2]$.

Step 7. Iterate steps 5 and 6 if necessary.

Runge-Kutta Methods

These methods are self-starting and are inherently stable. Kopal [1955] is a good reference for their derivation and discussion. Third- and fourth-order procedures are given below for $dy/dx = f(x,y)$, where $h =$ interval size.

For third-order procedures (error $\approx h^4$),

$$k_0 = hf(x_n, y_n)$$

$$k_1 = hf(x_n + 1/2 h, y_n + 1/2 k_0)$$

$$k_2 = hf(x_n + h, y_n + 2k_1 - k_0)$$

and

$$y_{n+1} = y_n + 1/6(k_0 + 4k_1 + k_2)$$

for all $n \geq 0$, with initial condition (x_0, y_0) .

For fourth-order procedures (error $\approx h^5$),

$$k_0 = hf(x_n, y_n)$$

$$k_1 = hf(x_n + 1/2 h, y_n + 1/2 k_0)$$

$$k_2 = hf(x_n + 1/2 h, y_n + 1/2 k_1)$$

$$k_3 = hf(x_n + h, y_n + k_2)$$

and

$$y_{n+1} = y_n + 1/6(k_0 + 2k_1 + 2k_2 + k_3)$$

Example

(Third-order) Let $dy/dx = x - 2y$, with initial condition $y_0 = 1$ when $x_0 = 0$, and let $h = 0.1$. Clearly, $x_n = nh$. To calculate y_1 , proceed as follows:

$$k_0 = 0.1[x_0 - 2y_0] = -0.2$$

$$k_1 = 0.1[0.05 - 2(1 - 0.1)] = -0.175$$

$$k_2 = 0.1[0.1 - 2(1 - 0.35 + 0.2)] = -0.16$$

$$y_1 = 1 + \frac{1}{6}(-0.2 - 0.7 - 0.16) = 0.8234$$

Equations of Higher Order and Simultaneous Differential Equations

Any differential equation of second or higher order can be reduced to a simultaneous system of first-order equations by the introduction of auxiliary variables. Consider the following equations:

$$\frac{d^2x}{dt^2} + xy \frac{dx}{dt} + z = e^x$$

$$\frac{d^2y}{dt^2} + xy \frac{dy}{dt} = 7 + t^2$$

$$\frac{d^2z}{dt^2} + xz \frac{dz}{dt} + x = e^z$$

In the new variables $x_1 = x$, $x_2 = y$, $x_3 = z$, $x_4 = dx_1/dt$, $x_5 = dx_2/dt$, and $x_6 = dx_3/dt$, the equations become

$$\frac{dx_1}{dt} = x_4$$

$$\frac{dx_2}{dt} = x_5$$

$$\frac{dx_3}{dt} = x_6$$

$$\frac{dx_4}{dt} = -x_1x_2x_4 - x_3 + e^{x_1}$$

$$\frac{dx_5}{dt} = -x_3x_2x_5 + 7 + t^2$$

$$\frac{dx_6}{dt} = -x_1x_3x_6 - x_1 + e^{x_1}$$

which is a system of the general form

$$\frac{dx_i}{dt} = f_i(t, x_1, x_2, x_3, \dots, x_n)$$

where $i = 1, 2, \dots, n$. Such systems may be solved by simultaneous application of any of the above numerical techniques. A Runge–Kutta method for

$$\frac{dx}{dt} = f(t, x, y)$$

$$\frac{dy}{dt} = g(t, x, y)$$

is given below. The fourth-order procedure is shown.

Starting at the initial conditions x_0, y_0 , and t_0 , the next values x_1 and y_1 are computed via the equations below (where $\Delta t = h, t_j = h + t_{j-1}$):

$$\begin{aligned} k_0 &= hf(t_0, x_0, y_0) & l_0 &= hg(t_0, x_0, y_0) \\ k_1 &= hf\left(t_0 + \frac{h}{2}, x_0 + \frac{k_0}{2}, y_0 + \frac{l_0}{2}\right) & l_1 &= hg\left(t_0 + \frac{h}{2}, x_0 + \frac{k_0}{2}, y_0 + \frac{l_0}{2}\right) \\ k_2 &= hf\left(t_0 + \frac{h}{2}, x_0 + \frac{k_1}{2}, y_0 + \frac{l_1}{2}\right) & l_2 &= hg\left(t_0 + \frac{h}{2}, x_0 + \frac{k_1}{2}, y_0 + \frac{l_1}{2}\right) \\ k_3 &= hf(t_0 + h, x_0 + k_2, y_0 + l_2) & l_3 &= hg(t_0 + h, x_0 + k_2, y_0 + l_2) \end{aligned}$$

and

$$\begin{aligned} x_1 &= x_0 + 1/6(k_0 + 2k_1 + 2k_2 + k_3) \\ y_1 &= y_0 + 1/6(l_0 + 2l_1 + 2l_2 + l_3) \end{aligned}$$

To continue the computation, replace t_0, x_0 , and y_0 in the above formulas by $t_1 = t_0 + h, x_1$, and y_1 just calculated. Extension of this method to more than two equations follows precisely this same pattern.

230.9 Numerical Solution of Integral Equations

This section considers a method of numerically solving the Fredholm integral equation of the second kind:

$$u(x) = f(x) + \lambda \int_a^b k(x, t)u(t)dt \quad \text{for } u(x)$$

The method discussed arises because a definite integral can be closely approximated by any of several numerical integration formulas (each of which arises by approximating the function by some polynomial over an interval). Thus, the definite integral can be replaced by an integration formula which becomes

$$u(x) = f(x) + \lambda(b-a) \left[\sum_{i=1}^n c_i k(x, t_i)u(t_i) \right]$$

where t_1, \dots, t_n are points of subdivision of the t axis, $a \leq t \leq b$, and the c s are coefficients whose values depend upon the type of numerical integration formula used. Now, this must hold for all values of x , where $a \leq x \leq b$; so it must hold for $x = t_1, x = t_2, \dots, x = t_n$. Substituting for x successively t_1, t_2, \dots, t_n , and setting $u(t_i) = u_i$ and $f(t_i) = f_i$, we get n linear algebraic equations for the n unknowns u_1, \dots, u_n . That is,

$$u_i = f_i + (b-a)[c_1 k(t_i, t_1)u_1 + c_2 k(t_i, t_2)u_2 + \dots + c_n k(t_i, t_n)u_n], \quad i = 1, 2, \dots, n$$

These u_i may be solved for by the methods under the section entitled "Numerical Solution of Linear Equations."

230.10 Numerical Methods for Partial Differential Equations

The ultimate goal of numerical (discrete) methods for partial differential equations (PDEs) is the reduction of continuous systems (projections) to discrete systems that are suitable for high-speed computer solutions. The user must be cautioned regarding the fact that the seeming elementary nature of the

techniques holds pitfalls that can be seriously misleading. These approximations often lead to difficult mathematical questions of adequacy, accuracy, convergence, stability, and consistency. Convergence is concerned with the approach of the approximate numerical solution to the exact solution as the number of mesh units increase indefinitely in some sense. Unless the numerical method can be shown to converge to the exact solution, the chosen method is unsatisfactory.

Stability deals in general with error growth in the calculation. As stated before, any numerical method involves truncation and round-off errors. These errors are not serious unless they grow as the computation proceeds (i.e., the method is unstable).

Finite Difference Methods

In these methods, the derivatives are replaced by various finite differences. The methods will be illustrated for problems in two space dimensions (x,y) or (x,t) , where t is timelike. Using subdivisions $\Delta x = h$ and $\Delta y = k$ with $u(ih,jk) = u_{i,j}$, approximate $u_{x|i,j} = [(u_{i+1,j} - u_{i,j})/h] + O(h)$ (forward difference), a first-order $[O(h)]$ method, or $u_{x|i,j} = [(u_{i+1,j} - u_{i-1,j})/2h] + O(h^2)$ (central difference), a second-order method. The second derivative is usually approximated with the second-order method $[u_{xx|i,j} = [(u_{i+1,j} - 2u_{i,j} + u_{i-1,j})/h] + O(h^2)]$.

Example

Using second-order differences for u_{xx} and u_{yy} , the five-point difference equation (with $h = k$) for Laplace's equation $u_{xx} + u_{yy} = 0$ is $u_{i,j} = \frac{1}{4}[u_{i+1,j} + u_{i-1,j} + u_{i,j+1} + u_{i,j-1}]$. The accuracy is $O(h^2)$. This model is called *implicit* because one must solve for the total number of unknowns at the unknown grid points (i,j) in terms of the given boundary data. In this case, the system of equations is a linear system.

Example

Using a forward-difference approximation for u_t and a second-order approximation for u_{xx} , the diffusion equation $u_t = u_{xx}$ is approximated by the *explicit* formula $u_{i,j+1} = ru_{i-1,j} + (1 - 2r)u_{i,j} + ru_{i+1,j}$. This classic result permits step-by-step advancement in the t direction beginning with the initial data at $t = 0$ ($j = 0$) and guided by the boundary data. Here, the term $r = \Delta t / (\Delta x)^2 = k/h^2$ is restricted to be less than or equal to $1/2$ for stability and the truncation error is $O(k^2 + kh^2)$.

The Crank–Nicolson implicit formula that approximates the diffusion equation $u_t = u_{xx}$ is

$$\begin{aligned} -r\lambda u_{i-1,j+1} + (1 + 2r\lambda)u_{i,j+1} - r\lambda u_{i+1,j+1} &= r(1 - \lambda)u_{i-1,j} \\ &+ [1 - 2r(1 - \lambda)]u_{i,j} \\ &+ r(1 - \lambda)u_{i+1,j} \end{aligned}$$

The stability of this numerical method was analyzed by Crandall [Ames, 1993] where the λ, r stability diagram is given.

Approximation of the time derivative in $u_t = u_{xx}$ by a central difference leads to an always unstable approximation, the useless approximation

$$u_{i,j+1} = u_{i,j-1} + 2r(u_{i+1,j} - 2u_{i,j} + u_{i-1,j})$$

which is a warning to be careful.

The foregoing method is *symmetric* with respect to the point (i,j) , where the method is centered. Asymmetric methods have some computational advantages, so the Saul'yev method is described [Ames, 1993]. The algorithms ($r = k/h^2$)

$$(1+r)u_{i,j+1} = u_{i,j} + r(u_{i-1,j+1} - u_{i,j} + u_{i+1,j}) \quad (\text{Saul'yev A})$$

$$(1+r)u_{i,j+1} = u_{i,j} + r(u_{i+1,j+1} - u_{i,j} + u_{i-1,j}) \quad (\text{Saul'yev B})$$

are used as in any one of the following options:

1. Use Saul'yev A only and proceed line-by-line in the $t(j)$ direction, but *always* from the left boundary on a line.
2. Use Saul'yev B only and proceed line-by-line in the $t(j)$ direction, but *always* from the right boundary to the left on a line.
3. Alternate from line to line by first using Saul'yev A and then B, or the reverse. This is related to *alternating direction methods*.
4. Use Saul'yev A and Saul'yev B on the same line and average the results for the final answer (A first, and then B). This is equivalent to introducing the dummy variables $P_{i,j}$ and $Q_{i,j}$ such that

$$(1+r)P_{i,j+1} = U_{i,j} + r(P_{i-1,j+1} - U_{i,j} + U_{i+1,j})$$

$$(1+r)Q_{i,j+1} = U_{i,j} + r(Q_{i+1,j+1} - U_{i,j} + U_{i-1,j})$$

and

$$U_{i,j+1} = \frac{1}{2}(P_{i,j+1} + Q_{i,j+1})$$

This averaging method has some computational advantages because of the possibility of truncation error cancellation. As an alternative, one can retrain the $P_{i,j}$ and $Q_{i,j}$ from the previous step and replace $U_{i,j}$ and $U_{i+1,j}$ by $P_{i,j}$ and $P_{i+1,j}$, respectively, and $U_{i,j}$ and $U_{i-1,j}$ by $Q_{i,j}$ and $Q_{i-1,j}$, respectively.

Weighted Residual Methods

To set the stage for the method of finite elements, we briefly describe the weighted residual methods (WRMs), which have several variations — the interior, boundary, and mixed methods. Suppose the equation is $Lu = f$, where L is the partial differential operator and f is known function, of say x and y . The first step in WRM is to select a class of known basis functions b_i (e.g., trigonometric, Bessel, Legendre) to approximate $u(x,y)$ as $\sim \sum a_i b_i(x,y) = U(x,y,a)$. Often, the b_i are selected so that $U(x,y,a)$ satisfy the boundary conditions. This is essentially the *interior method*. If the b_i in $U(x,y,a)$ are selected to satisfy the differential equations, but not the boundary conditions, the variant is called the *boundary method*. When neither the equation nor the boundary conditions are satisfied, the method is said to be *mixed*. The least ingenuity is required here. The usual method of choice is the interior method.

The second step is to select an optimal set of constants, a_i , $i = 1, 2, \dots, n$, by using the residual $R_i(U) = LU - f$. This is done here for the interior method. In the boundary method, there are a set of boundary residual R_B , and, in the mixed method, both R_i and R_B . Using the spatial average $(w,v) = \int_V wv dV$, the criterion for selecting the values of a_i is the requirement that the n spatial averages

$$(b_i, R_E(U)) = 0, \quad i = 1, 2, \dots, n$$

These represent n equations (linear if the operator L is linear and nonlinear otherwise) for the a_j . Particular WRMs differ because of the choice of the b_j s. The most common follow.

1. *Subdomain*. The domain V is divided into n smaller, not necessarily disjoint, subdomains V_j with $w_j(x,y) = 1$ if (x,y) is in V_j , and 0 if (x,y) is not in V_j .
2. *Collocation*. Select n points $P_j = (x_j, y_j)$ in V with $w_j(P_j) = \delta(P - P_j)$, where
$$\int_V \phi(P) \delta(P - P_j) dP = \phi(P_j)$$
 for all test functions $\phi(P)$ which vanish outside the compact set V . Thus,
$$(w, R_E) = \int_V \delta(P - P_j) R_E dV = R_E[U(P_j)] \equiv 0$$
 (i.e., the residual is set equal to zero at the n points P_j).
3. *Least squares*. Here, the functional $I(a) = \int_V R_E^2 dV$, where $a = (a_1, \dots, a_n)$, is to be made stationary with respect to the a_j . Thus, $0 = \partial I / \partial a_j = 2 \int_V R_E (\partial R_E / \partial a_j) dV$, with $j = 1, 2, \dots, n$. The w_j in this case are $\partial R_E / \partial a_j$.
4. *Bubnov-Galerkin*. Choose $w_j(P) = b_j(P)$. This is perhaps the best-known method.
5. *Stationary functional (variational)*. With ϕ a variational integral (or other functional), set $\partial \phi[U] / \partial a_j = 0$, where $j = 1, \dots, n$, to generate the n algebraic equations.

Example

$u_{xx} + u_{yy} = -2$, with $u = 0$ on the boundaries of the square $x = \pm 1, y = \pm 1$. Select an interior method with $U = a_1(1-x^2)(1-y^2) + a_2x^2y^2(1-x^2)(1-y^2)$, whereupon the residual $R_E(U) = -2a_1(2-x^2-y^2) + 2a_2[(1-6x^2)y^2(1-y^2) + (1-6y^2)x^2(1-x^2)] + 2$. Collocating at $\left(\frac{1}{3}, \frac{1}{3}\right)$ and $\left(\frac{2}{3}, \frac{2}{3}\right)$ gives the two linear equations $-32a_1/9 + 32a_2/243 + 2 = 0$ and $-20a_1/9 - 400a_2/243 + 2 = 0$ for a_1 and a_2 .

WRM methods can obviously be used as approximate methods. We have now set the stage for *finite elements*.

Finite Elements

The WRM methods are more general than the *finite element* (FE) methods. FE methods require, in addition, that the basis functions be finite elements (i.e., functions that are zero except on a small part of the domain under consideration). A typical example of an often used basis is that of triangular elements. For a triangular element with Cartesian coordinates (x_1, y_1) , (x_2, y_2) , and (x_3, y_3) , define natural coordinates L_1, L_2 , and L_3 ($L_i \leftrightarrow (x_i, y_i)$) so that $L_i = A_i/A$ where

$$A = \frac{1}{2} \det \begin{bmatrix} 1 & x_1 & y_1 \\ 1 & x_2 & y_2 \\ 1 & x_3 & y_3 \end{bmatrix}$$

is the area of the triangle and

$$A_1 = \frac{1}{2} \det \begin{bmatrix} 1 & x & y \\ 1 & x_2 & y_2 \\ 1 & x_3 & y_3 \end{bmatrix}$$

$$A_2 = \frac{1}{2} \det \begin{bmatrix} 1 & x_1 & y_1 \\ 1 & x & y \\ 1 & x_3 & y_3 \end{bmatrix}$$

$$A_3 = \frac{1}{2} \det \begin{bmatrix} 1 & x_1 & y_1 \\ 1 & x_2 & y_2 \\ 1 & x & y \end{bmatrix}$$

Clearly $L_1 + L_2 + L_3 = 1$, and the L_i are one at node i and zero at the other nodes. In terms of the Cartesian coordinates,

$$\begin{bmatrix} L_1 \\ L_2 \\ L_3 \end{bmatrix} = \frac{1}{2A} \begin{bmatrix} x_2 y_3 - x_3 y_2, & y_2 - y_3, & x_3 - x_2 \\ x_3 y_1 - x_1 y_3, & y_3 - y_1, & x_1 - x_3 \\ x_1 y_2 - x_2 y_1, & y_1 - y_2, & x_2 - x_1 \end{bmatrix} \begin{bmatrix} 1 \\ x \\ y \end{bmatrix}$$

is the linear triangular element relation.

Tables of linear, quadratic, and cubic basis functions are given in the literature. Note that while the linear basis needs three nodes, the quadratic requires six, and the cubic basis ten. Various modifications, such as the Hermite basis, are described in the literature. Triangular elements are useful in approximating irregular domains.

For rectangular elements, the *chapeau* functions are often used. Let us illustrate with an example. Let $u_{xx} + u_{yy} = Q$, $0 < x < 2$, $0 < y < 2$, $u(x, 2) = 1$, $u(0, y) = 1$, $u_y(x, 0) = 0$, $u_x(2, y) = 0$, and $Q(x, y) = Q_w \delta(x-1) \delta(y-1)$:

$$\delta(x) = \begin{cases} 0 & x \neq 0 \\ 1 & x = 0 \end{cases}$$

Using four equal rectangular elements, map the element I with vertices at $(0,0)$, $(0,1)$, $(1,1)$, and $(1,0)$ into the local (canonical) coordinates (ξ, η) , $-1 \leq \xi \leq 1$, $-1 \leq \eta \leq 1$, by means of $x = \frac{1}{2}(\xi+1)$, $y = \frac{1}{2}(\eta+1)$. This mapping permits one to develop software that standardizes the treatment of all elements. Converting to (ξ, η) coordinates, our problem becomes $u_{\xi\xi} + u_{\eta\eta} = \frac{1}{4}Q$, $-1 \leq \xi \leq 1$, $-1 \leq \eta \leq 1$, $Q = Q_w \delta(\xi-1) \delta(\eta-1)$.

First, a trial function $\bar{u}(\xi, \eta)$ is defined as $u(\xi, \eta) \approx \bar{u}(\xi, \eta) = \sum_{j=1}^4 A_j \phi_j(\xi, \eta)$ (in element I) where the ϕ_j are the two-dimensional chapeau functions

$$\begin{aligned} \phi_1 &= \left[\frac{1}{2}(1-\xi) \frac{1}{2}(1-\eta) \right] & \phi_2 &= \left[\frac{1}{2}(1+\xi) \frac{1}{2}(1-\eta) \right] \\ \phi_3 &= \left[\frac{1}{2}(1+\xi) \frac{1}{2}(1+\eta) \right] & \phi_4 &= \left[\frac{1}{2}(1-\xi) \frac{1}{2}(1+\eta) \right] \end{aligned}$$

Clearly ϕ_i take the value one at node i , provide a bilinear approximation, and are nonzero only over elements adjacent to node i .

Second, the equation residual $R_E = \nabla^2 \bar{u} - \frac{1}{4}Q$ is formed and a WRM procedure is selected to formulate the algebraic equations for the A_i . This is indicated using the Galerkin method. Thus, for element I , we have

$$\int_{D_I} \int (\bar{u}_{\xi\xi} + \bar{u}_{\eta\eta} - Q) \phi_i(\xi, \eta) d\xi d\eta = 0, \quad i = 1, \dots, 4$$

Applying Green's theorem, this result becomes

$$\int_{D_I} \int \left[\bar{u}_{\xi}(\phi_i)_{\xi} + \bar{u}_{\eta}(\phi_i)_{\eta} + \frac{1}{4}Q\phi_i \right] d\xi d\eta - \int_{\partial D_I} (\bar{u}_{\xi}c_{\xi} + \bar{u}_{\eta}c_{\eta}) \phi_i ds = 0, \quad i = 1, 2, \dots, 4$$

Using the same procedure in all four elements and recalling the property that the ϕ_i in each element are nonzero only over elements adjacent to node i gives the following nine equations:

$$\sum_{e=1}^4 \left\{ \int_{D_e} \int \sum_{j=1}^9 A_j [(\phi_j)_{\xi}(\phi_j)_{\xi} + (\phi_j)_{\eta}(\phi_j)_{\eta}] + \frac{1}{4}Q\phi_j \right\} d\xi d\eta - \sum_{e=1}^4 \int_{\partial D_e} (\bar{u}_{\xi}c_{\xi} + \bar{u}_{\eta}c_{\eta}) \phi ds = 0, \quad i = 1, 2, \dots, 9$$

where the c_{ξ} and c_{η} are the direction cosines of the appropriate element (e) boundary.

Method of Lines

The *method of lines*, when used on PDEs in two dimensions, reduces the PDE to a system of ordinary differential equations (ODEs), usually by finite difference or finite element techniques. If the original problem is an initial value (boundary value) problem, then the resulting ODEs form an initial value (boundary value) problem. These ODEs are solved by ODE numerical methods.

Example

$u_t = u_{xx} + u^2$, $0 < x < 1$, $0 < t$, with the initial value $u(x, 0) = x$, and boundary data $u(0, t) = 0$, $u(1, t) = \sin t$. A discretization of the space variable (x) is introduced and the time variable is left continuous. The approximation is $\dot{u}_i = (u_{i+1} - 2u_i + u_{i-1})/h^2 + u_i^2$. With $h = 1/5$, the equations become

$$u_0(t) = 0$$

$$\dot{u}_1 = \frac{1}{25}[u_2 - 2u_1] + u_1^2$$

$$\dot{u}_2 = \frac{1}{25}[u_3 - 2u_2 + u_1] + u_2^2$$

$$\dot{u}_3 = \frac{1}{25}[u_4 - 2u_3 + u_2] + u_3^2$$

$$\dot{u}_4 = \frac{1}{25}[\sin t - 2u_4 + u_3] + u_4^2$$

$$u_5 = \sin t$$

and $u_1(0)=0.2$, $u_2(0)=0.4$, $u_3(0)=0.6$, and $u_4(0)=0.8$.

230.11 Discrete and Fast Fourier Transforms

Let $x(n)$ be a sequence that is nonzero only for a finite number of samples in the interval $0 \leq n \leq (N-1)$. The quantity

$$X(k) = \sum_{n=0}^{N-1} x(n)e^{-i(2\pi/N)nk}, \quad k = 0, 1, \dots, N-1$$

is called the *discrete Fourier transform* (DFT) of the sequence $x(n)$. Its inverse (IDFT) is given by

$$x(n) = \frac{1}{N} \sum_{k=0}^{N-1} X(k)e^{i(2\pi/N)nk}, \quad n = 0, 1, \dots, N-1 \quad (i^2 = -1)$$

Clearly, DFT and IDFT are finite sums and there are N frequency values. Also, $X(k)$ is periodic in k with period N .

Example

$$x(0) = 1, \quad x(1) = 2, \quad x(2) = 3, \quad x(3) = 4$$

$$X(k) = \sum_{n=0}^3 x(n)e^{-i(2\pi/4)nk}, \quad k = 0, 1, 2, 3, 4$$

Thus,

$$X(0) = \sum_{n=0}^3 x(n) = 10$$

and

$$X(1) = x(0) + x(1)e^{-i\pi/2} + x(2)e^{-i\pi} + x(3)e^{-i3\pi/2} = 1 - 2i - 3 + 4i = -2 + 2i; \quad X(2) = -2; \quad X(3) = -2 - 2i.$$

DFT Properties

1. Linearity: If $x_3(n) = ax_1(n) + bx_2(n)$, then $X_3(k) = aX_1(k) + bX_2(k)$.
2. Symmetry: For $x(n)$ real, $\text{Re}[X(k)] = \text{Re}[X(N-k)]$, $\text{Im}[X(k)] = -\text{Im}[X(N-k)]$.
3. Circular shift: By a circular shift of a sequence defined in the interval $0 \leq n \leq N-1$, we mean that, as values *fall off* from one end of the sequence, they are appended to the other end. Denoting this by $x(n \oplus m)$, we see that positive m means shift left and negative m means shift right. Thus, $x_2(n) = x_1(n \oplus m) \Leftrightarrow X_2(k) = X_1(k)e^{i(2\pi/N)km}$.
4. Duality: $x(n) \Leftrightarrow X(k)$ implies $(1/N)X(n) \Leftrightarrow x(-k)$.
5. Z-transform relation: $X(k) = X(z)|_{z=e^{i(2\pi/N)k}}$, $k = 0, 1, \dots, N-1$.
6. Circular convolution: $x_3(n) = \sum_{m=0}^{N-1} x_1(m)x_2(n \oplus m) = \sum_{\ell=0}^{N-1} x_1(n \oplus \ell)x_2(\ell)$ where $x_2(n \oplus m)$ corresponds to a circular shift to the right for positive m .

One fast algorithm for calculating DFTs is the radix-2 *fast Fourier transform* developed by J. W. Cooley and J. W. Tucker. Consider the two-point DFT $X(k) = \sum_{n=0}^1 x(n)e^{-i(2\pi/2)nk}$, $k = 0, 1$. Clearly, $X(k) = x(0) + x(1)e^{-ink}$. So $X(0) = x(0) + x(1)$ and $X(1) = x(0) - x(1)$. This process can be extended to DFTs of length $N = 2^r$, where r is a positive integer. For $N = 2^r$, decompose the N -point DFT into *two* $N/2$ -point DFTs. Then, decompose each $N/2$ -point DFT into *two* $N/4$ -point DFTs, and so on until eventually we have $N/2$ *two*-point DFTs. Computing these as indicated above, we recombine them into $N/4$ four-point DFTs and then $N/8$ eight-point DFTs, and so on, until the DFT is computed. The total number of DFT operations (for large N) is $O(N^2)$, and that of the FFT is $O(N \log_2 N)$, quite a saving for large N .

230.12 Software

Some available software packages are listed here.

General Packages

General software packages include Maple, Mathematica, and Matlab. All contain algorithms for handling a large variety of both numerical and symbolic computations.

Special Packages for Linear Systems

In the IMSL Library, there are three complementary linear system packages of note.

LINPACK is a collection of programs concerned with *direct* methods for general (or full) symmetric, symmetric positive definite, triangular, and tridiagonal matrices. There are also programs for least squares problems, along with the QR algorithm for eigensystems and the singular value decompositions of rectangular matrices. The programs are intended to be completely machine independent, fully portable, and run with good efficiency in most computing environments. The LINPACK User's Guide by Dongarra et al. is the basic reference.

ITPACK is a modular set of programs for iterative methods. The package is oriented toward the sparse matrices that arise in the solution of PDEs and other applications. While the programs apply to full matrices, that is rarely profitable. Four basic iteration methods and two convergence acceleration methods are in the package. There is a Jacobi, SOR (with optimum relaxation parameter estimated), symmetric SOR, and reduced system (red-black ordering) iteration, each with semi-iteration and conjugate gradient acceleration. All parameters for these iterations are automatically estimated. The practical and theoretical background for ITPACK is found in Hagemen and Young [1981].

YALEPACK is a substantial collection of programs for sparse matrix computations.

Ordinary Differential Equations Packages

Also in IMSL, one finds such sophisticated software as DVERK, DGEAR, or DREBS for initial value problems. For two-point boundary value problems, one finds DTPTB (use of DVERK and multiple shooting) or DVCPR.

Partial Differential Equations Packages

DISPL was developed and written at Argonne National Laboratory. DISPL is designed for nonlinear second-order PDEs (parabolic, elliptic, hyperbolic [some cases], and parabolic elliptic). Boundary conditions of a general nature and material interfaces are allowed. The spatial dimension can be either one or two and in Cartesian, cylindrical, or spherical (one dimension only) geometry. The PDEs are reduced to ordinary DEs by Galerkin discretization of the spatial variables. The resulting ordinary DEs in the timelike variable are then solved by an ODE software package (such as GEAR). Software features include

graphics capabilities, printed output, dump/restart facilities, and free format input. DISPL is intended to be an engineering and scientific tool and is not a finely tuned production code for a small set of problems. DISPL makes no effort to control the spatial discretization errors. It has been used to successfully solve a variety of problems in chemical transport, heat and mass transfer, pipe flow, etc.

PDELIB was developed and written at Los Alamos Scientific Laboratory. PDELIB is a library of subroutines to support the numerical solution of evolution equations with a timelike variable and one or two space variables. The routines are grouped into a dozen independent modules according to their function (i.e., accepting initial data, approximating spatial derivatives, advancing the solution in time). Each task is isolated in a distinct module. Within a module, the basic task is further refined into general-purpose flexible lower-level routines. PDELIB can be understood and used at different levels. Within a small period of time, a large class of problems can be solved by a novice. Moreover, it can provide a wide variety of outputs.

DSS/2 is a differential systems simulator developed at Lehigh University as a transportable numerical method of lines (NMOL) code. See also LEANS.

FORSIM is designed for the automated solution of sets of implicitly coupled PDEs of the form

$$\frac{\partial u_i}{\partial t} = \phi_i(x, t, u_i, u_j, \dots, (u_i)_x, \dots, (u_i)_{xx}, (u_j)_{xx}, \dots), \quad \text{for } i = 1, \dots, N$$

The user specifies the ϕ_i in a simple FORTRAN subroutine. Finite difference formulas of any order may be selected for the spatial discretization and the spatial grid need not be equidistant. The resulting system of time-dependent ODEs is solved by the method of lines.

SLDGL is a program package for the self-adaptive solution of nonlinear systems of elliptic and parabolic PDEs in up to three space dimensions. Variable step size and variable order are permitted. The discretization error is estimated and used for the determination of the optimum grid and optimum orders. This is the most general of the codes described here (not for hyperbolic systems, of course). This package has seen extensive use in Europe.

FIDISOL (finite difference solver) is a program package for nonlinear systems of two- or three-dimensional elliptic and parabolic systems in rectangular domains or in domains that can be transformed analytically to rectangular domains. This package is actually a redesign of parts of SLDGL, primarily for the solution of large problems on vector computers. It has been tested on the CYBER 205, CRAY-1M, CRAY X-MP/22, and VP 200. The program vectorizes very well and uses the vector arithmetic efficiently. In addition to the numerical solution, a reliable error estimate is computed.

CAVE is a program package for conduction analysis via eigenvalues for three-dimensional geometries using the method of lines. In many problems, much time is saved because only a few terms suffice.

Many industrial and university computing services subscribe to the IMSL Software Library. Announcements of new software appear in *Directions*, a publication of IMSL. A brief description of some IMSL packages applicable to PDEs and associated problems is now given. In addition to those packages just described, two additional software packages bear mention. The first of these, the ELLPACK system, solves elliptic problems in two dimensions with general domains and in three dimensions with box-shaped domains. The system contains over 30 numerical methods modules, thereby providing a means of evaluating and comparing different methods for solving elliptic problems. ELLPACK has a special high-level language making it easy to use. New algorithms can be added or deleted from the system with ease.

Second, TWODEPEP is IMSL's general finite element system for two-dimensional elliptic, parabolic, and eigenvalue problems. The Galerkin finite elements available are triangles with quadratic, cubic, or quartic basic functions, with one edge curved when adjacent to a curved boundary, according to the isoparametric method. Nonlinear equations are solved by Newton's method, with the resulting linear system solved directly by Gauss elimination. PDE/PROTRAN is also available. It uses triangular elements with piecewise polynomials of degree 2, 3, or 4 to solve quite general steady state, time-dependent, and

eigenvalue problems in general two-dimensional regions. There is a simple user input. Additional information may be obtained from IMSL. NASTRAN and STRUDL are two advanced finite element computer systems available from a variety of sources. Another, UNAFEM, has been extensively used.

Dimensional Analysis

William F. Ames
Georgia Institute of Technology

[231.1 Units and Variables](#)
[231.2 Method of Dimensions](#)

231.1 Units and Variables

Dimensional analysis is a mathematical tool whose use will enable the scientist and engineer to save time in planning experiments and correlating results of experiments. The method arose in the science of mechanics. In this science three *units* are regarded as fundamental, namely, *length*, *mass*, and *time*. Other employed units are called *derived units*. For example, velocity and acceleration are derived units defined by reference to the two fundamental units — length and time. The units of force-momentum, mechanical energy, and power are dependent on all three of the fundamental units. The study of electricity, heat transfer, and so forth requires the inclusion of other fundamental units such as charge.

Here the fundamental units adopted are *length* (in centimeters), L ; *mass* (in grams), M ; and *time* (in seconds), T . This is the CGS system of units. Others are the British, or foot, pound, second (FPS) system and the MKS system, which is closely allied to the CGS system. The dimensional formulas of some basic physical variables in the CGS system are given in [Tables 231.1](#) through [231.3](#).

Some *variables* are dimensionless. For example, angle is defined as arc/radius; strain as volume/volume; and specific gravity as density/density (dimensions $(L^{-3} M)/(L^{-3} M) = L^0 M^0$). In addition there are dimensional constants: c , the velocity of light in a vacuum, has dimensions LT^{-1} , and g , the gravitational constant, has dimensions $L^3 M^{-1} T^{-2}$. Some dimensionless constants also appear. An example is the Reynolds number $N_{Re} = Dv\rho/\mu$ (D is diameter), which has dimensions $(L \cdot LT^{-1} \cdot L^{-3} M)/(L^{-1} MT^{-1}) = L^0 M^0 T^0$. Some dimensionless groups are listed in [Table 231.4](#).

231.2 Method of Dimensions

The *method of dimensions* is based on the simple observation that the dimensions on both sides of an equation must be the same. To illustrate, suppose we wish to find the distance s traveled in a given time by a particle of mass m falling from rest under the uniform acceleration due to gravity g . Assuming $s = f(g, t, m) = Cg^a t^b m^c$, where C is an unknown dimensionless constant and the indices a , b , and c are to be determined. Examining the dimensions in a dimensional formula we have

$$L = (LT^{-2})^a T^b M^c$$

Clearly $a = 1$, $b = 2$, and $c = 0$, so $s = Cgt^2$. It is not within the realm of dimensional analysis to evaluate C .

Another example is the two-body problem of astronomy. Suppose a planet of mass m rotates about the sun (mass \bar{M}) in an orbit that is an ellipse of major diameter D . The physical quantities that will affect the sought-for period, t , appear to be the mass of the sun, the mass of the planet, the diameter D ,

TABLE 231.1 Dimensional Physical Quantities

| Physical Quantity | Exponents of Dimensions | | | Formula |
|-------------------------------------|-------------------------|----------|----------|------------------|
| | <i>L</i> | <i>M</i> | <i>T</i> | |
| Volume density | -3 | 1 | 0 | $L^{-3}M$ |
| Length per unit volume | -2 | 0 | 0 | L^{-2} |
| Area density | -2 | 1 | 0 | $L^{-2}M$ |
| Curvature | -1 | 0 | 0 | L^{-1} |
| Linear density | -1 | 1 | 0 | $L^{-1}M$ |
| Angle | 0 | 0 | 0 | |
| Mass | 0 | 1 | 0 | M |
| Length | 1 | 0 | 0 | L |
| Mass \times length | 1 | 1 | 0 | LM |
| Area | 2 | 0 | 0 | L^2 |
| Moment of inertia | 2 | 1 | 0 | L^2M |
| Volume | 3 | 0 | 0 | L^3 |
| Speed of density change | -3 | 1 | -1 | $L^{-3}M T^{-1}$ |
| Velocity per unit volume | -2 | 0 | -1 | $L^{-2} T^{-1}$ |
| Momentum per unit volume | -2 | 1 | -1 | $L^{-2}M T^{-1}$ |
| Velocity per unit area | -1 | 0 | -1 | $L^{-1} T^{-1}$ |
| Viscosity | -1 | 1 | -1 | $L^{-1}M T^{-1}$ |
| Frequency | 0 | 0 | -1 | T^{-1} |
| Mass per second | 0 | 1 | -1 | $M T^{-1}$ |
| Velocity | 1 | 0 | -1 | $L T^{-1}$ |
| Momentum | 1 | 1 | -1 | $LM T^{-1}$ |
| Kinematic viscosity | 2 | 0 | -1 | $L^2 T^{-1}$ |
| Action | 2 | 1 | -1 | $L^2M T^{-1}$ |
| Volume per second | 3 | 0 | -1 | $L^3 T^{-1}$ |
| Acceleration of density change | -3 | 1 | -2 | $L^{-3}M T^{-2}$ |
| Acceleration per unit volume | -2 | 0 | -2 | $L^{-2} T^{-2}$ |
| Force per unit volume | -2 | 1 | -2 | $L^{-2}M T^{-2}$ |
| Acceleration per unit area | -1 | 0 | -2 | $L^{-1} T^{-2}$ |
| Pressure | -1 | 1 | -2 | $L^{-1}M T^{-2}$ |
| Angular acceleration | 0 | 0 | -2 | T^{-2} |
| Surface tension | 0 | 1 | -2 | $M T^{-2}$ |
| Acceleration | 1 | 0 | -2 | $L T^{-2}$ |
| Force | 1 | 1 | -2 | $LM T^{-2}$ |
| Temperature | 2 | 0 | -2 | $L^2 T^{-2}$ |
| Energy, torque | 2 | 1 | -2 | $L^2M T^{-2}$ |
| Rate of change of volume per second | 3 | 0 | -2 | $L^3 T^{-2}$ |
| Power | 2 | 1 | -3 | $L^2M T^{-2}$ |

TABLE 231.2 Dimensional Thermal Quantities

| Physical Quantity | Thermal Units | Dynamic Units |
|-------------------------------|-------------------------------|-----------------------------|
| Temperature | θ | θ |
| Quantity of heat | H | L^2MT^{-2} |
| Specific heat | Dimensionless | Dimensionless |
| Heat capacity per unit mass | $L^0 M^{-1}T^0H\theta^{-1}$ | $L^2M^0T^{-2}\theta^{-1}$ |
| Heat capacity per unit volume | $L^{-3}M^0T^0H\theta^{-1}$ | $L^{-1}M T^{-2}\theta^{-1}$ |
| Temperature gradient | $L^{-1}M^0T^0H\theta^{-1}$ | $L^{-1}M^0T^0\theta^{-1}$ |
| Conductivity | $L^{-1}M^0T^{-1}H\theta^{-1}$ | $LMT^{-3}\theta^1$ |
| Entropy | $H\theta^{-1}$ | $L^2MT^{-2}\theta^{-1}$ |

| Weber number | N_{We} | $LV^2\rho/\sigma_{gc}$ |

and the gravitational constant G . Thus, we try $t = \overline{CM}^a m^b D^c G^d +$ (similar terms), where the similar terms must have the same dimensions, that is, 0 in length, 0 in mass, and 1 in time. The dimensional equation becomes $T = M^a M^b L^c (L^3 M^{-1} T^{-2})^d$. Hence

$$\begin{aligned} \text{(length)} \quad & 0 = c + 3d \\ \text{(mass)} \quad & 0 = a + b - d \\ \text{(time)} \quad & 1 = -2d \end{aligned}$$

The solution of this system is $d = -1/2$, $c = 3/2$, a is arbitrary, and $b = -1/2 - a$. Therefore, $t = \overline{CM}^a m^{(-1/2)-a} D^{3/2} G^{-1/2}$ or $t^2 = C'(\overline{M}/m)^{2a} (D^3/Gm)$, which is Kepler's law (the square of the period of a planet is proportional to the cube of the major axis of the orbit). The constants C' and a must be evaluated by experiment.

Many other examples are found in the literature. This section closes with the determination of the height, h , that a liquid rises in a capillary tube. The relevant equation is $h = C \cdot \rho^a r^b s^c g^d \theta^e$, where ρ is the fluid density, r is the radius of the tube, s is the surface tension of the fluid, g is the acceleration of gravity, and θ is the contact angle. The dimensional equation becomes $L = (L^{-3}M)^a L^b (MT^{-2})^c (LT^{-1})^d$, which gives rise to the following three linear equations:

| | |
|----------|-------------------|
| (length) | $1 = -3a + b + d$ |
| (mass) | $0 = a + c$ |
| (time) | $0 = -2c - 2d$ |

in the four unknowns a , b , c , and d . We may express any three of the unknowns in terms of the fourth. Choosing a we find $c = -a$, $d = a$, and $b = 1 + 2a$, so $h = cr(r^2\rho g/s)^a$. Experiments show that h is inversely proportional to r , so that $a = -1$. Thus $h = C(s/r\rho g)$.

- [232.6 Summary](#)

Visualization is the process of seeing something. In the computer graphics field, the term *visualization* has a more specific meaning, and refers to computational techniques to display and understand behavior. The field of computer graphics visualization is still young; much of its fundamental work took place in the late 1980s. Today, it has grown to become one of the key commercial applications of computer graphics. Key technical aspects of computer graphics visualization include the three-dimensional (3-D) display of objects; display of scalar, vector, and tensor quantities; continuum volume display techniques; and animation over time.

232.1 3-D Display of Objects

Most modern computer graphics equipment uses display technology similar to that of television, where a two-dimensional array of dots known as *pixels* have individual dot colors set to produce a composite image. Turning data into such a screen image involves representing the data as geometric components, such as lines or polygons, *transforming* these components to a particular view from the observer, coloring or *rendering* these components, and converting them to dots on the screen through a process known as *scan conversion*.

Transformations are generally performed through matrix multiplication of the coordinates of each component, effecting operations including *rotation*, *scaling*, and *translation*. The transformation of a point P to its transformed position P' takes the form:

$$[P'] = [T][P] = [r][s][t][P]$$

Scaling and translation matrices can be combined in the form:

$$\begin{bmatrix} s_x & 0 & 0 & \Delta_x \\ 0 & s_y & 0 & \Delta_y \\ 0 & 0 & s_z & \Delta_z \\ 0 & 0 & 0 & 1 \end{bmatrix}$$

which multiplies the vector $[x, y, z, W]$, with the fourth element being a nonzero *homogenous coordinate* factor of x , y , and z . The rotational transformation is added by multiplying this matrix by matrices corresponding to rotations about the x, y , and z axes:

$$\begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & \cos\theta & -\sin\theta & 0 \\ 0 & \sin\theta & \cos\theta & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} \cos\theta & 0 & \sin\theta & 0 \\ 0 & 1 & 0 & 0 \\ -\sin\theta & 0 & \cos\theta & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} \cos\theta & -\sin\theta & 0 & 0 \\ \sin\theta & \cos\theta & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix}$$

Other transformations include the simulation of *perspective*, which reduces the x and y coordinates in the current view as a function of the z coordinate, and *clipping*, which removes portions of components intersected by either screen boundaries or an arbitrary *clipping plane*.

Rendering techniques generally involve setting a color or color function across each component, often based on the effects of a light source from the observer to the screen. For example, a square polygon facing the observer may be red, while its color may change toward darker shades of red as the polygon is rotated, becoming completely dark when 90° from the observer. Shading techniques may compute color as a continuous function across a component. Gouraud shading, for example, interpolates a color value across a polygon from its corner values, while another technique known as Phong shading computes color from an interpolation of the light source vector itself across the polygon. More advanced rendering techniques include *ray tracing*, which computes the behavior of light rays to simulate effects such as reflectance, shadows, and translucency, and *texture mapping*, which simulates a pattern or image across surfaces of the displayed model.

232.2 Scalar Display Techniques

One of the fundamental operations of visualization is the display of a single variable in space. Some of the visual techniques for displaying scalar field values include:

Color coding. The outside visible surfaces of a model are color-coded with values corresponding to the scalar value (Figure 232.1). For example, a structural model may have elements of high stress colored red, and low stress colored blue.

Isovalue display. An *isovalue* is a region of constant scalar value. In the general case, an isovalue can be idealized as a point in one-dimensional space, a curve in two dimensions, and a surface in three dimensions (Figure 232.2). One particular form of isovalue display, the *contour plot*, displays bands of color on model surfaces corresponding to ranges of isovalues. Isosurfaces are surfaces of constant 3-D scalar value.

Particle displays and implicit isovalues. A color-coded distribution of particles within a 3-D scalar field gives an overview of values throughout the field and can be useful in situations where isosurfaces obscure portions of the interior model. Another application of particle display is to compute and display particles at points corresponding to a particular scalar value. As the density of such particles increases, the resulting image approaches the isosurface of the scalar value in the limit.

FIGURE 232.1 Contour representation of a scalar value. FIGURE 232.2 Isosurfaces of a scalar value.

232.3 Vector and Tensor Field Display

The comprehensible display of multidimensional quantities remains a key area of visualization research. Particular applications include the display of flow fields, multivariate field analysis problems, and examination of derived quantities such as gradients. Some of the current techniques used in vector and tensor field display include the following:

Vector and tensor symbols. Symbols, often known as *glyphs*, use size, shape and color to show multiple values at a point in space. For example, a three-pointed triad may have each point colored and sized according to the value of different quantities at that point. More complex glyphs may vary the shape, direction, and color of multiple components to show complex states of behavior, such as the state of a tensor field.

Vector and tensor field curves. Path curves can be created through a vector or tensor field, generally representing the path of a vector quantity from specified starting locations. Further dimensions of information can be displayed across these path curves by varying quantities such as color, thickness, and cross-sectional geometry.

Particle field display. A distribution of particles within a field can represent a multivariate quantity by varying attributes such as particle density, color, size, and shape. As one example, [Figure 232.3](#) shows a particle distribution whose density varies by the gradient, or rate of change, of a state of stress in the Cartesian x , y , and z directions.

All of these techniques share a common approach of combining several visual techniques within a single image to display multivariate behavior. In addition, the use of animation (discussed below) adds the dimension of time and motion to evaluating complex behavior visually.

232.4 Continuum Volume Visualization

A 3-D field, particularly a sampled field such as a medical image, can be represented as a field of volume elements or *voxels*. These voxels can be viewed as tiny cubes connecting a regular array of sample points within the volume. Continuum volume visualization techniques generate imagery by performing operations on the voxel field. Such algorithms can allow an entire scalar-valued field to be represented within a single image, using techniques such as translucency and color variation, and can also provide a more accurate means of computing discrete images, such as isosurfaces ([Figure 232.4](#)). Above all, a

FIGURE 232.3 Particle representation of the gradient of a scalar value. Dot color varies by scalar value, while dot density varies by gradient.

FIGURE 232.4 Isovalues of density within a voxel data set.

voxel representation of a volume keeps an entire volume's data in a form suited to direct visualization and analysis.

Many voxel-based techniques operate in either *image space* or *voxel space*. Image space techniques often involve casting rays through each dot of the screen image into the projected voxel array, computing contributions to the ray's color and opacity from each voxel the ray intersects. Such algorithms may work from front to back, stopping when a ray becomes opaque or exits the volume, or back to front. Preclassification of the voxel space can help optimize these techniques or allow computations to be performed in parallel.

Voxel space techniques evaluate voxels to create polygons which contribute to the image. One such example, the Marching Cubes algorithm patented in 1987 by General Electric, examines which vertices of a voxel are above or below a threshold value, and then orders these binary values into a bit string whose value is used to look up the topology of any isosurface polygons passing through the voxel.

232.5 Animation Over Time

With increasing computing capabilities, a growing area of interest in visualization is the display of behavior which varies with time or motion.

At its most basic level, animation is simply the generation and playback of individual images to produce the sensation of continuous movement, which humans perceive at a rate between 10 and 30 frames per second. The steps involved in producing animated visualization sequences include:

Interpolation of behavior. Within each individual frame, aspects, such as result values or model deformation, can be interpolated between the initial and final positions. While simple linear interpolation is most common, this interpolation function can incorporate issues, such as acceleration and deceleration, as well.

Motion of the object. The position of the model can be interpolated linearly, or along a path, generally using the same function of incrementation as would be used for behavior. Issues in the general case of object motion include continuity across multiple connecting path segments, and the combination of one or more viewing transformations, such as translation and rotation.

Motion of the observer. The observer's position can be likened to the location of a camera within a scene. This camera position can also be interpolated along a path, moving into, out of, or around a scene, while accounting for display characteristics, such as perspective and lighting.

Frame capture and playback. While animated sequences can be directly generated and displayed when adequate computing and display resources exist, animation above a certain level of complexity must be stored frame by frame for later playback. Frame capture can be accomplished in computer memory, as images saved in a given format on computer disk, or by using special-purpose hardware, such as videotape controllers or writable video discs.

232.6 Summary

Techniques such as these share a common purpose of making objects and behavior more comprehensible to the human observer. In particular, they provide engineers with a means to better understand complex 3-D behavior. Trends towards the future in this area include computing performance improvements ranging from better display throughput to massively parallel architectures, a greater degree of interactivity, improved user interfaces, and further development of display algorithms.

Defining Terms

Glyph — A symbol displaying multivariate field values at a point in space.

Isovalue — A region of constant scalar value within a field of geometry. For example, an *isosurface* represents constant-value surfaces within a 3-D volume.

Pixel — A unit two-dimensional screen dot location in a computer graphics image.

Ray tracing — A technique for realistic display of geometry and volumetric data, involving computing the path of a light ray from screen pixel locations to its projected or reflected locations within the 3-D model.

Scan conversion — The process of converting geometric entities, such as lines and polygons, to projected screen dot (pixel) locations on a computer graphics display.

Voxel — A unit volume element within a regular 3-D array, describing a discrete volume space.

A.2 International System of Units (SI)

The International System of units (SI) was adopted by the 11th General Conference on Weights and Measures (CGPM) in 1960. It is a coherent system of units built from seven *SI base units*, one for each of the seven dimensionally independent base quantities: the meter, kilogram, second, ampere, kelvin, mole, and candela, for the dimensions length, mass, time, electric current, thermodynamic temperature, amount of substance, and luminous intensity, respectively. The definitions of the SI base units are given below. The *SI derived units* are expressed as products of powers of the base units, analogous to the corresponding relations between physical quantities but with numerical factors equal to unity.

In the International System there is only one SI unit for each physical quantity. This is either the appropriate SI base unit itself or the appropriate SI derived unit. However, any of the approved decimal prefixes, called *SI prefixes*, may be used to construct decimal multiples or submultiples of SI units.

It is recommended that only SI units be used in science and technology (with SI prefixes where appropriate). Where there are special reasons for making an exception to this rule, it is recommended always to define the units used in terms of SI units. This section is based on information supplied by IUPAC.

Definitions of SI Base Units

Meter: The meter is the length of path traveled by light in vacuum during a time interval of $1/299\,792\,458$ of second (17th CGPM, 1983).

Kilogram: The kilogram is the unit of mass; it is equal to the mass of the international prototype of the kilogram (3rd CGPM, 1901).

Second: The second is the duration of $9\,192\,631\,770$ periods of the radiation corresponding to the transition between the two hyperfine levels of the ground state of the cesium-133 atom (13th CGPM, 1967).

Ampere: The ampere is that constant current which, if maintained in two straight parallel conductors of infinite length, of negligible circular cross section, and placed 1 meter apart in vacuum, would produce between these conductors a force equal to 2×10^{-7} newton per meter of length (9th CGPM, 1948).

Kelvin: The kelvin, unit of thermodynamic temperature, is the fraction $1/273.16$ of the thermodynamic temperature of the triple point of water (13th CGPM, 1967).

Mole: The mole is the amount of substance of a system which contains as many elementary entities as there are atoms in 0.012 kilogram of carbon-12. When the mole is used, the elementary entities must be specified and may be atoms, molecules, ions, electrons, or other particles, or specified groups of such particles (14th CGPM, 1971). Examples of the use of the mole:

- 1 mol of H_2 contains about 6.022×10^{23} H_2 molecules, or 12.044×10^{23} H atoms.
- 1 mol of HgCl has a mass of 236.04 g.

- 1 mol of Hg_2Cl_2 has a mass of 472.08 g.
- 1 mol of Hg_2^{2+} has a mass of 401.18 g and a charge of 192.97 kC.
- 1 mol of $\text{Fe}_{0.91}\text{S}$ has a mass of 82.88 g.
- 1 mol of e^- has a mass of 548.60 μg and a charge of -96.49 kC .
- 1 mol of photons whose frequency is 10^{14} Hz has energy of about 39.90 kJ.

Candela: The candela is the luminous intensity, in a given direction, of a source that emits monochromatic radiation of frequency $540 \times 10^{12}\text{ Hz}$ and that has a radiant intensity in that direction of $(1/683)$ watt per steradian (16th CGPM, 1979).

Names and Symbols for the SI Base Units

| Physical Quantity | Name of SI Unit | Symbol for SI Unit |
|---------------------------|-----------------|--------------------|
| Length | meter | m |
| Mass | kilogram | kg |
| Time | second | s |
| Electric current | ampere | A |
| Thermodynamic temperature | kelvin | K |
| Amount of substance | mole | mol |
| Luminous intensity | candela | cd |

SI Derived Units with Special Names and Symbols

| Physical Quantity | Name of SI Unit | Symbol for SI Unit | Expression in Terms of SI Base Units |
|---|-----------------|--------------------|--|
| Frequency ^a | hertz | Hz | s^{-1} |
| Force | newton | N | $\text{m}\cdot\text{kg}\cdot\text{s}^{-2}$ |
| Pressure, stress | pascal | Pa | $\text{N}\cdot\text{m}^{-2} = \text{m}^{-1}\cdot\text{kg}\cdot\text{s}^{-2}$ |
| Energy, work, heat | joule | J | $\text{N}\cdot\text{m} = \text{m}^2\cdot\text{kg}\cdot\text{s}^{-2}$ |
| Power, radiant flux | watt | W | $\text{J}\cdot\text{s}^{-1} = \text{m}^2\cdot\text{kg}\cdot\text{s}^{-3}$ |
| Electric charge | coulomb | C | $\text{A}\cdot\text{s}$ |
| Electric potential, electromotive force | volt | V | $\text{J}\cdot\text{C}^{-1} = \text{m}^2\cdot\text{kg}\cdot\text{s}^{-3}\cdot\text{A}^{-1}$ |
| Electric resistance | ohm | Ω | $\text{V}\cdot\text{A}^{-1} = \text{m}^2\cdot\text{kg}\cdot\text{s}^{-3}\cdot\text{A}^{-2}$ |
| Electric conductance | siemens | S | $\Omega^{-1} = \text{m}^{-2}\cdot\text{kg}^{-1}\cdot\text{s}^3\cdot\text{A}^2$ |
| Electric capacitance | farad | F | $\text{C}\cdot\text{V}^{-1} = \text{m}^{-2}\cdot\text{kg}^{-1}\cdot\text{s}^4\cdot\text{A}^2$ |
| Magnetic flux density | tesla | T | $\text{V}\cdot\text{s}\cdot\text{m}^{-2} = \text{kg}\cdot\text{s}^{-2}\cdot\text{A}^{-1}$ |
| Magnetic flux | weber | Wb | $\text{V}\cdot\text{s} = \text{m}^2\cdot\text{kg}\cdot\text{s}^{-2}\cdot\text{A}^{-1}$ |
| Inductance | henry | H | $\text{V}\cdot\text{A}^{-1}\cdot\text{s} = \text{m}^2\cdot\text{kg}\cdot\text{s}^{-2}\cdot\text{A}^{-2}$ |
| Celsius temperature ^b | degree Celsius | $^{\circ}\text{C}$ | K |
| Luminous flux | lumen | lm | $\text{cd}\cdot\text{sr}$ |
| Illuminance | lux | lx | $\text{cd}\cdot\text{sr}\cdot\text{m}^{-2}$ |
| Activity (radioactive) | becquerel | Bq | s^{-1} |
| Absorbed dose (of radiation) | gray | Gy | $\text{J}\cdot\text{kg}^{-1} = \text{m}^2\cdot\text{s}^{-2}$ |
| Dose equivalent (dose equivalent index) | sievert | Sv | $\text{J}\cdot\text{kg}^{-1} = \text{m}^2\cdot\text{s}^{-2}$ |
| Plane angle | radian | rad | 1 = $\text{m}\cdot\text{m}^{-1}$ |
| Solid angle | steradian | sr | 1 = $\text{m}^2\cdot\text{m}^{-2}$ |

^a For radial (circular) frequency and for angular velocity the unit rad s^{-1} , or simply s^{-1} , should be used, and this may not be simplified to Hz. The unit Hz should be used only for frequency in the sense of cycles per second.

^b The Celsius temperature θ is defined by the equation

$$\theta/^{\circ}\text{C} = T/\text{K} - 237.15$$

The SI unit of Celsius temperature interval is the degree Celsius, $^{\circ}\text{C}$, which is equal to the kelvin, K. $^{\circ}\text{C}$ should be treated as a single symbol, with no space between the $^{\circ}$ sign and the letter C. (The symbol $^{\circ}\text{K}$, and the symbol $^{\circ}$, should no longer be used.)

Units in Use Together with the SI

These units are not part of the SI, but it is recognized that they will continue to be used in appropriate contexts. SI prefixes may be attached to some of these units, such as milliliter, ml; millibar, mbar; mega-electronvolt, MeV; and kilotonne, kt.

| Physical Quantity | Name of Unit | Symbol for Unit | Value in SI Units |
|-------------------|---|--------------------------------|--|
| Time | minute | min | 60 s |
| Time | hour | h | 3600 s |
| Time | day | d | 86 400 s |
| Plane angle | degree | ° | ($\pi/180$) rad |
| Plane angle | minute | ' | ($\pi/10\,800$) rad |
| Plane angle | second | " | ($\pi/648\,000$) rad |
| Length | angstrom ^a | Å | 10^{-10} m |
| Area | barn | b | 10^{-28} m ² |
| Volume | liter | l, L | dm ³ = 10^{-3} m ³ |
| Mass | tonne | t | Mg = 10^3 kg |
| Pressure | bar ^a | bar | 10^5 Pa = 10^5 N·m ⁻² |
| Energy | electronvolt ^b | eV (= $e \times V$) | $\approx 1.60218 \times 10^{-19}$ J |
| Mass | unified atomic mass unit ^{b,c} | u (= $m_a(^{12}\text{C})/12$) | $\approx 1.66054 \times 10^{-27}$ kg |

^a The angstrom and the bar are approved by CIPM for “temporary use with SI units,” until CIPM makes a further recommendation. However, they should not be introduced where they are not used at present.

^b The values of these units in terms of the corresponding SI units are not exact, since they depend on the values of the physical constants e (for the electronvolt) and N_A (for the unified atomic mass unit), which are determined by experiment.

^c The unified atomic mass unit is also sometimes called the dalton, with symbol Da, although the name and symbol have not been approved by CGPM.

A.3 Conversion Constants and Multipliers

Recommended Decimal Multiples and Submultiples

| Multiple for Submultiple | Prefix | Symbol | Multiple for Submultiple | Prefix | Symbol |
|-----------------------------|--------|--------|-----------------------------|--------|--------------|
| 10^{18} | exa | E | 10^{-1} | deci | d |
| 10^{15} | peta | P | 10^{-2} | centi | c |
| 10^{12} | tera | T | 10^{-3} | milli | m |
| 10^9 | giga | G | 10^{-6} | micro | μ (Greek mu) |
| 10^6 | mega | M | 10^{-9} | nano | n |
| 10^3 | kilo | k | 10^{-12} | pico | p |
| 10^2 | hecto | h | 10^{-15} | femto | f |
| 10 | deca | da | 10^{-18} | atto | a |

Conversion Factors — Metric to English

| To Obtain | Multiply | By |
|-----------------------|------------------|----------------------------------|
| Inches | Centimeters | 0.393 700 787 4 |

Temperature Factors

$$^{\circ}\text{F} = 9/5(^{\circ}\text{C}) + 32$$

$$\text{Fahrenheit temperature} = 1.8 (\text{temperature in kelvins}) - 459.67$$

$$^{\circ}\text{C} = 5/9 [(^{\circ}\text{F}) - 32]$$

$$\text{Celsius temperature} = \text{temperature in kelvins} - 273.15$$

$$\text{Fahrenheit temperature} = 1.8 (\text{Celsius temperature}) + 32$$

Conversion of Temperatures

| From | To | | From | To | |
|------------|---------|---------------------------------------|---------|------------|-----------------------------------|
| Fahrenheit | Celsius | $t_C = \frac{t_F - 32}{1.8}$ | Celsius | Fahrenheit | $t_F = (t_C \times 1.8) + 32$ |
| | | | | Kelvin | $T_K = t_C + 273.15$ |
| | | | | Rankine | $T_R = (t_C + 273.15) \times 1.8$ |
| | Kelvin | $T_k = \frac{t_F - 32}{1.8} + 273.15$ | Kelvin | Celsius | $t_C = T_K - 273.15$ |
| | Rankine | $T_R = t_F + 459.67$ | Rankine | Rankine | $T_R = T_K \times 1.8$ |
| | | | | Fahrenheit | $t_F = T_R - 459.67$ |
| | | | | Kelvin | $T_K = \frac{T_R}{1.8}$ |

A.4 Physical Constants

General

Equatorial radius of the earth = 6378.388 km = 3963.34 miles (statute)

Polar radius of the earth = 6356.912 km = 3949.99 miles (statute)

1 degree of latitude at 40° = 69 miles

1 international nautical mile = 1.150 78 miles (statute) = 1852 m = 6076.115 ft

Mean density of the earth = 5.522 g/cm³ = 344.7 lb/ft³

Constant of gravitation (6.673 ± 0.003) × 10⁻⁸.cm³.g⁻¹.s⁻²

Acceleration due to gravity at sea level, latitude 45° = 980.6194 cm/s² = 32.1726 ft/s²

Length of seconds pendulum at sea level, latitude 45° = 99.3575 cm = 39.1171 in.

1 knot (international) = 101.269 ft/min = 1.6878 ft/s = 1.1508 miles (statute)/h

1 micron = 10⁻⁴ cm

1 angstrom = 10⁻⁸ cm

Mass of hydrogen atom = (1.673 39 ± 0.0031) × 10⁻²⁴ g

Density of mercury at 0°C = 13.5955 g/mL

Density of water at 3.98°C = 1.000 000 g/mL

Density, maximum, of water, at 3.98°C = 0.999 973 g/cm³

Density of dry air at 0°C, 760 mm = 1.2929 g/L

Velocity of sound in dry air at 0°C = 331.36 m/s = 1087.1 ft/s

Velocity of light in vacuum = (2.997 925 ± 0.000 002) × 10¹⁰ cm/s

Heat of fusion of water, 0°C = 79.71 cal/g

Heat of vaporization of water, 100°C = 539.55 cal/g

Electrochemical equivalent of silver 0.001 118 g/s international amp

Absolute wavelength of red cadmium light in air at 15°C, 760 mm pressure = 6438.4696 Å

Wavelength of orange-red line of krypton 86 = 6057.802 Å

π Constants

$\pi = 3.14159\ 26535\ 89793\ 23846\ 26433\ 83279\ 50288\ 41971\ 69399\ 37511$

$1/\pi = 0.31830\ 98861\ 83790\ 67153\ 77675\ 26745\ 02872\ 40689\ 19291\ 48091$

$\pi^2 = 9.8690\ 44010\ 89358\ 61883\ 44909\ 99876\ 15113\ 53136\ 99407\ 24079$

A.5 Symbols and Terminology for Physical and Chemical Quantities

| Name | Symbol | Definition | SI Unit |
|---------------------------|----------------------------|---|----------------------------------|
| Classical Mechanics | | | |
| Mass | m | | kg |
| Reduced mass | μ | $\mu = m_1 m_2 / (m_1 + m_2)$ | kg |
| Density, mass density | ρ | $\rho = m/V$ | kg·m ⁻³ |
| Relative density | d | $d = \rho/\rho^0$ | 1 |
| Surface density | ρ_A, ρ_S | $\rho_a = m/A$ | kg·m ⁻² |
| Specific volume | v | $v = V/m = 1/\rho$ | m ³ ·kg ⁻¹ |
| Momentum | \mathbf{p} | $\mathbf{p} = m\mathbf{v}$ | kg·m·s ⁻¹ |
| Angular momentum, action | \mathbf{L} | $\mathbf{L} = \mathbf{r} \times \mathbf{p}$ | J·s |
| Moment of inertia | I, J | $I = \sum m_i r_i^2$ | kg·m ² |
| Force | \mathbf{F} | $\mathbf{F} = d\mathbf{p}/dt = m\mathbf{a}$ | N |
| Torque, moment of a force | $\mathbf{T}, (\mathbf{M})$ | $\mathbf{T} = \mathbf{r} \times \mathbf{F}$ | N·m |
| Energy | E | | J |
| Potential energy | E_p, V, Φ | $E_p = -\int \mathbf{F} \cdot d\mathbf{s}$ | J |

| Name | Symbol | Definition | SI Unit |
|--|----------------------|--|---------------------------------------|
| Kinetic energy | E_k, T, K | $E_k = (1/2)mv^2$ | J |
| Work | W, w | $W = \int \mathbf{F} \cdot d\mathbf{s}$ | J |
| Hamilton function | H | $H(q, p) = T(q, p) + V(q)$ | J |
| Lagrange function | L | $L(q, \dot{q}) = T(q, \dot{q}) - V(q)$ | J |
| Pressure | p, P | $p = F/A$ | Pa, N·m ⁻² |
| Surface tension | γ, σ | $\gamma = dW/dA$ | N·m ⁻¹ , J·m ⁻² |
| Weight | $G (W, P)$ | $G = mg$ | N |
| Gravitational constant | G | $F = Gm_1m_2/r^2$ | N·m ² ·kg ⁻² |
| Normal stress | σ | $\sigma = F/A$ | Pa |
| Shear stress | τ | $\tau = F/A$ | Pa |
| Linear strain, relative elongation | ε, e | $\varepsilon = \Delta l/l$ | 1 |
| Modulus of elasticity, Young's modulus | E | $E = \sigma/\varepsilon$ | Pa |
| Shear strain | γ | $\gamma = \Delta x/d$ | 1 |
| Shear modulus | G | $G = \tau/\gamma$ | Pa |
| Volume strain, bulk strain | θ | $\theta = \Delta V/V_0$ | 1 |
| Bulk modulus, compression modulus | K | $K = -V_0(dp/dV)$ | Pa |
| Viscosity, dynamic viscosity | η, μ | $\tau_{xz} = \eta(dv_x/dz)$ | Pa·s |
| Fluidity | ϕ | $\phi = 1/\eta$ | m·kg ⁻¹ ·s |
| Kinematic viscosity | ν | $\nu = \eta/\rho$ | m ² ·s ⁻¹ |
| Friction coefficient | $\mu, (f)$ | $F_{\text{frict}} = \mu F_{\text{norm}}$ | 1 |
| Power | P | $P = dW/dt$ | W |
| Sound energy flux | P, P_a | $P = dE/dt$ | W |
| Acoustic factors | | | |
| Reflection factor | ρ | $\rho = P_r/P_0$ | 1 |
| Acoustic absorption factor | $\alpha_a, (\alpha)$ | $\alpha_a = 1 - \rho$ | 1 |
| Transmission factor | τ | $\tau = P_{tr}/P_0$ | 1 |
| Dissipation factor | δ | $\delta = \alpha_a - \tau$ | 1 |

Electricity and Magnetism

| | | | |
|--|---------------------------|---|---------------------------------------|
| Quantity of electricity, electric charge | Q | | C |
| Charge density | ρ | $\rho = Q/V$ | C·m ⁻³ |
| Surface charge density | σ | $\sigma = Q/A$ | C·m ⁻² |
| Electric potential | V, ϕ | $V = dW/dQ$ | V, J·C ⁻¹ |
| Electric potential difference | $U, \Delta V, \Delta\phi$ | $U = V_2 - V_1$ | V |
| Electromotive force | E | $E = \int (F/Q) \cdot d\mathbf{s}$ | V |
| Electric field strength | \mathbf{E} | $\mathbf{E} = \mathbf{F}/Q = -\text{grad } V$ | V·m ⁻¹ |
| Electric flux | Ψ | $\Psi = \int \mathbf{D} \cdot d\mathbf{A}$ | C |
| Electric displacement | \mathbf{D} | $\mathbf{D} = \varepsilon\mathbf{E}$ | C·m ⁻² |
| Capacitance | C | $C = Q/U$ | F, C·V ⁻¹ |
| Permittivity | ε | $\mathbf{D} = \varepsilon\mathbf{E}$ | F·m ⁻¹ |
| Permittivity of vacuum | ε_0 | $\varepsilon_0 = \mu_0^{-1} \cdot c_0^{-2}$ | F·m ⁻¹ |
| Relative permittivity | ε_r | $\varepsilon_r = \varepsilon/\varepsilon_0$ | 1 |
| Dielectric polarization (dipole moment per volume) | \mathbf{P} | $\mathbf{P} = \mathbf{D} - \varepsilon_0\mathbf{E}$ | C·m ⁻² |
| Electric susceptibility | χ_e | $\chi_e = \varepsilon_r - 1$ | 1 |
| Electric dipole moment | p, μ | $\mathbf{p} = Q\mathbf{r}$ | C·m |
| Electric current | I | $I = dQ/dt$ | A |
| Electric current density | \mathbf{j}, \mathbf{J} | $I = \int \mathbf{j} \cdot d\mathbf{A}$ | A·m ⁻² |
| Magnetic flux density, magnetic induction | \mathbf{B} | $\mathbf{F} = Q\mathbf{v} \times \mathbf{B}$ | T |
| Magnetic flux | Φ | $\Phi = \int \mathbf{B} \cdot d\mathbf{A}$ | Wb |
| Magnetic field strength | \mathbf{H} | $\mathbf{B} = \mu\mathbf{H}$ | A·m ⁻¹ |
| Permeability | μ | $\mathbf{B} = \mu\mathbf{H}$ | N·A ⁻² , H·m ⁻¹ |
| Permeability of vacuum | μ_0 | | H·m ⁻¹ |
| Relative permeability | μ_r | $\mu_r = \mu/\mu_0$ | 1 |
| Magnetization (magnetic dipole moment per volume) | \mathbf{M} | $\mathbf{M} = \mathbf{B}/\mu_0 - \mathbf{H}$ | A·m ⁻¹ |
| Magnetic susceptibility | $\chi, \kappa, (\chi_m)$ | $\chi = \mu_r - 1$ | 1 |
| Molar magnetic susceptibility | χ_m | $\chi_m = V_m\chi$ | m ³ ·mol ⁻¹ |
| Magnetic dipole moment | \mathbf{m}, μ | $E_p = -\mathbf{m} \cdot \mathbf{B}$ | A·m ² , J·T ⁻¹ |
| Electrical resistance | R | $R = U/I$ | Ω |

| Name | Symbol | Definition | SI Unit |
|---------------------------------|--------------------------|---|-------------------|
| Conductance | G | $G = 1/R$ | S |
| Loss angle | δ | $\delta = (\pi/2) + \phi_T - \phi_U$ | 1, rad |
| Reactance | X | $X = (U/I) \sin \delta$ | Ω |
| Impedance (complex impedance) | Z | $Z = R + iX$ | Ω |
| Admittance (complex admittance) | Y | $Y = 1/Z$ | S |
| Susceptance | B | $Y = G + iB$ | S |
| Resistivity | ρ | $\rho = E/j$ | $\Omega \cdot m$ |
| Conductivity | κ, γ, σ | $\kappa = 1/\rho$ | $S \cdot m^{-1}$ |
| Self-inductance | L | $E = -L(dI/dt)$ | H |
| Mutual inductance | M, L_{12} | $E_1 = L_{12}(dI_2/dt)$ | H |
| Magnetic vector potential | \mathbf{A} | $\mathbf{B} = \nabla \times \mathbf{A}$ | $Wb \cdot m^{-1}$ |
| Poynting vector | \mathbf{S} | $\mathbf{S} = \mathbf{E} \times \mathbf{H}$ | $W \cdot m^{-2}$ |

Electromagnetic Radiation

| | | | |
|---|---------------------------------------|--|--------------------------------|
| Wavelength | λ | | m |
| Speed of light | | | |
| In vacuum | c_0 | | $m \cdot s^{-1}$ |
| In a medium | c | $c = c_0/n$ | $m \cdot s^{-1}$ |
| Wavenumber in vacuum | $\tilde{\nu}$ | $\tilde{\nu} = \nu / c_0 = 1 / n\lambda$ | m^{-1} |
| Wavenumber (in a medium) | σ | $\sigma = 1/\lambda$ | m^{-1} |
| Frequency | ν | $\nu = c/\lambda$ | Hz |
| Circular frequency, pulsance | ω | $\omega = 2\pi\nu$ | $s^{-1}, rad \cdot s^{-1}$ |
| Refractive index | n | $n = c_0/c$ | 1 |
| Planck constant | h | | J·s |
| Planck constant/ 2π | \hbar | $\hbar = h/2\pi$ | J·s |
| Radiant energy | Q, W | | J |
| Radiant energy density | ρ, w | $\rho = Q/V$ | $J \cdot m^{-3}$ |
| Spectral radiant energy density | | | |
| In terms of frequency | ρ_ν, w_ν | $\rho_\nu = d\rho/d\nu$ | $J \cdot m^{-3} \cdot Hz^{-1}$ |
| In terms of wavenumber | $\rho_{\tilde{\nu}}, w_{\tilde{\nu}}$ | $\rho_{\tilde{\nu}} = d\rho/d\tilde{\nu}$ | $J \cdot m^{-2}$ |
| In terms of wavelength | ρ_λ, w_λ | $\rho_\lambda = d\rho/d\lambda$ | $J \cdot m^{-4}$ |
| Einstein transition probabilities | | | |
| Spontaneous emission | A_{nm} | $dN_n/dt = -A_{nm}N_n$ | s^{-1} |
| Stimulated emission | B_{nm} | $dN_n/dt = -\rho_\nu(\tilde{\nu}_{nm}) \times B_{nm}N_n$ | $s \cdot kg^{-1}$ |
| Stimulated absorption | B_{mn} | $dN_n/dt = \rho_\nu(\tilde{\nu}_{nm})B_{mn}N_m$ | $s \cdot kg^{-1}$ |
| Radiant power, radiant energy per time | Φ, P | $\Phi = dQ/dt$ | W |
| Radiant intensity | I | $I = d\Phi/d\Omega$ | $W \cdot sr^{-1}$ |
| Radiant exitance (emitted radiant flux) | M | $M = d\Phi/dA_{source}$ | $W \cdot m^{-2}$ |
| Irradiance (radiant flux received) | $E, (I)$ | $E = d\Phi/dA$ | $W \cdot m^{-2}$ |
| Emittance | ε | $\varepsilon = M/M_{bb}$ | 1 |
| Stefan–Boltzmann constant | σ | $M_{bb} = \sigma T^4$ | $W \cdot m^{-2} \cdot K^{-4}$ |
| First radiation constant | c_1 | $c_1 = 2\pi^5hc_0^2/15$ | $W \cdot m^2$ |
| Second radiation constant | c_2 | $c_2 = hc_0/k$ | K·m |
| Transmittance, transmission factor | τ, T | $\tau = \Phi_{tr}/\Phi_0$ | 1 |
| Absorptance, absorption factor | α | $\alpha = \Phi_{abs}/\Phi_0$ | 1 |
| Reflectance, reflection factor | ρ | $\rho = \Phi_{refl}/\Phi_0$ | 1 |
| (Decadic) absorbance | A | $A = \lg(1 - \alpha_i)$ | 1 |
| Napierian absorbance | B | $B = \ln(1 - \alpha_i)$ | 1 |
| Absorption coefficient | | | |
| (Linear) decadic | a, K | $a = A/l$ | m^{-1} |
| (Linear) napierian | α | $\alpha = B/l$ | m^{-1} |
| Molar (decadic) | ε | $\varepsilon = a/c = A/cl$ | $m^2 \cdot mol^{-1}$ |
| Molar napierian | κ | $\kappa = \alpha/c = B/cl$ | $m^2 \cdot mol^{-1}$ |
| Absorption index | k | $k = \alpha / 4\pi\tilde{\nu}$ | 1 |
| Complex refractive index | \hat{n} | $\hat{n} = n + ik$ | 1 |
| Molar refraction | R, R_m | $R = \frac{(n^2 - 1)}{(n^2 + 2)} V_m$ | $m^3 \cdot mol^{-1}$ |
| Angle of optical rotation | α | | 1, rad |

| Name | Symbol | Definition | SI Unit |
|--|---|---|--|
| Solid State | | | |
| Lattice vector | \mathbf{R}, \mathbf{R}_0 | | m |
| Fundamental translation vectors for the crystal lattice | $\mathbf{a}_1; \mathbf{a}_2; \mathbf{a}_3,$ $\mathbf{a}; \mathbf{b}; \mathbf{c}$ | $\mathbf{R} = n_1\mathbf{a}_1 + n_2\mathbf{a}_2 + n_3\mathbf{a}_3$ | m |
| (Circular) reciprocal lattice vector | \mathbf{G} | $\mathbf{G} \cdot \mathbf{R} = 2\pi m$ | m^{-1} |
| (Circular) fundamental Translation vectors for the reciprocal lattice | $\mathbf{b}_1; \mathbf{b}_2; \mathbf{b}_3,$ $\mathbf{a}^*; \mathbf{b}^*; \mathbf{c}^*$ | $\mathbf{a}_i \cdot \mathbf{b}_k = 2\pi\delta_{ik}$ | m^{-1} |
| Lattice plane spacing | d | | m |
| Bragg angle | θ | $n\lambda = 2d \sin \theta$ | 1,rad |
| Order of reflection | n | | 1 |
| Order parameters | | | |
| Short range | σ | | 1 |
| Long range | s | | 1 |
| Burgers vector | b | | m |
| Particle position vector | r, \mathbf{R}_j | | m |
| Equilibrium position vector of an ion | \mathbf{R}_0 | | m |
| Displacement vector of an ion | \mathbf{u} | $\mathbf{u} = \mathbf{R} - \mathbf{R}_0$ | m |

A.6 Elementary Algebra and Geometry

Fundamental Properties (Real Numbers)

| | |
|---|------------------------------------|
| $a + b = b + a$ | Commutative law for addition |
| $(a + b) + c = a + (b + c)$ | Associative law for addition |
| $a + 0 = 0 + a$ | Identity law for addition |
| $a + (-a) = (-a) + a = 0$ | Inverse law for addition |
| $a(bc) = (ab)c$ | Associative law for multiplication |
| $a\left(\frac{1}{a}\right) = \left(\frac{1}{a}\right)a = 1, a \neq 0$ | Inverse law for multiplication |
| $(a)(1) = (1)(a) = a$ | Identity law for multiplication |
| $ab = ba$ | Commutative law for multiplication |
| $a(b + c) = ab + ac$ | Distributive law |
| Division by zero is not defined. | |

Exponents

For integers m and n ,

$$a^n a^m = a^{n+m}$$

$$a^n / a^m = a^{n-m}$$

$$(a^n)^m = a^{nm}$$

$$(ab)^m = a^m b^m$$

$$(a/b)^m = a^m / b^m$$

Fractional Exponents

$$a^{p/q} = (a^{1/q})^p$$

where $a^{1/q}$ is the positive q th root of a if $a > 0$ and the negative q th root of a if a is negative and q is odd. Accordingly, the five rules of exponents given above (for integers) are also valid if m and n are fractions, provided a and b are positive.

Irrational Exponents

If an exponent is irrational (e.g., $\sqrt{2}$), the quantity, such as $a^{\sqrt{2}}$, is the limit of the sequence $a^{1.4}, a^{1.41}, a^{1.414}, \dots$

Operations with Zero

$$0^m = 0 \quad a^0 = 1$$

Logarithms

If x , y , and b are positive and $b \neq 1$,

$$\log_b(xy) = \log_b x + \log_b y$$

$$\log_b(x/y) = \log_b x - \log_b y$$

$$\log_b x^p = p \log_b x$$

$$\log_b(1/x) = -\log_b x$$

$$\log_b b = 1$$

$$\log_b 1 = 0 \quad \text{Note: } b^{\log_b x} = x$$

Change of Base ($a \neq 1$)

$$\log_b x = \log_a x \log_a b$$

Factorials

The factorial of a positive integer n is the product of all the positive integers less than or equal to the integer n and is denoted $n!$. Thus,

$$n! = 1 \cdot 2 \cdot 3 \cdot \dots \cdot n$$

Factorial 0 is defined: $0! = 1$.

Stirling's Approximation

$$\lim_{n \rightarrow \infty} (n/e)^n \sqrt{2\pi n} = n!$$

Binomial Theorem

For positive integer n

$$(x + y)^n = x^n + nx^{n-1}y + \frac{n(n-1)}{2!}x^{n-2}y^2 + \frac{n(n-1)(n-2)}{3!}x^{n-3}y^3 + \dots + nxy^{n-1} + y^n$$

Factors and Expansion

$$(a + b)^2 = a^2 + 2ab + b^2$$

$$(a - b)^2 = a^2 - 2ab + b^2$$

$$(a + b)^3 = a^3 + 3a^2b + 3ab^2 + b^3$$

$$(a - b)^3 = a^3 - 3a^2b + 3ab^2 - b^3$$

$$(a^2 - b^2) = (a - b)(a + b)$$

$$(a^3 - b^3) = (a - b)(a^2 + ab + b^2)$$

$$(a^3 + b^3) = (a + b)(a^2 - ab + b^2)$$

Progression

An *arithmetic progression* is a sequence in which the difference between any term and the preceding term is a constant (d):

$$a, a + d, a + 2d, \dots, a + (n - 1)d$$

If the last term is denoted $l [= a + (n - 1)d]$, then the sum is

$$s = \frac{n}{2}(a + l)$$

A *geometric progression* is a sequence in which the ratio of any term to the preceding term is a constant r . Thus, for n terms,

$$a, ar, ar^2, \dots, ar^{n-1}$$

The sum is

$$S = \frac{a - ar^n}{1 - r}$$

Complex Numbers

A complex number is an ordered pair of real numbers (a, b) .

Equality: $(a, b) = (c, d)$ if and only if $a = c$ and $b = d$

Addition: $(a, b) + (c, d) = (a + c, b + d)$

Multiplication: $(a, b)(c, d) = (ac - bd, ad + bc)$

The first element (a, b) is called the *real* part, the second the *imaginary* part. An alternative notation for (a, b) is $a + bi$, where $i^2 = (-1, 0)$, and $i = (0, 1)$ or $0 + 1i$ is written for this complex number as a convenience. With this understanding, i behaves as a number, that is, $(2 - 3i)(4 + i) = 8 - 12i + 2i - 3i^2 = 11 - 10i$. The conjugate of $a + bi$ is $a - bi$, and the product of a complex number and its conjugate is $a^2 + b^2$. Thus, *quotients* are computed by multiplying numerator and denominator by the conjugate of the denominator, as illustrated below:

$$\frac{2 + 3i}{4 + 2i} = \frac{(2 + 3i)(4 - 2i)}{(4 + 2i)(4 - 2i)} = \frac{14 + 8i}{20} = \frac{7 + 4i}{10}$$

Polar Form

The complex number $x + iy$ may be represented by a plane vector with components x and y :

$$x + iy = r(\cos \theta + i \sin \theta)$$

(See Figure A.1.) Then, given two complex numbers $z_1 = r_1(\cos \theta_1 + i \sin \theta_1)$ and $z_2 = r_2(\cos \theta_2 + i \sin \theta_2)$, the product and quotient are:

FIGURE A.1 Polar form of complex number.

Product: $z_1 z_2 = r_1 r_2 [\cos(\theta_1 + \theta_2) + i \sin(\theta_1 + \theta_2)]$

Quotient: $z_1 / z_2 = (r_1 / r_2) [\cos(\theta_1 - \theta_2) + i \sin(\theta_1 - \theta_2)]$

Powers: $z^n = [r(\cos\theta + i \sin\theta)]^n = r^n [\cos n\theta + i \sin n\theta]$

$$z^{1/n} = [r(\cos\theta + i \sin\theta)]^{1/n}$$

Roots:

$$= r^{1/n} \left[\cos \frac{\theta + k \cdot 360}{n} + i \sin \frac{\theta + k \cdot 360}{n} \right] \quad k = 0, 1, 2, \dots, n-1$$

Permutations

A permutation is an ordered arrangement (sequence) of all or part of a set of objects. The number of permutations of n objects taken r at a time is

$$\begin{aligned} p(n, r) &= n(n-1)(n-2) \cdots (n-r+1) \\ &= \frac{n!}{(n-r)!} \end{aligned}$$

A permutation of positive integers is “even” or “odd” if the total number of inversions is an even integer or an odd integer, respectively. Inversions are counted relative to each integer j in the permutation by counting the number of integers that follow j and are less than j . These are summed to give the total number of inversions. For example, the permutation 4132 has four inversions: three relative to 4 and one relative to 3. This permutation is therefore even.

Combinations

A combination is a selection of one or more objects from among a set of objects regardless of order. The number of combinations of n different objects taken r at a time is

$$C(n, r) = \frac{P(n, r)}{r!} = \frac{n!}{r!(n-r)!}$$

Algebraic Equations

Quadratic

If $ax^2 + bx + c = 0$, and $a \neq 0$, then roots are

$$x = \frac{-b \pm \sqrt{b^2 - 4ac}}{2a}$$

Cubic

To solve $x^3 + bx^2 + cx + d = 0$, let $x = y - b/3$. Then the *reduced cubic* is obtained:

$$y^3 + py + q = 0$$

where $p = c - (1/3)b^2$ and $q = d - (1/3)bc + (2/27)b^3$. Solutions of the original cubic are then in terms of the reduced cubic roots y_1, y_2, y_3 :

$$x_1 = y_1 - (1/3)b \quad x_2 = y_2 - (1/3)b \quad x_3 = y_3 - (1/3)b$$

The three roots of the reduced cubic are

$$y_1 = (A)^{1/3} + (B)^{1/3}$$

$$y_2 = W(A)^{1/3} + W^2(B)^{1/3}$$

$$y_3 = W^2(A)^{1/3} + W(B)^{1/3}$$

where

$$A = -\frac{1}{2}q + \sqrt{\left(\frac{1}{27}p^3 + \frac{1}{4}q^2\right)}$$

$$B = -\frac{1}{2}q - \sqrt{\left(\frac{1}{27}p^3 + \frac{1}{4}q^2\right)}$$

$$W = \frac{-1 + i\sqrt{3}}{2}, \quad W^2 = \frac{-1 - i\sqrt{3}}{2}$$

When $(1/27)p^3 + (1/4)q^2$ is negative, A is complex; in this case A should be expressed in trigonometric form; $A = r(\cos \theta + i \sin \theta)$ where θ is a first or second quadrant angle, as q is negative or positive. The three roots of the reduced cubic are

$$y_1 = 2(r)^{1/3} \cos(\theta/3)$$

$$y_2 = 2(r)^{1/3} \cos\left(\frac{\theta}{3} + 120^\circ\right)$$

$$y_3 = 2(r)^{1/3} \cos\left(\frac{\theta}{3} + 240^\circ\right)$$

Geometry

Figure A.2 to A.12 are a collection of common geometric figures. Area (A), volume (V), and other measurable features are indicated.

FIGURE A.2 Rectangle. $A = bh$.

FIGURE A.3 Parallelogram. $A = bh$.

FIGURE A.4 Triangle. $A = \frac{1}{2}bh$.

FIGURE A.5 Trapezoid. $A = \frac{1}{2}(a+b)h$.

FIGURE A.6 Circle. $A = \pi R^2$; circumference = $2\pi R$; arc length $S = R\theta$ (θ in radians).

FIGURE A.7 Sector of circle. $A_{\text{sector}} = \frac{1}{2}R^2\theta$; $A_{\text{segment}} = \frac{1}{2}R^2(\theta - \sin\theta)$.

FIGURE A.8 Regular polygon of n sides. $A = (n/4)b^2\cot(\pi/n)$; $R = (b/2)\csc(\pi/n)$.

FIGURE A.9 Right circular cylinder. $V = \pi R^2 h$; lateral surface area = $2\pi R h$.

FIGURE A.10 Cylinder (or prism) with parallel bases. $V = Ah$.

FIGURE A.11 Right circular cone. $V = \frac{1}{3}\pi R^2 h$; lateral surface area = $\pi R l = \pi R \sqrt{R^2 + h^2}$.

FIGURE A.12 Sphere. $V = \frac{4}{3}\pi R^3$; surface area = $4\pi R^2$.

A.7 Table of Derivatives

In the following table, a and n are constants, e is the base of the natural logarithms, and u and v denote functions of x .

1. $\frac{d}{dx}(a) = 0$

2. $\frac{d}{dx}(x) = 1$

3. $\frac{d}{dx}(au) = a \frac{du}{dx}$

4. $\frac{d}{dx}(u+v) = \frac{du}{dx} + \frac{dv}{dx}$

5. $\frac{d}{dx}(uv) = u \frac{dv}{dx} + v \frac{du}{dx}$
6. $\frac{d}{dx}(u/v) = \frac{v \frac{du}{dx} - u \frac{dv}{dx}}{v^2}$
7. $\frac{d}{dx}(u^n) = nu^{n-1} \frac{du}{dx}$
8. $\frac{d}{dx}e^u = e^u \frac{du}{dx}$
9. $\frac{d}{dx}a^u = (\log_e a)a^u \frac{du}{dx}$
10. $\frac{d}{dx}\log_e u = (1/u) \frac{du}{dx}$
11. $\frac{d}{dx}\log_a u = (\log_a e)(1/u) \frac{du}{dx}$
12. $\frac{d}{dx}u^v = v u^{v-1} \frac{du}{dx} + u^v (\log_e u) \frac{dv}{dx}$
13. $\frac{d}{dx}\sin u = \cos u \frac{du}{dx}$
14. $\frac{d}{dx}\cos u = -\sin u \frac{du}{dx}$
15. $\frac{d}{dx}\tan u = \sec^2 u \frac{du}{dx}$
16. $\frac{d}{dx}\csc u = -\csc^2 u \frac{du}{dx}$
17. $\frac{d}{dx}\sec u = \sec u \tan u \frac{du}{dx}$
18. $\frac{d}{dx}\csc u = -\csc u \cot u \frac{du}{dx}$
19. $\frac{d}{dx}\sin^{-1} u = \frac{1}{\sqrt{1-u^2}} \frac{du}{dx}, \quad (-\frac{1}{2}\pi \leq \sin^{-1} u \leq \frac{1}{2}\pi)$
20. $\frac{d}{dx}\cos^{-1} u = \frac{-1}{\sqrt{1-u^2}} \frac{du}{dx}, \quad (0 \leq \cos^{-1} u \leq \pi)$
21. $\frac{d}{dx}\tan^{-1} u = \frac{1}{1+u^2} \frac{du}{dx}$
22. $\frac{d}{dx}\cot^{-1} u = \frac{-1}{1+u^2} \frac{du}{dx}$
23. $\frac{d}{dx}\sec^{-1} u = \frac{1}{u\sqrt{u^2-1}} \frac{du}{dx},$
 $\left(-\pi \leq \sec^{-1} u < -\frac{1}{2}\pi; 0 \leq \sec^{-1} u < \frac{1}{2}\pi\right)$
24. $\frac{d}{dx}\csc^{-1} u = \frac{1}{u\sqrt{u^2-1}} \frac{du}{dx},$
 $\left(-\pi < \csc^{-1} u \leq -\frac{1}{2}\pi; 0 < \csc^{-1} u \leq \frac{1}{2}\pi\right)$
25. $\frac{d}{dx}\sinh u = \cosh u \frac{du}{dx}$
26. $\frac{d}{dx}\cosh u = \sinh u \frac{du}{dx}$
27. $\frac{d}{dx}\tanh u = \operatorname{sech}^2 u \frac{du}{dx}$
28. $\frac{d}{dx}\operatorname{ctnh} u = -\operatorname{csch}^2 u \frac{du}{dx}$
29. $\frac{d}{dx}\operatorname{sech} u = -\operatorname{sech} u \tanh u \frac{du}{dx}$
30. $\frac{d}{dx}\operatorname{csch} u = -\operatorname{csch} u \operatorname{ctnh} u \frac{du}{dx}$
31. $\frac{d}{dx}\sinh^{-1} u = \frac{1}{\sqrt{u^2+1}} \frac{du}{dx}$
32. $\frac{d}{dx}\cosh^{-1} u = \frac{1}{\sqrt{u^2-1}} \frac{du}{dx}$
33. $\frac{d}{dx}\tanh^{-1} u = \frac{1}{1-u^2} \frac{du}{dx}$
34. $\frac{d}{dx}\operatorname{ctnh}^{-1} u = \frac{-1}{u^2-1} \frac{du}{dx}$
35. $\frac{d}{dx}\operatorname{sech}^{-1} u = \frac{-1}{u\sqrt{1-u^2}} \frac{du}{dx}$
36. $\frac{d}{dx}\operatorname{csch}^{-1} u = \frac{-1}{u\sqrt{u^2+1}} \frac{du}{dx}$

Additional Relations with Derivatives

$$\frac{d}{dx} \int_a^t f(x) dx = f(t) \qquad \frac{d}{dt} \int_t^a f(x) dx = -f(t)$$

If $x = f(y)$, then $\frac{dy}{dx} = \frac{1}{dx/dy}$

If $y = f(u)$ and $u = g(x)$, then $\frac{dy}{dx} = \frac{dy}{du} \cdot \frac{du}{dx}$ (chain rule)

If $x = f(t)$ and $y = g(t)$, then $\frac{dy}{dx} = \frac{g'(t)}{f'(t)}$, and $\frac{d^2y}{dx^2} = \frac{f'(t)g''(t) - g'(t)f''(t)}{[f'(t)]^3}$

(Note: Exponent in denominator is 3.)

A.8 Integrals

Elementary Forms

- $\int a \, dx = ax$
- $\int a \cdot f(x) \, dx = a \int f(x) \, dx$
- $\int \phi(y) \, dx = \int \frac{\phi(y)}{y'} \, dy$, where $y' = \frac{dy}{dx}$
- $\int (u + v) \, dx = \int u \, dx + \int v \, dx$, where u and v are any functions of x
- $\int u \, dv = u \int v \, du = uv - \int v \, du$
- $\int u \frac{dv}{dx} \, dx = uv - \int v \frac{du}{dx} \, dx$
- $\int x^n \, dx = \frac{x^{n+1}}{n+1}$, except $n = -1$
- $\int \frac{f'(x) \, dx}{f(x)} = \log f(x)$, $[df(x) = f'(x) \, dx]$
- $\int \frac{dx}{x} = \log x$
- $\int \frac{f'(x) \, dx}{2\sqrt{f(x)}} = \sqrt{f(x)}$, $[df(x) = f'(x) \, dx]$
- $\int e^x \, dx = e^x$
- $\int e^{ax} \, dx = e^{ax} / a$
- $\int b^{ax} \, dx = \frac{b^{ax}}{a \log b}$, ($b > 0$)
- $\int \log x \, dx = x \log x - x$
- $\int a^x \log a \, dx = a^x$, ($a > 0$)
- $\int \frac{dx}{a^2 + x^2} = \frac{1}{a} \tan^{-1} \frac{x}{a}$

$$17. \int \frac{dx}{a^2 - x^2} = \begin{cases} \frac{1}{a} \tanh^{-1} \frac{x}{a} \\ \text{or} \\ \frac{1}{2a} \log \frac{a+x}{a-x}, (a^2 > x^2) \end{cases}$$

$$18. \int \frac{dx}{x^2 - a^2} = \begin{cases} -\frac{1}{a} \operatorname{ctnh}^{-1} \frac{x}{a} \\ \text{or} \\ \frac{1}{2a} \log \frac{x-a}{x+a}, (x^2 > a^2) \end{cases}$$

$$19. \int \frac{dx}{\sqrt{a^2 - x^2}} = \begin{cases} \sin^{-1} \frac{x}{|a|} \\ \text{or} \\ -\cos^{-1} \frac{x}{|a|}, (a^2 > x^2) \end{cases}$$

$$20. \int \frac{dx}{\sqrt{x^2 \pm a^2}} = \log(x + \sqrt{x^2 \pm a^2})$$

$$21. \int \frac{dx}{x\sqrt{x^2 - a^2}} = \frac{1}{|a|} \sec^{-1} \frac{x}{a}$$

$$22. \int \frac{dx}{x\sqrt{a^2 \pm x^2}} = -\frac{1}{a} \log \left(\frac{a + \sqrt{a^2 \pm x^2}}{x} \right)$$

Forms Containing $(a + bx)$

For forms containing $a + bx$, but not listed in the table, the substitution $u = (a + bx)/x$ may prove helpful.

$$23. \int (a + bx)^n dx = \frac{(a + bx)^{n+1}}{(n+1)b}, (n \neq -1)$$

$$24. \int x(a + bx)^n dx = \frac{1}{b^2(n+2)}(a + bx)^{n+2} - \frac{a}{b^2(n+1)}(a + bx)^{n+1}, (n \neq -1, -2)$$

$$25. \int x^2(a + bx)^n dx = \frac{1}{b^3} \left[\frac{(a + bx)^{n+3}}{n+3} - 2a \frac{(a + bx)^{n+2}}{n+2} + a^2 \frac{(a + bx)^{n+1}}{n+1} \right]$$

$$26. \int x^m(a + bx)^n dx = \begin{cases} \frac{x^{m+1}(a + bx)^n}{m+n+1} + \frac{an}{m+n+1} \int x^m(a + bx)^{n-1} dx \\ \text{or} \\ \frac{1}{a(n+1)} \left[-x^{m+1}(a + bx)^{n+1} + (m+n+2) \int x^m(a + bx)^{n+1} dx \right] \\ \text{or} \\ \frac{1}{b(m+n+1)} \left[x^m(a + bx)^{n+1} - ma \int x^{m-1}(a + bx)^n dx \right] \end{cases}$$

$$27. \int \frac{dx}{a + bx} = \frac{1}{b} \log(a + bx)$$

$$28. \int \frac{dx}{(a + bx)^2} = -\frac{1}{b(a + bx)}$$

$$29. \int \frac{dx}{(a+bx)^3} = -\frac{1}{2b(a+bx)^2}$$

$$30. \int \frac{x \, bx}{a+bx} = \begin{cases} \frac{1}{b^2}[a+bx - a \log(a+bx)x] \\ \text{or} \\ \frac{x}{b} - \frac{a}{b^2} \log(a+bx) \end{cases}$$

$$31. \int \frac{xbx}{(a+bx)^2} = \frac{1}{b^2} \left[\log(a+bx) + \frac{a}{a+bx} \right]$$

$$32. \int \frac{xdx}{(a+bx)^n} = \frac{1}{b^2} \left[\frac{-1}{(n-2)(a+bx)^{n-1}} + \frac{a}{(n-1)(a+bx)^{n-1}} \right] \quad n \neq 1, 2$$

$$33. \int \frac{x^2 dx}{a+bx} = \frac{1}{b^3} \left[\frac{1}{2}(a+bx)^2 - 2a(a+bx) + a^2 \log(a+bx) \right]$$

$$34. \int \frac{x^2 dx}{(a+bx)^2} = \frac{1}{b^3} \left[a+bx - 2a \log(a+bx) - \frac{a^2}{a+bx} \right]$$

$$35. \int \frac{x^2 dx}{(a+bx)^3} = \frac{1}{b^3} \left[\log(a+bx) + \frac{2a}{a+bx} - \frac{a^2}{2(a+bx)^3} \right]$$

$$36. \int \frac{x^2 dx}{(a+bx)^n} = \frac{1}{b^3} \left[\frac{-1}{(n-3)(a+bx)^{n-3}} + \frac{2a}{(n-2)(a+bx)^{n-2}} - \frac{a^2}{(n-1)(a+bx)^{n-1}} \right] \quad n \neq 1, 2, 3$$

$$37. \int \frac{dx}{x(a+bx)} = -\frac{1}{a} \log \frac{a+bx}{x}$$

$$38. \int \frac{dx}{x(a+bx)^2} = \frac{1}{a(a+bx)} - \frac{1}{a^2} \log \frac{a+bx}{x}$$

$$39. \int \frac{dx}{x(a+bx)^3} = \frac{1}{a^3} \left[\frac{1}{2} \left(\frac{2a+bx}{a+bx} \right)^2 + \log \frac{x}{a+bx} \right]$$

$$40. \int \frac{dx}{x^2(a+bx)} = -\frac{1}{ax} + \frac{b}{a^2} \log \frac{a+bx}{x}$$

$$41. \int \frac{dx}{x^3(a+bx)} = \frac{2bx-a}{2a^2x^2} + \frac{b^2}{a^3} \log \frac{x}{a+bx}$$

$$42. \int \frac{dx}{x^2(a+bx)^2} = -\frac{a+2bx}{a^2x(a+bx)} + \frac{2b}{a^3} \log \frac{a+bx}{x}$$

A.9 The Fourier Transforms

For a piecewise continuous function $F(x)$ over a finite interval $0 \leq x \leq \pi$, the *finite Fourier cosine transform* of $F(x)$ is

$$f_c(n) = \int_0^\pi f(x) \cos nx \, dx \quad (n = 0, 1, 2, \dots) \quad (\text{A.1})$$

If x ranges over the interval $0 \leq x \leq L$, the substitution $x' = \pi x/L$ allows the use of this definition also. The inverse transform is written

$$\bar{F}(x) = \frac{1}{\pi} f_c(0) + \frac{2}{\pi} \sum_{n=1}^{\infty} f_c(n) \cos nx \quad (0 < x < \pi) \quad (\text{A.2})$$

where $\bar{F}(x) = [F(x+0) + F(x-0)]/2$. We observe that $\bar{F}(x) = F(x)$ at points of continuity. The formula

$$\begin{aligned} f_c^{(2)}(n) &= \int_0^{\pi} F''(x) \cos nx \, dx \\ &= -n^2 f_c(n) - F'(0) + (-1)^n F'(\pi) \end{aligned} \quad (\text{A.3})$$

makes the finite Fourier cosine transform useful in certain boundary value problems.

Analogously, the *finite Fourier sine transform* of $F(x)$ is

$$f_s(n) = \int_0^{\pi} F(x) \sin nx \, dx \quad (n = 1, 2, 3, \dots) \quad (\text{A.4})$$

and

$$\bar{F}(x) = \frac{2}{\pi} \sum_{n=1}^{\infty} f_s(n) \sin nx \quad (0 < x < \pi) \quad (\text{A.5})$$

Corresponding to Eq. (A.6), we have

$$\begin{aligned} f_s^{(2)}(n) &= \int_0^{\pi} F''(x) \sin nx \, dx \\ &= -n^2 f_s(n) - nF(0) - n(-1)^n F(\pi) \end{aligned} \quad (\text{A.6})$$

Fourier Transforms

If $F(x)$ is defined for $x \geq 0$ and is piecewise continuous over any finite interval, and if

$$\int_0^{\infty} F(x) dx$$

is absolutely convergent, then

$$f_c(\alpha) = \sqrt{\frac{2}{\pi}} \int_0^{\infty} f(x) \cos(\alpha x) dx \quad (\text{A.7})$$

is the *Fourier cosine transform* of $F(x)$. Furthermore,

$$\bar{F}(x) = \sqrt{\frac{2}{\pi}} \int_0^{\infty} f_c(\alpha) \cos(\alpha x) d\alpha \quad (\text{A.8})$$

If $\lim_{x \rightarrow \infty} d^n F / dx^n = 0$, an important property of the Fourier cosine transform,

$$f_c^{(2r)}(\alpha) = \sqrt{\frac{2}{\pi}} \int_0^{\infty} \left(\frac{d^{2r}F}{dx^{2r}} \right) \cos(\alpha x) dx \quad (\text{A.9})$$

where $\lim_{x \rightarrow 0} d^r F / dx^r = a_r$, makes it useful in the solution of many problems.

Under the same conditions,

$$f_s(\alpha) = \sqrt{\frac{2}{\pi}} \int_0^{\infty} F(x) \sin(\alpha x) dx \quad (\text{A.10})$$

defines the *Fourier sine transform* of $F(x)$, and

$$\bar{F}(x) = \sqrt{\frac{2}{\pi}} \int_0^{\infty} f_s(\alpha) \sin(\alpha x) d\alpha \quad (\text{A.11})$$

Corresponding to Eq. (A.9) we have

$$\begin{aligned} f_s^{(2r)}(\alpha) &= \sqrt{\frac{2}{\pi}} \int_0^{\infty} \frac{d^{2r}F}{dx^{2r}} \sin(\alpha x) dx \\ &= -\sqrt{\frac{2}{\pi}} \sum_{n=1}^r (-1)^n \alpha^{2n-1} a_{2r-2n} + (-1)^{r-1} \alpha^{2r} f_s(\alpha) \end{aligned} \quad (\text{A.12})$$

Similarly, if $F(x)$ is defined for $-\infty < x < \infty$, and if $\int_{-\infty}^{\infty} F(x) dx$ is absolutely convergent, then

$$f(\alpha) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} F(x) e^{i\alpha x} dx \quad (\text{A.13})$$

is the *Fourier transform* of $F(x)$, and

$$\bar{F}(x) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} f(\alpha) e^{-i\alpha x} d\alpha \quad (\text{A.14})$$

Also, if

$$\lim_{|x| \rightarrow \infty} \left| \frac{d^n F}{dx^n} \right| = 0 \quad (n = 1, 2, \dots, r-1)$$

then

$$f^{(r)}(\alpha) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} F^{(r)}(x) e^{i\alpha x} dx = (-i\alpha)^r f(\alpha) \quad (\text{A.15})$$

A.12 Table of Differential Equations

| Equation | Solution |
|--------------------------------|---|
| 1. $y' = \frac{dy}{dx} = f(x)$ | $y = \int f(x)dx + c$ |
| 2. $y' + p(x)y = q(x)$ | $y = \exp\left[-\int p(x)dx\right]\left\{c + \int \exp\left[\int p(x)dx\right]q(x)dx\right\}$ |

Equation

Solution

3. $y' + p(x)y = q(x)y^\alpha$
 $\alpha \neq 0, \alpha \neq 1$ Set $z = y^{1-\alpha} \rightarrow z' + (1-\alpha)p(x)z = (1-\alpha)q(x)$ and use 2
4. $y' = f(x)g(y)$ Integrate $\frac{dy}{g(y)} = f(x)dx$ (separable)
5. $\frac{dy}{dx} = f(x/y)$ Set $u = y/x \rightarrow u + x \frac{du}{dx} = f(u)$

$$\int \frac{1}{f(u)-u} du = \ln|x| + c$$
6. $y' = f\left(\frac{a_1x + b_1y + c_1}{a_2x + b_2y + c_2}\right)$ Set $x = X + \alpha, y = Y + \beta$
 Choose $\begin{cases} a_1\alpha + b_1\beta = -c_2 \\ a_2\alpha + b_2\beta = -c_2 \end{cases} \rightarrow Y' = f\left(\frac{a_1X + b_1Y}{a_2X + b_2Y}\right)$
 If $a_1b_2 - a_2b_1 \neq 0$, set $Y = Xu \rightarrow$ separable form

$$u + Xu' = f\left(\frac{a_1 + b_1u}{a_2 + b_2u}\right)$$

 If $a_1b_2 - a_2b_1 = 0$, set $u = a_1x + b_1y \rightarrow$

$$\frac{du}{dx} = a_1 + b_1f\left(\frac{u + c_1}{ku + c_2}\right)$$

$$a_2x + b_2y = k(a_1x + a_2y)$$

$$y = c_1 \cos ax + c_2 \sin ax$$
7. $y'' + a^2y = 0$ $y = c_1 e^{ax} + c_2 e^{-ax}$
8. $y'' - a^2y = 0$ Set $y = e^{-(a/2)x}u \rightarrow u'' + \left(b - \frac{a^2}{4}\right)u = 0$
9. $y'' + ay' + by = 0$ Set $y = e^{-1/2 \int a(x) dx} \rightarrow u'' + \left[b(x) - \frac{a^2}{4} - \frac{a'}{2}\right]u = 0$
10. $y'' + a(x)y' + b(x)y = 0$ i. If a is not an integer
 $y = c_1 J_a(x) + c_2 J_{-a}(x)$ (Bessel functions of first kind)
11. $x^2 y'' + xy' + (x^2 - a^2)y = 0$
 $a \geq 0$ (Bessel) ii. If a is an integer (say, n)
 $y = c_1 J_n(x) + c_2 Y_n(x)$ (Y_n is Bessel function of second kind)
12. $(1-x^2)y'' - 2xy' + a(a+1)y = 0$,
 a is a real (Legendre) $y(x) = c_1 P_a(x) + c_2 Q_a(x)$ (Legendre functions)
13. $y' + ay^2 = bx^n$ (integrable Riccati) a, b, n real Set $u' = ayu \rightarrow u'' - abx^n u = 0$ and use 14
14. $y'' - ax^{-1}y' + b^2x^\mu y = 0$ $y = x^p [c_1 J_\nu(kx^q) + c_2 Y_\nu(kx^q)]$
 where $p = (a+1)/2, \nu = (a+1)/(\mu+2), k = 2b/(\mu+2), q = (\mu+2)/2$
15. Item 13 shows that the Riccati equation is linearized by raising the order of the equation. The Riccati chain, which is linearizable by raising the order, is

$$u' = uy, \quad u'' = u[y' + y^2], \quad u''' = u[y'' + 3yy' + y^3],$$

$$u^{(iv)} = u[y''' + 4yy'' + 6y^2y' + 3(y')^2 + y^4], \dots$$

To use this consider the second-order equation $y'' + 3yy' + y^3 = f(x)$. The Riccati transformation $u' = yu$ transforms this equation to the linear form $u''' = uf(x)!$.
