as central receivers and, while close, they are not as commercially mature technologically as trough systems. In a power tower, two-axis tracking mirrors called heliostats reflect solar energy onto a thermal receiver that is located at the top of a tower in the center of the heliostat field. To maintain the sun's image on the centrally located receiver, each heliostat must track a position in the sky that is midway between the receiver and the sun. Power towers have been designed for different working fluids, including water/steam, sodium nitrate salts, and air. Each working fluid brings an associated set of design and operational issues; the two active tower design concepts in Europe and the U.S. utilize air and molten-nitrate salt as the working fluids. Both system designs incorporate thermal storage to increase the operating time of the plant, thereby allowing the solar energy to be collected when the sun shines, stored, and used to produce power when the sun is not shining. This feature, which allows power to be dispatched when needed, increases the “value” of the electricity generated with solar energy.

In the U. S., the choice of a molten-nitrate salt as the working fluid provides for high-temperature, low-pressure operation and thermal storage in the hot salt. The molten-salt approach uses cold salt (290°C) that is pumped from a cold storage tank, through the receiver where it is heated with 800 suns to 560°C. The hot salt is delivered to a hot salt storage tank. Electrical power is produced when hot salt is pumped from the hot tank and through a steam generator; the steam is then used to power a conventional Rankine turbine/generator. The salt, which has cooled, is returned to the cold tank. The optimal size for power towers is in the 100- to 300-megawatt range. Studies have estimated that power towers could operate at annual efficiencies of 15 to 18% and produce electrical power at a cost of \$.06 to \$.11 per kilowatt-hour. Advanced systems are focusing on reducing the cost of heliostats and on operational issues associated with plant operation and thermal storage.

Dish–Stirling Systems

Dish–Stirling systems track the sun and focus solar energy into a cavity receiver where it is absorbed and transferred to a heat engine/generator. [Figure 67.3](#) is a picture of a Dish–Stirling system. Although a Brayton engine has been tested on a dish and some companies are considering adapting microturbine technology to dish engine systems, kinematic Stirling engines are currently being used in all four Dish–Stirling systems under development today. Stirling engines are preferred for these systems because of their high efficiencies (thermal-to-mechanical efficiencies in excess of 40% have been reported), high power density (40 to 70 kW/liter for solar engines), and their potential for long-term, low-maintenance

FIGURE 67.3 Advanced dish development system (ADDs) on test at Sandia National Laboratories' National Solar Thermal Test Facility. (Photograph courtesy of Sandia National Laboratories)

operation. Dish–Stirling systems have demonstrated the highest efficiency of any large solar power technology, producing more than 3000 suns concentration, operating at temperatures in excess of 750°C, and at annual efficiencies of 23% solar-to-electric conversion. Dish–Stirling systems are modular, i.e., each system is a self-contained power generator, allowing their assembly into plants ranging in size from a few kilowatts to tens of megawatts. The near-term markets identified by the developers of these systems include remote power, water pumping, grid-connected power in developing countries, and end-of-line power conditioning applications.

The major issues being addressed by system developers are reliability, due to high-temperature, high-heat flux conditions, system availability, and cost. Current systems range in size from 10 to 25 kW, primarily because of the available engines. These systems are the least developed of the three concentrating solar power systems. Research and development is focusing on reliability improvement and solar concentrator cost reductions.

67.2 Photovoltaic Power Systems

Roger Messenger and Jerry Ventre

In 2002, worldwide shipments of photovoltaic (PV) modules passed the 500-megawatt mark as PV module shipments continued to grow at an annual rate near 25% [Maycock, 2002]. Another important milestone in the PV industry occurred in 2001. Of the 395 MW of PV installed during 2001, the capacity of grid-connected PV systems installed (204 MW) surpassed the capacity of stand-alone systems installed (191 MW). Improvements in all phases of deployment of PV power systems have contributed to the rapid acceptance of this clean electric power-producing technology.

The photovoltaic effect occurs when a photodiode is operated in the presence of incident light when connected to a load. Figure 67.4a shows the I-V characteristic of the photodiode. Note that the characteristic passes through the first, third, and fourth quadrants of the I-V plane. In the first and third quadrants, the device dissipates power supplied to the device from an external source. But in the fourth quadrant, the device generates power, since current leaves the positive terminal of the device. Photovoltaic cells are characterized by an open circuit voltage and a short circuit current, as shown in Figure 67.4b. Note that in Figure 67.4b, the current axis is inverted such that a positive current represents current leaving the device positive terminal. The short circuit current is directly proportional to the incident light intensity, while the open circuit voltage is proportional to the logarithm of the incident light intensity. Figure 67.4b shows that the cell also has a single point of operation where its output power is maximum. This point, labeled P_{max} , occurs at current, I_{mp} and voltage, V_{mp} . Since cells are relatively expensive, good system designs generally ensure that the cells operate as close as possible to their maximum power points.

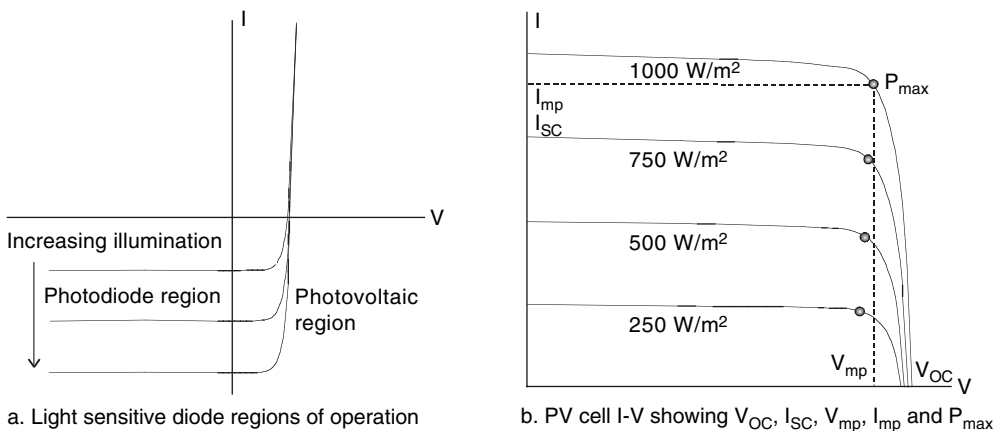

FIGURE 67.4 I-V characteristics of light sensitive diode.

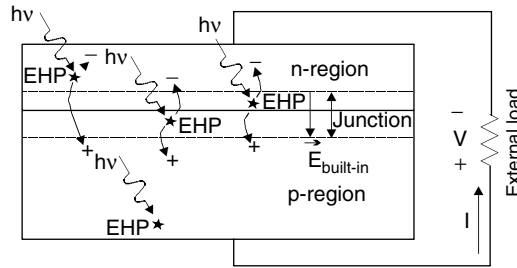

FIGURE 67.5 The illuminated pn junction showing the creation of electron-hole pairs.

The power generation mechanism that applies to conventional PV cells is shown in Figure 67.5. Photovoltaic power generation requires the presence of a pn junction. The pn junction is formed from a material, such as crystalline silicon, that has holes as the dominant charge carriers on the p-side and electrons as dominant carriers on the n-side. In simple terms, incident photons with sufficient energy interact with crystal lattice atoms in the PV cell to generate electron-hole pairs (EHP). If the EHP is generated sufficiently close to the pn junction, the negatively charged electron will be swept to the n-side of the junction and the positively charged hole will be swept to the p-side of the junction by the built-in electric field of the junction. The separation of the photon-generated charges creates a voltage across the cell, and if an electrical load is connected to the cell, the photon-generated current will flow through the load as shown in Figure 67.5.

Individual PV cells, with cell areas ranging from small to approximately 225 cm², generally produce only a few watts or less at about half a volt. Thus, to produce large amounts of power, cells must be connected in series-parallel configurations. Such a configuration is called a module. A typical crystalline silicon module will contain 36 cells and be capable of producing about 100 watts when operated at approximately 17 V and a current of approximately 6 A. Presently, the largest available module is a 300-watt unit that measures approximately 4 × 6 ft (see <http://www.asepv.com/aseprod.html> for more information). Although higher conversion efficiencies have been obtained, typical conversion efficiencies of commercially available crystalline silicon PV modules are in the 14% range, which means the modules are capable of generating approximately 140 W/m² of module surface area under standard test conditions. However, under some operating conditions where the module temperatures may reach 60°C, the module output power may be degraded by as much as 15%.

If the power of a module is still inadequate for the needs of the system, additional modules may be connected in series or in parallel until the desired power is obtained.

Stand-Alone PV Systems

Figure 67.6 shows a hierarchy of stand-alone PV systems. Stand-alone PV systems may be as simple as a module connected to an electrical load. The next level of complexity is to use a maximum power tracker or a linear current booster between module and load as a power matching device to ensure that the module delivers maximum power to the load at all times. These systems are common for pumping water and are the equivalent of a dc-dc matching transformer that matches source resistance to load resistance.

The next level of complexity involves the use of storage batteries to allow for the use of the PV-generated electricity when the sun is not shining. These systems also generally include an electronic controller to prevent battery overcharge and another controller to prevent overdischarge of the batteries. Many charge controllers perform both functions.

If loads are ac, an inverter can be incorporated into the system to convert the dc from the PV array to ac. A wide range of inverter designs are available with a wide range of output waveforms ranging from square waves to relatively well-approximated sine waves with minimal harmonic distortion. Most good inverters are capable of operating at conversion efficiencies greater than 90% over most of their output power range.

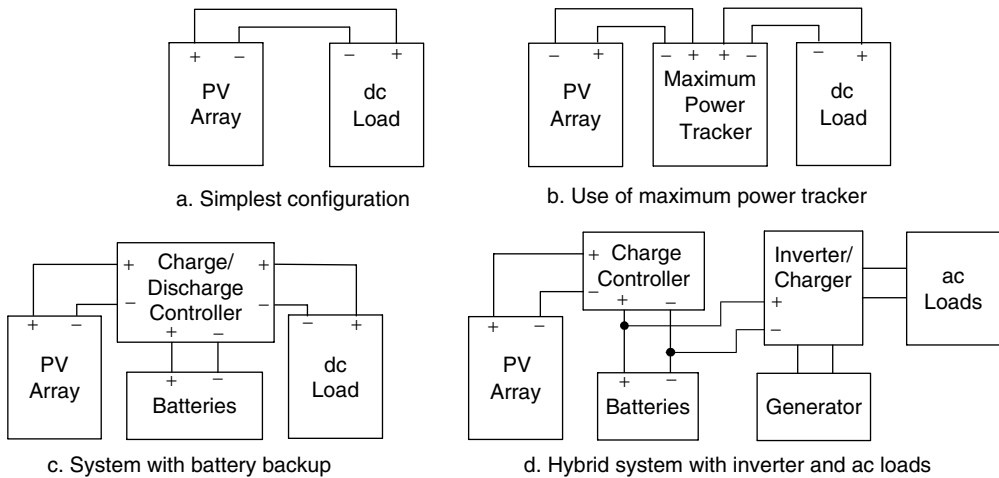

FIGURE 67.6 Four examples of stand-alone PV systems.

Available sunlight is measured in kWh/m²/day. However, since peak solar power, or “peak sun” is defined as 1 kW/m², the term peak sun hours (psh) is often used as an equivalent expression for available solar energy (i.e., 1 psh = 1 kWh/m²/day). A number of tabulations of psh are available [Sandia National Laboratories, 1995; see also www.nrel.gov and <http://solstice.crest.org/renewables/solrad/>]. In some regions, there is a large difference in seasonal available sunlight. In these regions with large seasonal differences in psh, it often makes sense to back up the solar electrical production with a fossil-fueled or wind generator. When more than one source of electricity is incorporated in a stand-alone system, the system is called a hybrid system. Elegant inverter designs incorporate circuitry for starting a generator if the PV system battery voltage drops too low.

Grid-Connected PV Systems

Grid-connected, or utility interactive, PV systems connect the output of the PV inverter directly to the utility grid and are thus capable of supplying power to the utility grid. An inverter operating in the utility interactive mode must be capable of disconnecting from the utility in the event of a utility failure. Elegant control mechanisms have been developed that enable the inverter to detect either an out-of-frequency-range or an out-of-voltage-range utility event. In essence, the output of the inverter monitors the utility voltage and delivers power to the grid as a current source rather than as a voltage source. Since the inverters are microprocessor controlled, they are capable of monitoring the grid in intervals separated by less than a millisecond, so it is possible for the inverter to keep the phase of the injected current very close to the phase of the utility voltage. Most inverter operating power factors are close to unity.

The simplest utility-interactive PV system connects the PV array to the inverter and connects the inverter output to the utility grid. It is also possible to incorporate battery backup into a utility-interactive PV system so that in the event of loss of the grid, the inverter will be able to power emergency loads. The emergency loads are connected to a separate emergency distribution panel so the inverter can still disconnect from the utility if the utility fails but then instantaneously switch from current source mode to voltage source mode to supply the emergency loads. [Figure 67.7](#) shows the two types of utility interactive systems.

Defining Terms

Grid-connected PV systems — Photovoltaic systems that interact with the utility grid, using the utility grid as a destination for excess electricity generated by the PV system or as a source of additional electricity needed to supply loads that exceed the PV system capacity.

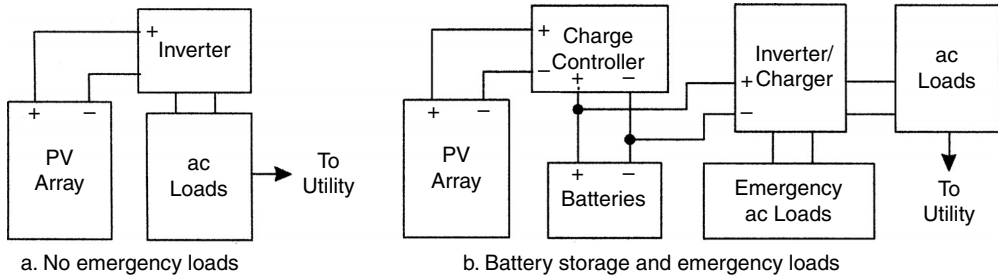

FIGURE 67.7 Utility interactive PV systems.

Heliostats — A system of mirrors that are controlled to reflect sunlight onto a power tower.

Photovoltaic cells — Cells made of various materials that are capable of converting light directly into electricity.

Photovoltaic systems — Systems that incorporate series and parallel combinations of photovoltaic cells along with power conditioning equipment to produce high levels of dc or ac power.

Power tower — A central receiving station upon which the sun is reflected by a system of mirrors to produce solar thermal electricity.

Solar thermal electric — The process of using the sun to heat a material that can be used to generate steam to drive a turbine to generate electricity.

Stand-alone PV systems — Photovoltaic systems that operate independently of a utility grid.

Trough electric systems — A system of parabolic troughs in which a liquid is passed through the focal point for superheating to produce solar thermal electricity.

Alan A. Kornhauser

*Virginia Polytechnic Institute and
State University*

An internal combustion (i.c.) engine is a heat engine in which the thermal energy comes from a chemical reaction within the working fluid. In external combustion engines, such as steam engines, heat is transferred to the working fluid through a solid wall and rejected to the environment through another solid wall. In i.c. engines, heat is released by a chemical reaction in the working fluid and rejected by exhausting the working fluid to the environment.

Internal combustion engines have two intrinsic advantages over other engine types:

1. They require no heat exchangers (except for auxiliary cooling). Thus, weight, volume, cost, and complexity are reduced.
2. They require no high-temperature heat transfer through walls. Thus, the maximum temperature of the working fluid can exceed maximum allowable wall material temperature.

They also have some intrinsic disadvantages:

1. Practically, working fluids are limited to air and products of combustion.
2. Nonfuel heat sources (waste heat, solar, nuclear) cannot be used.
3. There is little flexibility in combustion conditions because they are largely set by engine requirements. This can make low-emissions combustion hard to attain.

The advantages far outweigh the disadvantages. I.c. engines comprise more individual units and more rated power than all other types of heat engines combined.

FIGURE 68.1 Operating cycle for a four-stroke i.c. engine.

According to the definition given above, i.c. engines include reciprocating types, rotary (Wankel) types, and gas turbines. In customary usage, however, the title “internal combustion” is used only for the first two of these three types. A more proper designation might be “positive displacement internal combustion” engines. These are the engines described in this chapter.

68.1 Basics of Operation

The basic operation of an i.c. engine is shown in Figure 68.1. The typical engine cycle is divided into four steps:

1. *Intake.* Engine working volume increases. Intake valve opens to admit air or air/fuel mixture into the working volume.
2. *Compression.* Engine working volume decreases. Valves are closed, and the air or mixture is compressed. Work is done on the working fluid.
3. *Combustion and expansion.* Air/fuel mixture burns and releases chemical energy. If fuel was not admitted previously, it is injected at this point. Pressure and temperature inside the working volume increase dramatically. Working volume increases, and work (much greater than that of compression) is done by the working fluid.
4. *Exhaust.* Engine working volume decreases. Exhaust valve opens to expel combustion products from the working volume.

The engine shown is a four-stroke reciprocating type; details would vary for two-stroke or rotary engines.

68.2 Engine Classifications

I.c. engines can be classified in various ways. Some important classifications are:

Spark ignition/compression ignition. In **spark ignition** (s.i., gasoline, petrol, or Otto) engines, the fuel is either mixed with the air prior to the intake stroke or shortly after inlet valve closure. An electric spark ignites the mixture. In **compression ignition** (c.i., oil, or diesel) engines, the fuel is injected after the compression process. The high temperature of the compressed gas causes ignition.

Four-stroke/two-stroke. In **four-stroke** engines, the working cycle is as shown in Figure 68.1. A complete four-stroke cycle takes two crankshaft revolutions, with each stage (intake, compression, expansion, exhaust) comprising about 180° . A complete two-stroke cycle takes only one crankshaft revolution. In a **two-stroke**, engine intake and exhaust strokes are eliminated: gas exchange occurs

FIGURE 68.2 Engine arrangements.

when the piston is near bottom center position between the expansion and compression strokes. Because the piston does not provide pumping action, some external device is required to ensure that fresh air or mixture replaces the combustion products.

Mechanical layout. Various mechanical layouts are shown in Figure 68.2. Reciprocating i.c. engines use multiple piston-cylinder arrangements driving a single crankshaft. The total number of cylinders per engine ranges from one to 20 or more, with one, four, six, and eight the most common. The cylinders can be arranged in line, in a vee, radially, or horizontally opposed. Rotary i.c. engines use an approximately triangular rotor which revolves eccentrically in a lobed stator. The spaces between the rotor and the stator go through essentially the same processes shown in Figure 68.1. A single rotor-stator pair is thus equivalent to three cylinders. Additional rotor-stator pairs can be stacked on a single shaft to form larger engines.

Intake system. In **naturally aspirated** engines, the pumping action of the piston face draws air into the cylinder. In crankcase **scavenged** engines, the pumping action of the back side of the piston in the crankcase forces air into the cylinder. In **supercharged** engines, a compressor, typically driven off the crankshaft, forces air into the cylinder. In **turbocharged** engines, the compressor is driven by a turbine that recovers work from the exhaust gas.

Besides the major classifications above, engines can be classified by valve number and design (two, three, or four valves per cylinder; rocker arm or overhead cam; cross-, loop-, or uniflow-scavenged), by fuel addition method (carbureted, fuel injected), by combustion chamber shape (tee, ell, flat, wedge, hemisphere, bowl-in-piston), and by cylinder wall cooling method (air, water).

68.3 Spark Ignition Engines

Idealized and Actual Cycles

The spark ignition (s.i) engine can be idealized as an **Otto** cycle using an ideal gas with constant specific heat [Figure 68.3(a)]. The Otto cycle consists of isentropic compression, constant volume heating (simulating combustion), isentropic expansion, and constant volume cooling (simulating intake and exhaust). The **thermal efficiency** of an Otto cycle (Figure 68.4) is $\eta_t = 1 - r_v^{1-\gamma}$, where r_v is the **compression ratio** and γ is the gas specific heat ratio.

The actual engine “cycle” [Figure 68.3(c)] differs from the Otto cycle:

1. In that heat transfer occurs during compression and expansion
2. In that combustion takes place gradually during compression and expansion rather than instantaneously
3. In the presence of intake and exhaust processes
4. In the variation in gas composition and gas specific heat

For a given r_v , the efficiency of a typical s.i. engine is considerably lower than that of the ideal cycle (Figure 68.4), and actual engine r_v is limited by combustion **knock**.

FIGURE 68.3 Pressure-volume diagrams for ideal and actual engine cycles.

FIGURE 68.4 Efficiency of ideal cycles and actual engines.

Combustion, Fuels, and Emissions

In an s.i. engine, air and vaporized fuel are generally premixed before they enter the cylinder. **Equivalence ratio** (ϕ) generally ranges from about 0.7 to 1.3, with lean mixtures (low ϕ) giving maximum efficiency and the rich mixtures (high ϕ) giving maximum power.

The mixture is heated by compression, but not enough to cause autoignition. Combustion is initiated by an electric spark. If the engine is operating properly, a turbulent flame front travels smoothly and rapidly across the cylinder space. It takes a 15 to 25° crank angle for the first 10% of the mixture to burn, while the next 85% is burned within an additional 35 to 60° [Figure 68.5(a)]. The low numbers of these ranges correspond to $\phi \approx 1$, high turbulence combustion chambers, and low engine speeds. The high numbers correspond to rich or lean mixtures, low turbulence combustion chambers, and high engine speeds. To time the heat release optimally, the spark is typically discharged 5 to 40° before top center, with this advance automatically varied according to engine speed and load. Because higher engine speeds result in increased turbulence and, thus, in increased flame speeds, the total crank angle for combustion increases only slightly as engine speed changes.

Under some operating conditions, the flame does not burn smoothly. In these cases the mixture ahead of the flame front is heated by compression and autoignites before the flame arrives. The resulting deto-

FIGURE 68.5 Heat release rates for s.i. and c.i. engines.

FIGURE 68.6 Effect of knock on cylinder pressure.

nation wave causes an extremely rapid pressure rise (Figure 68.6), which is noisy and can damage the engine. Because of the noise, the phenomenon is known as *knock*. Knock can be avoided by decreasing the pressure ratio, using more knock-resistant fuels, increasing flame speed, retarding the spark, and designing the combustion chamber to ensure that the last mixture burned is in the coolest part of the cylinder.

S.i. engines are usually fueled with gasoline, alcohol, or natural gas but can use other liquid or gaseous fuels. It is important that any s.i. fuel be resistant to autoignition. This resistance is expressed in terms of the **octane number** of the fuel, based on an empirical scale on which iso-octane has been assigned a rating of 100 and *n*-heptane a rating of zero. Typical gasolines have octane numbers in the 85 to 105 range; these octane numbers are usually obtained with the aid of additives. Liquid s.i. engine fuels must be adequately volatile to evaporate fully prior to ignition but not so volatile as to cause problems with storage and transfer.

Besides carbon dioxide and water, the combustion process in s.i. engines produces several pollutants (Figure 68.7): carbon monoxide (CO), unburned hydrocarbons (HCs), and nitric oxide (NO). Large amounts of CO are formed as an equilibrium product in rich mixtures, while smaller amounts remain in the products of lean mixtures due to chemical kinetic effects. HCs are left over from the combustion of rich mixtures and from flame quenching at walls and crevices in lean mixtures. NO is formed from air at high temperatures, and the chemical kinetics allow it to remain as the burned gas cools.

Most contemporary engines meet emissions standards by using **catalytic converters** in their exhaust systems. Some engines use **two-way catalysts** to reduce CO and HC emissions, while relying on lean operation to reduce flame temperature and give acceptable NO emissions. Other engines use **three-way**

FIGURE 68.7 Effect of equivalence ratio on s.i. engine emissions.

catalysts to reduce CO, HC, and NO emissions. Three-way catalysts are only effective when the engine operates near stoichiometric air–fuel ratio; flame temperature can be reduced by exhaust gas recirculation. Engines with both types of catalytic converters operate rich for maximum power. The temporary increase in emissions can either be accepted or alleviated by pumping air into the exhaust system between the engine and the converter.

Control

The control system of an s.i. engine must govern engine output, but it must also regulate equivalence ratio and spark timing. Since the ranges of ϕ and spark timing over which the engine will run smoothly are limited, engine output is varied by reducing air flow while holding ϕ and timing essentially constant. Control of ϕ and timing is generally directed toward maximizing efficiency and minimizing emissions at a given speed and torque.

Engine output is usually controlled by throttling the intake air flow with a butterfly-type throttle valve. This reduces net output by reducing the heat release and increasing the pumping work [Figure 68.3(d)]. Other methods (late intake valve closing, shutting down cylinders of multicylinder engines) have been tried to reduce output with less efficiency penalty, but they are not widely used.

There are two basic methods of mixing fuel and air for s.i. engines: carburetion and fuel injection. A **carburetor** [Figure 68.8(a)] provides intrinsic control of ϕ by putting fuel and air flow through restrictions with the same differential pressure. The intrinsic control is imperfect because air is compressible while liquid fuels are not. Various corrective methods are used to provide near-constant lean ϕ over most of the air flow range, with enrichment to $\phi > 1$ for starting and maximum power operation. The manifold between the carburetor and the cylinder(s) must be arranged so that fuel evaporates fully and is evenly distributed among the cylinders. Due to the difficulty in obtaining low emissions levels, no contemporary U.S. production automobiles use carburetors.

A **fuel injector** [Figure 68.8(b)] injects a spray of fuel into the air stream. In throttle body injection, a single injector serves for multiple cylinders; in port injection (more common), each cylinder has its own injector. Port injectors are timed to spray fuel while the inlet valve is closed, to allow evaporation time. They are typically controlled by digital electronics. The volume of injected fuel is controlled in response to various measurements, including speed, inlet manifold vacuum, and exhaust oxygen concentration. The mixture is kept lean (two-way catalyst) or stoichiometric (three-way catalyst), except for starting and maximum power. Figure 68.8 shows carburetors and fuel injectors used for liquid fuels; the arrangements for gaseous fuels are similar.

FIGURE 68.8 S.i. engine fuel addition devices.

The high voltage (10 to 25 kV) for the ignition spark is provided either by interrupting current through a choke or discharging a capacitor. The spark advance is typically regulated in response to engine speed and manifold vacuum; high speeds and high vacuums require more advance. The switching required for spark generation and control can be done either mechanically or electronically. Some electronically controlled engines incorporate vibrational knock sensors to retard the spark if required. For older designs, control is almost entirely mechanical, with the necessary adjustments to the fuel addition and ignition systems made through pressure-driven diaphragms, centrifugal speed sensors, and linkages. On newer designs, control is mainly through electronic sensors, digital electronics, and solenoid actuators.

Advantages

Relative to compression ignition engines, s.i. engines have higher mass and volume power density, lower first cost, greater fuel availability (for automotive use), and wider speed range. Emissions are lower with use of a catalytic converter. The advantages of s.i. engines become more pronounced for smaller sizes.

68.4 Compression Ignition Engines

Idealized and Actual Cycles

The compression ignition (c.i.) engine can be idealized as a diesel cycle using an ideal gas with constant specific heat [Figure 68.3(b)]. The **diesel** cycle consists of isentropic compression, constant pressure heating (simulating combustion), isentropic expansion, and constant volume cooling (simulating intake and exhaust). The thermal efficiency of a diesel cycle (Figure 68.4) is $\eta_t = 1 - r_v^{1-\gamma}(r_c^\gamma - 1)/(r_c - 1)/\gamma$. The **cutoff ratio**, r_c , idealizes the volume ratio over the fuel addition period.

The actual engine cycle [Figure 68.3(c)] differs from the diesel cycle:

1. In that heat transfer occurs during compression and expansion
2. In that combustion takes place at varying rather than constant pressure
3. In that combustion continues after the end of fuel addition
4. In the presence of intake and exhaust processes
5. In the variation in gas composition and gas specific heat

For a given r_v and r_c , the efficiency of a typical c.i. engine is considerably lower than that of the ideal cycle (Figure 68.4). The pressure–volume diagrams for actual s.i. and c.i. engines are quite similar.

Combustion, Fuels, and Emissions

In a c.i. engine, air is compressed before fuel is added. Fuel is injected as a fine spray beginning slightly before the volume reaches a minimum and ignites after coming in contact with the hot air. Overall equivalence ratio (ϕ) generally ranges from about 0.15 to 0.8, with lean mixtures (low ϕ) corresponding to idle and low power, and rich mixtures corresponding to full power with considerable smoke emission. Since the fuel and air are not premixed, combustion takes place at near $\phi = 1$, no matter what the overall ϕ .

C.i. engine combustion takes place in four stages [Figure 68.5(b)]. In the ignition delay period, fuel evaporates, mixes with the air, and reacts slowly. In the premixed combustion phase, the fuel that evaporated and mixed during the delay period burns rapidly in a process similar to that in s.i. knock. In the mixing–controlled combustion phase, a diffusion flame exists at the boundary between a rich atomized fuel–air mixture and the remaining air in the cylinder. In the late combustion phase, the pockets of fuel that so far have escaped the flame are consumed. Since the premixed combustion has a rapid pressure rise that causes rough operation, it is desirable to minimize the amount of fuel vaporized before it begins. This is done by minimizing ignition delay time and evaporation rate during that time. Minimum delay is obtained by injecting at the optimum time (10 to 15° before top center), with high cylinder wall temperature, high compression ratio, and high cetane number fuel. Indirect injection (see below) gives little premixed combustion.

The combustion process in c.i. engines does not speed up with increased turbulence as much as the process in s.i. engines does. For large, low-speed engines, combustion is adequate when the fuel is injected directly into the center of a relatively quiescent combustion chamber. For medium-size, medium-speed engines, the combustion chamber must be designed for increased turbulence in order for combustion to take place in the time available. In small, high-speed engines, combustion is initiated in a small, hot, highly turbulent prechamber. The fuel and burned gases from the prechamber then expand into the main combustion chamber and combine with the remaining air. Engines with a single chamber are known as **direct injection** (d.i.) engines, while those with a prechamber are known as **indirect injection** (i.d.i.) engines (Figure 68.9).

C.i. engines are fueled with petroleum oils consisting of longer-chain molecules than those in gasolines. Depending on the engine design, oils ranging from crude to kerosene can be used. It is important that any c.i. fuel have adequate autoignition properties. The ignition quality is expressed in terms of the **cetane number** of the fuel, based on an empirical scale on which *n*-hexadecane (cetane) has been assigned a rating of 100 and heptamethylnonane (isocetane) a rating of 15. Typical c.i. fuels have cetane numbers in the 30 to 60 range. For heavy, low-cost c.i. fuels, high pour point can be a problem. Some of these fuels must be heated before they can be pumped.

FIGURE 68.9 C.i. engine combustion chamber types.

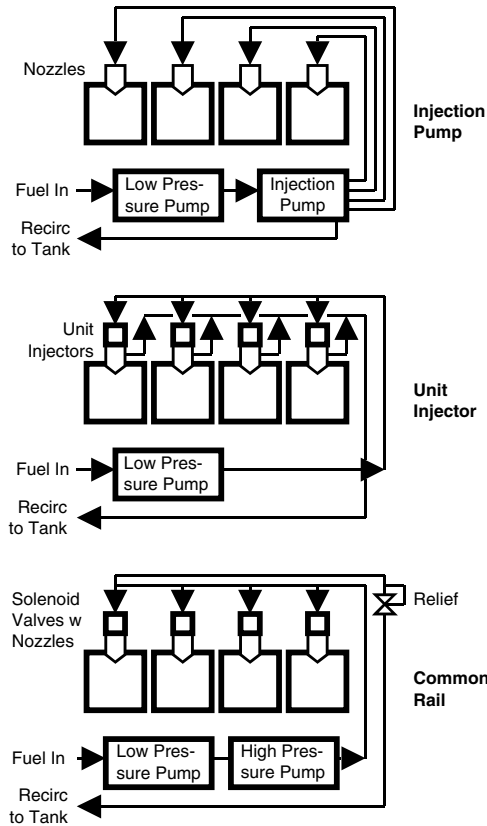

FIGURE 68.10 C.i. fuel systems.

Besides carbon dioxide and water, the combustion process in c.i. engines produces several pollutants, the most important of which are soot (carbon plus hydrocarbons), nitric oxide (NO), and nitrogen dioxide (NO₂). Carbonaceous soot is formed by fuel pyrolysis in rich regions near the flame front. Hydrocarbons then adsorb onto the soot particles during expansion and exhaust. Soot emissions are highest at high loads. NO and NO₂ are formed from air at high temperatures, and the chemical kinetics allow them to remain as the burned gases cool. Carbon monoxide and gaseous hydrocarbon emissions from diesel engines are relatively small.

Control

C.i. engines are not throttled, but are controlled by regulating the amount of fuel injected and the injection timing. Because of the required high injection pressures, large diesel engine fuel injectors are mechanically rather than electrically driven; systems for small engines may use electric pumps. Three types of systems are used: injection pump, unit injector, and common-rail (Figure 68.10). In an **injection pump** system, a central pump timed to the camshaft delivers fuel to nozzles located at each cylinder. The pump typically has individual barrels for each cylinder, but a single barrel with a fuel distributor is also used. In a **unit injector** system, there are a pump and nozzle on each cylinder, driven by a shaft running over all the cylinder heads. In a **common rail** system, a central pump supplies high-pressure fuel to a common header, and each cylinder has a solenoid-operated valve and nozzle. Common rail systems are suitable only for low injection pressures (small engines); injection pump systems are suitable for medium injection pressure (medium engines); unit injector systems are suitable for high injection pressures (large engines).

The injection start and duration are varied according to engine load and operating conditions. In the past, the control was generally accomplished through purely mechanical means and consisted mainly of increasing the injection duration in response to increased torque demand and advancing injection timing at higher speeds. In recent years, however, electronically controlled common rail systems, injector pumps, and unit injectors have become common. In the injector pump and unit-injector systems, the power is supplied mechanically, but fuel delivery is controlled by unloading solenoids. Electronic control allows fuel delivery to be carefully adjusted in response to engine operating conditions and is useful in achieving low emissions.

Since c.i. engines are not throttled at reduced load, they do not provide engine braking. For heavy vehicle use, c.i. engines are often fitted with auxiliary compression brakes that increase engine pumping work by opening the exhaust valves near top center.

Advantages

Relative to spark ignition engines, c.i. engines have higher thermal efficiency at full load and much higher thermal efficiency at low load. They also are capable of using inexpensive fuels such as heavy fuel oil.

68.5 Gas Exchange Systems

The torque of an internal combustion engine is primarily limited by the mass of air that can be captured in the cylinder. Intake system design is therefore a major factor in determining the torque for a given engine displacement. Since residual exhaust gas takes up space that could be used for fresh charge, exhaust system design also affects engine output. Exhaust design is also driven by the need to muffle the noise generated by the sudden flow acceleration at exhaust valve opening.

Four-Stroke Intake and Exhaust

Air flow into a naturally aspirated four-stroke engine is optimized by reducing charge temperature, by reducing flow friction in the intake system, by reducing residual exhaust gas, and by tuning and extended valve opening.

It has been found experimentally that engine air flow and torque are inversely proportional to the square root of the stagnation temperature of the air entering the cylinder. In s.i. engines, torque is increased by the cooling effect of fuel evaporation. This effect is much larger with alcohol fuels, which are therefore used in many racing cars. Torque is adversely affected by heat transfer to the intake air from the hot cylinder and intake manifold. In carbureted s.i. engines, some heat transfer is necessary to prevent fuel from puddling in the intake manifold.

According to both experiment and theory, engine torque is proportional to the pressure of the air entering the cylinder. This pressure is increased by minimizing the intake pressure drop. Intake valves are thus made as large as possible. High performance engines utilize two or three intake valves per cylinder to maximize flow area. Intake piping is normally designed for minimum pressure drop. However, in carbureted s.i. engines, the intake manifold is often designed for optimal fuel evaporation and distribution rather than for minimum flow friction. Intake air cleaners are designed for minimum flow resistance consistent with adequate dirt removal.

Cylinder pressure just prior to exhaust valve opening is much higher than atmospheric, but pressure falls rapidly when the exhaust valve opens. Back pressure due to exhaust system pressure drop increases the concentration of burned gas in the charge and thus reduces torque. The effect of exhaust system pressure drop is less than that of intake system pressure drop, but two exhaust valves per cylinder are often used to minimize pressure drop. Exhaust system pressure drop is usually increased by the use of a muffler to reduce exhaust noise.

Good intake and exhaust system design makes use of the dynamic effects of gas acceleration and deceleration. Most engine designs incorporate open periods well over 180° of crank angle: intake valves

open 5 to 30° before top center and close 45 to 75° after bottom center; exhaust valves open 40 to 70° before bottom center and close 15 to 35° after top center. (The longer valve open times correspond to high performance engines.) Valves are thus open when piston motion is in the opposite direction from the desired gas flow. At high engine speeds, the correct flow direction is maintained by pressure differences and by gas inertial effects. At low engine speeds, an extended valve open period is detrimental to performance. Some engines incorporate variable valve timing to obtain optimum performance over a range of speeds.

The extended valve open period is generally used in combination with intake and exhaust **tuning**. Intake systems are often acoustically tuned as organ-pipe resonators, Helmholtz resonators, or more complex resonating systems. By tuning the intake to three, four, or five times the cycle frequency, pressure at the intake valve can be increased during the critical periods near valve opening and closing. Such tuning is usually limited to diesel, port fuel injected, or one carburetor per cylinder engines because the design of intake manifolds for other carbureted engines and throttle-body injected engines is dominated by the need for good fuel distribution. The tuning penalizes performance at some speeds away from the design speed. Branched exhaust systems are tuned so that, at design speed, expansion waves reflected from the junctions arrive at the exhaust valve when it is near closing. Individual cylinder exhaust systems are tuned as organ-pipe resonators. In either case, performance away from the design speed is penalized.

Two-Stroke Scavenging

In a two-stroke engine, intake and exhaust take place simultaneously, and some means of air pumping is needed for gas exchange (Figure 68.11). Small s.i. engines are generally crankcase scavenged — the bottom face of the piston is used to pump the air and oil is generally added to the fuel to lubricate the crank bearings. Larger engines use either rotary superchargers or turbochargers. These allow more freedom in crankcase lubrication. The cylinder and piston are arranged to maximize inflow of fresh charge and outflow of exhaust while minimizing their mixing. Cross-scavenging [Figure 68.12(a)] and loop-scavenging [Figure 68.12(b)] require only cylinder wall ports; uniflow scavenging [Figure 68.12(c)] requires poppet valves as well.

Scavenging spark ignition engines involves a trade-off between residual gas left in the cylinder and air-fuel mixture lost out the exhaust. In compression ignition engines, only air is lost through the exhaust.

FIGURE 68.11 Scavenging and supercharging systems.

FIGURE 68.12 Scavenging arrangements.

Two-stroke s.i. engines are thus used mainly where low weight and first cost are of primary importance, while two-stroke c.i. engines can be built to be suitable for any service. In recent years some two-stroke s.i. engines have featured fuel injection into the cylinder after the exhaust port closes, eliminating loss of fuel out the exhaust.

Supercharging and Turbocharging

The output of a given i.c. engine can be increased by providing an auxiliary air compressor, or supercharger, to increase the pressure and, thus, the density of the air entering the cylinder intake. Although it actually applies to all types of auxiliary air compression systems, the term *supercharger* is generally used to describe systems driven by the engine output shaft. Air compression systems powered by an exhaust gas-driven turbine are known as *turbochargers*. When supercharging or turbocharging is added to a naturally aspirated engine, the engine is usually modified to reduce its compression ratio. However, the overall compression ratio is increased.

Most shaft-driven superchargers are positive displacement compressors; the most common are the Roots blower (Figure 68.11) and the twin-screw compressor. Shaft-driven, positive-displacement superchargers have the advantages of increasing their delivery in proportion to engine speed and of responding almost instantly to speed changes. Their disadvantage is that the use of shaft power to drive the compressor results in decreased overall thermal efficiency. Roots blowers are unacceptably inefficient at pressure ratios greater than about two.

Turbochargers have the advantage of maintaining thermal efficiency while increasing engine output. Their main disadvantage is that the turbine-compressor rotor takes a finite time to accelerate upon an increase in engine output. The result is **turbo lag**, a delay in engine response upon demand for a rapid increase in power.

68.6 Design Details

Engine Arrangements

Various engine cylinder arrangements are shown in Figure 68.2.

In-line engines are favored for applications in which some sacrifice in compactness is justified by mechanical simplicity and ease of maintenance. They are also used where the need for a narrow footprint overrides length and height considerations. The in-line design is most popular for small utility and automobile engines, large truck engines, and very large marine and stationary engines.

Vee engines are used where compactness is important. Vee engines are used for medium and large automobile engines, small truck engines, locomotive engines, and medium-size marine and stationary engines.

Opposed engines are used primarily where low height is important — in some automobiles and for small marine engines meant for below-deck installation. They are also used for some small aircraft engines, where they allow for ease in air cooling and servicing.

Radial engines are used primarily in aircraft, where their design allows for efficient air cooling.

Rotary (Wankel) engines have been used primarily in sports cars. They have not captured a major share of any market sector.

Valve Gear

Poppet valves on four-stroke and uniflow two-stroke engines fall into one of three categories: valve-in-block, valve-in-head/rocker arm, or valve-in-head/overhead cam. The arrangements are illustrated in Figure 68.13.

Valve-in-block engines are the cheapest to manufacture. In an L-head arrangement, intake and exhaust valves are on the same side of the cylinder; in a T-head engine, they are on opposite sides. The valves are directly driven by a camshaft located in the block, gear, or chain driven at half the crankshaft speed.

FIGURE 68.13 Valve arrangements.

The performance of these engines suffers from the elongated shape of the combustion chamber, and the designs are currently used only for inexpensive utility engines.

Valve-in-head/**rocker arm** engines have the valves installed in the cylinder head while maintaining a camshaft in the block. The design allows compact combustion chambers, but control of valve motion suffers from the slack in the long mechanical drive train. A majority of production automobile engines have this type of valve drive.

Valve-in-head/**overhead cam** engines have valves in the cylinder head directly driven by a camshaft running over all the heads. The design allows both compact combustion chamber design and accurate control of valve motion, but is more expensive to manufacture and more difficult to maintain than rocker arm designs. In recent years, overhead cam designs have become increasingly common in high-performance automobile engines.

Various arrangements for variable valve timing are now marketed, but none has achieved a large market share. Most engines have fixed valve timing.

Lubrication

The bearings of most i.c. engines are plain or grooved journal bearings. In the crankshaft bearings, a hydrodynamic film is maintained by rotation; in the piston pin bearings, the maintenance of a film depends on the oscillating nature of the load. For the connecting rod bearings the two effects are combined.

The most critical lubrication areas in an i.c. engine are at the piston rings, which are required to seal the high-pressure gas in the cylinder and prevent excess oil from entering the cylinder. Typical designs have two compression rings to seal the gases and an oil control ring to wipe oil from the cylinder wall. Piston rings ride on a hydrodynamic film at midstroke, but are in a boundary lubrication regime near top and bottom center. Lubrication is aided by good ring (alloy cast iron) and cylinder wall (cast iron or chrome-plated steel) materials.

Low-cost four-stroke engines are splash lubricated by running the crankshaft partly in an oil pan, but most engines have force-feed lubrication systems that deliver filtered oil to the bearings, the cylinder walls below the piston, and the valve train. Smaller engines depend on convection from the oil pan to cool the oil, while others have auxiliary oil coolers.

On small two-stroke engines with crankcase scavenging, lubrication is provided by mixing a small percentage of oil into the fuel entering the crankcase. On these engines rolling-contact bearings are often used on crankshafts, piston pins, and connecting rods.

Cooling

Most large i.c. engines are liquid cooled, and most small engines are air cooled. About a third of the energy input to a typical engine is dissipated through the cooling system. Liquid-cooled engines use either water or an aqueous ethylene glycol solution as coolant. When the glycol is used, it gives lower freezing and higher boiling points, but also increases the viscosity of the coolant. Although some natural-convection cooling systems have been built, most engines have the coolant pumped through numerous passages in the cylinder walls and heads and then into a heat exchanger where the heat is transferred to the environment. Small marine engines are typically cooled directly with water from the environment.

TABLE 68.1 Design and Performance Data for Various Internal Combustion Engines

| Application and Type | Cylinders/ Arrangement | Displ. (l) | Comp. Ratio | Rated Power (kW) | Rated Speed (rpm) | Mass (kg) |
|--------------------------------------|---------------------------|---------------|----------------|------------------------|-------------------------|----------------------|
| Utility, two-stroke, s.i., c.s. | 1 | 0.10 | 9.0 | 8.9 | 9000 | 5.0 |
| Marine, two-stroke, s.i., c.s. | 1 | 0.13 | 10.5 | 7.5 | 8000 | 6.6 |
| Utility, four-stroke, s.i., n.a. | 1 | 0.17 | 6.2 | 2.5 | 3600 | 13.9 |
| Motorcycle, two-stroke, s.i., c.s. | 2/in-line | 0.30 | 7.1 | 19.4 | 7000 | — |
| Utility, 4-stroke, s.i., n.a. | 1 | 0.45 | 8.7 | 11.9 | 3600 | 38.2 |
| Motorcycle, four-stroke, s.i., n.a. | 2/in-line | 0.89 | 10.6 | 61 | 6800 | — |
| Automobile, four-stroke, s.i., n.a. | 4/in-line | 2.2 | 9.0 | 73 | 5200 | — |

Note: c.s.: crankcase scavenged; n.a.: naturally aspirated; t.c.: turbocharged.

Source: Based on Taylor, C. F. 1985. *The Internal Combustion Engine in Theory and Practice*, 2nd ed. MIT Press, Cambridge, MA.

Air-cooled engines have finned external surfaces on their pistons and heads to improve heat transfer and fans to circulate air over the engine. The larger passages needed for air require that the cylinders be more widely spaced than for liquid-cooled engines. While most air-cooled engines are small, many large aircraft engines have been air cooled.

68.7 Design and Performance Data for Typical Engines

Design and performance data for various engines are given in Table 68.1.

Defining Terms

Carburetor — Controls fuel–air mixture by flowing air and fuel across restrictions with the same differential pressure.

Catalytic converter — Uses catalyst to speed up chemical reactions, normally slow, which destroy pollutants.

Cetane number — Empirical number quantifying ignition properties of c.i. engine fuels.

Common rail — Fuel injection with solenoids controlling flow from a single high-pressure header.

Compression ignition engine — Fuel and air compressed separately, ignited by high air compression temperatures.

Compression ratio — Ratio of maximum working volume to minimum working volume.

Cutoff ratio — Fraction of expansion stroke during which heat is added in diesel cycle.

Diesel cycle — Thermodynamic idealization of compression ignition engine.

Direct injection c.i. engine — Fuel is injected directly into the main combustion chamber.

Equivalence ratio — Fuel/air ratio relative to fuel/air ratio for stoichiometric combustion.

Four-stroke engine — One power stroke per cylinder per two revolutions.

Fuel injector — Controls fuel–air mixture by metering fuel in proportion to measured or predicted air flow.

Indirect injection c.i. engine — Fuel is injected into a prechamber connected to the main combustion chamber.

Injection pump — Delivers metered high-pressure fuel to all fuel injector nozzles of a c.i. engine.

Knock — Spark ignition engine phenomenon in which the fuel–air mixture detonates instead of burning smoothly.

Naturally aspirated engine — Piston face pumping action alone draws in air.

Octane number — Empirical number quantifying antiknock properties of s.i. fuels.

Otto cycle — Thermodynamic idealization of spark ignition engine.

Overhead cam engine — Valves are in head, driven by camshaft running over top of head.

Rocker arm engine — Valves are in head, driven from camshaft in block of push rods and rocker arms.

Scavenging — Intake/exhaust process in two-stroke engines.

Spark ignition engine — Fuel and air compressed together, ignited by electric spark.

Supercharged engine — Shaft-driven air compressor forces air into cylinder.

Thermal efficiency — Engine work divided by heat input or lower heating value of fuel used.

Three-way catalyst — Catalyst that reduces CO, HC, and NO emissions. Engine must run stoichiometric.

Tuning — Designing intake and exhaust so that flow is acoustically reinforced at design speed.

Two-stroke engine — One power stroke per cylinder per revolution.

Two-way catalyst — Catalyst that reduces CO and HC emissions. Engine may run lean or stoichiometric.

Turbo lag — The delay in response of a turbocharged engine upon demand for rapid power increase.

Turbocharged engine — Air forced into cylinder by compressor driven by exhaust gas turbine.

Unit injector — Combination pump and nozzle which delivers metered fuel to a single c.i. engine cylinder.

Valve-in-block engine — Low-cost design in which valves are driven directly by a camshaft in the cylinder block.

Gas Turbines

Lee S. Langston
University of Connecticut

George Opdyke, Jr.
Dykewood Enterprises

- 69.1 Gas Turbine Usage
- 69.2 Gas Turbine Cycles
- 69.3 Gas Turbine Components
Compressors and Turbines • Combustors

In the history of energy conversion, the gas turbine is a relatively new prime mover. The first practical gas turbine used to generate electricity ran at Neuchatel, Switzerland, in 1939 and was developed by the Brown Boveri firm. The first gas turbine-powered airplane flight also took place in 1939, in Germany, using the gas turbine developed by Hans P. von Ohain. In England the 1930s invention and development of the aircraft gas turbine by Frank Whittle resulted in a similar British flight in 1941.

The name *gas turbine* is somewhat misleading, for it implies a simple turbine that uses gas as a working fluid. Actually, a gas turbine (as shown schematically in [Figure 69.1](#)) has a *compressor* to draw in and compress gas (usually air), a *combustor* (or burner) to add fuel to heat the compressed gas, and a *turbine* to extract power from the hot gas flow. The gas turbine is an internal combustion (IC) engine employing a continuous combustion process, as distinct from the intermittent combustion occurring in a diesel or Otto cycle IC engine.

Because the 1939 origin of the gas turbine lies both in the electric power field and in aviation, there has been a profusion of “other names” for the gas turbine. For land and marine applications it is generally called a *gas turbine*, but also a *combustion turbine*, a *turboshaft engine*, and sometimes a *gas turbine engine*. For aviation applications it is usually called a *jet engine*, and various other names (depending on the particular aviation configuration or application) such as *jet turbine engine*, *turbojet*, *turbofan*, *fanjet*, and *turboprop* or *prop jet* (if it is used to drive a propeller). The compressor–combustor–turbine part of the gas turbine ([Figure 69.1](#)) is commonly termed the *gas generator*.

69.1 Gas Turbine Usage

In an aircraft gas turbine, all of the turbine power is used to drive the compressor (which may also have an associated fan or propeller). The gas flow leaving the turbine is then accelerated to the atmosphere in an exhaust nozzle [[Figure 69.1\(a\)](#)] to provide *thrust* or *propulsion power*. Gas turbine or jet engine thrust power is the mass flow momentum increase from engine inlet to exit, multiplied by the flight velocity.

A typical jet engine is shown in [Figure 69.2](#). Such engines can range from about 100 pounds thrust (1bt)(445 N) to as high as 100,000 lbt, (445,000 N), with dry weights ranging from about 30 lb (134 N) to 20,000 lb (89 000 N). The jet engine of [Figure 69.2](#) is a *turbofan* engine, with a larger-diameter compressor-mounted fan. Thrust is generated both by air passing through the fan (bypass air) and through the gas generator itself. With a large frontal area, the turbofan generates peak thrust at low (takeoff) speeds, making it most suitable for commercial aircraft. A *turbojet* does not have a fan and

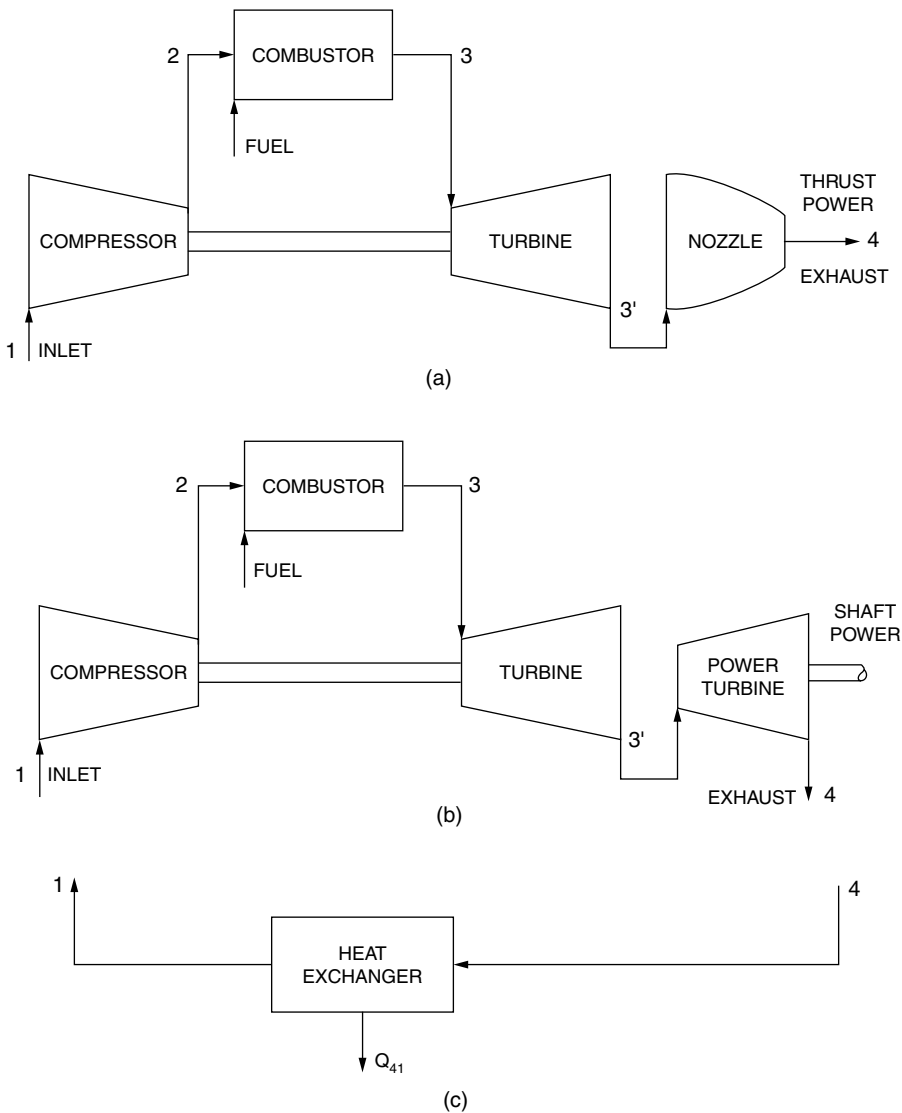

FIGURE 69.1 Gas turbine schematics. (a) Jet engine, a gas turbine (open cycle) used to produce thrust power. (b) Gas turbine (open cycle) used to produce shaft power. (c) Heat exchanger added to (b) yields a closed-cycle gas turbine (combustor becomes another heat exchanger since closed-cycle working fluid cannot sustain combustion).

generates all of its thrust from air that passes through the gas generator. Turbojets have smaller frontal areas and generate peak thrusts at high speeds, making them most suitable for fighter aircraft.

In nonaviation gas turbines, only part of the turbine power is used to drive the compressor. The remainder, the “useful power,” is used as output *shaft power* to turn an energy conversion device [Figure 69.1(b)] such as an electrical generator or a ship’s propeller. [The second “useful power” turbine shown in Figure 69.1 (b) need not be separate from the first turbine.]

A typical land-based gas turbine is shown in Figure 69.3. Such units can range in power output from 0.05 to as high as 240 MW. The unit shown in Figure 69.3 is also called an *industrial* or *frame machine*. Lighter-weight gas turbines derived from jet engines (such as in Figure 69.2) are called *aeroderivative* gas turbines and are most frequently used to drive natural gas line compressors and ships and to provide peaking and intermittent power for electrical utility applications.

FIGURE 69.2 A modern jet engine used to power Boeing 777 aircraft. This is a Pratt and Whitney PW4084 turbofan, which can produce 84,000 pounds (374 kN) of thrust (about 63 MW at 168 m/sec). It has a 112 in. (2.85 m) diameter front-mounted fan, a flange-to-flange length of 192 inches (4.87 m), and a mass of about 15,000 pounds (6804 kg). (Courtesy of Pratt and Whitney.)

FIGURE 69.3 A modern land-based gas turbine used for electrical power production and for mechanical drives. This General Electric MS7001FA gas turbine is rated at 168 MW and is about 44 ft (13.4 m) in length and weighs approximately 377,000 lb (171,000 kg). Similar units have been applied to mechanical drive applications up to 108,200 hp. (Courtesy of General Electric.)

Some of the principal advantages of the gas turbine are as follows:

1. It is capable of producing large amounts of useful power for a relatively small size and weight.
2. Since motion of all its major components involves pure rotation (i.e., no reciprocating motions as in a piston engine), its mechanical life is long and the corresponding maintenance costs are relatively low.
3. Although the gas turbine must be started by some external means (a small external motor or another gas flow source, such as another gas turbine), it can be brought up to full load conditions in minutes, in contrast to a steam turbine plant, whose start-up time is measured in hours.
4. A wide variety of fuels can be utilized. Natural gas is commonly used in land gas turbines, whereas light distillate (kerosene-like) oils power aircraft gas turbines. Diesel oil or specially treated residual oils can also be used, as well as combustible gases derived from blast furnaces, refineries, and coal gasification.
5. The usual working fluid is atmospheric air. As a basic power supply, the gas turbine requires no coolant (e.g., water).

In the past, one of the major disadvantages of the gas turbine was its lower thermal efficiency (hence, higher fuel usage) when compared to other IC engines and to steam turbine power plants. However, during the last 50 years, continuous engineering development work has pushed the lower thermal efficiency (18% for the 1939 Neuchatel gas turbine) to present levels of 40% for simple cycle operation and above 55% for combined cycle operation. Even more fuel-efficient gas turbines are in the planning stages, with simple cycle efficiencies predicted as high as 45 to 47% and combined cycles in the 60% range. These projected values are significantly higher than values for other prime movers, such as steam power plants.

69.2 Gas Turbine Cycles

The ideal gas Brayton cycle (1876, and also proposed by Joule in 1851) — shown in graphic form in Figure 69.4 as a pressure-volume diagram — is an idealized representation of the properties of a fixed mass of gas (working fluid) as it passes through a gas turbine in operation (Figure 69.1).

A unit mass of ideal gas (e.g., air) is compressed isentropically from point 1 to point 2. This represents the effects of an ideal adiabatic compressor [Figure 69.1(a) and Figure 69.1(b)] and any isentropic gas

FIGURE 69.4 Brayton cycle pressure (P) versus volume (V) diagram for a unit mass of working fluid (e.g., air), showing work (W) and heat (Q) inputs and outputs.

flow deceleration for the case of an aviation gas turbine in flight [Figure 69.1(a)]. The ideal work necessary to cause the compression is represented by the area between the pressure axis and the isentropic curve 1–2.

The unit gas mass is then heated at constant pressure from 2 to 3 in Figure 69.4 by the exchange of heat input, Q_{23} . This isobaric process is the idealized representation of heat addition caused by the combustion of injected fuel into the combustor in Figure 69.1 (a) and Figure 69.1(b). The mass flow rate of the fuel is very much lower than that of the working fluid (roughly 1:50), so the combustion products can be neglected as a first approximation.

The unit gas mass is then isentropically expanded (lower pressure and temperature and higher volume) from 3 to 4 in Figure 69.4, where $P_4 = P_1$. In Figure 69.1 this represents flow through the turbine (to point 3') and then flow through the exit nozzle in the case of the jet engine [Figure 69.1(a)], or flow through the power turbine in Figure 69.1(b) (point 4). In Figure 69.4 the area between the pressure axis and the isentropic curve 3–3' represents the ideal work, $W_{33'}$, derived from the turbine. This work has to be equal to the ideal compressor work W_{12} (the area bounded by curve 1–2). The ideal “useful work,” $W_{3'4}$, in Figure 69.4 (area bounded by the isentropic curve 3'–4) is that which is available to cause output *shaft power* [Figure 69.1(b)] or *thrust power* [Figure 69.1(a)].

The Brayton cycle is completed in Figure 69.4 by a constant pressure process in which the volume of the unit gas mass is decreased (temperature decrease) as heat Q_{41} is rejected. Most gas turbines operate in an *open cycle* mode, in which, for instance, air is taken in from the atmosphere (point 1 in Figure 69.1 and Figure 69.4) and discharged back into the atmosphere (point 4), with exiting working fluid mixing to reject Q_{41} . In a *closed cycle* gas turbine facility the working fluid is continuously recycled by ducting the exit flow (point 4) through a heat exchanger [shown schematically in Figure 69.1(c)] to reject heat Q_{41} at (ideally) constant pressure and back to the compressor inlet (point 1). Because of its confined, fixed mass working fluid, the closed cycle gas turbine is *not* an internal combustion engine, so the combustor shown in Figure 69.1 is replaced with an input heat exchanger supplied by an external source of heat. The latter can take the form of a nuclear reactor, the fluidized bed of a coal combustion process, or some other heat source.

The ideal Brayton cycle thermal efficiency, η_B , can be shown [Bathie, 1984] to be

$$\eta_B = 1 - \frac{T_4}{T_3} = 1 - \frac{1}{r^{(k-1)/k}} \quad (69.1)$$

where the absolute temperatures T_3 and T_4 correspond to the points 3 and 4 in Figure 69.4, $k = c_p/c_v$ is the ratio of specific heats for the ideal gas, and r is the compressor pressure ratio,

$$r = \frac{P_2}{P_1} \quad (69.2)$$

Thus, the Brayton cycle thermal efficiency increases with both the turbine inlet temperature, T_3 , and compressor pressure ratio, r . Modern gas turbines have pressure ratios as high as 30:1 and turbine inlet temperatures approaching 3000°F (1649°C).

The effect of real (nonisotropic) compressor and turbine performance can be easily seen in the expression for the net useful work $W_{\text{net}} = W_{3'4}$ [Huang, 1988],

$$W_{\text{net}} = \eta_T c_p T_3 \left[1 - \frac{1}{r^{(k-1)/k}} \right] - \frac{c_p T_1}{\eta_C} [r^{(k-1)/k} - 1] \quad (69.3)$$

where c_p is the specific heat at constant pressure, and η_T and η_C are the thermal (adiabatic) efficiencies of the turbine and compressor, respectively. This expression shows that for large W_{net} one must have high values for η_T , η_C , r , and T_3 . For modern gas turbines, η_T can be as high as 0.92 and η_C can reach 0.88.

A gas turbine that is configured and operated to closely follow the ideal Brayton cycle (Figure 69.4) is called a *simple cycle* gas turbine. Most aircraft gas turbines operate in a simple cycle configuration since attention must be paid to engine weight and frontal area.

However, in land or marine applications, additional equipment can be added to the simple cycle gas turbine, leading to increases in thermal efficiency and/or the net work output of a unit. Three such modifications are regeneration, intercooling, and reheating.

Regeneration involves the installation of a heat exchanger through which the turbine exhaust gases [point 4 in Figure 69.1(b) and Figure 69.4] pass. The compressor exit flow [point 2 in Figure 69.1(b) and Figure 69.4] is then heated in the exhaust gas heat exchanger before the flow enters the combustor. If the regenerator is well designed — that is, if the heat exchanger effectiveness is high and the pressure drops are small — the cycle efficiency will be increased over the simple cycle value. However, the relatively high cost of such a regenerator must also be taken into account.

Intercooling also involves use of a heat exchanger. An intercooler is a heat exchanger that cools compressor gas during the compression process. For instance, if the compressor consists of a high- and a low-pressure unit, the intercooler could be mounted between them to cool the flow and decrease the work necessary for compression in the high-pressure compressor. The cooling fluid could be atmospheric air or water (e.g., sea water in the case of a marine gas turbine). It can be shown that net work output of a given gas turbine is increased with a well-designed intercooler. Recent studies of gas turbines equipped with extensive turbine convective and film cooling show that intercooling can also allow increases in thermal efficiency by providing cooling fluid at lower temperatures, thereby allowing increased turbine inlet temperatures [T_3 in Equation (69.1)].

Reheating occurs in the turbine and is a way to increase turbine work without changing compressor work or exceeding the material temperature limits in the turbine. If a gas turbine has a high-pressure and a low-pressure turbine, a reheater (usually another combustor) can be used to “reheat” the flow between the two turbines. Reheat in a jet engine is accomplished by adding an afterburner at the turbine exhaust, thereby increasing thrust, with a greatly increased fuel consumption rate.

A *combined cycle* gas turbine power plant, frequently identified by the abbreviation *CCGT*, is essentially an electrical power plant in which a gas turbine provides useful work (W_B) to drive an electrical generator. The gas turbine exhaust energy (Q_{BR}) is then used to produce steam in a heat exchanger (called a *heat recovery steam generator*) to supply a steam turbine (see Chapter 74) whose useful work output (W_R) provides the means to generate more electricity. If the steam is used for heat (e.g., heating buildings), the unit would be called a *cogeneration plant* (see Chapter 75). The sketch in Figure 69.5 is a simplified thermodynamic representation of a CCGT and shows it to be two heat engines (Brayton and Rankine) coupled in series. The “upper” engine is the gas turbine (represented as a Brayton cycle heat engine), whose energy input is Q_{IN} . It rejects heat (Q_{BR}) as the input energy to the “lower” engine (the steam turbine, represented as a Rankine cycle heat engine). The Rankine heat engine then rejects unavailable energy (heat) as Q_{OUT} by means of a steam condenser. The combined thermal efficiency (η_{CC}) can be derived fairly simply [Huang, 1988] and is given as

FIGURE 69.5 Schematic of combined cycle (CC), Brayton (B), and Rankine (R) heat engines, showing work (W) and heat (Q) inputs and outputs. (Courtesy Global Gas Turbine News.)

$$\eta_{CC} = \eta_B + \eta_R - \eta_B \eta_R \quad (69.4)$$

where $\eta_B = W_B/Q_{IN}$ and $\eta_R = W_R/Q_{BR}$ are the thermal efficiencies of the Brayton and Rankine cycles, respectively.

Taking $\eta_B = 40\%$ (a good value for modern gas turbines) and $\eta_R = 30\%$ (a reasonable value at typical CCGT conditions), the sum minus the product in Equation (69.4) yields $\eta_{CC} = 58\%$, a value of combined cycle efficiency greater than either of the individual efficiencies.

This remarkable equation gives insight into why CCGTs are so efficient. The calculated value of η_{CC} represents an upper bound on an actual CCGT, since Equation (69.4) does not account for efficiencies associated with transferring Q_{BR} (duct losses, irreversibilities due to heat transfer, etc.) Actual efficiency values as high as 52 to 54% have been attained with CCGT units during the last few years, thus coming close to values given by Equation (69.4).

69.3 Gas Turbine Components

A greater understanding of the gas turbine and its operation can be gained by considering its three major components (Figure 69.1, Figure 69.2, and Figure 69.3): the compressor, the combustor, and the turbine. The features and characteristics of turbines and compressors will be touched on here only briefly. A longer treatment of the combustor will be given, since environmental considerations make knowledge of its operation and design important to a wider audience.

Compressors and Turbines

The turbine and compressor components are mated by a shaft, since the former powers the latter. A *single-shaft* gas turbine has but one shaft connecting the compressor and turbine components. A *twin-spool* gas turbine has two concentric shafts, a longer one connecting a low-pressure compressor to a low-pressure turbine (the low spool), which rotates inside a shorter, larger-diameter shaft. The latter connects the high-pressure turbine with the higher-pressure compressor (the high spool), which rotates at higher speeds than the low spool. A *triple-spool* engine would have a third, intermediate-pressure compressor-turbine spool.

Gas turbine compressors can be centrifugal, axial, or a combination of both. Centrifugal compressors (radial outflow) are robust, generally cost less, and are limited to pressure ratio of 6 or 7 to 1. They are found in early gas turbines or in modern, smaller gas turbines.

The more efficient, higher-capacity axial flow compressor is used on most gas turbines (e.g., Figure 69.2 and Figure 69.3). An axial compressor is made up of a number of stages, each stage consisting of a row of rotating blades (airfoils) and a row of stationary blades (called *stators*) configured so the gas flow is compressed (adverse or unfavorable pressure gradient) as it passes through each stage. It has been said that compressor operation can founder upon a metaphoric rock, and that rock is called *stall*. Care must be taken in compressor operation and design to avoid the conditions that lead to blade stall, or flow separation. The collective behavior of blade separation can lead to compressor stall or surge, which manifests itself as an instability of gas flow through the entire gas turbine.

Turbines are generally easier to design and operate than compressors, since the flow is expanding in an overall favorable pressure gradient. Axial flow turbines (Figure 69.2 and Figure 69.3) will require fewer stages than an axial compressor for the same pressure change magnitude. There are some smaller gas turbines that utilize centrifugal turbines (radial inflow) but most utilize axial turbines (e.g., Figure 69.3).

Turbine design and manufacture are complicated by the need to ensure turbine component life in the hot gas flow. The problem of ensuring durability is especially critical in the first turbine stage, where temperatures are highest. Special materials and elaborate cooling schemes must be used to allow metal alloy turbine airfoils that melt at 1800 to 1900°F (982 to 1038°C) to survive in gas flows with temperatures as high as $T_3 = 3000^\circ\text{F}$ (1649°C).

Combustors

A successful combustor design must satisfy many requirements and has been a challenge from the earliest gas turbines of Whittle and von Ohain. The relative importance of each requirement varies with the application of the gas turbine, and, of course, some requirements are conflicting, requiring design compromises to be made. The basic design requirements can be classified as follows:

1. High combustion efficiency at all operating conditions.
2. Low levels of unburned hydrocarbons and carbon monoxide, low oxides of nitrogen at high power, and no visible smoke.
3. Low pressure drop. Three to four percent is common.
4. Combustion stability limits must be wider than all transient operating conditions.
5. Consistently reliable ignition must be attained at very low ambient temperatures, and at high altitudes (for aircraft).
6. Smooth combustion, with no pulsations or rough burning.
7. A small exit temperature variation for good turbine life requirements.
8. Useful life (thousands of hours), particularly for industrial use.
9. Multifuel use. Characteristically, natural gas and diesel fuel are used for industrial applications and kerosene for aircraft.
10. Length and diameter compatible with engine envelope.
11. Designed for minimum cost, repair, and maintenance.
12. Minimum weight (for aircraft applications).

A combustor consists of at least three basic parts: a casing, a flame tube, and a fuel injection system. The casing must withstand the cycle pressures and may be a part of the structure of the gas turbine. It encloses a relatively thin-walled flame tube, within which combustion takes place, and a fuel injection system. Sometimes the diffusing passage between the compressor and the combustor is considered a part of the combustor assembly as well.

The flame tube can be either tubular or annular. In early engines the pressure casings were tubular and enclosed the flame tubes. This configuration is called a *can combustor*. One or more can be used on an engine. If an annular casing encloses can-type flame tubes, this is called a *can-annular* or *cannular* combustor. An annular combustor consists of both an annular casing and an annular flame tube and is a common design used in aircraft gas turbines. Industrial engines often use can or cannular combustors because of their relative ease of removal.

Fuel injectors can be pressure atomizing, air atomizing, or air blast types. The specific styles vary widely and are often designed and manufactured by specialist suppliers. For industrial engines an injector may be required to supply atomized liquid fuel, natural gas, and steam or water (for nitric oxide reduction).

Compared to other prime movers, gas turbines are considered to produce very low levels of combustion pollution. The gas turbine emissions of major concern are unburned hydrocarbons, carbon monoxide, oxides of nitrogen (NO_x), and smoke. Although the contribution of jet aircraft to atmospheric pollution is less than 1% [Koff, 1994], jet aircraft emissions injected directly into the upper troposphere have doubled between the latitudes of 40 and 60 degrees north, increasing ozone by about 20%. In the stratosphere, where supersonic aircraft fly, NO_x will deplete ozone. Both effects are harmful, so NO_x reduction in gas turbine operation is a challenge for the twenty-first century [Schumann, 1993].

Defining Terms

Aeroderivative — An aviation propulsion gas turbine (jet engine) used in a nonaviation application (e.g., an electric power plant).

Brayton cycle — Ideal gas cycle that is approximated by a gas turbine simple cycle (see [Figure 69.4](#)).

Combined cycle — The combination of a gas turbine power plant and a steam turbine power plant. The gas turbine exhaust is used as heat input to generate steam.

Gas generator — The compressor, combustor, and turbine components of a gas turbine.

Jet engine — An aviation gas turbine used for aircraft propulsion.

Rankine cycle — Ideal gas cycle that is approximated by a simple steam turbine power plant cycle.

Alternative Sources of Electrical Power • Next-Generation Commercial Systems

Nuclear power systems use the controlled release of **nuclear energy** as a heat source for the generation of electricity or for direct thermal heat. The advantages of nuclear power include extremely high power density, large energy release per unit mass of fuel, and the production of energy without the emission of greenhouse gases. The disadvantages include the relatively high capital cost, the production of radioactive materials requiring careful handling and disposal, and the operation of components in a severe radiation environment.

70.1 Nuclear Power Applications

There are both terrestrial and space applications of nuclear power systems: commercial nuclear power production of electricity; nuclear propulsion of ocean-going vessels; and high-reliability electricity and heat for remote locations, including energy sources for space satellites, space science probes, and space propulsion systems.

Terrestrial Nuclear Power

Commercial Nuclear Electric Power

The commercial application of nuclear energy followed closely on the military release of nuclear energy in the nuclear weapons developed during World War II. The first commercial nuclear power plant was completed in the late 1950s, and there are presently (in 2002) 103 operating nuclear power plants in the U.S., generating 20% of the national electricity supply. Worldwide there are 436 operating nuclear power plants, with 13 countries obtaining more than one-third of their electricity from nuclear power, including France, Belgium, Sweden, Ukraine, and South Korea. The principal types of commercial nuclear power systems in use include the **pressurized water reactor (PWR)** and the **boiling water reactor (BWR)**. These two reactor types comprise over 80% of the current operating power reactors. A third type of power reactor is the pressurized heavy water reactor (PHWR), typified by the Canadian-designed CANDU reactor series. Reactor designs being considered for future applications include the **liquid metal fast**

breeder reactor (LMFBR) and **high-temperature gas cooled reactor (HTGR)**. The former Soviet block countries operate two Russian designs, a PWR-like reactor called the VVER and a graphite-moderated, water-cooled thermal reactor, the **pressure-tube graphite reactor (PTGR)**, also called the RBMK. The RBMK is the reactor type that experienced the Chernobyl Unit 4 reactor accident.

The design and operation of commercial nuclear power systems require the use of complex nuclear and thermal-hydraulic design codes incorporating basic engineering principles and engineering correlations. While scoping analysis principles are outlined in the following sections, the serious practitioner is encouraged to read the reference materials and the current technical literature.

Nuclear Propulsion

The U.S. and Russian navies have a major commitment to nuclear propulsion for their surface and submarine fleets. Nuclear power enables a vessel to travel long distances at high speed without refueling and supports an extended submerged operation, as no oxygen is consumed for combustion. The U.S. has 75 submarines and nine aircraft carriers that are nuclear powered. The Russian fleet is similarly equipped with nuclear propulsion systems. The pressurized water reactor (PWR) commercial reactor type was demonstrated by the naval nuclear propulsion program. The storage of spent reactor cores as high-level waste (HLW) is a technical issue for naval operations, especially for the Russian navy, which has a large inventory of obsolete and surplus nuclear vessels but limited infrastructure to deal with radioactive materials. International programs are being developed to assist the Russian Federation in responsible stewardship of these materials.

Space Nuclear Power

Power sources for space operations are limited by the high cost of launching a system to orbit. A high premium is placed on system reliability, due to the inaccessibility of systems in use and the high cost of alternative power systems. The options for space power include the conversion of solar energy to electricity. Solar electricity has two principal disadvantages: the requirement for battery backup power during periods of unavailability of sunlight and the decreased solar radiation for deep space missions outward from the sun. Nuclear space power systems do not suffer from either of these limitations but have been limited by public acceptance of the launch of nuclear materials, due primarily to the perception of the environmental risk of launch accident-initiated dispersal of radioactive materials. However, recognizing that nuclear energy is an enabling technology for deep space exploration, NASA has requested \$950 million over 5 years beginning in FY2003 to develop both radioisotope power systems and fission reactors for propulsion and planetary power systems.

Radioisotope Systems

The nuclear power system that has found the most application in U.S. space missions is the radioisotope thermoelectric generator (RTG). Electricity is produced by a thermoelectric converter, powered by the thermal energy from the decay of a long-lived alpha-emitting isotope of plutonium, ${}_{94}\text{Pu}^{238}$, with a half-life of 88 years. Several planetary exploration missions have been powered by RTGs. The two Voyager spacecraft launched in 1977, now over 10 billion kilometers from Earth, continue to send data due to their long-lived RTG power sources.

Space Reactors

Small nuclear reactors were used in the former Soviet Union's space power program. Reactors powering thermoelectric energy conversion systems were routinely used in earth observation satellites. The U.S. space program launched and operated in space only one nuclear reactor, SNAP-10A, during the early space program. Fission reactors have been proposed to provide power for Mars-based habitats including the production of oxygen separated from the Martian atmosphere to fuel the return to Earth. Fission reactor system concepts for propulsion include **nuclear thermal propulsion (NTP)**, which uses a nuclear reactor to heat an exhaust propellant, and **nuclear electric propulsion (NEP)**, which uses nuclear energy to produce electricity, which then is used to power an ion drive propulsion system. Either concept

represents a near order of magnitude improvement in drive energy per launch mass over conventional chemical rockets.

70.2 Nuclear Power Fundamentals

Fission

The basic source of energy in nuclear power is the fissioning of the nucleus of an isotope of uranium or plutonium. The energy released per fission depends on the particular isotope, and is approximately 3.2×10^{-11} J (joules) for the thermal neutron fission of ${}_{92}\text{U}^{235}$, the most common nuclear fuel. Thus approximately 3.1×10^{10} fissions/sec are required to produce 1 W of thermal energy. Typical commercial nuclear power systems produce 1000 MW of electrical power at a thermal efficiency of about 33%. In such a commercial power system 1 kg of nuclear fuel will produce about 240,000 kilowatt hours of energy, whereas 80,000 kg of coal would be required to produce the same amount of energy.

The fission process is initiated by the absorption of a neutron into the nucleus of a heavy isotope. The energy released from the fission of a nucleus is distributed among various products of the process, including nuclear fragments, neutrons, and gamma rays. An average fission releases two or three excess neutrons. These excess neutrons are available to initiate further fissions; hence, nuclear fission in a suitable assemblage of materials can be a self-sustaining process. Control of the power of a nuclear power system depends on the control of the neutron population, typically through the use of neutron absorbers in movable structures called **control rods**.

In most fissions, approximately 80% of the energy released is carried by two large nuclear fragments, or fission fragments. The fission fragments have very short ranges in the fuel material and come to rest releasing thermal energy and capturing electrons to become fission product atoms. Fission products are typically radioactive, having a spectrum of radioactive decay products and half-lives. Fission products are neutron rich, and a small fraction decay by neutron emission, adding to the neutron population in the reactor. Such fission products are termed *fission product precursors*, and their radioactive decay influences the time-dependent behavior of the overall neutron population in the reactor. These **delayed neutrons** play an essential role in the control of the reactor power.

The thermal energy deposited in nuclear fuel, coolant, and structural material is dependent on the type of radiation carrying the energy. Neutrons are absorbed in stable nuclei, causing the **transmutation** to a radioactive element. Such a capture event releases an energetic photon, a capture gamma, which deposits its energy in the surrounding material. Subsequent radioactive decay of these radionuclides releases additional radiation energy in the form of decay gamma and decay beta radiation. All of the energy released in beta decay is not available to be locally deposited, due to the extremely long range of the antineutrinos, which share the energy available with the beta radiation. Table 70.1 delineates the distribution of energy from a typical fission, including information on the heat produced in the reactor from each source. The convenient unit of energy used is the MeV (mega-electron-volt), where 1 MeV is equal to 1.6×10^{-13} J.

TABLE 70.1 Energy Distribution among Products of Fission

| Energy Source | Energy (MeV) | Heat Produced |
|-------------------|--------------|---------------|
| Fission fragments | 168 | 168 |
| Fast neutrons | 5 | 5 |
| Prompt gammas | 7 | 7 |
| Decay gammas | 7 | 7 |
| Capture gammas | — | 5 |
| Decay betas | 20 | 8 |
| Total | 207 | 200 |

Radioactivity

Elements that undergo radioactive decay are called radioisotopes. Such isotopes hold excess energy in their nuclei and are therefore unstable. They move toward stability by the process of radioactive decay. A radioisotope can be characterized by the energetic radiation that is emitted in the decay process and by the probability of decay per unit time, the decay constant, λ . The products from a radioactive decay include the daughter isotope and one or more radiation emissions. The three most common radiation emissions are alpha, beta, and gamma radiation. Alpha radiation consists of an energetic helium nucleus, beta radiation is an energetic electron, and gamma radiation is a photon of electromagnetic radiation released from nuclear energy level transitions. The activity of a radioactive substance, A , is the number of decays per second and the number of radiations emitted per second, assuming a single radiation per decay:

$$A = \lambda N = \lambda N_0 e^{-\lambda t} \quad (70.1)$$

where t is the time in seconds and N_0 is the initial number of atoms present at $t = 0$. The unit of activity is the Becquerel (Bq), with 1 Bq corresponding to 1 decay per second (dps). The non-SI unit in common use for activity is the curie (Ci), with $1\text{Ci} = 3.7 \times 10^{10}$ dps. The half-life of an isotope is the time for half of the atoms of a given sample to decay, $T_{1/2}$. The decay constant and half-life are related through the following formula:

$$T_{1/2} = \ln 2 / \lambda \quad (70.2)$$

Criticality

The assemblage of nuclear fuel and other material into a device which will support sustained fission is called a **nuclear reactor**. The central region of the reactor is involved in fission energy release, containing the nuclear fuel and related structural and energy transfer materials, and is called the **reactor core**. The typical nuclear fuel for a commercial power reactor is an oxide of uranium that has been enriched in the fuel isotope, ${}_{92}\text{U}^{235}$. While a number of fuel forms are in use, the predominant form is compressed and sintered pellets of the ceramic oxide UO_2 . These pellets are stacked in cladding tubes of **zircaloy**, forming fuel pins, which are held in rectangular arrays of fuel elements by structural guides. The fuel elements are arranged in a rectangular array by core guides to form the reactor core. Coolant passes axially along the fuel elements and through the core.

The neutrons born in fission are typically high-energy neutrons, with an average energy of about 3×10^{-13} J. However, the likelihood of producing fission is higher for low-energy neutrons, those in collisional (thermal) equilibrium with the reactor. Such thermal neutrons have energies of about 4×10^{-21} J. Neutrons in the reactor lose energy through elastic and inelastic collisions with light nuclei, called moderator materials. Collisions with light nuclei are more efficient in reducing neutron energy; therefore, typical materials used to moderate the energy of the neutrons are hydrogen in the form of water, deuterium in water, and carbon in graphite.

Reactor Kinetics

Neutrons are born in the fission process at high energy. Such **fast neutrons** travel through the core, scattering from nuclei and losing energy until they are absorbed, leak from the reactor core, or are thermalized. Thermal neutrons diffuse through the reactor core, gaining or losing energy in thermal equilibrium with the nuclei of core materials until they are absorbed or leak from the system. Those neutrons absorbed in nuclear fuel may cause fission, leading to additional fast neutrons. The behavior of neutrons in the reactor can be described in terms of a neutron life cycle, with the ratio of neutrons in one generation to those in the previous generation given by the multiplication constant k . The time variation of the reactor power is a function of the multiplication constant, with the reactor condition

TABLE 70.2 Critical Constant versus Reactor Power Behavior

| Condition of Reactor | Multiplication Constant | Reactor Power |
|----------------------|-------------------------|---------------|
| Critical | $k = 1$ | Steady |
| Supercritical | $k > 1$ | Increasing |
| Subcritical | $k < 1$ | Decreasing |

termed subcritical, critical, or supercritical, depending on the value of k for the present configuration, as shown in Table 70.2.

The value of k is dependent on geometric and material properties in the reactor and can be varied by introducing or withdrawing absorbing materials or control rods. Six factors make up the average value of k for the reactor:

$$k = P_{fnt} P_{nt} \epsilon \eta f p \quad (70.3)$$

The first two factors are geometric, relating to the leakage of neutrons out of the core of the reactor to be lost by absorption in surrounding material. The fast nonleakage probability, P_{fnt} , is the probability that a fast neutron born in fission does not leak from the reactor before it is thermalized. The thermal nonleakage probability, P_{nt} , is the probability that a thermal neutron does not leak from the reactor prior to being absorbed. These two terms are a function of the geometry of the core and can be approximated as follows:

$$P_{fnt} P_{nt} = 1/(1 + M^2 B^2) \quad (70.4)$$

where M^2 is the neutron migration length and B^2 is the geometric buckling. The neutron migration length is

$$M^2 = L^2 + \tau \quad (70.5)$$

τ is the Fermi age, the mean square distance that a fast neutron travels in the reactor prior to becoming thermalized. L^2 is the mean square distance that a thermal neutron diffuses through the reactor prior to being absorbed. τ can be calculated from scattering theory, but this is beyond the scope of this treatment. L^2 is given in terms of the thermal neutron diffusion coefficient and the **mean free path** of thermal neutrons to absorption, λ_a , which are determined from the properties of the moderator, fuel, and structural material in the reactor core.

$$L^2 = \sqrt{D\lambda_a} \quad (70.6)$$

The geometric buckling is determined by the physical size and shape of the reactor. For a finite length cylinder (the common shape for power reactors), geometric buckling is given as:

$$B^2 = (2.405/R)^2 + (\pi/H)^2 \quad (70.7)$$

where R = radius and H = height.

The next four factors are based on the average properties of the materials that make up the reactor core and are independent of geometry:

ϵ is the fast fission factor, which is the number of neutrons produced in fission from all neutron energies divided by the number of neutrons produced by fissions from thermal neutrons. For a typical thermal reactor this parameter ranges from 1.0 to 1.05.

η is the number of fast neutrons produced per thermal neutron absorbed in the fuel. Thus η is a function of the mean free path of thermal neutrons to fission, the absorption mean free path, and

the number of neutrons produced in an average thermal fission, ν . For a typical PWR, ν has a value of about 2.5.

$$\eta = \nu(\lambda_a^F / \lambda_f) \quad (70.8)$$

f is the thermal utilization, which is the fraction of absorbed thermal neutrons that are absorbed in the fuel material; thus it is a ratio including the mean free path for absorption in fuel, λ_a^F , and the mean free path including all absorptions, λ_a^T :

$$f = \lambda_a^T / \lambda_a^F \quad (70.9)$$

p is the resonance escape probability, the likelihood that a neutron makes the transition from fast to thermal energy without being captured by a nuclear resonance, which leads to loss of the neutron without producing fission. While generally speaking the probability of neutron absorption increases with decreasing neutron energy, there exist specific neutron energies, or resonance energies, that align with the properties of heavy nuclei and have very high probability of neutron absorption. The resonance escape probability depends substantially on the heterogeneous geometry of the reactor, because neutrons leaving the fuel can thermalize in a moderator, thereby skipping over the resonance energies prior to reentering the fuel by diffusion. **Neutron transport theory** must be used to compute p .

In practice, the reactivity, ρ , is often used instead of the multiplication constant, where

$$\rho = (k - 1) / k \quad (70.10)$$

Changes in core configuration or material properties can be characterized as reactivity insertions, where ρ equal to zero corresponds to steady power operation, a positive reactivity insertion (withdrawing an absorber control rod, for example) leads to a power increase, and a negative reactivity insertion (inserting an absorber control rod) leads to a power decrease.

Intelligent reactor design will seek to establish self-stabilizing dynamic behavior of the reactor. This is accomplished through the careful consideration of reactivity coefficients during design. Reactivity coefficients are measures of feedback characteristics of the design. Two important reactivity coefficients are the moderator coefficient and the fuel Doppler coefficient.

The moderator coefficient measures the feedback effect on reactor reactivity with a change in the density of the moderator. If the reactor is designed with slightly less than the optimum amount of moderator, then any decrease in moderator density, either through an increase in temperature or a loss of moderator, will result in a decrease in reactivity and hence a decrease in reactor power. This results in a self-stabilizing condition since an increase in temperature will decrease reactor power, hence restabilizing temperature.

The fuel Doppler coefficient addresses the property of resonance capture within the nuclear fuel. As temperature increases, the range of energies over which any given resonance is effective increases. If the reactor is designed properly this can be a very strong and very rapid self-stabilizing effect protecting the fuel against even very quick events.

The value of these reactivity coefficients is that their effects are inherent in the design and require no active controls or human interaction.

Reactor Thermal Hydraulics

The transfer of thermal energy through a coolant to an energy conversion system is more complex for a nuclear power system than for a combustion-fueled power system. Most of the fission energy is deposited in the nuclear fuel, typically a high-temperature ceramic with poor conductivity. Transfer of heat to the coolant

TABLE 70.3 Annual Radiation Exposures

| | |
|---|---------|
| Occupational limit | 50 mSv |
| General public limit | 1.0 mSv |
| Average background exposure from nonnuclear power sources [natural and medical radiation (dental x-rays and medical treatment)] | 3.5 mSv |

occurs through conduction in the fuel pellet; conduction, radiation, and convection in the gap between the pellet and the cladding; conduction through the cladding; and convection to the coolant, flowing in channels along the fuel pins. Material properties of the fuel change over time with fuel **burnup**, due to fission product entrainment, radiation damage, and thermal cycling, which leads to pellet swelling and cracking.

The balance of plant for a nuclear power plant is similar to that of a conventional power plant; for additional details refer to [Chapter 71](#), on power plants, and [Chapter 74](#), on turbines. However, the presence of coolant-borne radioisotopes may place additional constraints on the operation of steam generators and primary coolant pumps in a nuclear system. Thermal energy management systems are the major source of operational and maintenance costs for a commercial nuclear power system.

Radiation Protection

Analysis of the radiation hazard from nuclear energy systems must include the effect of such systems on materials, biological systems, and the environment. The radiation environment of the fission process requires shielding of radiation-sensitive systems from the radiation produced during reactor operation, principally neutrons and gammas. The fission products produced and the **transuranic** (TRU) isotopes require environmental isolation and long-term storage.

Radiation protection concepts include methods of dealing with both external and internal sources of radiation. National and international standards on radiation protection are set by the National and International Commissions on Radiation Protection (NCRP and ICRP). Standards are enforced through guidelines and procedures promulgated by federal agencies, such as the U.S. Nuclear Regulatory Commission (NRC) and the U.S. Environmental Protection Agency (EPA). The general public and the radiation worker are protected from exposure to radiation far below levels known to cause harm.

Radiation damage occurs due to the deposition of energy in materials, which leads to ionization and atomic displacement damage. The damage to biological systems is a function of the type of radiation and is due to the production of oxidizing radicals following radiation's ionizing effect. Each source of radiation is characterized by its relative biological effectiveness (*RBE*), which is the damage of a given amount of the particular radiation relative to the damage of the same energy deposited by 100 keV x-rays. The unit of absorbed dose is the gray, where 1 gray (Gy) = 1 J (absorbed energy)/kg (mass of material). The unit of radiation exposure is the sievert (Sv), where

$$\text{Dose (Sv)} = \text{Absorbed dose (Gy)} \times \text{RBE} \quad (70.11)$$

The radiation exposure principle that is applied in all occupational exposures is “as low as reasonably achievable” (ALARA). Thus the actual average occupational exposure and public exposure due to nuclear power operations is much less than allowed (see [Table 70.3](#)).

Radiation protection from external sources of radiation relies on three principles: time, distance, and shielding. The exposure to radiation can be minimized by (a) minimizing the time of the exposure to the source; (b) maximizing the distance from the source; (c) interposing absorbing materials, or shielding materials, between the source and the individual; or (d) some appropriate combination of these three strategies. Exposure to radiation from internal sources is controlled by minimizing the ingestion or inhalation of such sources. Regulations exist on the allowable maximum permissible concentration (MPC) of each radioisotope in air and water, based on daily consumption and keeping lifetime exposures below acceptable limits.

Nuclear Fuel Cycle

The nuclear fuel cycle encompasses the following processes from the exploration for uranium ore to the final disposition of the nuclear waste in a geological repository:

Exploration: Uranium and thorium are naturally occurring elements that exist in the earth's crust. Geological evaluation of the potential of a region is followed by monitoring for the low levels of natural radiation produced by the ores.

Mining: Both open-pit and underground mining is done for uranium ore (pitchblende). Major suppliers of uranium ore include Canada, Australia, Niger, Namibia, Uzbekistan, Russia, Kazakhstan, the U.S., and South Africa (listed in order of 2000 production). Canada supplied nearly a third of the uranium mined in 2000, and Australia and Canada combined accounted for more than half.

Milling: Uranium is separated from the ore by physical and chemical means and converted to U_3O_8 (yellowcake).

Enrichment: Natural uranium contains 0.711% (by weight) fuel isotope ${}_{92}U^{235}$. The remainder (>99%) is ${}_{92}U^{238}$, which can be used to breed fuel but is not itself usable as fuel in a thermal reactor. Some process must be used to increase the ${}_{92}U^{235}$ concentration in order to make the fuel usable in light water reactors. Enrichment methods include gaseous diffusion of UF_6 gas, centrifugal enrichment, and laser enrichment. In the U.S., gaseous diffusion plants originally built for the nuclear weapons program are employed for commercial enrichment. In Europe and Russia, gaseous diffusion has been largely replaced with more energy-efficient centrifuge systems. Laser enrichment remains under development.

Fabrication: The enriched UF_6 must be converted to the ceramic form (UO_2) and pressed into pellets, which are sintered and encased in a cladding material. Fuel pins are bound together into fuel assemblies.

Use in reactor: Fuel assemblies are placed in the core of the reactor and over a period of reactor operation, fission energy is extracted. A typical reactor operation time is 18 months, with fuel allowing extensions to 24 months being developed. Fuel management often dictates installing a third of the core as unburned fuel assemblies and discharging a third of the core as spent fuel at each refueling operation. When initially charged to the reactor, the fuel contains about 4% ${}_{92}U^{235}$ and 96% ${}_{92}U^{238}$. When the nuclear fuel is discharged it contains about 1% ${}_{92}U^{235}$, 1% plutonium created from neutron absorptions in ${}_{92}U^{238}$, 95% ${}_{92}U^{238}$, and 3% fission products.

Interim storage: The spent fuel removed from the core must be cooled in water-filled storage pits for 6 months to a year, in order for the residual heat and radioactivity to decay. Following use in a reactor, the spent fuel elements are depleted in the useful nuclear fuel isotopes and contain fission products and transuranic elements. While they are no longer useful for production of electricity, special handling is required due to the residual radioactivity. The decay of fission products continues to provide an internal heat source for the fuel element, which requires cooling during an interim storage period. The heat source is a function of the duration of reactor operation, but following steady power operation the time dependence has the following variation:

$$P(t) = 0.066P_0[t^{-1/5} - (t + t_0)^{-1/5}] \quad (70.12)$$

where P_0 is the power level during operation for time t_0 , and t is the time in seconds after shutdown. Table 70.4 shows the relative heat generation of spent fuel assuming a 1-year operating period. Note that while the heat generation does decrease markedly, heat generation does continue for an extended period and adequate cooling must be provided.

With the significant delays in long-term disposal facilities, the period of interim storage has been extended longer than initially planned. In some reactor facilities the space in water-filled storage pools has been exceeded. In these cases, older fuel with reduced heat generation has been successfully placed in dry cask storage. Dry casks are large steel and/or concrete vessels that can be adequately cooled by passive convection to ambient air.

Reprocessing: As can be seen from the description of discharged fuel above, the spent fuel still contains significant usable material with only 3% of it actually being waste. Recovery and reuse of this material

TABLE 70.4 Decay Heat of Spent Nuclear Fuel after One Year of Operation

| Time after Shutdown | Fraction of Operating Power (%) |
|---------------------|---------------------------------|
| 1 minute | 2.7 |
| 1 hour | 1.1 |
| 1 day | 0.47 |
| 1 month | 0.14 |
| 1 year | 0.027 |
| 10 years | 0.0025 |

can be achieved through reprocessing, where the spent fuel is dissolved and the waste products chemically separated from usable material. However, this process produces separated plutonium, which generates weapons proliferation concerns and the expense of the process is currently challenged by relatively inexpensive new nuclear fuel. The United States has foregone reprocessing because of the proliferation concern and intends to directly dispose of spent fuel without recycling. European and Japanese nuclear programs do use reprocessing to recycle nuclear fuel.

Waste disposal: High-level radioactive waste storage includes both the storage of spent fuel elements in a geological repository and the storage of vitrified waste from the reprocessing stream in such a repository. A geologic repository would place high level waste far underground.

Transportation: The transporting of nuclear materials poses special hazards, due to the potential radiological hazard of the material being shipped. Specially designed and extremely robust shipping casks have been developed with government funding that are able to withstand a highway accident including potential vehicle fire without the release of radionuclides to the environment.

Nuclear safety: Handling of nuclear materials within the nuclear fuel cycle requires special consideration of criticality safety, in order to keep these materials from accidentally coming into a critical configuration outside the confined environment of the reactor core.

Nuclear material safeguards: Nuclear materials, in particular those materials which are key to the development of a nuclear weapon, such as separated plutonium, must be protected from diversion into the hands of terrorists. Special safeguard procedures have been developed to control special nuclear material (SNM). Special nuclear material includes plutonium and highly enriched uranium. However, uranium fuel used in common commercial reactors has enrichment far below that required for weapon uses.

Reactor Types

The most common commercial power reactor type is the **pressurized water reactor (PWR)**. In this design, water is used as both a coolant and a moderator. Water is circulated through the reactor core picking up the heat from the nuclear fission. The heated water is routed to steam generators which are large tube and shell heat exchanges. The shell side water is held at a reduced pressure relative to the primary circuit water and is allowed to boil. The generated steam is then routed to a relatively conventional Rankine cycle electrical generating power plant.

The second most common commercial power reactor is the **boiling water reactor (BWR)**. This design is similar to the PWR using water as a coolant and moderator; however, it differs in that it operates at a lower pressure allowing water to boil directly in the primary vessel. This avoids the need for steam generators, but since the primary water will have some entrained radioactive material in the form of activated corrosion products, the steam plant will be contaminated, complicating maintenance. Between them, PWR and BWR reactors account for over 80% of the current commercial nuclear power plants.

The next most common design is the **pressurized heavy water reactor (PHWR)**. In this design the moderator and coolant is heavy water, that is water comprised of oxygen and deuterium, the first heavy isotope of hydrogen. Although a less efficient moderator than hydrogen, deuterium has the advantage of a much smaller probability of neutron absorption. This allows a critical reactor to be fueled with natural uranium and avoids the expensive process of isotopic enrichment for the nuclear fuel. This cost advantage

TABLE 70.5 Common Commercial Nuclear Power Systems

| Reactor Type | Output (thermal/electric) | Fuel Form | Coolant/Moderator |
|---|---------------------------|---|-----------------------------------|
| Pressurized water reactor (PWR) | 3400 MWth/1150 MWe | UO ₂ pellets, 2 to 4% enriched uranium | H ₂ O/H ₂ O |
| Boiling water reactor (BWR) | 3579 MWth/1178 MWe | UO ₂ pellets, 2 to 4% enriched uranium | H ₂ O/H ₂ O |
| Pressure tube heavy water reactor (CANDU) | 2180 MWth/648 MWe | UO ₂ pellets, natural uranium | D ₂ O/D ₂ O |
| Pressure tube graphite reactor (PTGR) | 3200 MWth/950 MWe | UO ₂ pellets, 1.8 to 2.4% enriched uranium | H ₂ O/graphite |
| Liquid metal fast breeder reactor (LMFBR) | 3000 MWth/1200 MWe | Mixed UO ₂ and PuO ₂ pellets, 10 to 20% plutonium | Liquid sodium/none (fast reactor) |

is offset by the need to isotopically separate deuterium from normal water. Canada is the major producer of PHWRs with its CANDU reactor series. India has produced an indigenous PHWR, albeit based on the CANDU design. PHWRs make up just under 8% of the world's commercial nuclear power plants.

The nuclear power systems in common use throughout the world are listed in Table 70.5, along with information on the fuel form, coolant type, moderator, and typical size.

Reactor Operations, Licensing, and Regulation

The licensing of nuclear power systems in the U.S. is the responsibility of the NRC. State public utility commissions are involved in general oversight of electric power generation by electric utilities, including those with nuclear power plants. Industry associations are involved in the development and promulgation of best industry practices. Two such organizations are the Institute for Nuclear Power Operations (INPO) and the Nuclear Energy Institute (NEI). Similar organizations exist to support international nuclear power operations, including the International Atomic Energy Agency (IAEA), a branch of the United Nations, and the World Association of Nuclear Operators (WANO), an international nuclear power utility industry association.

Radioactive Waste Management

The radioactive wastes generated by nuclear power systems must be handled responsibly, minimizing the radiation exposure to employees and the general public, while providing long-term environmental isolation. Radioactive wastes are characterized as low-level wastes (LLW) or high-level wastes (HLW).

LLW consists of materials contaminated at low levels with radioisotopes but requiring no shielding during processing or handling. LLW is generated not only by nuclear power plant operations but also from medical procedures, university research activities, and industrial processes that use radioisotopes. LLW is judged to have minimal environmental impact, and the preferred method of disposal is shallow land burial in approved facilities. LLW is handled by individual states and state compacts, under authority granted by the U.S. Congress in the Low-Level Radioactive Waste Policy Act of 1980. In 1995, U.S. commercial power reactors each produced an average of about 100 cubic meters of LLW. With the high cost of LLW disposal, efforts to reduce this volume have been undertaken.

HLW includes spent nuclear fuel and the residue of nuclear fuel reprocessing. There is presently (2002) no commercial reprocessing of spent nuclear fuel in the U.S., based on U.S. nonproliferation policy. However, there is a substantial amount of HLW in the U.S. that was generated by the nuclear weapons production program. This is currently stored at U.S. DOE sites, and the required facilities for processing prior to long-term storage are being constructed. European countries and Japan have active programs for the reprocessing of spent reactor fuel. In the U.S., under the Nuclear Waste Policy Act of 1982, HLW is scheduled for long-term geological repository storage, with the U.S. Department of Energy assigned to manage both storage and disposal programs. A national geological repository is being developed at

Yucca Mountain, Nevada. The Department of Energy has formally recommended the site, and in July 2002, the U.S. Senate approved the plan. The NRC now has the disposal plan under review. It is not expected to be ready for permanent storage of HLW until 2010. In the interim, electric utilities are using on-site wet-well or dry-cask storage of their spent fuel.

70.3 Economics of Nuclear Power Systems

Existing commercial power plants are currently very competitive with other forms of electrical generation. The majority of the cost of nuclear electrical production is amortization of the capital cost of the plant; fuel and O&M account for a small fraction of the cost of power. Nuclear fuel and O&M costs are roughly equivalent to coal-fired plants and significantly less than natural gas-fired plants with their high fuel cost. The current generation of U.S. nuclear units has largely amortized their original capital cost and is now producing electricity at relatively low cost.

Capacity factors have steadily improved, from 76% in 1996 to over 89% in 2001. Useful fuel life has been extended with the period between refueling outages going from 12 months to 18 and promised further extensions to 24 months. Refueling outages have been dramatically shortened and forced outages significantly reduced. The number of nuclear operating utilities has been reduced as a set of highly efficient nuclear-dominated operators has bought up nuclear generating assets. The result is a smaller number of better operated and more economically viable nuclear operators.

New construction within the U.S. is still limited by the high capital cost and uncertainties in the regulatory environment. New plant concepts exist to address construction cost and schedule, and the NRC has developed a streamlined licensing process; however, neither the new concepts nor NRC process have yet been put to the test.

Alternative Sources of Electrical Power

The primary competing sources of electric power are fossil fuel-fired generation, that is, coal and natural gas. While coal retains approximately a 50% share of electrical generation, essentially all of the near-term future expansion in the U.S. is slated to be natural gas. The extremely low capital cost and short construction times of natural gas gives that source a great advantage over its competitors. Natural gas also produces less environmental pollution than does coal. It produces significantly less sulfur and nitrous oxides and, due to its greater carbon efficiency, less greenhouse gases than coal.

The public is becoming more aware of the greenhouse gas produced by fossil fuels and concerned about the resulting global warming. While there has been some recognition that nuclear generation of electricity avoids all greenhouse gas emissions, this has not resulted in a large increase in public support for nuclear energy. Misunderstandings of the magnitude and true hazard of HLW and of power plant safety still limit public support. Lack of a demonstration of economical new construction in the U.S. limits investments in new commercial power reactors in this country. However, according to the World Nuclear Association, worldwide 27 new commercial power reactors are under construction (as of September 2002) and an additional 31 are being planned.

Next-Generation Commercial Systems

In conjunction with the Electrical Power Research Institute and three major U.S. reactor vendors, the U.S. Department of Energy developed three advanced light water reactor designs. These were the ABB Combustion Engineering's System 80+ PWR design, Westinghouse's AP600, and General Electric's Advanced Boiling Water Reactor (ABWR) design. All three were reviewed by the NRC and given final design approval. None of these systems has been built in the U.S. However, two ABWRs have been constructed and are operating in Japan. These plants were complete in 52 months. The Koreans have two PWRs under construction that are largely based on the system 80+ design, and construction is expected to take only 48 months.

These advanced light water reactors are driving down the capital cost of nuclear units. The AP600 designers are attempting to bring the total cost of power of their concept down to 3.2¢/kilowatt hour. That price would be instantly competitive in the U.S. market.

Beyond light water reactors, considerable attention has been given to pebble-bed modular reactors. In this concept the fuel is uranium carbide microspheres encased in silicon carbon shells and compressed into tennis ball-sized spheres. The fuel spheres or pebbles are held in a vessel with helium gas forced through as a coolant. The hot helium is then used to drive a conventional Brayton cycle gas turbine. The benefits of the concept are extremely high thermal efficiency and an essentially indestructible fuel form. Even in the event of a loss of all forced cooling, the fuel will retain its fission products. Other graphite-moderated, gas-cooled configurations have been proposed, also offering high thermal efficiency and extremely robust nuclear fuel.

While decreased relative to prior years, research continues on breeder reactor concepts. These concepts have been challenged by high cost and the proliferation concerns of plutonium production. However, their strong appeal is the utilization of a majority of the 95% of the energy content currently abandoned in a once-through reactor fuel cycle.

Defining Terms

Boiling water reactor (BWR) — Allows the liquid coolant to boil in the core, and the primary loop includes steam separators and dryers and the generation of steam within the primary vessel.

Burnup — The quantity of energy released, in megawatt-days per metric ton of fuel; also the change in quantity of nuclear fuel due to fissioning.

CANDU — A reactor using natural uranium with deuterated water for both cooling and moderation, the preferred reactor of the Canadian nuclear power program. No fuel enrichment is required, but deuterium must be separated from water.

Control rods — Devices including elements that strongly absorb neutrons, used to control the neutron population in a nuclear reactor.

Delayed neutrons — Neutrons born from the decay of neutron-rich fission products. The emission of these neutrons is controlled by the radioactive decay of their parent fission product; hence, they are delayed from the fission event.

Fast neutrons — Neutrons born in fission, typically with energies well above the thermal range.

Liquid metal fast breeder reactor (LMFBR) — A reactor that operates on a fast neutron spectrum and breeds additional nuclear fuel from nonfuel ${}_{92}\text{U}^{238}$. Sodium metal is the liquid coolant, and a secondary sodium coolant loop transfers energy through a heat exchanger to a tertiary loop of water, which generates steam for a turbine.

Mean free path — The average distance that a neutron of a given energy travels through matter prior to an interaction of the type specified (i.e., scattering or absorption).

Moderator — A material that scatters neutrons rather than absorbing them, typically a light element that causes neutrons to lose energy efficiently during scattering.

Nuclear energy — The release of energy from fissioning the nucleus, as opposed to fossil energy, which releases energy from chemical combustion.

Nuclear reactor — An assemblage of materials designed for the controlled release of nuclear energy.

Neutron transport theory — The theory that includes the detailed spatial and time behavior of neutrons traveling through matter; transport analysis requires detailed understanding of the nuclear properties of materials.

Pressure-tube graphite reactor (PTGR) — A reactor in which fuel assemblies are contained in water-filled tubes that provide flowing cooling. Those tubes penetrate a graphite block, with the graphite providing neutron moderation.

Pressurized water reactor (PWR) — The PWR has a pressurized primary loop that transfers heat through a heat exchanger to a secondary water loop that includes the steam generator. Heat transfer in the core occurs in the subcooled phase.

Reactor core — The central region of a nuclear reactor, where fission energy is released.

Thermal neutrons — Neutrons that have kinetic energies comparable to the thermal energy of surrounding materials and hence are in collisional equilibrium with those materials.

Transmutation — The change of a nucleus to a different isotope through a nuclear reaction such as the absorption of a neutron and the subsequent emission of a photon (capture gamma).

Transuranic — Isotopes higher in atomic number than uranium; they are created by nuclear transmutations from neutron captures.

Zircaloy — An alloy of zirconium that is used for cladding of nuclear fuel. Zirconium has a very small probability of absorbing neutrons, so it makes a good cladding material.

University of Wisconsin

Power plants convert a primary source of energy to electrical energy. The primary sources are:

1. *Fossil fuels*, such as coal, petroleum, and gas.
2. *Nuclear fuels*, such as uranium, plutonium, and thorium in fission and deuterium and tritium in fusion.
3. *Renewable energy*, such as solar, wind geothermal, hydro, and energy from the oceans. The latter could be due to tides, waves, or the difference in temperature between surface and bottom, called *ocean-temperature energy conversion (OTEC)*.

Systems that convert these primary sources to electricity are in turn generally classified as follows:

1. The **Rankine cycle**, primarily using water and steam as a working fluid, but also other fluids, such as ammonia, a hydrocarbon, a freon, and so on. It is widely used as the conversion system for fossil and nuclear fuels, solar energy, geothermal energy, and OTEC.
2. The **Brayton cycle**, using, as a working fluid, hot air–fossil fuel combustion products or a gas, such as helium, that is heated by nuclear fuel.
3. The combined cycle, a combination of Rankine and Brayton cycles in series.
4. Wind or water turbines, using wind, hydropower, ocean tides, or ocean waves.
5. Direct energy devices, which convert some primary sources to electricity directly (without a working fluid), such as photovoltaic cells for solar energy and fuel cells for some gaseous fossil fuels.

In the mid-1990s, U.S. power plants generated more than 550,000 megawatts. About 20% of this capacity was generated by fission nuclear fuels using the Rankine cycle. A smaller fraction was generated by hydropower, and a meager amount by other renewable sources. The largest portion used fossil fuels

FIGURE 71.1 A flow diagram of a fossil-fuel Rankine-cycle power plant with one closed feedwater heater with drains pumped forward, five closed feedwater heaters with drains cascaded backward, and one open feedwater heater. HP = high-pressure turbine. IP = intermediate-pressure turbine. LP = low-pressure turbine. EG = electric generator. CO = condenser. CP = condensate pump. FP = feedwater pump. EC = economizer. DR = steam drum. BO = boiler. SU = superheaters. RE = reheaters.

and the Rankine cycle. Nuclear power plants and some of the renewables are described elsewhere in this chapter. The following section describes fossil-Rankine-type power plants.

71.1 The Rankine Cycle

Rankine is a versatile cycle that can use a wide variety of heat sources. In its most common form, it uses water and steam as a working fluid. It can be built to generate large quantities of electric power, exceeding 1000 megawatts in a single power plant. It has the highest conversion efficiency (ratio of electrical energy generated to heat energy added) of all large practical conversion systems.

Figure 71.1 shows a flow diagram of a Rankine cycle. High-pressure, superheated steam is admitted to a **steam turbine** at 1, commonly at 170 bar (about 2500 psia) and 540°C (about 1000°F), though new developments call for higher values with pressures in the supercritical range, above 221 bar (3208 psia). Steam expands through the turbine to 2, becoming a two-phase mixture of steam and water, usually 80% steam by mass, where the pressure and temperature are typically 0.07 bar and 40°C (about 1 psia and 104°F) but vary according to the available cooling conditions in the **condenser**.

The turbine exhaust at 2 is cooled in a condenser at constant pressure and temperature, condensing to a saturated liquid at 3. The condensate is then pumped through a feedwater system, where it is heated in stages by a series of **feedwater heaters**, to 4, where the temperature is just below the boiling temperature at the maximum pressure in the cycle. Heat is then added to feedwater in a **steam generator**, converting it to steam at 1.

71.2 The Turbine

The energy imparted by the steam from 1 to 2 is converted to mechanical work by the turbine, which in turn drives an electric generator to produce electricity, according to the following formula:

$$W_T = \sum (m \cdot \Delta h) \times \eta_T \quad (71.1)$$

where W_T = turbine mechanical power, kW or British thermal units (Btu)/h; m = mass flow rate of steam through each turbine section, kg/h or lb/h; Δh = enthalpy drop of steam through each turbine section, kJ/kg or Btu/lb; and η_T = overall turbine efficiency = ratio of turbine shaft power to power imparted by the steam to the turbine, and

$$W_G = W_T \times \eta_G \quad (71.2)$$

where W_g = electrical generator power and η_G = electrical generator efficiency.

Modern power plant turbines are made of multiple sections, usually in *tandem* (on one axis). The first section, a high-pressure turbine, made largely of **impulse blading**, receives inlet steam and exhausts to a reheater in the steam generator. The reheated steam, at about 20% of the pressure and about the same temperature as at 1, enters an intermediate-pressure turbine made of **reaction blading**, from which it leaves in two or three parallel paths to two or three low-pressure turbines, *double-flow* and also made of reaction blading. Steam enters each in the center and exhausts at both ends, resulting in four or six paths to the condenser. This configuration divides up the large volume of the low-pressure steam — and therefore the height and speed of the turbine blades — and eliminates axial thrust on the turbine shaft. [Chapter 74](#) of this text describes steam turbines in greater detail.

71.3 The Condenser

The process of condensation is necessary if net power is to be generated by a power plant. (If the turbine exhaust were to be pumped back directly to the steam generator, the pumping power would be greater than the electrical power output, resulting in net negative power. Also, the second law of thermodynamics stipulates that not all heat added to a thermodynamic cycle can be converted to work; hence, some heat must be rejected.) The condenser is where heat is rejected.

To increase the cycle efficiency, the rejected heat must be minimized so that a higher percentage of the heat added is converted to work. This is done by operating the condenser at the lowest temperature, and hence the lowest pressure, possible by using the lowest-temperature coolant available, usually water from a nearby large supply, such as a river, lake, or ocean. Most power plants are situated near such bodies of water. When cooling water goes through a condenser, its temperature rises before it is readmitted to its source. To minimize this heating and its undesirable effect on the environment and to conserve water, cooling towers may be used. The heat rejected to the environment by the condenser Q_R is given by

$$Q_R = m_c(h_2 - h_3) \quad (71.3)$$

where m_c = steam mass flow rate to condenser = mass flow rate of turbine inlet steam at 1 minus steam bled from the turbine for feedwater heating, as discussed later.

The most common condenser is the *surface condenser*, [Figure 71.2](#). It is a shell-and-tube heat exchanger, composed of a steel shell with water boxes on each side connected by water tubes. Cooling water from the coolest part of the source is cleaned of debris by an intake mechanism and pumped by large circulating pumps to one of the water boxes, from which it goes through the tubes, exiting at the other box, and back to its source, at such a location to avoid reentry of the heated water to the condenser. Such a condenser is of the *one-pass* kind. A *two-pass* condenser is one in which one box is divided into two compartments. The incoming water enters half the tubes from one compartment, reverses direction in the second box, and returns through the other half of the tubes to the second compartment of the first box. One-pass condensers require twice the quantity of cooling water as two-pass condensers but result in lower condenser pressures and higher power plant efficiencies and are used where there are ample supplies of water. Surface condensers are large in size, often exceeding 100,000 m² (more than a million square feet) of tube surface area, and 15 to 30 m (50 to 100 ft) tube lengths in large power plants.

Another type, called the *direct-contact* or *open* condenser, is used in special applications, such as with geothermal power plants, with OTEC, and when dry cooling towers (below) are used. A direct-contact

FIGURE 71.2 A flow diagram of a power plant cooling system, with a two-pass surface condenser and a wet, mechanical-induced-draft, cross-flow cooling tower.

condenser is further classified as a *spray condenser*, a *barometric condenser*, or a *jet condenser*. The latter two are not widely used.

A spray direct-contact condenser is one in which demineralized cooling water is mixed with the turbine exhaust via spray nozzles. The mixture becomes a saturated liquid condensate. A fraction of it equal to the turbine flow goes to the cycle; the balance is cooled in a dry cooling tower and then recirculated to the condenser spray nozzles. The ratio of cooling water to turbine flow is large, about 20 to 25. In geothermal plants the fraction equal to the turbine flow may be returned to the ground. In OTEC it is returned to the ocean.

71.4 The Condenser Cooling System

A condenser cooling system may be open (or *once-through*) or partially closed, using **cooling towers**. The latter are classified into *wet natural-draft cooling towers*, *wet mechanical-draft cooling towers*, and *dry cooling towers*.

Once-Through Cooling System

Here, cooling water is taken from the source (usually at a depth where it is sufficiently cool), passed through the condenser, then returned to the source at a point that ensures against short circuiting of the warmer water back to the condenser, such as downstream of the intake. Once-through systems are the most efficient means of cooling a condenser but require large quantities of water and discharge warm water back to the source. Environmental regulations often prohibit the use of once-through systems, in which case cooling towers are used.

Wet Cooling Towers

In a wet cooling tower, the warm condenser water is essentially cooled by direct contact with atmospheric air. It is sprayed over a lattice of slats or bars, called a *fill* or *packing*, which increases its surface-to-volume ratio, as in Figure 71.2. Atmospheric air passes by the water in a *cross-flow* or *counterflow* manner. The water is cooled by exchanging heat with the cooler air and, more importantly, by partial evaporation into the heated and, hence, lower-relative-humidity air.

Because of evaporative losses, wet towers do not eliminate the need for water, but they appreciably reduce it, since these losses are a fraction of the total water flow. An additional loss is due to *drift*, in which

unevaporated water drops escape with the air. *Drift eliminators* are added to reduce this loss. Evaporative losses depend upon the climatic conditions and could be as high as 1.5% of total water flow. Drift could be as high as 2.5% of the evaporative losses. An additional loss is *blowdown* or *bleed*. Warm water in the tower contains suspended solids and is fully aerated. Chemical additives are used to inhibit microbiological growth and scales. Thus, a certain percentage of the circulating cooling water is bled to maintain low concentrations of these contaminants. The bleed, nearly as high as the evaporative loss if high purity is to be maintained, is often returned to the source after treatment to minimize pollution. All losses must be compensated for by *makeup*; power plants using wet cooling towers are also sited near bodies of water. Other problems of wet towers are icing and fogging due to exiting saturated air in cold weather.

Mechanical- and Natural-Draft Cooling Towers

Atmospheric air flows through cooling towers either mechanically or naturally. In the former, it is moved by one or more fans. Because of distribution problems, leaks, and possible recirculation of the hot humid exit air, most mechanical towers move the air by *induced-draft* fans. These are placed at the top and suck the hot air through the tower. Such towers are usually multicell with several fans placed in stacks atop a bank of towers, the number depending upon the size of the power plant. The fans are usually multibladed (made of aluminum, steel, or fiberglass), are driven at low speeds by electric motors through reduction gearing, and could be as large as 10 m (33 ft) in diameter. Mechanical-draft cooling towers consume power and are relatively noisy.

In the natural-draft cooling tower, air flows by a natural driving force, F_D , caused by the density differences between the cool air outside and the warm air inside the tower, given by

$$F_D = (\rho_o - \rho_i)Hg \quad (71.4)$$

where ρ_o and ρ_i = average densities of air outside and inside the tower; H = height of the tower; and g = the gravitational acceleration.

Because the difference between the densities is small, H is large — about 130 m (430 ft). The towers are imposing structures that are visible from afar and are costly to build, but consume no power. The water distribution system and fill are placed at the bottom, and most of the tower height is open space of circular cross-section. The vertical profile is hyperbolic, which offers good resistance to wind pressures. Natural-draft cooling towers are usually made of reinforced concrete and sit on stilts and are mostly of the counterflow type.

A compromise between mechanical and natural draft towers is called the *hybrid* or *fan-assisted hyperbolic* cooling tower. A number of forced draft fans surround the bottom to augment the natural driving force of a shorter hyperbolic tower. The hybrid consumes less power than a mechanical and is smaller and less costly than a natural tower.

Dry and Wet-Dry Cooling Towers

Dry cooling towers are used when a power plant is sited far from adequate sources of water, near coal mines or other abundant fuel to reduce transportation costs, near large power consumers to reduce electrical transmission costs, or in arid areas. They are essentially closed-type heat exchangers in which warm condenser water passes through a large number of finned tubes cooled by atmospheric air, and no water is lost due to evaporation, drift, and so on. They are usually easier to maintain than wet towers and do not suffer from fogging or icing.

Dry cooling towers, however, are not as effective. Lacking evaporative cooling, they have lower heat transfer capabilities, resulting in large heat exchanger surfaces and land areas. This also results in higher condenser water temperatures and hence higher back pressures on the turbine than with wet towers, resulting in lower power plant efficiencies. The problem is aggravated further during periods of high atmospheric air temperatures.

Dry cooling towers may be mechanical or natural draft. They also may be designed to operate in *direct* or *indirect* modes. In the direct mode, the turbine exhaust steam passes through large finned tubes that are cooled by the atmospheric air. Indirect dry towers, more common, use a conventional surface condenser with an intermediate coolant, such as water, or a two-phase fluid, such as ammonia. The latter, under development, improves heat transfer and results in lower penalties on the cycle efficiency.

Wet-dry cooling towers are combinations of the above. Warm condenser water enters a dry section of the tower — reducing its temperature partially — then goes on to a wet section. Parallel air flows to each section combine to a common exit. This reduces fogging and evaporative losses, but at the expense of more complexity and cost.

71.5 The Feedwater System

The condensate at 3 (in [Figure 71.1](#)) is returned to the cycle to be converted to steam for reentry to the turbine at 1. Called the *feedwater*, it is pumped by condensate and feedwater pumps — to overcome flow pressure losses in the feedwater system and the steam generator — and enters the turbine at the desired pressure. The feedwater is heated successively to a temperature close to the saturated temperature at the steam generator pressure. This process, called *regeneration* or *feedwater heating*, results in marked improvement in cycle efficiency and is used in all modern Rankine cycle power plants, both fossil and nuclear.

Regeneration is done in stages in feedwater heaters, which are of two types: (1) *closed* or *surface* type and (2) *open* or *direct-contact* type. The former are further classified into *drains cascaded backwards* and *drains pumped forward*. All types use steam bled from the turbine at pressures and temperatures chosen to match the temperatures of the feedwater in each feedwater heater. The amount of steam bled from the turbine is a small fraction of the total turbine flow because it essentially exchanges its latent heat of vaporization with sensible heat of the single-phase feedwater.

Closed feedwater heaters are shell-and-tube heat exchangers where the feedwater flows inside tubes and the bled steam condenses over them. Thus, they are much like condensers but are smaller and operate at higher pressures and temperatures. The steam that condenses is returned to the cycle. It is either cascaded backwards — that is, throttled to the next lower-pressure feedwater heater — or pumped forward into the feedwater line. The cascade type is most common (see [Figure 71.1](#)).

Open feedwater heaters, on the other hand, mix the bled steam with the feedwater, resulting in saturated liquid. The mix is then pumped by a feedwater pump to the next higher-pressure feedwater heater. Most power plants use one open-type feedwater heater, which doubles as a means to rid the system of air and other noncondensable gases; this type is often referred to as a *deaerating* or *DA* heater. It is usually placed near the middle of the feedwater system, where the temperature is most conducive to deaeration.

The mass flow rate of the bled steam to the feedwater heaters is obtained from energy balances on each heater [El-Wakil, 1984]. This determines the mass flow rate in each turbine section [which is necessary to evaluate the turbine work [Equation (71.1)] and the heat rejected by the condenser [Equation (71.3)].

71.6 The Steam Generator

A modern fossil-fuel power plant steam generator is a complex system. Combustion gases pass successively through the boiler, superheaters, reheaters, economizer, and air preheater and finally leave through a stack.

The Fuel System

Fuel is burned in a furnace with excess air (more than stoichiometric or chemically correct). This combustion air is forced through the system from the atmosphere by a **forced-draft fan**, resulting in combustion gases at about 1650°C (3000°F). At steam generator exit the air (now called *flue gases*) is drawn out by an *induced-draft fan* at about 135 to 175°C (275 to 350°F) into the stack. This seemingly high temperature represents an energy loss to the system but is necessary to prevent condensation of

water vapor in the gases, which would combine with other combustion products to form acids and to facilitate flue gas dispersion into the atmosphere.

Pulverized Coal Firing

Furnaces have undergone much evolution. With coal, the old mechanical stokers have given way to **pulverized coal** firing in most modern systems. To pulverize, *run-of-the-mill* (as shipped from the mine) coal, averaging about 20 cm (8 in.) in size, is reduced to below 2 cm (0.75 in.) by *crushers*, which are of several types, including *rings*, *Bradford breakers*, and *hammer mills*. The crushed coal is then dried by air at 345°C (650°F) or more, obtained from the air preheater. The coal is then ground by pulverizers, which are usually classified according to speed. A common one is the medium-speed (75 to 225 rpm) *ball-and-race pulverizer*, which grinds the coal between two surfaces. One surface consists of steel balls that roll on top of the other surface, similar to a large ball bearing. Hot air then carries the powdery coal in suspension to a *classifier*, which returns any escaping large particles back to the grinders.

Pulverized coal is classified as 80% passing a #200 mesh screen (0.074 mm openings) and 99.99% through a #50 mesh screen (0.297 mm). It is fed to the furnace burners via a set of controls that also regulate primary (combustion) air to suit load demands. Large steam generators have more than one pulverizer system, each feeding a number of burners for a wide range of load control. Burners may be designed to burn pulverized coal only or to be multifuel, capable of burning pulverized coal, oil, or gas.

Cyclone Furnaces

A **cyclone furnace** burns crushed coal (about 95% passing a #4 mesh screen, about 5 mm). It is widely used to burn poorer grades of coal that contain high percentages of ash and volatile matter. Primary air, about 20% of the total combustion air, and the rest, secondary and tertiary air, enter the burner successively and tangentially, imparting a centrifugal motion to the coal. This good mixing results in high rates of heat release and high combustion temperatures that melt most of the ash into a molten slag. This drains to a tank at the bottom of the cyclone where it gets solidified, broken, and removed. Ash removal materially reduces erosion and fouling of steam generator surfaces and reduces the size of particulate matter-removal equipment such as electrostatic precipitators and bag houses. The disadvantages of cyclone firing are high power requirements and, because of the high temperatures, the production of more pollutants, such as oxides of nitrogen, NO_x .

Fluidized-Bed Combustion

Another type of furnace uses **fluidized-bed combustion**. Crushed coal particles, 6 to 20 mm (0.25 to 0.75 in.) in size, are injected into a bed above a bottom grid. Air from a plenum below flows upwards at high velocity so that the drag forces on the particles are at least equal to their weight, and the particles become free or fluidized with a swirling motion that improves combustion efficiency. Combustion occurs at lower temperatures than in a cyclone, reducing NO_x formation. About 90% of the sulfur dioxide that results from sulfur in the coal is largely removed by the addition of limestone (mostly calcium carbonate, CaCO_3 , plus some magnesium carbonate, MgCO_3) that reacts with SO_2 and some O_2 from the air to form calcium sulfate, CaSO_4 , and CO_2 . The former is a disposable dry waste. Technical problems, such as the handling of the calcium sulfate, are under active study.

The Boiler

The boiler is that part of the steam generator that converts saturated water or low-quality steam from the economizer to saturated steam. Early boilers included fire-tube, scotch marine, straight-tube, and Stirling boilers. The most recent are water-tube–water-wall boilers. Water from the economizer enters a steam drum, then flows down insulated down-comers, situated outside the furnace to a header. The latter feeds vertical closely spaced water tubes that line the furnace walls. The water in the tubes receives heat

from the combustion gases and boils to a two-phase mixture. The density difference between the down-comer and the tubes causes a driving force that circulates the mixture up the tubes and into the drum. The tubes also cool the furnace walls. There are several water-wall designs. A now-common one is the *membrane* design, in which 2.75- to 3-in. tubes on 3.75- to 4-in. centers are connected by welded membranes that act as fins to increase the heat-transfer surface as well as form a pressure-tight wall protecting the furnace walls. The steam drum now contains a two-phase bubbling mixture, from which dry steam is separated by gravity and mechanically with baffles, screens, and centrifugal separators.

Superheaters and Reheaters

Dry-saturated steam from the boiler enters a primary and then a secondary superheater in series, which convert it to superheated steam. The superheaters are made of 2- to 3-in. diameter U-tube bundles made of special high-strength alloy steels of good strength and corrosion resistance, suitable for high-temperature operation. The bundles are usually hung from the top, and called *pendant tubes*, or from the side, and called *horizontal tubes*. Another type, supported from the bottom and called the *inverted tube*, is not widely used.

Superheated steam enters the high-pressure turbine and exhausts from it to return to the steam generator, where it is reheated to about the same turbine inlet temperature in a set of reheaters, downstream of and similar in design to the superheaters. The reheated steam enters the intermediate-pressure and then the low-pressure turbines, as explained above.

Superheaters and reheaters may be of the *radiant* or *convection* types. The former, in view of the luminous combustion flames in the furnace, receives heat primarily by radiation. This heat transfer mode causes the exit steam temperature to decrease with increasing load (steam flow). The latter receives heat by convection, the main form of heat transfer in superheaters and reheaters, which causes the exit steam temperature to increase with load. To obtain fairly constant steam temperatures, *attemperators* are placed between the primary and secondary sections of superheaters and reheaters. In its most common form, an attemperator maintains the desired temperatures by spraying regulated amounts of lower-temperature water from the economizer or boiler directly into the steam.

The Economizer

The flue gases leave the reheaters at 370 to 540°C (700 to 1000°F). Rather than reject their energy to the atmosphere, with a consequent loss of plant efficiency, flue gases now heat the feedwater leaving the last (highest pressure) feedwater heater to the inlet temperature of the steam generator. This is done in the *economizer*. At high loads the economizer exit may be low-quality water–steam mixture. Economizers are usually made of tubes, 1.75 to 2.75 in. in diameter, arranged in vertical sections between headers and placed on 1.75 to 2 in. spacings. They may be plain-surfaced, finned, or studded to increase heat transfer. Smaller spacings and studs are usually used with clean ash-free burning fuels, such as natural gas.

Air Preheater

Flue gases leave the economizer at 315 to 425°C (600 to 800°F). They are now used in an *air preheater* to heat the atmospheric air, leaving the forced-draft fan to about 260 to 345°C (500 to 650°F) before admitting it to the furnace, thus reducing total fuel requirements and increasing plant efficiency. Air preheaters may be recuperative or regenerative. *Recuperative* preheaters are commonly counterflow shell-and-tube heat exchangers in which the hot flue gases flow inside and the air outside vertical tubes, 1.5 to 4 in. in diameter. A hopper is placed at bottom to collect soot from inside the tubes. *Regenerative* preheaters use an intermediate medium. The most common, called *ljungstrom*, is rotary and is driven by an electric motor at 1 to 3 rpm through reduction gearing. The rotor has 12 to 24 sectors that are filled with a heat-absorbing material such as corrugated steel sheeting. About half the sectors are exposed to and are heated by the hot flue gases moving out of the system at any one instant; as the sectors rotate, they become exposed to and heat the air that is moving in the opposite direction (into the system)

Environmental Systems

Besides cyclone and fluidized-bed combustion, there are other systems that reduce the impact of power generation on the environment. Flue gas desulfurization systems, also called **scrubbers**, use aqueous slurries of lime–limestone to absorb SO_2 . **Electrostatic precipitators** remove particulate matter from the flue gases. Here, wire-to-discharge electrodes carry a 40 to 50 kV current and are centrally located between grounded plates or collection electrodes. The resulting current charges the soot particles, which migrate to the plates, where they are periodically removed. Fabric filters or **baghouses** also remove particulate matter. They are made of a large number of vertical hollow cylindrical elements — 5 to 15 in. in diameter and up to 40 ft high, made of various porous fabrics (wool, nylon, glass fibers, etc.) — through which the flue gases flow and get cleaned in the manner of a household vacuum cleaner. The elements are also periodically cleaned.

71.7 Cycle and Plant Efficiencies and Heat Rates

The heat added to the power plant, Q_A , and the cycle, Q_C are given by the following:

$$Q_A = m_f \times \text{HHV} \quad (71.5a)$$

$$Q_C = Q_A \times \eta_{sg} = m_1(h_1 - h_4) \quad (71.5b)$$

where m_f = the mass flow rate of fuel to the furnace, in kg/h or lb/h, and HHV = higher heating value of fuel, in kJ/kg or Btu/lb.

The plant efficiency, η_p , and cycle efficiency, η_C , are given by the following:

$$\eta_p = W_G / Q_A \quad (71.6a)$$

$$\eta_C = W_T / Q_C \quad (71.6b)$$

The value η_p , given above, is often referred to as the plant *gross efficiency*. Since some of the generator power, W_G , is used within the plant to power various equipment, such as fans, pumps, pulverizers, lighting, and so on, a *net efficiency* is often used, in which W_G is reduced by this auxiliary power. Another parameter that gives a measure of the economy of operation of the power plant is called the **heat rate**, HR. It is given by the ratio of the heat added in Btu/h to the plant power in kW, which may be gross or net. For example,

$$\text{Net plant HR, Btu/kWh} = (Q_A, \text{ Btu/h}) / (W_G - \text{auxiliary power, kW}) \quad (71.7)$$

The lower the value of HR is, the better. A benchmark net HR is 10,000, equivalent to a net plant efficiency of about 34%. It could be as high as 14,000 for older plants and as low as 8500 for modern plants.

Defining Terms

Baghouse — Removes particulate matter from the flue gases by porous fabric filters.

Brayton cycle — A cycle in which a gas (most commonly air) is compressed, heated, and expanded in a gas turbine to produce mechanical work.

Condenser — A heat exchanger in which the exhaust vapor (steam) of the turbine in a Rankine cycle is condensed to liquid, usually by cooling water from an outside source, for return back to the steam generator.

Cooling tower — A heat exchanger in which the condenser cooling water is in turn cooled by atmospheric air and returned back to the condenser.

- Cyclone furnace** — A furnace in which crushed coal is well mixed with turbulent air, resulting in good heat release and high combustion temperatures that melt the coal ash content into removable molten slag, thus reducing furnace size and the fly ash content of the flue gases and eliminating the cost of coal pulverization.
- Electrostatic precipitator** — A system that removes particulate matter from the flue gases by using one electrode at high voltage to electrically charge the particles, which migrate to the other grounded electrode, where they are periodically removed.
- Feedwater heaters** — Heat exchangers that successively heat the feedwater before entering the steam generator using steam that is bled from the turbine.
- Fluidized-bed furnace** — A furnace in which crushed coal is floated by upward air — resulting in a swirl motion that improves combustion efficiency, which in turn gives lower combustion temperatures and reduced NO_x in the flue gases — and in which limestone is added to convert much of the sulfur in the coal to a disposable dry waste.
- Forced-draft fan** — The fan that forces atmospheric air into the steam generator to be heated first by an air preheater and then by combustion in the furnace.
- Heat rate** — The rate of heat added to a power plant in Btu/h to produce one kW of power.
- Impulse blades** — Blades in the high-pressure end of a steam turbine and usually symmetrical in shape that ideally convert kinetic energy of the steam leaving a nozzle into mechanical work.
- Once-through cooling** — The exhaust vapor from the turbine of a Rankine cycle is condensed by cool water obtained from an available supply such as a river, lake, or the ocean, and then returned to that same supply.
- Pulverized coal** — A powdery coal that is prepared from crushed and dried coal and then ground, often between steel balls and a race.
- Rankine cycle** — A closed cycle that converts the energy of a high-pressure and high-temperature vapor produced in a steam generator (most commonly steam) into mechanical work via a turbine, condenser, and feedwater system.
- Reaction blades** — Blades downstream of impulse blades in a steam turbine and having an airfoil shape that convert some of both kinetic and enthalpy energies of incoming steam to mechanical work.
- Scrubbers** — A desulfurization system that uses aqueous slurries of lime–limestone to absorb SO₂ in the flue gases.
- Steam generator** — A large complex system that transfers the heat of combustion of the fuel to the feedwater, converting it to steam that drives the turbine. The steam is usually superheated at subcritical or supercritical pressures (critical pressure = 3208 psia or 221 bar). A modern steam generator is composed of economizer, boiler, superheater, reheater, and air preheater.
- Steam turbine** — A machine that converts steam energy into the rotary mechanical energy that drives the electric generator. It is usually composed of multiple sections that have impulse blades at the high-pressure end, followed by reaction blades.

Kyle K. Wetzel
Wetzel Engineering, Inc.

Wind turbines are mechanical devices that convert the kinetic energy of the wind into useful shaft power. [Figure 72.1](#) shows an example of a modern wind farm employing large electric-generating wind turbines, the 112-MW Gray County Wind Farm built in 2001 in Kansas.

72.1 Power in the Wind

Wind turbines extract energy from the air. The power available in the wind is in the form of kinetic energy. The power, P , contained in a wind of speed V and air density ρ passing through an area A normal to the wind equals the product of the rate of mass flow of air through that area and the kinetic energy per unit of mass of the wind, resulting in the equation

$$P = (\rho AV) \cdot \left(\frac{1}{2} V^2 \right) = \frac{1}{2} \rho AV^3 \quad (72.1)$$

where P is generally measured in units of watts, ρ in kilograms per cubic meter, A in square meters, and V in meters per second. Equation (72.1) reflects the fundamental and critically important result that the power from a wind turbine is proportional to the area swept by the rotor, the air density, and the cube of the wind speed.

Wind power potential at a given geographic site is based on the long-term average wind speed. Two different classification systems exist, as summarized in [Table 72.1](#) and [Table 72.2](#). The system shown in [Table 72.1](#) is widely used in the United States and serves as the basis for the wind resource atlas of the U.S. shown in [Figure 72.2](#) [Elliott et al., 1986]. This classification is based upon the mean wind speed as measured at a height of 10 m above the ground.

Class 6 sites are rare but presently most economical for development of wind power, while Class 5 sites are frequently developed. Class 4 sites are presently marginal, but areas shaded as Class 4 in [Figure 72.2](#) may contain local sites with Class 5 or even Class 6 resource. In recent years, researchers have begun combining the data contained in [Figure 72.2](#) with models of atmospheric physics and geographical information system (GIS) databases of local topography to create high-resolution maps of local wind resource. Some maps have resolution as fine as a quarter mile. The National Wind Technology Center at the National Renewable Energy Laboratory in Golden, Colorado, has sponsored much of this research and maintains a library of these maps. Interactive versions of some of the maps are available online at

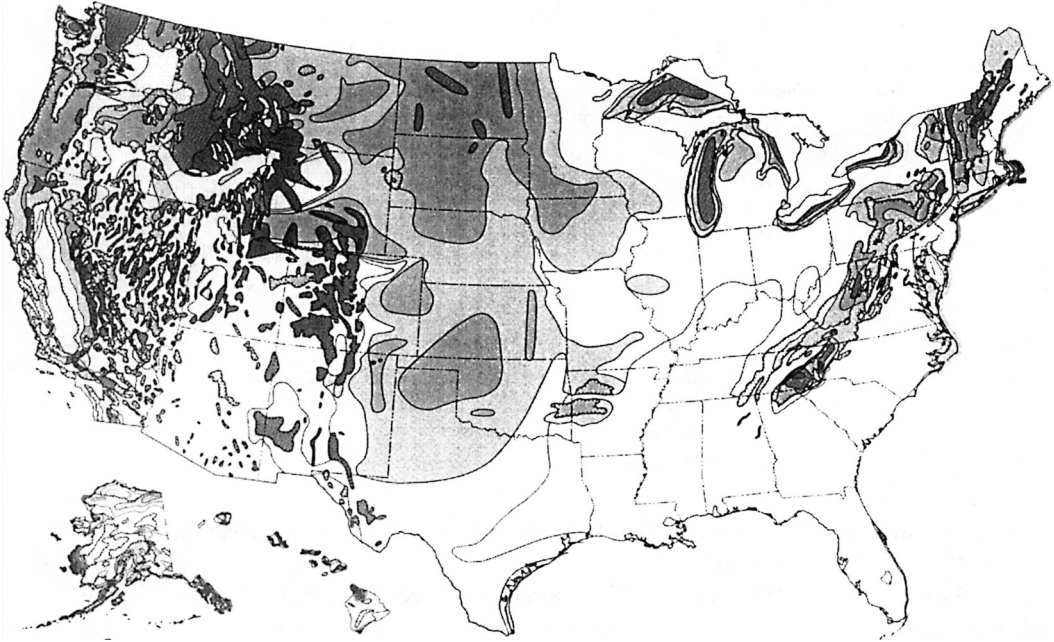

FIGURE 72.2 U.S. wind resource map. (Source: Elliott, D. L. 1986. *Wind Energy Resource Atlas of the United States*, DOE/CH 10093-4. Solar Technical Information Program, National Renewable Energy Laboratory, Golden, CO. p. 12.)

the NWTC website (www.nrel.gov/wind). While such maps are useful for identifying potential sites, wind power developers routinely install meteorological towers with anemometers and record wind speed data for at least a year before proceeding with a project.

The data shown in [Table 72.1](#) for 50-m height is based upon an assumption that the wind speed aloft follows the commonly employed one-seventh power law where the wind speed, V , at some height, h , above ground follows the trend $V(h) \sim h^{1/7}$. Although it is frequently assumed that this relationship applies to flat grassy terrain, vertical gradients in wind speed can vary significantly from the one-seventh power law. Zero gradients and even negative gradients have been observed, particularly in hilly or mountainous terrain. Therefore, meteorological towers are generally instrumented with anemometers at several heights, typically the height of the bottom, middle, and top of the rotor of the wind turbine a developer plans to use.

[Table 72.2](#) summarizes the classification defined by the International Electrotechnical Commission [IEC, 1999], which is based upon the average wind speed at the height of the wind turbine rotor hub (i.e., the axis of rotation). Turbulence Classes A and B are also defined based upon the average turbulence at the hub height. The IEC Classifications are used exclusively for turbine design certification purposes as described in [Section 72.8](#). Most large-scale turbines are presently designed for and installed in IEC Class II and III sites.

72.2 Types of Wind Turbines

Wind turbine configurations are most fundamentally classified as drag devices or lift devices depending upon whether they derive their motion from aerodynamic drag or aerodynamic lift.

The simplest form of a wind turbine is the Savonius type (illustrated in [Figure 72.3](#)), which relies upon differential drag to provide its driving force. This type has found some limited application in water-pumping activities where high starting torque is of great benefit.

Modern commercial wind turbines designed to generate electricity utilize aerodynamic lift to provide their driving force. The rotational rate of a drag device is limited because the tangential velocity of the

FIGURE 72.3 Typical wind turbine configurations.

device cannot exceed the speed of the wind. This means that the aerodynamic forces acting on a drag device are limited to those produced by the wind alone. A lifting device can rotate much faster, meaning that the velocity relative to the rotor can be much higher than the wind speed. A lifting rotor can utilize the vector sum of the rotational speed and the wind speed, yielding a power magnification on the order of a factor of 100 [Rohatgi and Nelson, 1994].

There are two broad categories of wind turbines: **horizontal axis (HAWT)** and **vertical axis (VAWT)**. Both types typically have two or three blades, although HAWTs have been built with single blades and with more than three blades. Augmentation devices have been proposed for both types, but the additional energy extraction has not proved sufficient to justify the increased cost and complexity.

VAWTs can receive wind from any direction and thus require no aligning devices. They also benefit from having their generators at ground level, which simplifies servicing. However, severe alternating

FIGURE 72.4 Cut-away view of a typical horizontal axis wind turbine. (Source: Eldridge, F. R. 1975. *Wind Machines*, National Science Foundation, Grant Number AFR-75-12937. Energy Research and Development Administration, Washington, DC. p. 30.)

FIGURE 72.5 Actuator disk.

stresses are induced by the windstream on the blades as they rotate about the vertical shaft, and VAWTs cannot exploit the higher winds aloft from which HAWTs on tall towers benefit. The large, utility-scale wind turbine industry has abandoned VAWTs during the past decade in favor of HAWTs. Figure 72.4 illustrates the major components of a modern HAWT.

72.3 Power from a Wind Turbine: Axial Momentum Theory

By extracting energy from the wind, a wind turbine reduces the velocity of the air passing through its rotor. Figure 72.5 illustrates an actuator disk placed in an airstream without a duct or shroud. In this simplified model, the air flow experiences a change in pressure as it passes through the disk. If one assumes that the air flow is incompressible and inviscid, then it follows from Bernoulli's Law that the total pressure, p_t , remains constant upstream of the disk as the flow decelerates from its freestream velocity, V , to the velocity at the rotor disk, u . Then the flow experiences a discontinuous drop in total and static pressure, Δp , as it passes through the disk. Again the total pressure remains constant as the flow continues to decelerate further downstream, returning the static pressure far downstream of the rotor to ambient. The pressure drop across the rotor is given by

$$\Delta p = p_{t,upstream} - p_{t,downstream} = \frac{1}{2}\rho V^2 - \frac{1}{2}\rho u_1^2 \quad (72.2)$$

where u_1 is the velocity far downstream of the rotor. The axial thrust force, T , acting on the disk equals the product of the pressure drop across the disk and the area, A , of the disk. This force must equal the change in momentum experienced by the flow:

$$T = \Delta p A = (\rho u A) \cdot (V - u_1) \quad (72.3)$$

Substituting Equation (72.2) into Equation (72.3) results in the fundamental result that

$$u = \frac{1}{2}(V + u_1) \quad (72.4)$$

or, in words, that half the deceleration of the flow occurs upstream of the actuator disk, and half occurs downstream.

This methodology, called **momentum theory**, is the theoretical basis for propeller, helicopter, and wind turbine rotor analysis, and was originally formulated by Glauert [1947].

It is convenient to define an **axial induction factor**, a , given by $u = (1 - a)V$, which, when combined with Equation (72.4) yields that $u_1 = (1 - 2a)V$, and that

$$T = 2\rho AV^2 a(1 - a) \quad (72.5)$$

The power, P , extracted from the wind by the turbine equals the product of the thrust force, T , and the air velocity at the disk, u , resulting in

$$P = 2\rho AV^3 a(1 - a)^2 \quad (72.6)$$

To calculate the efficiency of energy capture, a power coefficient is defined as

$$C_p = \frac{\text{Power extracted}}{\text{Power available}} \quad (72.7)$$

Substituting Equation (72.1) for the denominator and Equation (72.6) for the numerator in Equation (72.7) yields

$$C_p = 4a(1 - a)^2 \quad (72.8)$$

Since mass flow through the disk and downstream must be maintained for energy extraction, it is impossible to extract all of the energy available in the airstream by bringing the freestream velocity to zero. There is a limit to the available energy capture, which is reflected as a maximum value of $C_{pmax} = 16/27 = 0.593$ called the **Betz limit**. It can be calculated by taking the first derivative of Equation (72.8) with respect to a , setting it equal to zero, and solving for $a = 1/3$. The maximum power extraction is limited to 59.3% of the power available in the wind stream and occurs when $u = \frac{2}{3}V$ and $u_1 = \frac{1}{3}V$, that is, the freestream wind velocity is slowed to two-thirds of its original value at the rotor disk.

An axial force coefficient can be defined by normalizing the thrust by the dynamic pressure

$$C_T = \frac{T}{0.5\rho AV^2} = 4a(1 - a) \quad (72.9)$$

Finding the maximum for this equation shows that $C_{Tmax} = 1$ occurs when $a = 0.5$.

Momentum theory is constrained to values of the induced flow factor, a , less than 0.5, since values of a greater than 0.5 imply flow reversal downstream of the actuator disk, in which case momentum theory

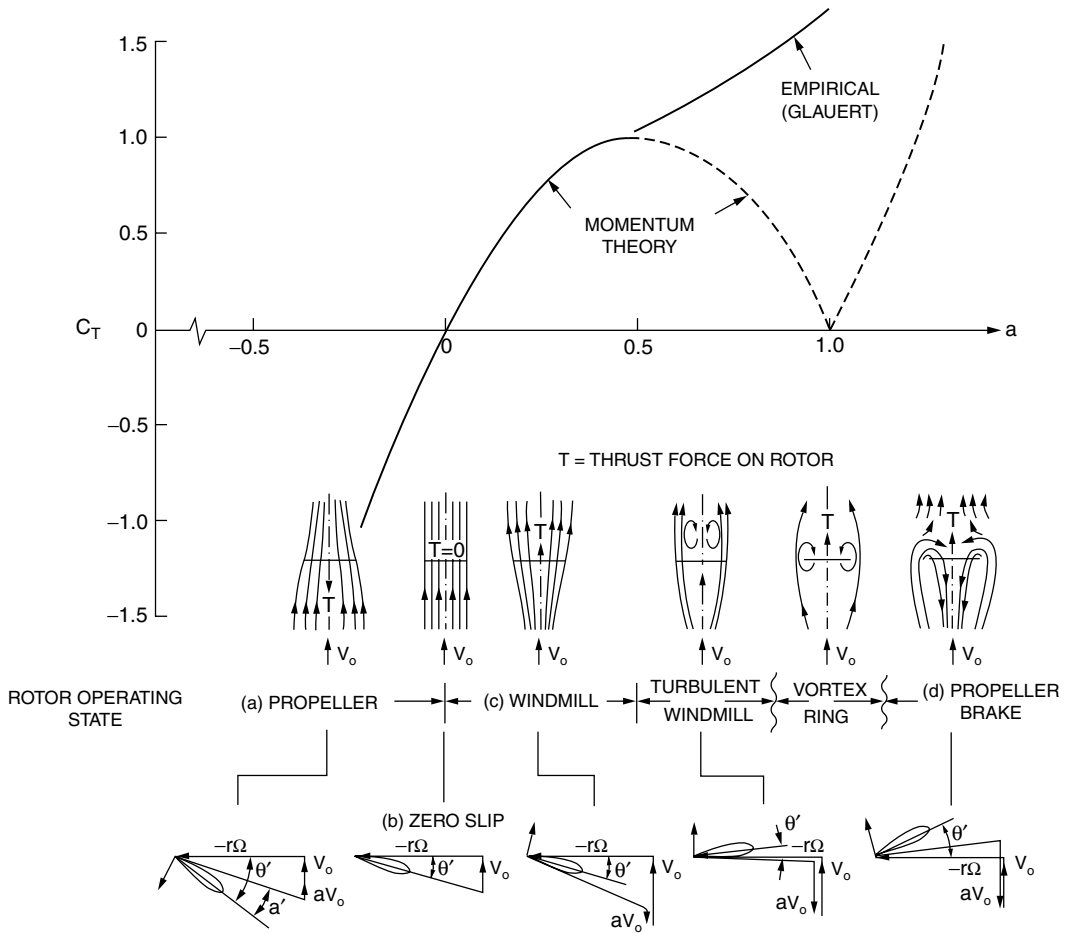

FIGURE 72.6 Wind turbine operating states. (Source: Eggleston, D. M. and Stoddard, F. S. 1987. *Wind Turbine Engineering Design*, Van Nostrand Reinhold, New York. p. 32.)

no longer applies. Figure 72.6 shows the flow states of a wind turbine rotor and the relationships of power and thrust coefficients to the axial induction factor, a . The curves show dotted lines for $a > 0.5$, since momentum theory does not apply, and indicate trends based on empirical data.

72.4 Power from a Wind Turbine: Blade Element Momentum (BEM) Theory

The Axial Momentum Theory presented above does not account for the swirl induced by the rotor, the aerodynamic drag acting on the rotor blades, or the radial variation in the flow through a rotor. **Blade Element Momentum (BEM) Theory** is often used to account for these effects.

The BEM method assumes first that the airstream flowing in to an actuator disk as shown in Figure 72.5 can be treated as a series of concentric and independent annular stream tubes and that mass and momentum do not flow across the boundaries of these imaginary stream tubes. The axial momentum theory presented in the previous section can be applied independently to the portion of the total flow in each such annulus. In that sense each radial section of a rotor blade on a horizontal axis wind turbine interacts with the freestream flow in one of these distinct annular stream tubes.

Figure 72.7 shows the airfoil cross-section of one such radial station, r , on a rotating wind turbine rotor blade, where it is assumed that the inflow is axial and that the blades are rigid. The interaction of

FIGURE 72.7 Blade element diagram.

the sectional aerodynamics with the inflow, V , induces a velocity, u' , that has both an axial component which acts to reduce the axial velocity at the rotor plane, u , and a swirl component, ωr , which generally adds to the tangential velocity due to the rotor rotation, Ωr . The relative velocity, V_{rel} , seen by the section is thus the vector sum of the axial velocity at the rotor plane, u , and the total tangential velocity, $(\Omega + \omega)r$, and approaches the section at a flow angle ϕ relative to the plane of rotation. The blade section is set at a pitch angle, θ , relative to the plane of rotation to result in an angle of attack of α . Again, we adopt the axial induction factor notation, a , defined as before, and similarly define a swirl induction factor, a' , given by $\omega = a'\Omega$. Lift, L , and drag, D , are induced on the section, respectively, perpendicular and parallel to the relative velocity. The vector sum of the lift and drag can be decomposed into in-plane and out-of-plane components of force, measured in Newtons:

$$dF_x = \frac{1}{2} \rho c \cdot [V^2(1-a)^2 + \Omega^2 r^2(1+a')^2] \cdot \{C_L \sin \phi - C_D \cos \phi\} dr \quad (72.10)$$

$$dF_y = \frac{1}{2} \rho c \cdot [V^2(1-a)^2 + \Omega^2 r^2(1+a')^2] \cdot \{C_L \cos \phi + C_D \sin \phi\} dr \quad (72.11)$$

where standard definitions of lift and drag coefficient, C_L and C_D , from airfoil theory are employed, c is the sectional chord length in meters, and ρ is the air density in kilograms per cubic meter. The in-plane force, dF_x , is the component that induces torque about the axis of rotation, while the out-of-plane force, dF_y , induces out-of-plane deflection of the rotor blades.

Figure 72.7 and Equation (72.10) and Equation (72.11) illustrate several important points. First, increasing the shaft speed, Ω , will significantly increase the force up to the point where the inflow angle, ϕ , becomes so small that the term $\{C_L \sin \phi - C_D \cos \phi\}$ in Equation (72.10) starts to decline faster than the $(\Omega r)^2$ term is increasing. This generally limits optimal rotor blade tip speeds to less than ten times the

freestream wind speed, while most modern wind turbine rotor blades are optimized for a **Tip Speed Ratio**, $X = \Omega R/V$, of between five and eight. Second, for relatively high tip speed ratios, mid-span and outboard regions of the blade will experience significantly higher out-of-plane forces than in-plane loading.

It can be shown [Glauert, 1947] that Equation (72.4) and Equation (72.5) still apply to each annular stream tube, and conservation of momentum dictates that the sum of the out-of-plane forces acting on the same radial section of all of the B blades on a rotor must equal the change in momentum of the stream tube passing through those sections:

$$dF_y = 2\rho V^2 a(1-a) \cdot (2\pi r) dr \quad (72.12)$$

It can also be shown [Glauert, 1947] that the change in angular momentum of the flow far downstream of the rotor is twice that at the rotor. Balancing the in-plane force with the change in angular momentum results in:

$$dQ = dF_x r = (2\omega r) \cdot \rho u \cdot (2\pi r) r dr = (2a'\Omega r) \cdot \rho u \cdot (2\pi r) r dr \quad (72.13)$$

Equation (72.10) through Equation (72.13) can be solved for the axial and swirl induction factors

$$a = \frac{\sigma C_y}{4 \sin^2 \phi + \sigma C_y} \quad (72.14)$$

$$a' = \frac{\sigma C_x}{4 \sin \phi \cos \phi - \sigma C_x} \quad (72.15)$$

where σ is the sectional blade solidity, given by $\sigma = Bc/2\pi r$ and C_x and C_y are, respectively, the coefficients of in-plane and out-of-plane loading given by $C_x = \{C_L \sin \phi - C_D \cos \phi\}$ and $C_y = \{C_L \cos \phi + C_D \sin \phi\}$. Because of the dependence of ϕ on a and a' , Equation (72.14) and Equation (72.15) must be solved iteratively. During the design process the twist angle and chord length of each blade section are adjusted so as to maximize the edgewise force, dF_x , at each station for the design tip speed ratio and pitch setting. For off-design tip speed ratios and pitch settings, the same equations can be used to determine the performance.

Once dF_x is known at all radial stations, the total mechanical power produced by B blades can be calculated by integrating the torque produced by this force from the blade root to the blade tip and multiplying by the shaft speed:

$$P = B\Omega \int_{r_{root}}^{r_{tip}} r dF_x \quad (72.16)$$

Rotor power curves are typically plotted against the tip speed ratio, X . These curves are unique for a given rotor with fixed pitch and can be performance-tailored by modifying the airfoil section characteristics, pitch angle of the blades, and the blade twist over the span of the rotor. Sample power coefficient–tip speed ratio curves for various rotors are shown in [Figure 72.8](#). One will note that high-speed rotors with low solidity have higher conversion efficiency, although they generally produce less torque than high-solidity rotors, especially at startup.

Because of electrical considerations mentioned in the next section, wind turbines are often operated at a fixed shaft speed. One shortcoming of fixed-speed operation is that as the wind speed varies the rotor blades are frequently not operating at optimal tip speed ratio, and the power coefficient will be less than the design value, meaning that energy capture is reduced. Transient loads are also generally higher on fixed-speed turbines since the rotor cannot accelerate or decelerate in response to wind gusts. If the shaft speed can be varied with the wind speed to maintain constant tip speed ratio, then the energy

FIGURE 72.8 Typical performance curves for various wind turbine configurations. (Source: Eldridge, F. R. 1975. *Wind Machines*, National Science Foundation, Grant Number AER-75-12937. Energy Research and Development Administration, Washington, DC. p. 55.)

capture is maximized and transient loads can be absorbed better. These two types of turbines are generally referred to simply as **fixed speed** or **variable speed** wind turbines.

Steady-state BEM algorithms for wind turbine rotor design and analysis were incorporated into a code called PROPSH [Tangler, 1983], which in that form and in its current form of WT_Perf [Buhl, 2000] have been widely used for designing wind turbine rotors.

72.5 Electromechanical Considerations

The power calculated by the BEM analysis is the mechanical power produced by the rotor. The electrical power produced by a wind turbine is also a product of the efficiency of the mechanical and electrical systems. Figure 72.4 illustrates the construction of a typical horizontal-axis wind turbine.

Wind turbine drive train arrangements are generally divided into two classes: direct drive generators and geared systems. Most small wind turbines (10 kW and smaller) dispense with the gearbox and directly connect the aerodynamic rotor to the generator. Nearly all of the commercially available machines presently employ permanent magnet alternators. Since wind turbines both small and large have similar tip speeds, small turbines exhibit much higher shaft speeds on the order of hundreds of revolutions per minute, at which PM alternators can efficiently operate. These turbines are generally variable speed, generating a variable frequency current which is rectified and either used for battery charging or other DC applications or is reinverted at line frequency (50 or 60 Hz) for applications where the system is connected to the grid.

Large, utility-scale wind turbines rated on the order of 1 MW and larger typically exhibit low-speed shaft speeds of under 25 rpm, well below the shaft speeds typical of electric generators. Therefore, direct drive configurations in this size are rare but do exist.

In most large wind turbines, however, the power from the rotor is transmitted to the generator via a speed-increasing gearbox. These gear units usually have two or three stages producing gear ratios of between 1:20 and 1:100. Mechanical efficiencies of wind turbine gearboxes are typically on the order of 95% near rated.

Nearly all utility-scale wind turbine manufacturers employ induction generators, mostly squirrel cage designs, which are basically the same as AC induction motors. This is in contrast to most of the power industry, which employs synchronous generators. The primary reason that wind turbines have traditionally employed induction generators is that they are relatively easy to connect to an AC grid despite the constant fluctuations in wind speed and hence shaft torque. With no load applied, an induction motor or generator connected to an electrical grid with alternating current will turn at its synchronous speed, N_s , which is given in rpm by the formula

$$N_s = \frac{120f_{AC}}{n_p} \text{ [rpm]} \quad (72.17)$$

where f_{AC} is the AC line frequency (i.e., 50 or 60 Hz depending upon where in the world one is located) and n_p is the number of poles in the generator. For example, a six-pole generator operating in the U.S. has a synchronous speed, N_s , of 1,200 rpm. If mechanical power is put into the machine as in the generator mode, then the shaft speed, N , will increase above the synchronous speed. The generator will continue to generate at line frequency. The slip, s , is the fraction of the synchronous speed below it at which the machine operates, given by $s = (N_s - N)/N_s$, where s is generally negative for generator mode according to electrical industry convention. The power increases as the slip increases, but most machines are designed to reach rated power at small values of slip typically on the order of 1 to 3%. This means that such turbines operate at a relatively fixed speed. Induction generators typically have efficiencies of 94 to 96% at rated.

The problem with variable speed operation using either a squirrel cage induction generator or a conventional synchronous generator (either wound rotor or permanent magnet rotor) is that the generator produces current with a variable frequency that cannot be directly connected to the grid. The current must be rectified and reinverted using expensive power electronics. Such power conversion also adds an additional source of electrical losses on the order of 2%.

An alternative electrical configuration that allows for a wider range of shaft speed employs the use of a doubly fed induction generator, in which the rotor and stator are wound separately. Only the stator is connected directly to the AC grid. The generator rotor is allowed to generate a variable frequency AC current, which is rectified and reinverted at the line frequency using power electronics and is then fed to the grid. Values of slip can range $\pm 30\%$ both subsynchronous and supersynchronous. In the subsynchronous mode, power is actually fed to the rotor from the line, while in the supersynchronous mode, power is fed from the rotor to the line. The stator always feeds power to the grid. At full supersynchronous slip of 30%, approximately 24% of the total power output of the generator is produced by the rotor, and the frequency converter power electronics must be sized to accommodate this power instead of 100% power conversion necessary with a variable speed squirrel cage electric machine. The industry trend in recent years has been towards wider use of variable speed operation.

A typical wind turbine power curve reflecting both aerodynamic power coefficient and electromechanical efficiencies is shown in [Figure 72.9](#). This illustrates an important feature of wind power: a wind turbine will not always produce power at its nameplate rated capacity if the wind is not blowing strongly enough to produce that much power from the size of rotor installed on the turbine. The wind speed at which the turbine reaches its rated power is referred to as the **Rated Wind Speed**, below which the turbine will produce less than rated power. The rated wind speed of a turbine can be reduced by increasing the

FIGURE 72.9 Wind turbine power curve. (Source: Eldridge, F. R. 1975. *Wind Machines*, National Science Foundation, Grant Number AER-75-12937. Energy Research and Development Administration, Washington, DC. p. 56.)

size of the rotor, but this will also increase the loads for which the structural and mechanical systems must be designed. For large, utility-scale wind turbines designed for IEC Class II, the rotors are typically sized so that the power loading is approximately 400 watts per square meter swept by the rotor. For example, a typical 1.5-MW turbine will feature a 70-m diameter rotor. Turbines designed for IEC Class III will typically employ rotors with 10% larger diameters.

The power output of a wind turbine can also generally be improved at most sites by installing it on a taller tower to take advantage of vertical gradients in wind speed. This also increases the cost of the tower, however, and so some optimal height generally exists. The trend in the industry has been that tower heights are typically 100 to 130% of the rotor diameter.

72.6 Power Regulation and Control

Several power regulation and control issues must be addressed in a modern HAWT. When the wind speed increases to a value at which the generator is producing rated power, some control action must occur so that the generator does not exceed its rated capacity and overheat. Typical methods of power regulation at **rated wind speed** are **pitch regulation**, **stall regulation**, and **yaw control** or **furling**. Pitch regulation is accomplished by providing rotating bearings at the blade root and actively changing the blade pitch angle relative to the wind, thus regulating power. Stall control is accomplished by designing the rotor so that aerodynamic stall is reached at rated wind speed and the rotor power is limited by airfoil stall. Yaw control or furling turns the entire rotor out of the wind either vertically or horizontally at rated wind speed and regulates power by reducing the rotor area exposed to the wind. The latter approach is generally only employed on small wind turbines.

In addition to power regulation, loss of generator load and overspeed protection is required in case the load on the rotor is lost during operation. Loss of load will allow the rotor speed and thrust to rise rapidly and will result in turbine destruction in moderate winds if not brought under control rapidly.

Pitch control rotors usually have a fail-safe pitch change to the feather position in an emergency shutdown, whereas stall control turbines use rotor tip brakes, a large mechanical brake that activates upon overspeed, or a combination of the two. Yaw control turbines simply yaw out of the wind to control overspeed.

Additional controls regulate turbine cut-in when the wind increases above starting wind speed, and cut-out in very high winds or in case of excessive vibration or other problem. Finally, most large HAWTs employ yaw drives to maintain alignment with the wind.

72.7 Energy Capture and Cost of Energy

Once a turbine power curve is established, it can be used with wind frequency information in order to estimate the annual energy production available at a given site. Wind speeds fluctuate continuously but have been shown to generally follow a Weibull frequency distribution. One special type of Weibull distribution is the Rayleigh distribution, which is often used for energy capture estimation. The Rayleigh distribution is based only on average wind speed at the hub height where the turbine is to be located and can be calculated using the following equation:

$$f(V) = \frac{\pi}{2} \frac{V}{V_{ave}^2} \exp \left[-\frac{\pi}{4} \left(\frac{V}{V_{ave}} \right)^2 \right] \quad (72.18)$$

where V is the center of a wind speed bin of width 1 m/sec, ft/sec, and so on in consistent units, and V_{ave} is the average wind speed, also in consistent units.

Assuming a Rayleigh distribution at hub height, annual energy can be estimated by first adjusting the power curve for air density variation due to site elevation, if required, and then using the Rayleigh frequency distribution and power curve to determine the number of hours per year the turbine will operate at each wind speed interval and summing the number of operating hours times the power level for each interval over all wind speeds. This results in an estimation of the **Gross Annual Energy Production (GAEP)**. The **Net Annual Energy Production (NAEP)** is determined by adjusting GAEP for turbine availability and subtracting losses such as line losses in the electrical collection system. Availability of 95 to 97% is common.

Once NAEP and the initial capital cost of the wind turbine system are known, the cost of energy (COE) can be calculated. The COE from a wind turbine is calculated by adding the life cycle annual cost of the initial capital investment (including turbine, tower, construction and development costs, etc.), annualized equipment replacement costs (referred to as Levelized Parts Replacement or LPR), and annual operation and maintenance (O&M) costs and dividing this total annualized cost by the net annual energy production. Units are usually expressed in dollars or cents per kWh. The equation is as follows:

$$COE = \frac{ACC + LPR + O\&M}{NAEP} \quad (72.19)$$

where ACC is the annualized capital cost, which is a function of the initial capital investment and the cost of financing the project.

The COE from windpower has declined significantly during the past 20 years, from roughly \$0.40 per kWh in 1980 to approximately \$0.035 per kWh today at sites where wind farms are typically being developed in the U.S.

72.8 Design and Certification of Wind Turbines

The design of wind turbines has undergone a significant transformation during the past decade, with the development by the International Electrotechnical Commission of Standard 61400 for the design of Wind Turbine Generator Systems. The 61400 standard includes the following Parts:

- IEC 61400-1 (1999) Part 1: Safety requirements (Edition 2)
- IEC 61400-2 (1996) Part 2: Safety of small wind turbines
- IEC 61400-11 (2002) Part 11: Acoustic noise measurement techniques
- IEC 61400-12 (1998) Part 12: Wind turbine power performance testing
- IEC 61400-13 (2001) Part 13: Measurement of mechanical loads
- IEC 61400-21 (2001) Part 21: Measurement and assessment of power quality characteristics of grid connected wind turbines
- IEC 61400-23 (2001) Part 23: Full-scale structural testing of rotor blades
- IEC 61400-24 (2002) Part 24: Lightning protection

A second edition of Part 2 has been developed and should be published during 2004.

These standards provide guidelines defining the operating conditions for which wind turbines must be designed and tested. Manufacturers of turbines work with certification agencies to ensure that the standards have been followed in the development of new turbine designs, and Type Certificates are issued to manufacturers certifying that the turbine as designed is suitable for operation in one of the IEC Classes defined in [Table 72.2](#). They also issue Site Suitability Certificates certifying that a given turbine design is suitable for use at a particular site where meteorological data have been collected and against which the turbine design has been verified.

The IEC 61400-1 standard prescribes the Normal Wind Conditions, including the wind speed frequency distribution, the normal vertical wind speed profile (NWP), and the Normal Turbulence Model (NTM). The wind speed probability distribution is presumed to follow a Rayleigh distribution as shown in Equation (72.18) for the purposes of design load calculations. During site suitability analyses, however, actual meteorological data may exist from which the actual wind speed frequency distribution may be calculated. IEC 61400-1 also prescribes a vertical wind profile exponent of $\alpha = 0.2$, where

$$V(z) = V_{hub}(z/z_{hub})^\alpha \quad (72.20)$$

where z is the height above ground, z_{hub} is the height of the rotor hub, $V(z)$ is the wind speed at height z , and V_{hub} is the wind speed at hub height. In the NTM the standard deviation, σ_I , of longitudinal wind speed is prescribed to vary with wind speed as follows:

$$\sigma_I = I_{15}(15 + aV_{hub})/(a + 1) \quad (72.21)$$

where I_{15} and a are given in [Table 72.2](#) for turbulence classes A and B and V_{hub} is in units of m/sec.

IEC 61400-1 also defines a number of extreme wind conditions, including Extreme Wind Speed (EWS), Extreme Operating Gust (EOG), Extreme Direction Change (EDC), Extreme Coherent Gust (ECG), Extreme Coherent Gust with Direction Change (ECD), and Extreme Wind Shear (EWS) for both horizontal and vertical shear. Most of the extreme wind conditions are defined for both 1-year and 50-year frequencies of occurrence. The Standard also prescribes a series of Design Load Conditions (DLCs) for which a turbine must be designed, including several different DLCs for each of (1) power production, (2) power production with a system fault, (3) startup, (4) normal shutdown, (5) emergency shutdown, (6) parked or idling, (7) parked with fault conditions, and (8) transport, assembly, maintenance, and repair. Partial safety factors for loads, material properties, and consequences of failure are defined. Requirements for fatigue analysis are also defined.

72.9 Dynamic and Structural Analysis of Wind Turbines

The Blade Element Momentum (BEM) method discussed in Section 72.4 assumes the inflow is normal to the rotor plane, spatially uniform, and steady. In reality, the wind approaching a rotor typically is highly turbulent. It varies spatially across the face of the rotor, includes significant horizontal and vertical components in the rotor plane, and varies temporally at fairly high frequencies. In the process of engineering wind turbine designs, a number of computer codes can be employed that will generate

models of the inflow. IECWind can be used to generate relatively simple models of the various IEC extreme wind conditions. These models prescribe a time history of the hub height wind speed as well as corresponding time histories of the inflow yaw angle, vertical component of the inflow, and the horizontal and vertical shear. SNLWIND-3D [Veers, 1988; Kelley, 1993] can be used to generate time histories of full field turbulence. Both codes are available from the National Renewable Energy Laboratory.

BEM methods can still be used to analyze the loads on a blade in a turbulent flow in a sense that is discrete both spatially and temporally. A number of computer codes exist that perform this analysis. One of the most commonly used in the U.S. is AeroDyn [Laino and Hansen, 2002], which is available through NREL. The blade is modeled aerodynamically as a series of elements, and at any moment in time the aerodynamic loads acting on each element on each blade must satisfy the BEM equations presented above. AeroDyn and similar codes use the inflow models produced by codes such as SNLWIND-3D or IECWind as input. They are also coupled to separate codes that can model the dynamic response of the wind turbine system to the loads induced by the wind. A number of sophisticated dynamic simulators exist. These codes generally model the tower, drive train, and rotor blades with a series of elements, joints, and constraints which approximate the mass, inertial, stiffness, and mechanical characteristics of the various components. The models also include simulations of the electrical and control characteristics of the system.

When a simulation is run, at any one time step codes such as AeroDyn receive information from the dynamic simulator about the position and motion of every element on each rotor blade and also receive information from the wind inflow file about the inflow characteristics. AeroDyn then calculates the aerodynamic loads on each element of each blade, taking into account all effects that influence the wind velocity at the blade element, including the inflow and the rotation of the blade, as well as the rates of out-of-plane deflection and torsional deflection of the blade. The calculated loads are then provided as input back to the dynamic simulator, which integrates the response of the turbine system forward to the next time step. Time steps are typically very small, on the order of 1% of the period of the rotor revolution or less. In this manner, one can conduct a time-stepping simulation of the operation of a wind turbine during either an extreme wind condition or during turbulent operation.

Such simulations can be used to generate time histories of the turbine dynamics, including critical information such as the maximum deflection of the rotor blades, as well as time histories of key loads on the blades, hub, tower top, tower base, and elsewhere. They can also be used to generate simulations of the power performance of the turbine during operation in turbulent conditions. Simulations are typically run for all of the DLCs required by IEC as well as multiple simulations of operation in turbulent conditions over a range of mean wind speeds at which the turbine will operate.

The extreme loads and time histories of transient loads are used as input to models of the turbine structure. Finite Element Analysis methods are applied to all the major components in a wind turbine, especially the blades, hub, shaft, main frame, and tower. The structural integrity of these components is checked against both extreme loads and the fatigue induced by transient loads.

The dynamic and structural simulations serve as the basis for finalizing wind turbine designs before prototypes are built and tested. Type certification is granted based upon the results of these analyses as well as testing conducted in accordance with IEC Standard 61400, Parts 11, 12, 13, 21, and 23, as discussed in Section 72.8.

72.10 Applications and Development of Wind Power

In excess of 100,000 small electric-generating wind turbine systems of less than 20 kW capacity are in use worldwide. Most small turbines are installed as single units or sometimes as a group of a small number of units. Many small wind turbines — particularly those in the 3 to 20 kW rating — are connected to the power grid, offsetting energy that would otherwise be supplied by the utility. Many other small turbines are installed in stand-alone applications, such as the 10-kW turbine shown in [Figure 72.10](#), supplying power to remote locations where the cost of utility connection is uneconomic. Sometimes coupled with diesel generators or solar electric panels in hybrid configurations, they are capable of

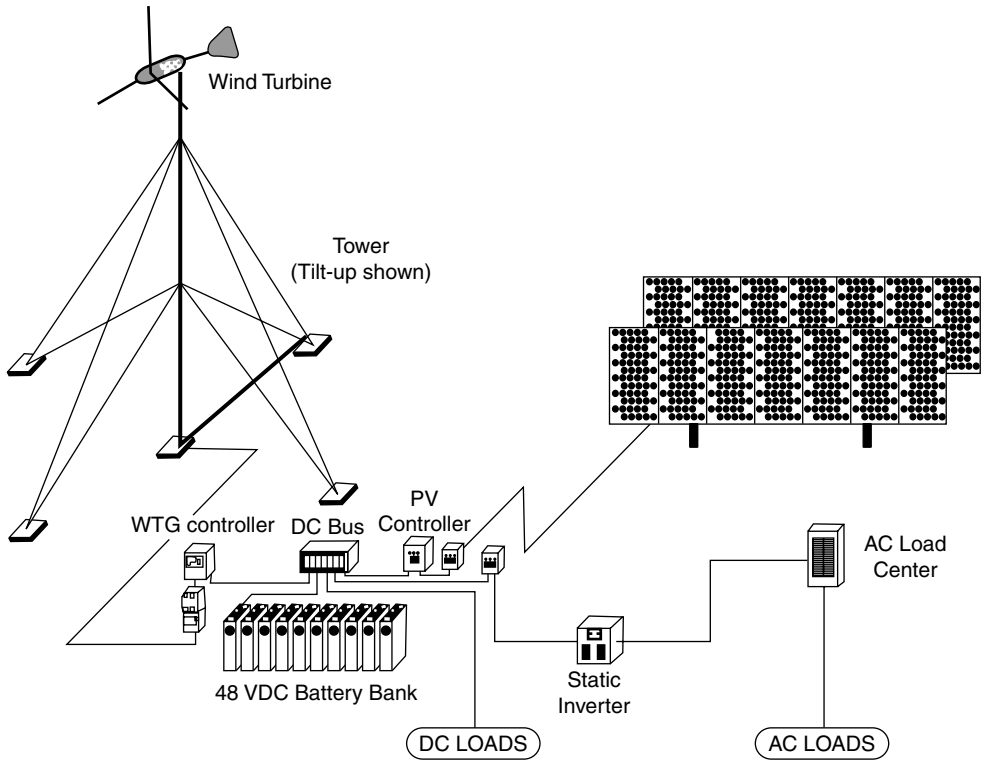

FIGURE 72.10 Example of a stand-alone hybrid wind system. (Source: Bergey, M. 1989. *An Overview of Wind Power for Remote Site Telecommunications Facilities*, Renewable Energy Power Supplies for Telecommunications Conference, British Wind Energy Association, London. p. 11. With permission.)

providing reliable power for basic necessities such as water pumping, lighting, refrigeration of medical supplies, or power for remote telecommunication facilities.

The vast majority of the world's wind power capacity is installed in the form of large, utility-scale wind turbines. Worldwide installed wind power capacity has grown at an annual rate of 30% in recent years, topping 31,000 MW at the end of 2002, as shown in [Figure 72.11](#). Development has been greatest in Europe — led by Germany, Spain, and Denmark — the United States, and India ([Figure 72.12](#)). In the United States, much of the recent development has occurred in the form of large wind farms ([Figure 72.1](#)) consisting of dozens or hundreds of large wind turbines and with total capacities of hundreds of megawatts. In Europe many turbines are installed singly or in small numbers, while the most recent trend is the development of off-shore wind farms utilizing multi-megawatt turbines. At the time of this writing, off-shore wind farms are being built with turbines rated as large as 3.6 MW each. In Europe, some off-shore sites are not too deep to sink foundations, and off-shore sites offer the advantage of consistent winds, generally lower turbulence levels, and elimination of land use issues. Interest is also growing in off-shore applications on the Eastern seaboard of the U.S.

A hydraulic turbine is a mechanical device that converts the potential energy associated with a difference in water elevation (**head**) into useful work. Modern hydraulic turbines are the result of many years of gradual development. Economic incentives have resulted in the development of very large units (exceeding 800 megawatts in capacity) with efficiencies that are sometimes in excess of 95%.

The emphasis on the design and manufacture of very large turbines is shifting to the production of smaller units, especially in developed nations, where much of the potential for developing large base-load plants has been realized. At the same time, the escalation in the cost of energy has made many smaller sites economically feasible and has greatly expanded the market for smaller turbines. The increased value of energy also justifies the cost of refurbishment and increasing the capacity of older facilities. Thus, a new market area is developing for updating older turbines with modern replacement runners having higher efficiency and greater capacity.

73.1 General Description

Typical Hydropower Installation

As shown schematically in [Figure 73.1](#), the hydraulic components of a hydropower installation consist of an intake, penstock, guide vanes or distributor, turbine, and draft tube. Trash racks are commonly provided to prevent ingestion of debris into the turbine. Intakes usually require some type of shape transition to match the passageway to the turbine and also incorporate a gate or some other means of stopping the flow in case of an emergency or turbine maintenance. Some types of turbines are set in an open flume; others are attached to a closed-conduit penstock.

Turbine Classification

There are two types of turbines, denoted as impulse and reaction. In an *impulse turbine* the available head is converted to kinetic energy before entering the runner; the power available is extracted from the

FIGURE 73.1 Schematic of a hydropower installation.

flow at approximately atmospheric pressure. In a *reaction turbine* the runner is completely submerged and both the pressure and the velocity decrease from inlet to outlet. The velocity head in the inlet to the turbine runner is typically less than 50% of the total head available.

Impulse Turbines

Modern impulse units are generally of the Pelton type and are restricted to relatively high head applications (Figure 73.2). One or more jets of water impinge on a wheel containing many curved buckets. The jet stream is directed inwardly, sideways, and outwardly, thereby producing a force on the bucket, which in turn results in a torque on the shaft. All kinetic energy leaving the runner is “lost.” A **draft tube** is generally not used since the runner operates under approximately atmospheric pressure and the head represented by the elevation of the unit above tailwater cannot be utilized. (In principle, a draft tube

FIGURE 73.2 Cross-section of a single-wheel, single-jet Pelton turbine. This is the third highest head Pelton turbine in the world, $H = 1447$ m, $n = 500$ rpm, $P = 35.2$ MW, $N_s \sim 0.038$. (Courtesy of Vevey Charmilles Engineering Works. Adapted from Raabe, J. 1985. *Hydro Power: The Design, Use, and Function of Hydromechanical, Hydraulic, and Electrical Equipment*, VDI Verlag, Dusseldorf, Germany.)

could be used, which requires the runner to operate in air under reduced pressure. Attempts at operating an impulse turbine with a draft tube have not met with much success.) Since this is a high-head device, this loss in available head is relatively unimportant. As will be shown later, the Pelton wheel is a low-specific speed device. Specific speed can be increased by the addition of extra nozzles, the specific speed increasing by the square root of the number of nozzles. Specific speed can also be increased by a change in the manner of inflow and outflow. Special designs such as the Turgo or crossflow turbines are examples of relatively high specific speed impulse units [Arndt, 1991].

Most Pelton wheels are mounted on a horizontal axis, although newer vertical-axis units have been developed. Because of physical constraints on orderly outflow from the unit, the number of nozzles is generally limited to six or fewer. Whereas **wicket gates** control the power of a reaction turbine, the power of the Pelton wheel is controlled by varying the nozzle discharge by means of an automatically adjusted needle, as illustrated in Figure 73.2. Jet deflectors or auxiliary nozzles are provided for emergency unloading of the wheel. Additional power can be obtained by connecting two wheels to a single generator or by using multiple nozzles. Since the needle valve can throttle the flow while maintaining essentially constant jet velocity, the relative velocities at entrance and exit remain unchanged, producing nearly constant efficiency over a wide range of power output.

Reaction Turbines

Reaction turbines are classified according to the variation in flow direction through the runner. In radial- and mixed-flow runners, the flow exits at a radius different from the radius at the inlet. If the flow enters the runner with only radial and tangential components, it is a radial-flow machine. The flow enters a mixed-flow runner with both radial and axial components. Francis turbines are of the radial- and mixed-flow type, depending on the design specific speed. A Francis turbine is illustrated in Figure 73.3.

Axial-flow propeller turbines are generally either of the fixed-blade or Kaplan (adjustable-blade) variety. The “classical” propeller turbine, illustrated in Figure 73.4, is a vertical-axis machine with a scroll case and a radial wicket gate configuration that is very similar to the flow inlet for a Francis turbine. The flow enters radially inward and makes a right-angle turn before entering the runner in an axial direction. The Kaplan turbine has both adjustable runner blades and adjustable wicket gates. The control system is designed so that the variation in blade angle is coupled with the wicket gate setting in a manner that achieves best overall efficiency over a wide range of flow rates.

FIGURE 73.3 Francis turbine, $N_s \sim 0.66$. (Adapted from Daily, J. W. 1950. Hydraulic machinery. In *Engineering Hydraulics*, H. Rouse, Ed., Wiley, New York. Reprinted with permission.)

FIGURE 73.4 Smith–Kaplan axial-flow turbine with adjustable-pitch runner blades, $N_s \sim 2.0$. (From Daily, J. W. 1950. *Hydraulic machinery*. In *Engineering Hydraulics*, H. Rouse, Ed., Wiley, New York. Reprinted with permission.)

Some modern designs take full advantage of the axial-flow runner; these include the tube, bulb, and Straflo types illustrated in Figure 73.5. The flow enters and exits the turbine with minor changes in direction. A wide variation in civil works design is also permissible. The tubular type can be fixed-propeller, semi-Kaplan, or fully adjustable. An externally mounted generator is driven by a shaft that extends through the flow passage either upstream or downstream of the runner. The bulb turbine was originally designed as a high-output, low-head unit. In large units, the generator is housed within the bulb and is driven by a variable-pitch propeller at the trailing end of the bulb. Pit turbines are similar in principle to bulb turbines, except that the generator is not enclosed in a fully submerged compartment (the bulb). Instead, the generator is in a compartment that extends above water level. This improves access to the generator for maintenance.

73.2 Principles of Operation

Power Available, Efficiency

The power that can be developed by a turbine is a function of both the head and flow available:

$$P = \eta \rho g Q H \quad (73.1)$$

FIGURE 73.5 Comparison between bulb (upper) and Straflo (lower) turbines. (Courtesy U.S. Dept. of Energy.)

where η is the turbine efficiency, ρ is the density of water (kg/m^3), g is the acceleration due to gravity (m/sec^2), Q is the flow rate (m^3/sec), and H is the net head in meters. *Net head* is defined as the difference between the *total head* at the inlet and the tailrace, as illustrated in [Figure 73.1](#). Various definitions of net head are used in practice, which depend on the value of the exit velocity head, $V_e^2/2g$, that is used in the calculation. The International Electrotechnical Test Code uses the velocity head at the draft tube exit.

The efficiency depends on the actual head and flow utilized by the turbine runner, flow losses in the draft tube, and the frictional resistance of mechanical components.

Similitude and Scaling Formulas

Under a given head, a turbine can operate at various combinations of speed and flow depending on the inlet settings. For reaction turbines the flow into the turbine is controlled by the wicket gate angle, α . The nozzle opening in impulse units typically controls the flow. Turbine performance can be described in terms of nondimensional variables,

$$\Psi = \frac{2gH}{\omega^2 D^2} \quad (73.2)$$

$$\phi = \frac{Q}{\sqrt{2gHD^2}} \quad (73.3)$$

where ω is the rotational speed of the turbine in radians per second and D is the diameter of the turbine.

The hydraulic efficiency of the runner alone is given by

$$\eta_h = \frac{\phi}{\sqrt{\Psi}} (C_1 \cos \alpha_1 - C_2 \cos \alpha_2) \quad (73.4)$$

where C_1 and C_2 are constants that depend on the specific turbine configuration, and α_1 and α_2 are the inlet and outlet angles that the absolute velocity vectors make with the tangential direction. The value of $\cos \alpha_2$ is approximately zero at peak efficiency. The terms ϕ , Ψ , α_1 , and α_2 are interrelated. Using model test data, isocontours of efficiency can be mapped in the $\phi\Psi$ plane. This is typically referred to as a *hill diagram*, as shown in [Figure 73.6](#).

FIGURE 73.6 Typical hill diagram. Information of this type is obtained in a turbine test stand (See [Figure 73.9](#)). (Adapted from Wahl, T. L. 1994. Draft tube surging times two: The twin vortex problem. *Hydro Rev.* 13(1):60–69, 1994. With permission.)

The **specific speed** is defined as

$$N_s = \frac{\omega \sqrt{Q}}{(2gH)^{3/4}} = \sqrt{\frac{\phi}{\psi}} \quad (73.5)$$

A given specific speed describes a specific combination of operating conditions that ensures similar flow patterns and the same efficiency in geometrically similar machines regardless of the size and rotational speed of the machine. It is customary to define the design specific speed in terms of the value at the design head and flow where peak efficiency occurs. The value of specific speed so defined permits a classification of different turbine types.

The specific speed defined herein is dimensionless. Many other forms of specific speed exist that are dimensional and have distinct numerical values depending on the system of units used [Arndt, 1991]. (The literature also contains two other minor variations of the dimensionless form. One differs by a factor of $1/\pi^{1/2}$ and the other by $2^{3/4}$.) The similarity arguments used to arrive at the concept of specific speed indicate that a given machine of diameter D operating under a head H will discharge a flow Q and produce a torque T and power P at a rotational speed given by

$$Q = \phi D^2 \sqrt{2gH} \quad (73.6)$$

$$T = T_{11} \rho D^3 2gH \quad (73.7)$$

$$P = P_{11} \rho D^2 (2gH)^{3/2} \quad (73.8)$$

$$\omega = \frac{2u_1}{D} = \omega_{11} \frac{\sqrt{2gH}}{D}, \quad \left[\omega_{11} = \frac{1}{\sqrt{\Psi}} \right] \quad (73.9)$$

with

$$P_{11} = T_{11} \omega_{11} \quad (73.10)$$

where T_{11} , P_{11} , and ω_{11} are also nondimensional. (The reader is cautioned that many texts, especially in the American literature, contain dimensional forms of T_{11} , P_{11} , and ω_{11} .) In theory, these coefficients are fixed for a machine operating at a fixed value of specific speed, independent of the size of the machine. Equation (73.6) through Equation (73.10) can be used to predict the performance of a large machine using the measured characteristics of a smaller machine or model.

73.3 Factors Involved in Selecting a Turbine

Performance Characteristics

Impulse and reaction turbines are the two basic types of turbines. They tend to operate at peak efficiency over different ranges of specific speed. This is due to geometric and operational differences.

Impulse Turbines

Of the head available at the nozzle inlet, a small portion is lost to friction in the nozzle and to friction on the buckets. The rest is available to drive the wheel. The actual utilization of this head depends on the velocity head of the flow leaving the turbine and the setting above tailwater. Optimum conditions, corresponding to maximum utilization of the head available, dictate that the flow leaves at essentially zero velocity. Under ideal conditions this occurs when the peripheral speed of the wheel is one half the jet velocity. In practice, optimum power occurs at a speed coefficient, ω_{11} , somewhat less than 1.0. This is illustrated in [Figure 73.7](#). Since the maximum efficiency occurs at fixed speed for fixed H , V_j must remain constant under varying flow conditions. Thus the flow rate Q is regulated with an adjustable nozzle. However, maximum efficiency occurs at slightly lower values of ω_{11} under partial power settings. Present nozzle technology is such that the discharge can be regulated over a wide range at high efficiency.

A given head and penstock configuration establishes the optimum jet velocity and diameter. The size of the wheel determines the speed of the machine. The design specific speed is approximately

$$N_s = 0.77 \frac{d_j}{D} \quad (\text{Pelton turbines}) \quad (73.11)$$

Practical values of d_j/D for Pelton wheels to ensure good efficiency are in the range 0.04 to 0.1, corresponding to N_s values in the range 0.03 to 0.08. Higher specific speeds are possible with multiple nozzle designs. The increase is proportional to the square root of the number of nozzles. In considering an impulse unit, one must remember that efficiency is based on net head; the net head for an impulse unit is generally less than the net head for a reaction turbine at the same gross head because of the lack of a draft tube.

FIGURE 73.7 Ideal and actual variable-speed performance for an impulse turbine. (Adapted from Daily, J. W. 1950. Hydraulic machinery. In *Engineering Hydraulics*, H. Rouse, Ed., Wiley, New York. With permission.)

Reaction Turbines

The main difference between impulse units and reaction turbines is that a pressure drop takes place in the rotating passages of the reaction turbine. This implies that the entire flow passage from the turbine inlet to the discharge at the tailwater must be completely filled. A major factor in the overall design of modern reaction turbines is the draft tube. It is usually desirable to reduce the overall equipment and civil construction costs by using high-specific speed runners. Under these circumstances the draft tube is extremely critical for both flow stability and efficiency. (This should be kept in mind when retrofitting on older, low-specific speed turbine with a new runner of higher capacity.) At higher specific speed a substantial percentage of the available total energy is in the form of kinetic energy leaving the runner. To recover this efficiently, considerable emphasis should be placed on the draft tube design.

The practical specific speed range for reaction turbines is much broader than for impulse wheels. This is due to the wider range of variables that control the basic operation of the turbine. The pivoted guide vanes allow for control of the magnitude and direction of the inlet flow. Because there is a fixed relationship between blade angle, inlet velocity, and peripheral speed for shock-free entry, this requirement cannot be completely satisfied at partial flow without the ability to vary blade angle. This is the distinction between the efficiency of fixed-propeller and Francis types at partial loads and the fully adjustable Kaplan design.

In Equation (73.4), optimum hydraulic efficiency of the runner would occur when α_2 is equal to 90° . However, the overall efficiency of the turbine is dependent on the optimum performance of the draft tube as well, which occurs with a little swirl in the flow. Thus, the best overall efficiency occurs with $\alpha_2 \approx 75^\circ$ for high-specific speed turbines.

The determination of optimum specific speed in a reaction turbine is more complicated than for an impulse unit since there are more variables. For a radial-flow machine, an approximate expression is

$$N_s = 1.64 \left[C_v \sin \alpha_1 \frac{B}{D_1} \right]^{1/2} \omega_{11} \quad (\text{Francis turbines}) \quad (73.12)$$

where C_v is the fraction of net head that is in the form of inlet velocity head and B is the height of the inlet flow passage (see Figure 73.3). N_s for Francis units is normally found to be in the range 0.3 to 2.5.

Standardized axial-flow machines are available in the smaller size range. These units are made up of standard components, such as shafts and blades. For such cases,

$$N_s \sim \frac{\sqrt{\tan\beta}}{n_b^{3/4}} \text{ (Propeller turbines)} \quad (73.13)$$

where β is the blade pitch angle and n_b is the number of blades. The advantage of controllable pitch is also obvious from this formula; the best specific speed is simply a function of pitch angle.

It should be further noted that ω_{11} is approximately constant for Francis units and N_s is proportional to $(B/D_1)^{1/2}$. It can also be shown that velocity component based on the peripheral speed at the throat, ω_{11e} , is proportional to N_s . In the case of axial-flow machinery, ω_{11} is also proportional to N_s . For minimum cost, peripheral speed should be as high as possible — consistent with cavitation-free performance. Under these circumstances N_s would vary inversely with the square root of head (H is given in meters):

$$N_s = \frac{C}{\sqrt{H}} \quad (73.14)$$

where the range of C is 8 to 11 for fixed-propeller units and Kaplan units and 6 to 9 for Francis units.

Performance Comparison

The physical characteristics of various runner configurations are summarized in Figure 73.8. It is obvious that the configuration changes with speed and head. Impulse turbines are efficient over a relatively narrow

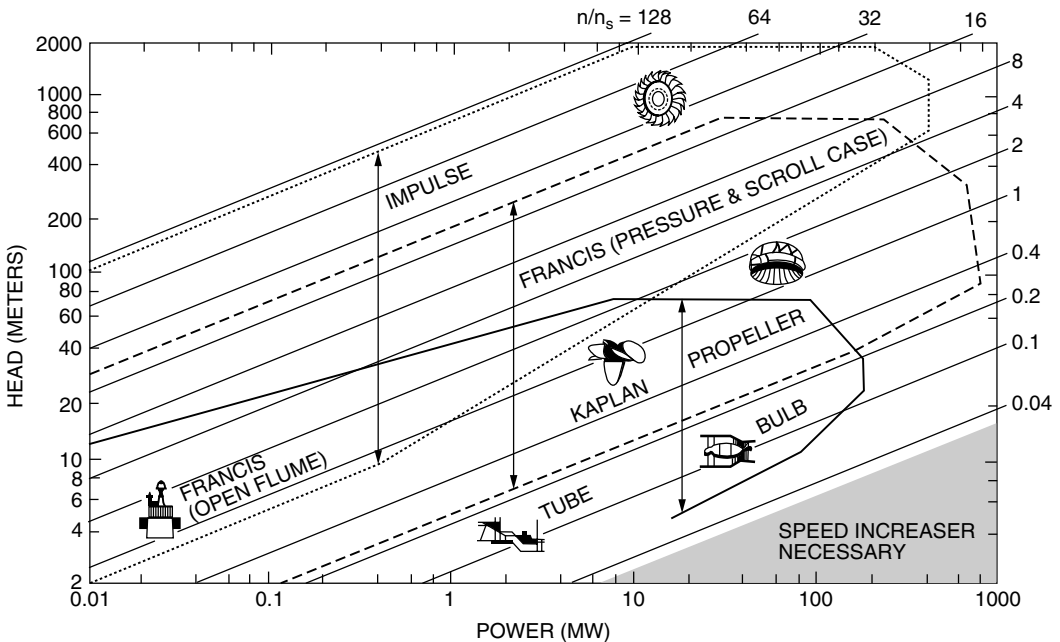

FIGURE 73.8 Application chart for various turbine types (n/n_s is the ratio of turbine speed in rpm, n , to specific speed defined in the metric system, $n_s = nP^{1/2}/H^{5/4}$, with P in kilowatts). (From Arndt, R. E. A. 1991. Hydraulic turbines. In *Hydropower Engineering Handbook*, J. S. Gulliver and R. E. A. Arndt, Eds., pp. 4.1–4.67. McGraw-Hill, New York. With permission.)

range of specific speed, whereas Francis and propeller turbines have a wider useful range. An important consideration is whether or not a turbine is required to operate over a wide range of load. Pelton wheels tend to operate efficiently over a wide range of power loading because of their nozzle design. In the case of reaction machines that have fixed geometry, such as Francis and propeller turbines, efficiency can vary widely with load. However, Kaplan and Deriaz [an adjustable-blade mixed-flow turbine (see Arndt, 1991)] turbines can maintain high efficiency over a wide range of operating conditions. The decision of whether to select a simple configuration with a relatively “peaky” efficiency curve or incur the added expense of installing a more complex machine with a broad efficiency curve will depend on the expected operation of the plant and other economic factors.

Note in [Figure 73.8](#) that there is an overlap in the range of application of various types of equipment. This means that either type of unit can be designed for good efficiency in this range, but other factors, such as generator speed and cavitation, may dictate the final selection.

Speed Regulation

The speed regulation of a turbine is an important and complicated problem. The magnitude of the problem varies with size, type of machine and installation, type of electrical load, and whether the plant is tied into an electrical grid. It should also be kept in mind that runaway or no-load speed can be higher than the design speed by factors as high as 2.6. This is an important design consideration for all rotating parts, including the generator.

The speed of a turbine has to be controlled to a value that matches the generator characteristics and the grid frequency:

$$n = \frac{120f}{N_p} \quad (73.15)$$

where n is turbine speed in rpm, f is the required grid frequency in Hz, and N_p is the number of poles in the generator. Typically, N_p is in multiples of 4. There is a tendency to select higher-speed generators to minimize weight and cost. However, consideration has to be given to speed regulation.

It is beyond the scope of this chapter to discuss the question of speed regulation in detail. Regulation of speed is normally accomplished through flow control. Adequate control requires sufficient rotational inertia of the rotating parts. When load is rejected, power is absorbed, accelerating the flywheel; when load is applied, some additional power is available from deceleration of the flywheel. Response time of the governor must be carefully selected, since rapid closing time can lead to excessive pressures in the penstock.

Opening and closing the wicket gates, which vary the flow of water according to the load, control a Francis turbine. The actuator components of a governor are required to overcome the hydraulic and frictional forces and to maintain the wicket gates in fixed position under steady load. For this reason, most governors have hydraulic actuators. On the other hand, impulse turbines are more easily controlled. This is due to the fact that the jet can be deflected or an auxiliary jet can bypass flow from the power-producing jet without changing the flow rate in the penstock. This permits long delay times for adjusting the flow rate to the new power conditions. The spear on needle valve controlling the flow rate can close quite slowly, say, in 30 to 60 sec, thereby minimizing any pressure rise in the penstock.

Several types of governors are available that vary with the work capacity desired and the degree of sophistication of control. These vary from pure mechanical to mechanical-hydraulic and electrohydraulic. Electrohydraulic units are sophisticated pieces of equipment and would not be suitable for remote regions. The precision of governing necessary will depend on whether the electrical generator is synchronous or asynchronous (induction type). There are advantages to the induction type of generator. It is less complex and therefore less expensive but typically has slightly lower efficiency. Its frequency is controlled by the frequency of the grid it feeds into, thereby eliminating the need for an expensive conventional governor. It cannot operate independently but can only feed into a network and does so with lagging power factor,

which may or may not be a disadvantage, depending on the nature of the load. Long transmission lines, for example, have a high capacitance, and, in this case, the lagging power factor may be an advantage.

Speed regulation is a function of the flywheel effect of the rotating components and the inertia of the water column of the system. The start-up time of the rotating system is given by

$$t_s = \frac{I\omega^2}{P} \quad (73.16)$$

where I = moment of inertia of the generator and turbine, $\text{kg} \cdot \text{m}^2$ [Bureau of Reclamation, 1966].

The start-up time of the water column is given by

$$t_p = \frac{\sum LV}{gH} \quad (73.17)$$

where L = the length of water column and V = the velocity in each component of the water column.

For good speed regulation, it is desirable to keep $t_s/t_p > 4$. Lower values can also be used, although special precautions are necessary in the control equipment. It can readily be seen that higher ratios of t_s/t_p can be obtained by increasing I or decreasing t_p . Increasing I implies a larger generator, which also results in higher costs. The start-up time of the water column can be reduced by reducing the length of the flow system, by using lower velocities, or by addition of surge tanks, which essentially reduce the effective length of the conduit. A detailed analysis should be made for each installation, since, for a given length, head, and discharge, the flow area must be increased to reduce t_p , which leads to associated higher construction costs.

Cavitation and Turbine Setting

Another factor that must be considered prior to equipment selection is the evaluation of the turbine with respect to tailwater elevations. Hydraulic turbines are subject to pitting, loss of efficiency, and unstable operation due to cavitation [Arndt, 1981, 1991; Arndt et al., 2000]. For a given head, a smaller, lower-cost, high-speed runner must be set lower (i.e., closer to tailwater or even below tailwater) than a larger, higher-cost, low-speed turbine runner. Also, atmospheric pressure or plant elevation above sea level is a factor, as are tailwater elevation variations and operating requirements. This is a complex subject that can only be accurately resolved by model tests. Every runner design will have different cavitation characteristics. Therefore, the anticipated turbine location or setting with respect to tailwater elevations is an important consideration in turbine selection.

Cavitation is not normally a problem with impulse wheels. However, by the very nature of their operation, cavitation is an important factor in reaction turbine installations. The susceptibility for cavitation to occur is a function of the installation and the turbine design. This can be expressed conveniently in terms of Thoma's sigma, defined as

$$\sigma_T = \frac{H_a - H_v - z}{H} \quad (73.18)$$

where H_a is the atmospheric pressure head, H is the vapor pressure head (generally negligible), and z is the elevation of a turbine reference plane above the tailwater (see Figure 73.1). Draft tube losses and the exit velocity head have been neglected.

The term σ_T must be above a certain value to avoid cavitation problems. The critical value of σ_T is a function of specific speed [Arndt, 1991]. The Bureau of Reclamation [1966] suggests that cavitation problems can be avoided when

$$\sigma_T > 0.26N_s^{1.64} \quad (73.19)$$

Equation (73.19) does not guarantee total elimination of cavitation, only that cavitation is within acceptable limits. Cavitation can be totally avoided only if the value of σ_T at an installation is much greater than the limiting value given in Equation (73.19). The value of σ_T for a given installation is known as the plant sigma, σ_p . Equation (73.19) should only be considered a guide in selecting σ_p , which is normally determined by a model test in the manufacturer's laboratory. For a turbine operating under a given head, the only variable controlling σ_p is the turbine setting z . The required value of σ_p then controls the allowable setting above tailwater:

$$z_{\text{allow}} = H_a - H_v - \sigma_p H \quad (73.20)$$

It must be borne in mind that H_a varies with elevation. As a rule of thumb, H_a decreases from the sea-level value of 10.3 m by 1.1 m for every 1000 m above sea level.

73.4 Performance Evaluation

Model Tests

Model testing is an important element in the design and development phases of turbine manufacture. Manufacturers own most laboratories equipped with model turbine test stands. Major hydro projects have traditionally had proof-of-performance tests in model scale as part of the contract (at either an independent laboratory or the manufacturer's laboratory). In addition, it has been shown that competitive model testing at an independent laboratory can lead to large savings at a major project because of improved efficiency. Recently, turbine design procedures have been dramatically improved through the use of sophisticated numerical analysis of the flow characteristics. These analysis techniques, linked with design programs, provide the turbine designer with powerful tools for achieving highly efficient turbine designs. In spite of this progress, computational methods require fine-tuning with model tests. In addition, model testing is necessary for determining performance over a range of operating conditions and for determining quasi-transitory characteristics. Model testing can also be used to eliminate or mitigate problems associated with vibration, cavitation, hydraulic thrust, and pressure pulsation [Fisher and Beyer, 1985].

A typical turbine test loop is shown in [Figure 73.9](#). All test loops perform basically the same function. A model turbine is driven by high-pressure water from a head tank and discharges into a tail tank, as shown. The flow is recirculated by a pump, usually positioned well below the elevation of the model to ensure cavitation-free performance of the pump while performing cavitation testing with the turbine model. One important advantage of a recirculating turbine test loop is that cavitation testing can be done over a wide range of cavitation indices at constant head and flow.

The extrapolation of model test data to prototype values has been a subject of considerable debate for many years. Equation 73.6 through Equation 73.10 can be used to predict prototype values of flow, speed, power, etc., from model tests. Unfortunately, there are many factors that lead to scale effects, i.e., the prototype efficiency and model efficiency are not identical at a fixed value of specific speed. The cited scale-up formulae are based on inviscid flow. There are several sources of energy loss, which lead to an efficiency that is less than ideal. All of these losses follow different scaling laws and, in principle, perfect similitude can only be achieved by testing the prototype. There have been several attempts at rationalizing the process of scaling up model test data. The International Electrotechnical Test Code and various ASME publications outline in detail the differences in efficiency between model and prototype. It should also be pointed out that other losses such as in the draft tube and "shock losses" at the runner inlet might not be independent of Reynolds number.

Numerical Simulation¹

Until very recently, the analysis of turbines and other components of hydropower facilities was largely dependent on approximate models such as the Euler Equation and Reynolds Averaged Navier–Stokes (RANS) models because the complete Navier–Stokes equations were considered to be too difficult to be solved for hydropower components. (See Section 33.4) The Euler equation model has been applied with reasonable success for turbine runner simulation, but energy losses and the efficiency could not be calculated. RANS models have been applied for the spiral case and the draft tube simulations with limited success. Goede et al. [1991] contains a good summary of experiences with the application of these computational methods to various hydropower components. Very recently, reliable commercial codes have become available and are being used with increasing frequency. Many of the current commercial codes rely on variants of RANS models although rapid progress is being made in adapting the large eddy simulation method (LES).

LES is a step forward in the application of CFD [Song et al., 1995]. This technique is able to more accurately capture the effects of turbulent flow in a turbine than previous techniques. At the present time, it requires a supercomputer to achieve sufficient resolution and good accuracy for final design purposes. Parallel processing with desktop computers shows promise and can presently be used for relatively simple geometry or for preliminary evaluation purposes. However, progress in its application is very rapid and it is anticipated that an entire computation may be carried out on a high-end desktop computer in the near future.

The components that require simulation include the spiral case, wicket gates, the runner, and the draft tube. Often the spiral case including stay vanes and wicket gates is modeled as a unit. This is necessary because the stay vanes and wicket gates are so close to each other that their mutual interactions cannot be ignored, and each stay vane may be of slightly different shape and orientation and cannot be modeled separately. A typical spiral case contains more than 20 stay vanes, and an equal number of wicket gates, requiring extensive computational resources for a complete simulation. A sample calculation is shown in Figure 73.10. In this example, the calculated energy loss through this device is 2.62% of the net available

¹This section prepared by Professor Charles Song of the Saint Anthony Falls Laboratory, University of Minnesota.

energy for this particular case. This is significant and justifies additional computational effort to minimize the losses.

The runner is the most extensively studied component of a turbine. Since all the blades in a runner are of the same geometric shape, only one or two flow passage models are commonly used for runner simulation. A complete model is required if vibration or cavitation due to nonsymmetrical modes of interactions between blades and vortices is to be studied. An important application of computer simulation is in the design of runners for units used for pumped storage. **Pumped-storage** schemes are becoming very popular for smoothing out the difference between energy demand and supply. Special care is required in the design because a runner must be designed to act efficiently both as a turbine and a pump. Because of viscous effects, a runner optimized under the turbine mode may have poor efficiency in the pump mode. Flow in the pumping mode can be unstable and more difficult to calculate. An LES-based analysis greatly facilitates the optimum design of this type of runner. Figure 73.11 is an example of the calculated flow in the pump mode. A small flow separation near the entrance can be observed. This kind of information is very useful to determine how the blade geometry can be modified to improve the performance.

FIGURE 73.11 Simulation of the velocity and pressure distribution in a pump turbine runner operating in the pumping mode. (Adapted from Song et al. *Hydro Rev.* XIV, No. 4, pp. 104–111. With permission.)

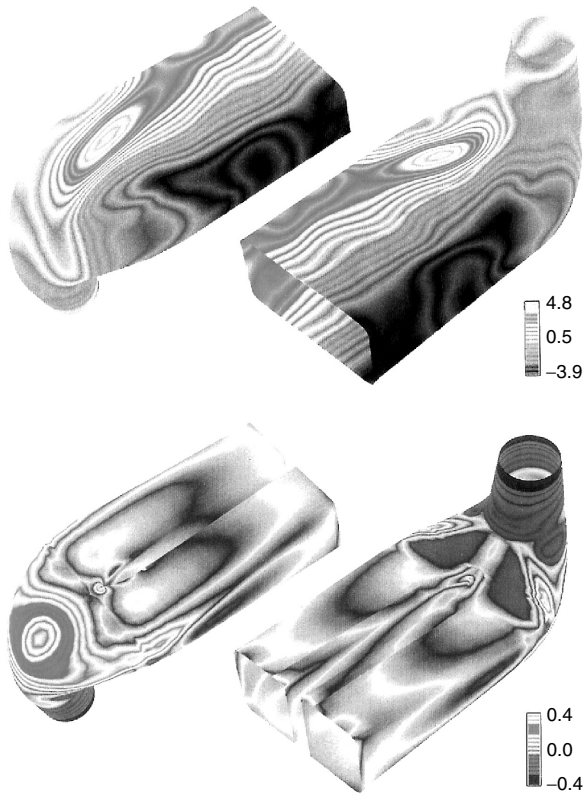

FIGURE 73.12 Simulation showing a comparison of the flow in a draft tube with and without a dividing wall. The pressure patterns on the walls indicate a very asymmetrical flow pattern without a divider wall (Figure 73.12a). With a wall in place a very uniform flow pattern is evident (Figure 73.12b). (Adapted from Song et al. *Hydro Rev.* XIV, No. 4, pp. 104–111. With permission.)

Draft tube design is an important factor in the efficiency and stability of operation of a turbine. Although a typical draft tube geometry is somewhat simpler than that of a runner, it takes much more advanced computational techniques to accurately simulate its performance. This is because the diffuser-like flow produces secondary currents, three-dimensional vortex shedding, and horseshoe vortices that are all very important contributors to energy loss. Current RANS models are ineffective for this flow. At the present time, only the LES model can fulfill the requirements for draft tube simulation. Figure 73.12 illustrates the complexity of the problem. The instantaneous pressure distribution on the walls of an elbow-type draft tube with a divider wall is compared with the same draft tube with the divider wall removed. A dramatic change in the flow pattern and pressure distribution occurs when the divider wall is removed. By removing the wall, the draft tube becomes a diffuser of large angle with very unstable flow. Clearly, the divider wall stabilizes the flow and reduces the energy loss due to vortex shedding. These types of simulations are invaluable in evaluating draft tube performance. This is underscored by the fact that many projects involve refurbishing existing units. Typically only the runner is replaced, usually with increased design flow. On many occasions, the existing draft tube is unable to operate efficiently at higher flow rates, canceling out any improvements that a new runner can provide.

Field Tests

Model tests and numerical simulations are only valid when geometric similitude is adhered to, i.e., there is no guarantee that the prototype machine is an accurate reproduction of the design. In addition, approach flow conditions, intake head losses, the effect of operating other adjacent units, etc., are not

simulated in model tests. For these reasons, field performance tests are often performed. There are several different types of field tests, which serve different purposes. The *absolute* efficiency is measured for acceptance or performance tests. *Relative* efficiency is often measured when operating information or fine-tuning of turbine performance is desired. Field tests are also carried out for commissioning a site and for various problem-solving activities. Basic procedures are covered by codes of the American Society of Mechanical Engineering and the International Electrotechnical Commission. The major difference between an “absolute” and a relative or index test is in the measurement of flow rate. Net head is evaluated in the same manner for each procedure. There are a variety of methods for measuring flow that are code-accepted. These include the pressure-time technique, tracer methods (salt velocity, dye dilution), area-velocity (Pitot tubes or current meters), volumetric (usually on captive pumped storage sites), Venturi meters, and weirs. The thermodynamic method is actually a direct measure of efficiency. Flow is not measured. In addition to the code-accepted methods, it has been demonstrated that acoustic meters can measure flow in the field with comparable accuracy.

The *pressure-time technique* relies on measuring the change in pressure necessary to decelerate a given mass of fluid in a closed conduit. The method requires the measurement of the piezometric head at two cross-sections spaced a distance L apart. A downstream valve or gate is necessary for this procedure. This technique requires load rejection for each test point and the need to estimate or measure any leakage. An adequate length of conduit is required and the conduit geometry must be accurately measured [Hecker and Nystrom, 1987].

The *salt velocity method* is based on measuring the transit time, between two sensors, of an injected cloud of concentrated salt solution. Given the volume of the conduit between sensors, the flow rate may be calculated from the average transit time. Electrodes that measure the change in conductivity of the liquid detect the passage of the salt cloud at a given location.

The *dye-dilution method* is based on conservation of a tracer continuously injected into the flow. A sufficient length for complete mixing is necessary for accurate results. The data required are the initial concentration and injection flow rate of the tracer and the measured concentration of the fully mixed tracer at a downstream location. The method is quite simple, but care is necessary to achieve precise results.

In principle, *area-velocity measurements* are also quite simple. Either Pitot tubes or propeller-type current meters are used to measure point velocities that are integrated over the flow cross-section. The method is applicable to either closed conduits or open channels. A relatively uniform velocity distribution is necessary for accurate results. A single unit can be traversed across the conduit or a fixed or movable array of instruments can be used to reduce the time for data collection.

The *thermodynamic method* is a direct indication of turbine efficiency. Flow rate is not measured. In its simplest form, the method assumes adiabatic conditions, i.e., no heat transfer from the flow to its surroundings. Under these conditions, that portion of the available energy not utilized in the machine to produce useful work results in increased internal energy of the fluid, which is sensed as an increase in temperature.

Acoustic flow meters have been developed which produce results with a precision equal to or greater than the code-accepted methods. Flow velocity is determined by comparing acoustic travel times for paths diagonally upstream and downstream between pairs of transducers. The speed of sound is assumed constant. The difference in travel time is related to the component of flow velocity along the acoustic path (increased travel time upstream, decreased travel time downstream). An extensive evaluation and comparison of this method has been reported [Sullivan, 1983].

Index tests circumvent the problem of accurate flow measurement by measuring relative flow detected by the differential pressure between two points in the water passages leading to the runner. Often the differential pressure is measured with Winter–Kennedy taps which are positioned at the inner and outer radii of the spiral case of a turbine. Calibration of properly placed Winter–Kennedy taps shows that flow rate is very closely proportional to the square root of the pressure difference. Index testing is useful for calibration of relative power output versus gate opening and for optimizing the various combinations of gate opening and blade setting in Kaplan units. The use of index testing to optimize cam settings in Kaplan turbines has resulted in substantial increases in weighted efficiency (i.e., a flatter efficiency curve over the full range of operation).

Defining Terms

Draft tube — The outlet conduit from a turbine that normally acts as a diffuser. This is normally considered an integral part of the unit.

Forebay — The hydraulic structure used to withdraw water from a reservoir or river. This can be positioned a considerable distance upstream from the turbine inlet.

Head — The specific energy per unit weight of water. *Gross head* is the difference in water surface elevation between the forebay and tailrace. *Net head* is the difference between *total head* (the sum of velocity head, $V^2/2g$, pressure head, p/ρ_g , and elevation head, z) at the inlet and outlet of a turbine. Some European texts use specific energy per unit mass, for example, specific kinetic energy is $V^2/2$.

Pumped storage — A scheme in which water is pumped to an upper reservoir during off-peak hours and used to generate electricity during peak hours.

Runner — The rotating component of a turbine in which energy conversion takes place.

Specific speed — A universal number for a given machine design.

Spiral case — The inlet to a reaction turbine.

Surge tank — A hydraulic structure used to diminish overpressures in high-head facilities due to water hammer resulting from the sudden stoppage of a turbine.

Wicket gates — Pivoted, streamlined guide vanes that control the flow of water to the turbine.

Otakar Jonas

Jonas, Inc.

A **steam turbine** is a rotary engine that uses superheated or saturated steam produced by a steam generator (boiler) to convert the thermal energy into work (mechanical energy). Steam turbines are used for driving electric generators as “prime movers” or driving mechanical equipment such as compressors, fans, and pumps. Turbines have been in use for over 100 years, and no new technology currently available can replace them for high-energy-output applications. Steam turbine generators produce 80% of the 750,000 megawatts needed in the U.S. and the 3000 gigawatts worldwide. This chapter focuses on the basics of turbine and electric generator design, working principles, and descriptions of key components. Steam turbine problems and steam chemistry and corrosion are also briefly discussed. There is a large volume of information dealing with all aspects of turbine and electric generator design, operation, and maintenance that is beyond the intent of this chapter. Additional information is in the “References” and “Further Information” sections.

74.1 Design of Steam Turbines [1–13]

Development of modern steam turbines started in the 1800s. In Sweden, Gustav Laval introduced the first useful turbine in 1889. A turbine with multiple blade stages closer to today’s turbines was designed in 1883 in England by Parsons. Steam turbines are the simplest and most efficient engines for converting large amounts of heat energy into mechanical work. They use superheated or saturated steam generated

FIGURE 74.1 Typical tandem compound, single reheat condensing turbine. (Courtesy of EPRI.)

FIGURE 74.2 Radial flow double-rotation reaction turbine has only moving blades. (Courtesy of Power Magazine.)

in one of many types of steam generators [8–12]. As the steam expands, it acquires high velocity and exerts force on the turbine blades. The steam conditions range from a few psig saturated to 4500 psig, superheated to 1112°F and steam flows up to 15 million pounds per hour (nuclear). Turbines range in size from a few kilowatts (kW) or horsepower (hp) for one-stage units to 1500 MW for multiple-stage multiple-component units comprising high-pressure, intermediate-pressure, and up to three low-pressure double-flow turbines. Mechanical drive turbines range from single and double stage turbines to over 20 stages, depending on horsepower. The common size range for these machines is 5 hp to over 100,000 hp. Most larger modern turbines are multiple-stage axial flow horizontal units. Figure 74.1 shows a typical utility tandem-compound reheat turbine with a combined high pressure (HP) and intermediate pressure (IP) turbine and a two-flow low pressure (LP) turbine. There are other, infrequently used, designs of smaller turbines such as the radial flow designs (see Figure 74.2).

In Figure 74.1, steam enters from the main steam lines (pipes) through stop and control valves into the HP section. The first (control) stage is spaced somewhat apart from subsequent stages to allow for stabilization of the flow. After passing through the HP turbine, cold reheat piping carries the steam to the reheater and returns it in the hot reheat piping to the integrated HP and IP cylinder to pass through the IP turbine section. The flow exits the IP turbine through the IP exhaust hood and then passes through crossover piping to the LP turbine and exits to the condenser through the LP exhaust. The typical modern steam turbine has a number of extraction points throughout all sections for the steam to the feedwater heaters.

During its expansion through the LP turbine blades, the steam crosses the saturation line. The region where condensation begins, termed the “Phase Transition Zone” (PTZ) or “Wilson Line,” is the location where many of the corrosion damage mechanisms occur [14, 15]. In single reheat turbines at full load, this zone is usually at the last minus 1 stage, which is also in the transonic flow region where, at the sonic velocity (Mach = 1), sonic shock waves can be a source of blade excitation and cyclic stresses causing fatigue or corrosion fatigue [15–18].

Steam turbines can also be classified by their configuration. A steam turbine generator for electrical power generation can be classified as a tandem compound or cross compound unit. A tandem compound unit operates with all of the turbine sections rotating on a common shaft connected to one generator. A cross compound unit has the turbine sections on two separate shafts: the HP and IP turbines are on a single shaft connected to a single generator, whereas the LP turbine is on a separate shaft connected to a separate generator. Virtually all new steam turbine installations are the tandem compound type. Many **combined cycles** also have the gas and steam turbine and electric generator on one shaft (connected by

couplings). The number of exhaust flows to the condenser is a function of the number of low-pressure turbine sections. Utility turbine generators can have two, four, or six exhausts to the condenser. Large utility turbogenerators can be over 200 feet long and weigh over 2,000 tons.

Steam turbines are used in the following cycles [2, 4, 5, 8–11]:

- Fossil fuel drum and once-through (supercritical and subcritical) boiler cycles
- Combined gas turbine and steam turbine with HRSG (heat recovery steam generator)
- Nuclear PWR (pressurized water reactor), BWR (boiling water reactor), other
- Waste heat boiler
- Trash, baggage, black liquor, etc. in drum boiler cycles
- Geothermal
- Solar
- Ocean thermal energy (contemplated)

Most **steam turbine generators** for nonnuclear power generation rotate at the constant “speed” of 3600 rpm when they drive 60-Hz electric generators (U.S., Canada, etc.) and 3000 rpm for 50 Hz generators (Europe, etc.). Most nuclear turbines operate at 1800 rpm (60 Hz) and 1500 rpm (50 Hz) to accommodate higher steam flows using longer blades; since the blades are longer, the lower speed is necessary to reduce blade stresses. Steam flows over 12 million lb/h are needed for the large nuclear turbines because the steam inlet pressures and temperatures are low. The power output from a steam turbine is controlled by varying the control valve position on the steam chest, thereby admitting more or less steam to the turbine. The increased torque on the steam turbine generator shaft resulting from the increased steam flow increases the power (MW) output.

Mechanical drive turbines generally operate over a variable speed range with maximum speed over 20,000 rpm. They are useful in driving equipment that frequently operates at lower loads. As the load on a pump or fan is reduced, the turbine can slow down and reduce the capacity of the pump or fan. As the demand increases, the turbine increases speed as required to produce the flow. This infinite type of speed adjustment can result in large power savings compared to the constant speed operation of driven equipment.

The engineering disciplines used in steam turbine design include:

- Thermodynamics and flow (cycle, blade path, controls)
- Mechanical design (stresses, vibration, strength at low and high temperatures, creep)
- Electrical design (generator, controls and monitoring)
- Materials (strength, fatigue, fracture mechanics)
- Corrosion and water and steam chemistry

The modern design tools include:

- Finite element stress, temperature, and vibration analysis
- Computational flow dynamics (viscous, nonviscous, with condensation, with steam chemistry)
- Life prediction and fracture mechanics methods
- Prototype testing (performance, efficiency, vibration, etc.)
- Material mechanical fracture, fatigue, creep, erosion, and corrosion properties

Steam Turbine Developments

After the hundred years of history, major developments are still taking place in the design, operation, and maintenance of steam turbines. The driving forces for these developments are higher efficiency, increased reliability, and lower maintenance costs (including longer inspection intervals). The main long-term steam cycle and turbine developments are governed by the availability of better materials, which can operate for the **30-year turbine design life** at higher temperatures and are more resistant to fatigue, corrosion, and fracture. The developments of the last decades include:

TABLE 74.1 Steam Turbine Materials

| Component | Material |
|--------------------|---|
| Rotor | CrMoV, NiCrMoV low-alloy steel forging |
| Discs | NiCrMoV, CrMoV, NiCrMo low-alloy steel forging, 12Cr weld repair |
| Shell and piping | Carbon steel, low-alloy steels |
| Blades and shrouds | 12Cr stainless steels, 15-5PH, 17-4 PH, Ti6-4, PH13-8Mo |
| Erosion shields | Stellite Type 6B — weld deposited or soldered, same as blade, hardened blades |
| Stationary blades | 304 stainless steel and other stainless steels |
| Expansion bellows | AISI Types 321 or 304 stainless steels, Inconel 600 |
| Bearings | High tin babbitt cast on bronze |
| Valves | Body — low-alloy steel, stems — stainless steel, seats — stellite |
| Bolts | High temp. — heat-resistant alloys, low temp. — medium-strength steels |

- Turbines for advanced steam conditions for fossil fuel cycles (up to 4500 psi pressure and 1112°F superheat) — over 6% efficiency gain
- Turbines for cycling and peaking duty (can be shut down once a day)
- Longer last-stage blades and hollow stationary blades with moisture extraction slots leading to better efficiency
- Better blade path flow design (three-dimensional viscous flow) and curved and twisted stationary “banana” blades leading to better efficiency and cyclic stresses
- Better overall design allowing over 10-year inspection intervals
- Better control of steam purity preventing deposits which lead to corrosion and loss of efficiency and MW
- Turbine bypass for faster startups
- Retractable internal packings to prevent rubbing during startups
- Tilt pad bearings for better alignment
- Better rotor and blade materials
- Superconducting electric generators (under development)
- Magnetic bearings (under development)

Bearings

Turbine and driven equipment bearings range from pressure-lubricated journal type for large turbines through ring-oiled journal bearings for small units and ball bearings for very small turbines. The oil-lubricated journal bearings rely on maintaining an oil film between the bearing babbitt and the rotor shaft. Typically, each separate turbine section (HP, IP, and LP) has two radial bearings, and the whole turbine set has one axial bearing because the steam pressure differential across turbine stages creates a net thrust along the shaft.

Steam Turbine Materials

Typical materials used for various turbine components are listed in [Table 74.1](#). Requirements for these materials include resistance to creep and high temperature oxidation for the high pressure and intermediate pressure turbines and resistance to fatigue, corrosion fatigue, stress corrosion, pitting, and brittle fracture for all components [3, 7, 11, 16–18].

74.2 Working Principles [1–6]

The main steam turbine working principle [i.e., conversion of heat and pressure energy (Equation 74.1) to kinetic energy of steam and work] was demonstrated over 2200 years ago by a Greek named Hero — see [Figure 74.3](#). In his reaction turbine, the steam generated in a heated container (boiler) was shooting

FIGURE 74.3 Hero's reaction turbine.

FIGURE 74.4 Steam flow through impulse and reaction blading. (Courtesy of *Power Magazine*.)

out through two nozzles, spinning the whole device. In modern turbines, after multiple nozzles (stationary blades), there are rotating blades or buckets attached to a rotor.

Impulse vs. Reaction Blades

There are two fundamental types of steam turbine rotating blades from the perspective of how energy is transferred from the steam to the turbine shaft. The energy is transferred by the steam expanding through a series of stationary and rotating blade sections (stages). These blade sections can be of the **impulse** and **reaction** types and for longer blades, the two types are often combined.

In an **impulse** turbine blade stage, the steam is expanded through stationary nozzles to impact the rotating blades. The energy to rotate the turbine comes from the force of the steam impacting on the buckets.

In a **reaction stage**, the stationary nozzles and rotating blades are of similar shape, similar to an airplane wing profile. The steam expands, increases in velocity, and loses pressure as it passes through the blade sections. Pressure exists on the concave side of the profile and suction on the convex side. The resulting force generated by the velocity turns the rotor. Figure 74.4 illustrates the principles of impulse and reaction blading. A blade stage is a stationary plus rotating row of blades.

74.3 Thermodynamics and Efficiency [1–12]

The steam conditions in turbines and in the whole steam cycle are measured and calculated according to established practices. Steam tables and thermodynamic diagrams are used to derive related steam and water properties such as pressure, temperature, energy, and % moisture (quality) [2–4, 6, 12, 13]. For steam turbines, a Mollier (entropy–enthalpy) diagram is often used (see Figure 74.5 and Figure 74.6). The steam expansion lines in these diagrams represent the average blade or flow path conditions. The local conditions along the longer blades and elsewhere are different. The steam cycle conditions are usually shown in a **heat balance diagram** (see Figure 74.7 for a fossil fuel drum boiler cycle).

The **amount of power** that can be generated by a steam turbine is a function of the initial steam pressure and temperature, steam flow, exhaust pressure, and efficiency of the machine. Additionally, the bearings, electrical generator, and other losses need to be considered, since these losses reduce the power output.

The heat content of a gas (steam) is equal to $C_v T$ and is called intrinsic energy. The gas can also do work when its pressure is higher than some reference pressure. For steam turbines, the reference pressure

FIGURE 74.5 Mollier (entropy-enthalpy) chart with a turbine steam expansion line (used energy) and isentropic expansion line (available energy).

FIGURE 74.6 Mollier diagram with typical utility turbine expansion lines and efficiencies.

is usually the condenser pressure. This energy is referred to as the work term, Pv . The sum of the intrinsic energy and the work energy is called enthalpy, H , which in equation form is:

$$H = \left[C_v T + \frac{Pv}{J} \right] \text{ (BTU / lbm)} \quad (74.1)$$

Both the intrinsic energy, $C_v T$, and the work term, Pv , are determined by measuring P and T of the gas at rest. The total energy of a moving fluid such as steam flowing through a turbine has an additional kinetic energy term, $V^2/2g$. Thus, the total energy is:

$$\text{Total Energy} = \left[C_v T + \frac{Pv}{J} + \frac{V^2}{2g} \right] \text{ (BTU / lbm)} \quad (74.2)$$

where P = pressure (lb/ft²) absolute; v = specific volume (ft³/lbm); C_v = specific heat at constant volume (BTU/lbm/°F); T = absolute temperature ($T_{\text{measured}} + 459.6^\circ$); J = mechanical equivalent of heat (778.26 ft-lbm/BTU); g = acceleration of gravity (32 ft/sec²); and V = velocity (ft/sec).

In a steam turbine system, the mass and energy are preserved, and in the turbine itself, most of the steam enthalpy is converted to the kinetic energy of the moving steam by the blades and is then used to generate mechanical work.

The **efficiency** of a steam turbine is defined as the actual work produced divided by the (theoretical) work produced by an isentropic (constant entropy) expansion. An isentropic process is an idealized process that represents the amount of available energy (enthalpy). The second law of thermodynamics, however, states that the conversion of this thermal energy to useful work cannot be 100% efficient. In practical use, it will be less than 100% because of the second law and because of flow, condensation, mechanical, and electrical losses in the turbine generator itself.

Expressed mathematically (see Figure 74.5), the efficiency of a steam turbine is as follows:

$$\begin{aligned} \text{Efficiency} &= \text{Actual work} / \text{Work from isentropic expansion} \\ &= \text{Used energy} / \text{Available energy} \end{aligned} \quad (74.3)$$

Figure 74.6 shows a Mollier (entropy–enthalpy) chart in which the expansion of steam in a utility reheat turbine and in reheat and nonreheat nuclear turbines are illustrated. The efficiency is a function of the machine type, size, and design and the steam inlet and exhaust conditions.

Power output of a steam turbine is the mass flow of steam through the turbine multiplied by the difference in **enthalpy** across the turbine, with the result converted to kilowatts or horsepower. The inlet enthalpy is known from the steam conditions, whereas the exhaust enthalpy is a function of the efficiency of the expansion and the exhaust pressure/vacuum. Expressed mathematically, the power output for a simple nonextraction steam turbine would be as follows:

$$\text{Power output (kW)} = \text{Steam flow (lb/h)} \times (H_{\text{in}} - H_{\text{out}}) / 3413 \quad (74.4)$$

where H_{in} = enthalpy of steam at turbine inlet and H_{out} = enthalpy of steam at turbine outlet. The calculation of power output for a steam turbine can be illustrated by a simple example.

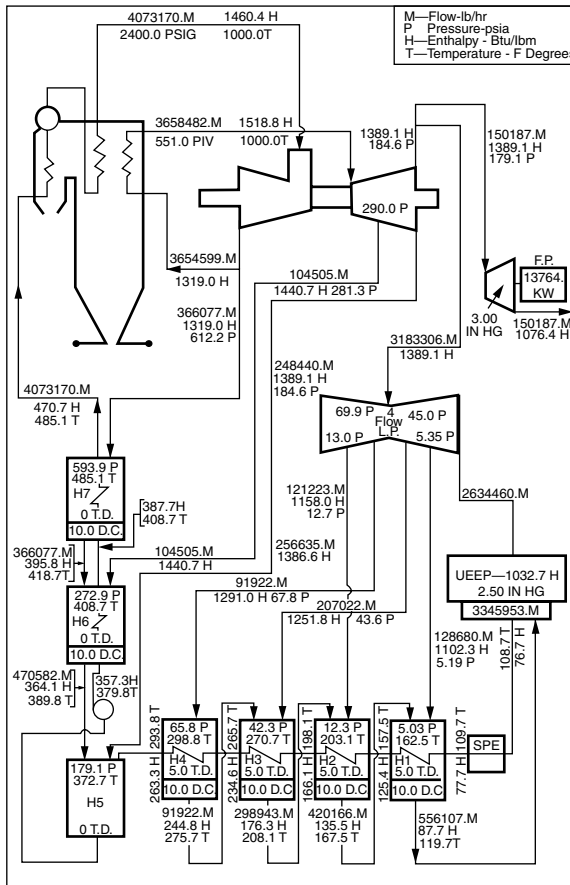

FIGURE 74.7 Heat balance diagram for a utility fossil fuel drum boiler cycle. (Courtesy of ASME.)

Example

An industrial, condensing, nonextraction steam turbine with a throttle pressure of 400 psig and 500 F (Figure 74.5) and a steam flow of 100,000 lb/h exhausts to a condenser at 3.0" Hga. The manufacturer states that the efficiency of this machine is 80.0%. Determine the power output of this machine.

Solution

From steam tables and Figure 74.5:

$$\text{Enthalpy of steam at 400 psig/500 F} = 1243.2 \text{ Btu/lb} \quad (\text{H1})$$

$$\text{Entropy of steam at 400 psig/500 F} = 1.5225 \text{ Btu/lb-}^\circ\text{F} \quad (\text{S1})$$

$$\text{Enthalpy of steam at S1 and 3.0" HgA} = 868.26 \text{ Btu/lb} \quad (\text{H2S})$$

$$\text{Exhaust enthalpy} = [(\text{H2S} - \text{H1}) \times 0.80] + \text{H1} = 943.23 \text{ Btu/lb} \quad (\text{H2})$$

$$\text{Power output} = [100,000 \text{ lb/h} \times (1243.2 - 943.23)]/3413 = 8789 \text{ kW}$$

where 3413 is in Btu/kWh.

In this example, the enthalpy of the supply steam could be determined from pressure and temperature measurements. The exhaust enthalpy, however, would not be known. The determination of enthalpy in a two-phase region (where steam and moisture coexist) by pressure and temperature measurements will only yield estimates of the actual enthalpy since the actual % moisture in the steam is not known. The exhaust enthalpy, however, could be estimated by back-calculating, since the power output would be measured during testing.

The above simplified example is based on a single-stage turbine with no steam extraction or induction. All of the steam entering the turbine produces power and then leaves the turbine exhaust. In practice, steam can be extracted from a turbine for the purposes of exporting steam to a process or improving cycle efficiency by heating boiler feed water.

Frequently, turbine performance is expressed as *turbine heat rate*. The heat rate is defined as the number of Btu that must be added to the working fluid (the steam) to generate one kWh of electrical power (Btu/kWh). The heat rate is a function not only of the process conditions but also of the cycle design. In a power station, the heat rate is affected by the number of feedwater heaters in the cycle, in addition to steam pressure, temperature, exhaust pressure, steam flow, the type of unit (reheat versus nonreheat), control valve position, and cycle losses.

Turbine heat rate is mathematically defined as

$$\text{Heat input to working fluid /kW output} \quad (74.5)$$

Heat rate can also be expressed in terms of efficiency, as follows:

$$\text{Heat rate} = 3413 / (\text{efficiency}) \quad (74.6)$$

where efficiency is expressed as a decimal.

Two important but frequently misunderstood parameters are the **expansion line end point (ELEP)** and the **used energy end point (UEEP)**. The expansion line end point represents the turbine exhaust enthalpy that would exist if there was no exhaust loss at the turbine exit. However, in practice, the expansion of the steam from the low-pressure turbine into the condenser results in a loss that is a function of the velocity through the turbine exhaust opening (exhaust hood). In the calculation of power output, the UEEP should be used (not the ELEP) because the exhaust loss does not contribute to the generation of power.

Steam cycle efficiency is much lower than the turbine efficiency, ranging from about 20 to 46% (for condensing cycles). The main loss is the exhaust loss where heat is removed by the condenser cooling water [12].

$$\text{Exhaust loss} = \text{UEEP} - \text{ELEP} \text{ (Btu/lb)} \quad (74.7)$$

74.4 Controls and Instrumentation

Control of turbine operation includes speed (rpm) and load control for turbogenerators operating at constant speed and speed and extraction and exhaust pressure control for industrial turbines where steam is used in various processes. There are other controls of the auxiliary systems and the supervisory instrumentation monitoring the turbine conditions. The industry trend is for more automatic control; today, some large power plants are fully automatic, having only one operator for the whole plant during normal operation.

Small-turbine needs in controls and instruments represent a minimum: speed governor, overspeed trip, throttle-pressure gage, throttle thermometer, exhaust-pressure gage, and tachometer. Where the turbine controls or affects exhaust-header pressure, its speed governor includes an exhaust-pressure regulator to adjust the governor control.

The list of requisite equipment grows with turbine capacity and rising steam conditions. As an example, the controls needed by some reheat turbines for automatic operation are shown in Figure 74.8. Shaft speed is one of the most important variables in running a turbine. Governing systems control speed in turbines large and small.

Speed governors are used to measure shaft speed and adjust the control/governor-valve openings to pass the needed steam flow to keep speed within governor's regulation range. To hold exact speed, speed-changer spring or bellows tension must be adjusted manually or by an automatic frequency-measuring device. When generators work in parallel, the speed changers are used to divide the total load between the turbines on the line. Governors can use a flyweight (see Figure 74.9) or hydraulic pump connected to the turbine shaft to sense its rotation.

A *load-limiting meter* overrides the speed governor to hold maximum load at any point the operator wants. The limiter controls steam flow during startup by setting governor valves as needed.

Stop and Control Valves

Valves control the flow of steam through a turbine. **Stop valves** are provided on the turbine to admit steam during normal operation or to shut off the steam very quickly in the event of an emergency. This function is often performed by a throttle-stop (also stop-throttle) valve, which controls steam flow to all inlet nozzles during turbine warmup and is fully open during load operation. These valves are normally fully opened or closed. The **control or governing valves** are located in the steam chest at the turbine

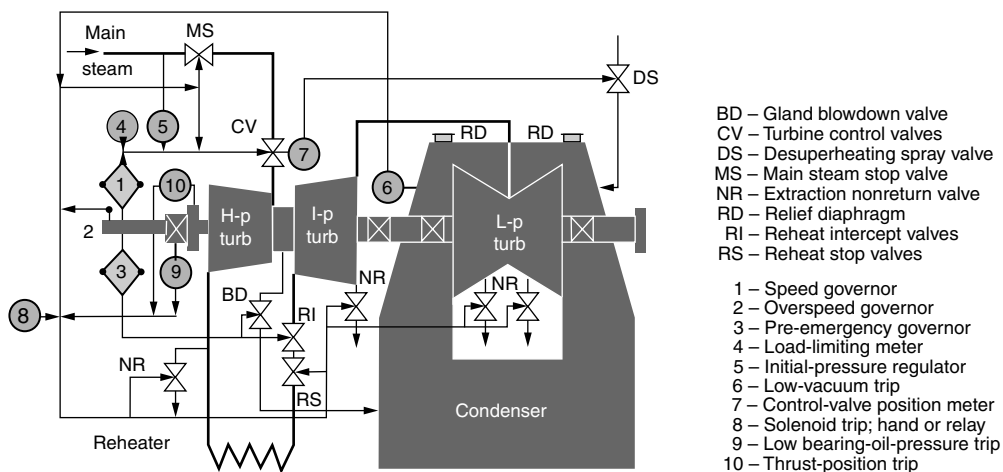

FIGURE 74.8 Elements of the automatic load control. (Courtesy of Power Magazine.)

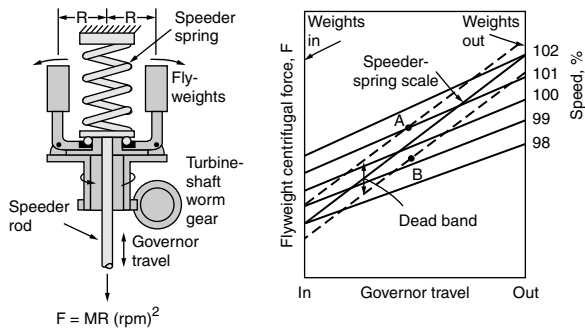

FIGURE 74.9 Flyweight governor balances the force of springs and rotating weights and moves speeder rod which is connected to a control valve. (Courtesy of *Power Magazine*.)

inlet and control the flow of steam to the turbine. On larger units, multiple control valves are used to provide better efficiency over the load range. [Figure 74.8](#) shows locations of the valves at the turbine steam inlet. The turbine control valves can be operated in either a **full arc admission** or **partial arc admission mode**. In full arc admission, all of the control valves are opened simultaneously, with the stop valve used to control flow. In this mode of operation, there is more even heating of the turbine rotor and casing. In partial arc admission, one control valve is opened at a time (sequentially). The turbine is not as evenly heated; but the efficiency of the turbine is better, since valve-throttling losses are reduced. The valves should be periodically exercised to ensure their reliable operation and prevent turbine overspeed and possible destruction.

Other Valves

For control of the steam extractions, **extraction valves** internal to the turbine or on the extraction piping are used. In large turbine piping, **reheat intercept valves** may be used to prevent turbine overspeed in case of turbine trip.

Supervisory Instruments

A supervisory instrument system monitors several operating variables on a steam turbine. It uses sensing elements or detectors, mounted on the turbine, which transmit electrical or fiber optic signals to remote recording and/or indicating instruments. Measured variables generally include turbine-shaft vibration, shaft eccentricity, shell expansion, differential expansion, control-valve position, turbine speed, and various turbine-metal temperatures. An example of the supervisory instrumentation for a utility turbine is given in [Figure 74.10](#).

74.5 Electric Generators [21–25]

The electric generator (see [Figure 74.11](#)) is a rotating machine that converts the mechanical work of the turbine into electrical power. This conversion is accomplished by inducing an electromotive force by the relative motion between a conductor and a magnetic field. The stationary part of a generator is called a **stator** or armature. The moving part is called a **rotor** or field. In order to create the magnetic field, an **exciter**, which is a separate rotating machine on the same shaft as the generator, provides the DC electricity to magnetize the rotor. The frequency of the AC voltage generated by a synchronous generator is proportional to the speed of the rotor in revolutions per unit time. A two-pole synchronous generator for a nonnuclear-type power plant must revolve at 3600 rpm to generate a 60-Hz voltage, as the following equation illustrates:

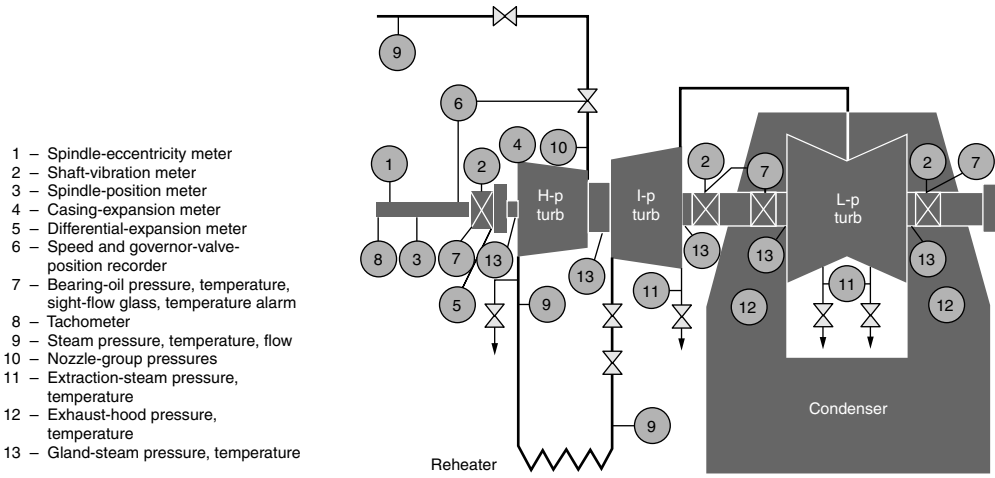

FIGURE 74.10 Typical supervisory instrumentation for a utility turbine. (Courtesy of Power Magazine.)

FIGURE 74.11 Schematic of an electric generator: 1, rotor; 2, retaining rings; 3, stator core; 4, stator bars; 5, fan; 6, hydrogen coolers; 7, head tank for cooling water. (Courtesy of Alstom.)

$$f = (P/2) \times (N / 60) \tag{74.8}$$

where f = frequency in Hz, P = the number of magnetic poles, and N = the speed of the rotor in rpm. A nuclear turbine operating at 1800 rpm would require a four-pole generator to generate 60 Hz. Standard voltages range from 550 to 20,000 volts.

Generator Cooling

Generators must be cooled to remove the heat produced by the windings.

Stator-Winding Cooling — Liquid flow through individual strands of the stator bar has been the method used to cool stators on large generators since the mid-1950s. Low-conductivity demineralized

water, the coolant used today, is supplied to the stator winding by an external pumping and cooling system. This closed system is designed to operate as an independent subloop in the turbine/generator control system. The generator is protected from loss of coolant flow and high coolant temperature by a load runback circuit, or a time-delayed trip circuit, depending on the load-following capability of the steam-supply system.

Rotor Cooling — For years, all large turbine/generators have been designed to operate in a hydrogen atmosphere, to capitalize on the improved cooling capability of hydrogen compared to air. A gas-control system performs the dual function of supplying hydrogen to the generator to maintain proper coolant operating pressure and carbon dioxide during hydrogen purging and filling operations. This system consists of regulators and controls for supplying the hydrogen and carbon dioxide and a control cabinet with the instruments necessary for monitoring generator gas pressure, purity, and temperature. Shaft oil seals and associated control equipment prevent hydrogen from leaking out of the generators. Some smaller turbine generators use air instead of hydrogen for rotor cooling.

74.6 Turbine Generator Auxiliaries

Many auxiliary systems that are required for operation are provided with a steam turbine generator. Some of the major auxiliary systems are briefly discussed below.

Steam Seals

At locations where the steam turbine shaft penetrates the casing(s), a steam seal system is used to prevent steam from leaking out of the seals which are above atmospheric pressure and air leaking into the LP turbine seals which are below atmospheric pressure. For medium and large turbines, **labyrinth seals** are used. For smaller turbines, shaft sealing can be accomplished by **graphite ring seals**. Labyrinth seals are noncontact seals between the turbine casing and rotor where ridges or strips are used to reduce steam leakage by multiple pressure drops through the seal.

A steam seal system uses steam leak-off from the high and intermediate seals during operation to seal the low-pressure seals. When the turbine is on-line, the machine is said to be “self-sealing.” When the turbine is being brought on-line, a separate source of steam is used to seal the turbine prior to establishing a condenser vacuum. [Figure 74.12](#) shows the typical flow pattern for a labyrinth steam seal system on a unit startup and during normal operation.

Internal seals that force most of the steam to flow through the blade path are also noncontact seals using similar principles as the labyrinth seals. Some use removable seal strips which are refurbished during turbine overhauls.

Turning Gear

During periods when the turbine is shut down and prior to startup, the hot rotor must be rotated to prevent bowing of the rotor shaft. This action is taken to prevent excessive vibration on startup and possible bearing damage and is usually accomplished with a motor-driven device operating at 3 to 5 rpm.

Lube Oil System

The turbine generator must be provided with an oil lubrication system for the bearings. The lubrication system consists of a number of shaft-driven and electric motor-driven pumps, filters, oil coolers, and an oil reservoir. The shaft-driven pump is used when the turbine is above 90% of rated speed. Below this speed, AC or DC motor-driven pumps are used. The high-pressure control oil system, which operates the control and stop valves and turbine governor, is supplied from the lube oil system. Bearing oil temperature is maintained at ~120°F at the inlet to the bearings. The bearings are supported in pedestals (metal boxes), from which the oil drains back into the oil reservoir.

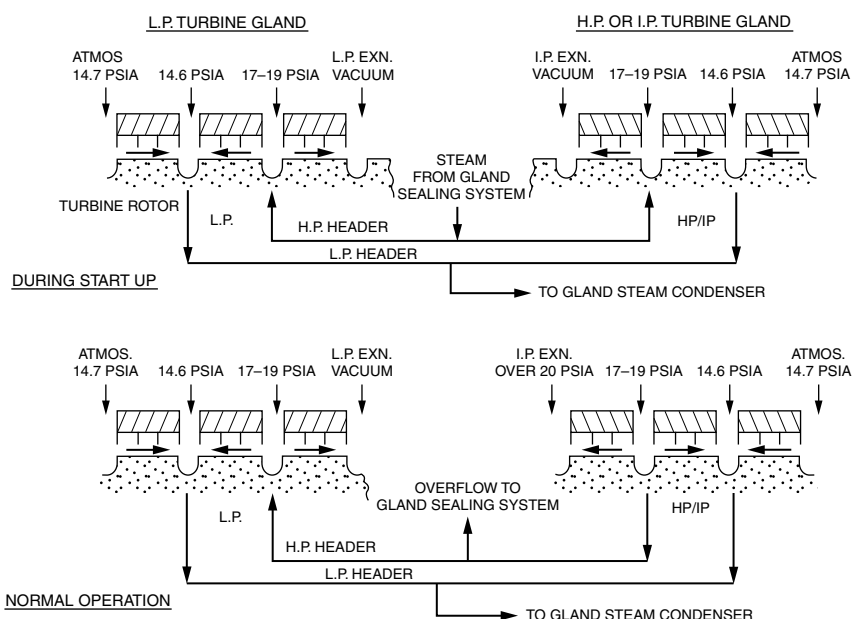

FIGURE 74.12 Typical flow pattern for a labyrinth steam seal system on a unit startup and during normal operation.

Hydraulic Fluid System

In modern turbines, the electro-hydraulic control system (EHC) uses hydraulic fluid for valve actuators. The EHC fluid system powers the hydraulic actuator at each steam valve. A fire resistant phosphate-ester fluid is usually used to minimize the fire hazard in case of a leak. The hydraulic fluid is also used in the emergency overspeed trip system.

Water Induction Protection

It is possible to induct water into the turbine from cold piping during a unit startup, an extraction line, the boiler, or a desuperheater. Water induction or **water hammer** incidents are more likely to occur during unit trips or load changes. The dense water, in comparison to the steam, can cause considerable damage to the blades, and the cold water in contact with hot turbine metal can cause cracking of metal or rubbing between moving and stationary parts due to differential expansion.

The ASME has developed a standard that should be followed when designing systems associated with a steam turbine. ASME TDP-1 provides design details on how to prevent water induction. Although the standard applies mainly to steam turbine generators, the guidelines are also applicable to mechanical drive turbines.

74.7 Steam Turbine Problems [1-7, 11, 15-19]

Turbines and their attached equipment are typically designed for a 30-year service, but many steam generating units in the United States are over 40 years old. The maintenance period for turbine disassembly, inspection, and major maintenance has now been extended up to 10 years, and up to 20-year warranties, during which there should not be any major damage, are being offered. Problems occur by wear, corrosion, erosion, cavitation, fatigue, and creep at high temperatures due to normal operation and operating errors. The main impact occurs when the turbine component damage results in an unexpected "forced outages." About 90% of the cost of forced outages is the cost of lost production and replacement power; it can be up to \$1 million/day. Table 74.2 lists the major problems.

TABLE 74.2 Turbine Corrosion, Erosion, and Deposition Problems

| Problem | Damage Mechanisms ^a | Root Causes ^b | Inspection and Detection ^c | Possible Safety Issues | Cost per Event ^d (\$ millions) |
|--------------------------------------|--------------------------------|--------------------------|---------------------------------------|------------------------|---|
| Disc/blade attachment cracking | SCC, cf, P | D, CH | UI, V, MP | Turbine wreck | 1 to 20 |
| Disc bore cracking | SCC, P | D, M | UI | Turbine wreck | 2 to 20 |
| Blade airfoil cracking | CF, P, WE | D, CH | V, VSA | Penetration of casing | 0.1 to 2 |
| Blade root cracking | CF, SCC, P | D, CH | V, UI | Penetration of casing | 0.2 to 2 |
| Blade airfoil and valve erosion | SPE | D, O of boiler | CM, V | None | 0.5 to 3 |
| Blade airfoil damage | FOD | Cleanliness, M | V, CM | None | 0.1 |
| Stationary blade cracking | CF, P | D, O | V, DP | None | Low |
| HP/IP turbine rotor cracking | LCF, CR | D, O, H, M | UI, MP | Turbine wreck | 2 to 30 |
| Rotor cracking | CF, F, P | D, O | MP, VSA | Turbine wreck | 2 to 10 |
| High temperature steam Pipe cracking | Creep, LCF, graphitization | D, O | UI, MP, MET | Failure | 1 to 20 |
| LP Casing weld cracking | SCC | D, M | V, DP, UI, MP | None | Low |
| Casing and extraction piping | FAC | D, CH | V, UI | Steam leak | 0.1 to 1 |
| Cross-over pipe, expansion bellows | SCC | D, CH | V, UI, leak | Steam leak | 0.1 to 2 |
| Bearing wear | Wear, F | Dirty oil, O | Vibration, V, temperature | None | 0.1 to 2 |
| Thrust bearing wear | Wear | CH — deposits on blades | V, rotor position | Turbine wreck | Up to 10 |
| Loss of MW and efficiency | Deposits, P, FOD, WE, SPE | CH, D, O, A | V, performance monitoring | None | Up to 2/year |
| Destructive overspeed | Fracture | O, CH | Not Applicable | Turbine wreck | Up to 200 |
| Turbine rubbing | Wear | O, CH | Vibration | None | 0.2 to 5 |

^a cf., corrosion fatigue; F, fatigue; SCC, stress corrosion cracking; P, pitting; FAC, flow-accelerated corrosion; LCF, low cycle fatigue; LCCF, low cycle corrosion fatigue; WE, water droplet erosion; FOD, foreign object damage; SPE, solid particle erosion; CR, creep.

^b D, design and material selection; CH, chemistry; O, operation; A, age; M, manufacturing and maintenance; CM, condition monitoring; MET, metallography.

^c V, visual; UI, ultrasonic inspection; MP, magnetic particle; EC, eddy current; DP, dye penetrant; VSA, vibration signature analysis.

^d Lost production and repairs per one event. The cost of lost production is typically much higher than the loss from repairs with a ratio of up to 10:1.

74.8 Steam Chemistry and Turbine Corrosion [11, 12, 15–19]

Chemical composition of turbine steam is important for prevention of turbine deposits, which could lower turbine efficiency and MW generating capacity and cause corrosion. Maintaining **steam purity** is often neglected. It is one of the main functions of boiler design and operation and steam cycle water purification to produce steam of the desired purity, which is determined by the turbine steam conditions. For superheated steam turbines, the concentrations of steam impurities, such as salts, hydroxides, silica, and metal oxides, should be in the low part per billion, ppb range (1 ppb is 10^{-9} by weight). For turbines using saturated and wet steam, the concentration can be higher.

When the concentration of a specific impurity in superheated steam exceeds its solubility, the impurity precipitates and deposits — having generally harmful effects. The solubility of steam impurities decreases as the steam expands and is the lowest at the lowest pressure turbine stages before condensation occurs. For a utility reheat turbine, solubility of NaCl and NaOH at this point is about 5 ppb and solubility of silica about 20 ppb. Salts, acids, and hydroxides, which concentrate by deposition on steam turbine surfaces, are hygroscopic, particularly near the saturation line, and form concentrated aqueous solutions that can be very corrosive. In the lower-pressure turbines, NaCl can concentrate from low ppb in

FIGURE 74.13 Mollier diagram with the LP steam turbine expansion line and regions of steam impurity concentration and corrosion.

superheated steam up to 28% solution in the so-called “salt zone.” Behavior of typical steam impurities in steam turbines is illustrated in the Mollier diagram shown in Figure 74.13.

Defining Terms

Blade Stage — The combination of one stationary and one rotating row of blades.

Buckets — Turbine blades.

Condensing turbine — Any turbine with an exhaust below atmospheric pressure. Turbine exhaust steam contains moisture droplets.

ELEP — Expansion line end point; enthalpy of exhaust steam if the exhaust loss at the turbine exit is neglected.

Enthalpy — A measure of the internally stored energy; the ability of a substance to provide useful work from energy, expressed in Btu/lb-°F.

Entropy — A measure of the ability of steam to give up heat to produce work. As the entropy of steam increases, the ability of the steam to do work decreases.

Feedwater heater — A heat exchanger that uses extraction steam to heat feedwater and condensate in a power station.

Governor — Regulates the turbine speed.

Heat balance diagram — Diagram that shows the temperature, pressure, enthalpy, and flow of all streams in the cycle.

Impulse blades — Blades that use the force of the steam impacting on the blades or buckets to rotate the turbine.

Mechanical drive turbine — A steam turbine connected to a pump, fan, or a similar device to provide motive power.

Mollier diagram — Entropy–enthalpy diagram, usually used for steam turbines because it conveniently shows the steam expansion lines and all parameters needed for efficiency and blade stage evaluations.

Noncondensing or back-pressure turbine — Any turbine with an exhaust above atmospheric pressure.

Reaction blade — Blades that use the force generated by the velocity in the stages to rotate the turbine.

Steam chemistry — The concentration of contaminants or additives in steam and resulting chemical characteristics of deposits and water droplets [11, 12, 14–19].

Steam purity — The concentration of contaminants or additives in steam.

Steam quality — Percent of saturated steam by weight in a steam/water mixture. Sometimes improperly used for chemical purity and water and steam chemistry.

Steam tables — Properties of steam (pressure, temperature, volume, enthalpy, entropy, etc.) shown in tabular or electronic form [13].

Steam turbine — A rotary engine that converts thermal energy to useful mechanical work by the impulse or reaction of steam.

Superheated, saturated, and wet steam — Terms describing the amount of liquid water in the steam.

Turbine-generator — A steam turbine connected to an electrical generator to produce electric power. Also, turbogenerator.

Turbine rotor — Shaft to which the rotating blades are attached.

UEEP — Used energy end point; enthalpy of steam at the turbine exhaust.

Water induction — The admission of water into a steam turbine.

M. Krarti

University of Colorado

This chapter provides a general description of the basic concepts of combined heat and power generation systems, their benefits, and their applications. First, an overview of the U.S. power industry with some historical background is presented. Then, a review of the fundamental theory of power cycles and cogeneration systems is outlined, followed by a description of commercially available cogeneration systems and their components. In addition, some guidelines and examples are presented to carry out feasibility analysis of cogeneration systems. Finally, a cogeneration case study is presented.

75.1 Introduction

Combined heat and power (CHP) and cogeneration are terms used interchangeably to denote the simultaneous generation of power (electricity) and usable thermal energy (heat) in a single, integrated system. A CHP plant derives its efficiency, and hence lower costs, by recovering and utilizing the heat produced as a byproduct of the electricity generation process, which would normally be wasted to the environment. The overall fuel efficiency of typical CHP installations can be in the range of 70 to 90%, compared with 35 to 50% for conventional electricity generation. Overall, CHP achieves a 35% reduction in primary energy usage compared with remote power stations and heat-only boilers. Moreover, CHP avoids transmission and distribution losses since it generally supplies electricity close to the generation site.

While the CHP concept is not new, it has been applied to a wide range of commercial buildings only recently. Indeed, until the 1980s, cogeneration systems were used only in large industrial or institutional facilities with high electricity demand (typically over 1000 kW). After the energy crisis of 1973, during which fuel and electricity prices had increased significantly (by a factor of five), the U.S. government passed in 1978 the National Energy Act (NEA), which includes the Public Regulatory Policies Act (PURPA). The PURPA regulations have forced utilities to purchase electricity and to provide supplementary or backup power to any qualified cogeneration facilities. The Energy Policy Act of 1992 has increased even more the appeal of cogeneration systems by opening up transmission line access and retail wheeling.

In addition to the favorable regulations, the development of energy-efficient cogeneration systems and small preengineered packaged cogeneration units has provided the needed incentives to encourage the implementation of systems capable of generating electricity and heat for commercial, institutional, and even residential applications. Currently, cogeneration systems are available over a wide range of sizes from less than 50 kW (micro-systems) to over 100 MW. Moreover, advances in controls have provided better procedures to operate and integrate the various components of cogeneration systems (including prime movers, electrical generators, and heat recovery systems). More recently, energy service companies (ESCOs) have increased awareness and interest of the public in onsite generation technologies.

In addition to their better overall energy efficiency compared to conventional utility plants, cogeneration systems offer the following benefits:

- Cleaner power generation sources with reduced No_x and carbon emissions
- Increased reliability and quality of electrical power since customers are less vulnerable to blackouts from utility power lines
- Added national energy security with diversified sources and locations of power generation
- Avoidance of transmission and distribution costs since no new lines would be needed if distributed cogeneration plants are available

To evaluate the feasibility of a cogeneration system, several technical and economic aspects as well as regulatory issues should be considered. Although this chapter provides some discussion of the main regulatory considerations and financial options for cogeneration in the U.S., the main focus of the chapter is to provide technical information and engineering principles that are necessary to understand the design and the operation of cogeneration systems. First, an overview of past, current, and future status of the electricity generation industry in the U.S. is presented.

75.2 Electricity Generation in the U.S.

Energy is essential to modern industrial societies. The availability of adequate and reliable energy supplies is required to maintain economic growth and to improve living standards. The major energy sources include fossil fuels (petroleum, natural gas, and coal), hydropower, and nuclear energy. [Table 75.1](#) illustrates the progression of energy consumption by region throughout the world. As expected, the industrialized countries (including North America and Western Europe) consumed more than 50% of the total energy used throughout the world during 1997. The U.S. alone, with less than 5% of the world's population, used about one-fifth of the world total energy consumption in 1997. Associated with the energy consumption are environmental and health impacts that have been only properly investigated in the last decade. In particular, the burning of fossil fuels has significantly increased levels of carbon emissions as indicated in [Table 75.1](#). The carbon emissions are believed to have major effects on changing the global climate by increasing global temperatures. To reduce the environmental impacts of producing electricity, several federal and state governments in the U.S. and abroad have set regulations and environmental restrictions to foster new alternatives for power generation including CHP plants and distributed generation systems. Additional incentives have been proposed for reducing energy consumption through energy efficiency and demand-side management programs.

To better understand the potential for combined heat and power systems, a brief review of the U.S. electrical power generation is provided below.

TABLE 75.1 Energy Consumption and Carbon Emissions by Region

| Region | Energy Consumption [Quadrillion Btu] | | | Carbon Emissions (Million Metric Tons) | | |

In the U.S., electricity is generated from either power plants fueled from primary energy sources (i.e., coal, natural gas, or fuel oil) or from nuclear power plants or renewable energy sources (such as hydro-electric, geothermal, biomass, wind, photovoltaic, and solar thermal sources). Coal is the fuel of choice for most existing U.S. electrical power plants as shown in Table 75.2. However, gas-fired power plants are expected to be more common in the future due partly to environmental concerns but also due the availability of more efficient and reliable combustion turbines.

The quantity of electricity sold by U.S. utilities has increased steadily for all end-use sectors as indicated by the data summarized in Table 75.3. The increase in electricity consumption could be even higher without the various energy conservation programs implemented by the federal or state governments and utilities. For instance, it is estimated that the demand-side-management programs provided by utilities saved about 35 billion kWh in electrical energy use during 1992 and over 56 billion kWh in 1997 (EIA, 2003).

The prices of electricity for all end-use sectors have actually decreased since 1982 after a recovery period from the 1973 energy crisis, as illustrated in Table 75.4. As expected, industrial customers enjoyed

TABLE 75.4 Average Retail Prices of Electric Energy Sold by U.S. Utilities by Sector in 1992 cents per kWh

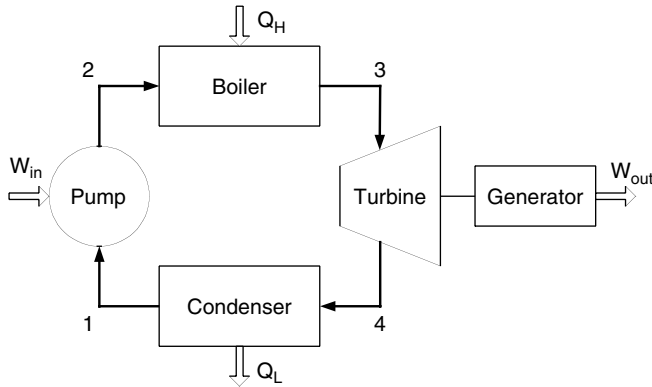

FIGURE 75.1 A rankine cycle used for power generation.

the lowest electricity prices over the years. Meanwhile, the cost of electricity for residential customers remained the highest.

75.3 Basics of Power Generation Cycles

Two types of heat engines are commonly used to generate electricity for both power-only plants and combined heat and power systems:

- **External combustion** engines use **water** as a working fluid. Steam power plants, operating as rankine cycles, are examples of external combustion systems. A typical rankine cycle includes a boiler, one or several turbines, a condenser, and a pump. Each of these components should be analyzed to determine the overall performance of the rankine cycle. One of the main advantages of a rankine cycle power plant is its capability of utilizing several types of fuel including coal, chemical wastes, heavy and light oils, biomass, and even natural gas. Figure 75.1 illustrates common components for a rankine cycle used to generate electricity.
- **Internal combustion engines** use **air** (actually a mixture of air, fuel, and combustion products) as a working fluid. Air-standard assumptions or cold-air-standard assumptions are generally used to analyze the internal combustion engines. Otto cycle (used for gasoline reciprocating engines), Diesel cycle (used for diesel reciprocating engines), and Brayton cycle (used for gas-turbines) are common internal combustion engines. The thermal efficiency of common internal combustion engines is summarized in [Table 75.5](#) as a function of the compression ratio, r , the cutoff ratio, r_c , and the pressure ratio, r_p [Cengel and Turner, 2001].

The thermal performance of all heat engines is expressed in terms of the first law thermal efficiency, η_{th} , as the ratio of net work produced, W_{net} , to the total heat input, Q_H :

TABLE 75.5 Basic Processes and Thermal Efficiency of Common Internal Combustion Cycles

| Cycle | Basic Processes of the Simplified Cycle | Thermal Efficiency |
|--|---|--|
| <i>Otto</i> for spark-ignition (SI) engines (closed cycle) | 1-2: isentropic compression; 2-3: constant volume heat addition; 3-4: isentropic expansion; 4-1: constant volume heat rejection | $\eta_{th,Otto} = 1 - \frac{1}{r^{k-1}}$ |
| <i>Diesel</i> for compression-ignition (CI) engines (closed cycle) | 1-2: isentropic compression; 2-3: constant pressure heat addition; 3-4: isentropic expansion; 4-1: constant volume heat rejection | $\eta_{th,Diesel} = 1 - \frac{1}{r^{k-1}} \left[\frac{r_c^k - 1}{k(r_c - 1)} \right]$ |
| <i>Brayton</i> for gas-turbines (open cycle) | 1-2: isentropic compression; 2-3: constant pressure heat addition; 3-4: isentropic expansion; 4-1: constant pressure heat rejection | $\eta_{th,Diesel} = 1 - \frac{1}{r_p^{(k-1)/k}}$ |

$$\eta_{th} = \frac{W_{net}}{Q_H} = \frac{W_{out} - W_{in}}{Q_H} \tag{75.1}$$

where W_{out} is the power output from the turbine-generator system and W_{in} is the power required to operate the cycle as illustrated in Figure 75.1 for a rankine cycle.

To better understand how to improve the thermal performance of power cycles, it is a common practice to consider the Carnot cycle with only reversible processes. Indeed, the Carnot cycle is the most efficient power cycle that can be theoretically executed between a heat source, T_H , and a heat sink, T_L . Carnot showed that the maximum possible thermal efficiency for a reversible power cycle operating between temperatures T_H and T_L is:

$$\eta_{th,Carnot} = 1 - \frac{T_L}{T_H} \tag{75.2}$$

Figure 75.2 illustrates the T-S (Temperature–Entropy) diagram of a Carnot power cycle operating between temperatures T_H and T_L . Equation (75.2) indicates that increasing the temperature T_H and lowering the temperature T_L are two options to increase the thermal efficiency of a power cycle. For a Rankine cycle power plant, T_L is typically 15°C (59°F) if the condenser is cooled by a nearby lake or river, and T_H is the steam temperature produced by the boiler. The maximum steam temperature achieved by the current boiler technology is about 620°C (1150°F). New materials such as ceramics offer promising applications to build boilers that can withstand higher steam pressure and temperatures. Thus, the highest Carnot efficiency that can be achieved today for vapor power cycles is about 68%. Actual efficiencies for utility power-only plants range from 30 to 45%.

FIGURE 75.2 A schematic T-S diagram for a Carnot power cycle.

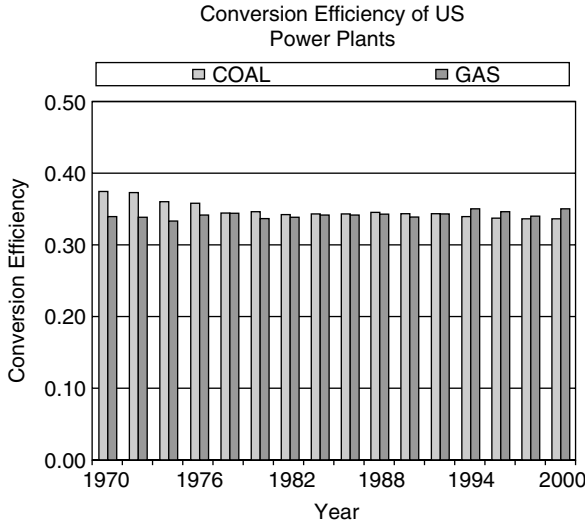

FIGURE 75.3 Annual average efficiencies for power-only utilities in the U.S since 1970.

Figure 75.3 illustrates the historical variation of the conversion efficiency achieved by U.S. electrical utility power plants from 1970 to 2000. Since 1970, the efficiency has remained almost constant at about 34% for both coal-fired and natural gas-fired power plants. These low efficiencies are inherent to the rankine cycle with the need to dispose of heat in the condenser as well as in the boiler exhausts. Indeed, a rankine cycle has to reject (thus waste) heat Q_L to the environment as indicated in [Figure 75.1](#).

If a portion of the heat rejection, Q_L , can be recovered and used through heat recovery systems, then the overall efficiency of the plant can be significantly increased. A combined heat and power (or cogeneration) plant provides a single and integrated system to generate electrical power, W_{net} , and useful thermal energy, Q_u ($Q_u < Q_L$). While the concept of recovering heat from a power cycle (i.e., combined heat and power generation) has been known and available since the 1800s, cogeneration has regained popularity only recently due to the incentives provided by the Public Utilities Regulatory Policies Act (PURPA) of 1978.

The first law thermal efficiency of a cogeneration plant that uses an energy input Q_H to produce a net electrical power, W_{net} , and a useful thermal energy, Q_u , can be defined as:

$$\eta_{th,cogen}^I = \frac{W_{net} + Q_u}{Q_H} \quad (75.3)$$

However, since the quality of electrical energy is higher than that of thermal energy (since work is usually two or three times more expensive than heat), the second law efficiency, using the exergy concept, would be a better measure of the performance of cogeneration systems. Thus, instead of using $W_{net} + Q_u$ to quantify the output of a cogeneration system, $W_{net} + Q_u(1 - T_0/T)$ should be considered:

$$\eta_{th,cogen}^{II} = \frac{W_{net} + Q_u(1 - T_0/T)}{Q_H} \quad (75.4)$$

where T is the temperature at which heat is delivered and T_0 is the temperature of the environment. The term $(1 - T_0/T)$ represents the thermal efficiency of a reversible cycle (i.e., Carnot cycle), as provided by Equation (75.2), to convert the heat Q_u into work. [Table 75.5](#) provides values for the term $(1 - T_0/T)$ for selected heat delivery temperatures, T , when the environment is set at $T_0 = 20^\circ\text{C}$ (68°F)

TABLE 75.6 Values for $(1 - T_0/T)$ for Various Heat Delivery Temperatures with $T_0 = 20^\circ\text{C}$ (68°F)

| Delivery Temperature, $^\circ\text{C}$ ($^\circ\text{F}$) | 100 $^\circ\text{C}$ (212 $^\circ\text{F}$) | 200 $^\circ\text{C}$ (392 $^\circ\text{F}$) | 300 $^\circ\text{C}$ (572 $^\circ\text{F}$) | 400 $^\circ\text{C}$ (752 $^\circ\text{F}$) | 500 $^\circ\text{C}$ (932 $^\circ\text{F}$) | 600 $^\circ\text{C}$ (212 $^\circ\text{F}$) |
|--|---|---|---|---|---|---|
| $(1 - T_0/T)$ | 0.214 | 0.381 | 0.489 | 0.565 | 0.621 | 0.664 |

It should be noted that typical cogeneration systems deliver thermal energy at temperatures in the range of 300°C (572°F) and 400°C (752°F), thus a value of 0.5 can be used for the term $(1 - T_0/T)$ to estimate the second law thermal efficiency of most cogeneration systems as expressed by Equation (75.4). As discussed later in this chapter, the PURPA efficiency is actually based on Equation (75.4) using a value of 0.5 for the term $(1 - T_0/T)$.

75.4 History of Cogeneration

Systems for combined heat and power generation have been in existence since the 1880s throughout the U.S. and Europe. Indeed, several industrial facilities generated their own electricity and steam using coal-fired boilers and steam-turbine generators. It is estimated that CHP systems produced up to 58% of the total electricity generated in the U.S.

However, in the mid-1900s, large central electrical power plants have been built with reliable utility grids. The electricity from these plants was produced at relatively low cost. As a consequence, industrial facilities started to purchase electricity from the power plants and thus reduced gradually their reliance on on-site generation. The contribution of CHP systems to the total U.S. electric power generation represented 15% in 1950 and only 4% in 1974 [EIA, 2000]. Large electric utility holding companies have been formed and expanded since the early 1900s. In 1920, the majority of the U.S. power industry was controlled by few privately owned electric power holding companies. These holding companies abused their power and charged consumers higher prices for electricity.

To reduce the monopoly of the privately owned electric utility holding companies, the federal government intervened by passing the Public Utility Holding Company Act (PUHCA) during 1935. Under the provisions of the PUHCA, the electric utility holding companies became regulated by the Securities and Exchange Commission. In a further effort to reduce electricity prices, government-owned hydroelectric power facilities were built including the Hoover Dam in 1936. The Bonneville Project Act of 1937 provided the federal government with means to oversee transmission and marketing of power produced from hydroelectric facilities. By 1941, power produced from publicly owned facilities represented 12% of the total utility generation.

Until the early 1970s, utilities were able to meet the ever-increasing electrical power demands at decreasing prices due to the economies of scale, technological advances, and declining fuel costs. However, a series of events that occurred during the 1970s has significantly impacted the U.S. electric power industry. These events include the oil embargo in 1973–1974 and the passage of the Clean Air Act in 1970 as well as the Energy Supply and Environmental Coordination Act in 1974. As a result of these events, prices of electrical power increased dramatically in the 1980s. Between 1973 and 1985, the prices of fuels and electricity increased by a factor of five.

As a reaction to the oil embargo, the federal government passed in 1978 the National Energy Act (NEA) in order to reduce U.S. dependence on foreign oil, develop alternative energy sources, and encourage energy conservation. The NEA comprises five different statutes:

- Public Utility Policy Act (PURPA)
- Energy Tax Act
- National Energy Conservation Policy Act
- Powerplant and Industrial Fuel Use Act
- Natural Gas Policy Act

PURPA has the most significant impact on the electric power industry and on the development of cogeneration in the U.S. Indeed, PURPA allowed nonutility facilities that meet certain ownership and efficiency criteria to sell electric power to utility companies. Specifically, PURPA sets the following legal obligations for the electric utility companies toward cogenerators defined as Qualified Facilities (QFs):

- Utility companies have to purchase cogenerated energy and capacity from QFs.
- Utility companies have to sell energy and capacity to QFs.
- Utility companies have to provide to QFs supplementary power, backup power, maintenance power, and interruptible power.
- Utility companies have to provide access to transmission grid to “wheel” to other electric utility companies.

The term “wheeling” refers to the process by which utilities can buy or sell electricity to or from other utilities in order to meet peak demands or shed excess generation. The wheeling process enables utilities to spend less on peaking power plants, thereby lowering capital expenditures required to meet high periods of electric power demands.

Additional legislation passed in the 1990s, including the Clean Air Act Amendments (CAAA) of 1990 and the Energy Policy Act (EPACT) of 1992, has provided new opportunities for cogeneration. In particular, EPACT provides incentives for nonutility generators to enter the wholesale market for electrical power by exempting them from the PUHCA constraints. The law creates a new category of power producers known as Exempt Wholesale Generators (EWGs). These EWGs are different from PURPA QFs in that they are not required to meet PURPA’s cogeneration criteria. In addition, utilities are not required to purchase electric power from EWGs.

Table 75.7 summarizes the major federal legislation that affected the U.S. power industry since the early 1930s.

Because of the passage of PURPA, multiple megawatt CHP projects have been developed and built especially at large industrial facilities including pulp and paper, steel, chemical, and refining plants. Recent advances in reciprocating engines and microcombustion turbines have made CHP more cost-effective for small applications, such as fast-food restaurants, as well as commercial buildings.

It is estimated that in 2000, CHP accounted for about 7.5% of electricity generation capacity and almost 9% of electricity generated in the U.S. [EIA, 2003]. Both the Department of Energy (DOE) and the Environmental Protection Agency (EPA) have recently set a goal to double U.S. CHP capacity between 1999 and 2010, from 46 to 92 GW. If this goal is achieved, CHP will represent about 14% of U.S. electric generating capacity. Figure 75.4 illustrates the progression of the actual and projected CHP contribution in generating U.S. electrical power. Unlike some European countries, the share of CHP in the total U.S. electricity generation remains rather small as indicated in Table 75.8. In Denmark, for instance, CHP generates over 40% of the total national electric power.

75.5 Components of Cogeneration Systems

Types of Cogeneration Systems

There are several types of cogeneration systems that are commercially available. In general, three categories of cogeneration systems can be considered:

1. *Conventional Cogeneration Systems:* These systems consist of large cogeneration units (more than 1000 kW) and require a thorough design process to select the size of all equipment and components (i.e., prime movers, electrical generators, and heat recovery systems).
2. *Packaged Cogeneration Systems:* These systems are small (below 1000 kW) and are easy to design and install since they are preengineered and preassembled units.
3. *Distributed Generation Technologies:* Some cogeneration systems can use a number of technologies that have been recently developed to produce both electricity and heat, including fuel cells.

TABLE 75.7 Major Federal Legislation Affecting the U.S Electric Power Industry

| Legislation | Year | Main Scope |
|---|------|--|
| Public Utility Holding Company Act (PUHCA) | 1935 | To reduce utility industry abuses by giving the Securities and Exchange Commission the authority to oversee holding companies |
| Bonneville Project Act | 1937 | To create the Bonneville Power Administration (BPA) to oversee the transmission and marketing of power produced in Northwest dams |
| Clean Air Act | 1970 | To establish programs to reduce emissions |
| Energy Supply and Environmental Coordination Act (ESECA) | 1974 | To allow the federal government to prohibit electric utilities from burning natural gas or petroleum products |
| Public Utility Regulatory Policies Act (PURPA) | 1978 | To promote conservation of electric energy by allowing nonutility generators and qualified cogenerators to sell power to utilities |
| Energy Tax Act (ETA) | 1978 | To allow tax credits for investment in cogeneration equipment and renewable technologies; these incentives were curtailed in the mid-1980s |
| National Energy Conservation Policy Act | 1978 | To require utilities to develop residential energy conservation plans in order to reduce growth in electricity demand |
| Powerplant and Industrial Fuel Use Act | 1978 | To replace ESECA of 1974 and extend federal government prohibition on the use of natural gas and petroleum in new power plants |
| Pacific Northwest Electric Power Planning and Conservation (PNEPPC) Act | 1980 | To create PNEPPC Council in order to coordinate the conservation and resource acquisition of the BPA |
| Electric Consumers Protection Act (ECPA) | 1986 | To set new environmental criteria in licensing hydroelectric power plants; to reduce significantly PURPA benefits for new hydroelectric projects; and to increase the enforcing powers of FERC |
| Clean Air Act Amendments (CAAA) | 1990 | To establish a new emissions-reduction program; generators of electricity are made responsible for large portion of the sulfur dioxide and nitrogen oxide reductions |
| Energy Policy Act (EPACT) | 1992 | To create a new category of electricity producers and to authorize FERC to open up the national electricity transmission system to wholesale suppliers |

Conventional Cogeneration Systems

A typical cogeneration plant consists of several pieces of equipment to produce electricity and heat (in the form of either steam or hot water). The quantity and the type of equipment in a cogeneration plant depend on the size of the system and the procedure used to generate electricity and heat. Generally, a conventional cogeneration system includes the following components:

1. A prime mover: this is the most important equipment in a cogeneration system. It is typically a turbine that generates mechanical power using a primary source of fuel. Three turbine types are commonly used in cogeneration plants: turbines operated by steam generated from boilers, gas turbines fueled by natural gas or light petroleum products, and internal combustion engines fueled by natural gas or distillate fuel oils.
2. A generator: a device that converts the mechanical power to electrical energy.
3. A heat recovery system: a set of heat exchangers that can recover heat from exhaust or engine cooling and convert it into a useful form (i.e., steam or hot water).

To operate a cogeneration plant, a robust control system is needed to ensure that all the individual pieces of equipment provide the expected performance. Two basic operation cycles are used to generate electricity and heat: either a bottoming cycle or a topping cycle.

Bottoming Cycle — In this cycle, the generation of heat is given the priority to supply process heating to the facility. Thermal energy is produced directly from fuel combustion (in the prime mover). Heat is then recovered and fed to the generator to produce electricity as illustrated in [Figure 75.5\(a\)](#). Industrial plants characterized by high-temperature heat requirements (such as steel, aluminum, glass, and paper industries) typically use bottoming cycle cogeneration systems.

Topping Cycle — Unlike the bottoming cycle, the generation of electricity takes precedence over the production of heat as indicated in [Figure 75.5\(b\)](#). The waste heat is then recovered and converted to either steam or hot water. Most existing cogeneration systems are based on topping cycles. A hybrid of a topping cycle commonly used by several industrial facilities and even by electrical utilities is the combined cycle as depicted in [Figure 75.5\(c\)](#). In this cycle, a gas turbine is typically used to produce electricity. The exhaust gas is then fed to a heat recovery steam generator to generate more electricity using a steam turbine. For a cogeneration plant, a small portion of steam can be converted into a useful form of thermal energy.

Three types of prime movers are generally considered for large and medium conventional cogeneration systems including steam turbines, reciprocating engines, and gas turbines. A brief overview of each prime mover type is provided below.

Steam Turbines

Steam turbines are the oldest and most versatile prime movers used in power generation. In the U.S., most electricity is generated from power plants that use steam turbines. However, steam turbines are also utilized in combined heat and power systems, combined cycle power plants, and district heating systems. The capacity of steam turbines ranges from 50 kW to several hundred MW. Several types of steam turbines are used today in power generation applications including:

- *Condensing turbines.* These are power-only utility turbines. They exhaust directly to condensers that maintain vacuum conditions at the discharge.
- *Noncondensing turbines,* also referred to as back-pressure turbines. They exhaust steam to the facility mains at conditions close to the process heat requirements.
- *Extraction turbines.* They have openings in their casing for extraction of a portion of the steam at some intermediate pressure before condensing the remaining of the steam.

The electrical generating efficiency of steam turbines varies from 37% for large electric utility plants to 10% for small plants that produce electricity as a byproduct of steam generation. The common applications of steam turbines for combined heat and power systems involve industrial processes where

solid or waste fuels are readily available. In the U.S., it is estimated that more than 580 industrial and institutional facilities use steam engines to produce about 19,000 MW of electric capacity. Table 75.9 lists typical cost and performance parameters for selected cogeneration systems using steam turbines.

Reciprocating Engines

Reciprocating internal combustion engines are widely used technology to generate power for several applications including institutional and industrial facilities and combined heat and power systems. The

capacity of reciprocating engines varies from a few kilowatts to over 5 MW. Two basic types of reciprocating engines are utilized for power generation applications:

- Spark ignition (SI) engines generally use natural gas. SI engines are now commonly used for duty-cycle stationary power applications.
- Compression ignition (CI) or diesel engines have been historically popular for both small and large power generation applications. However, diesel engines are now restricted to emergency and standby applications due to emission concerns.

The electric efficiency of reciprocating engines ranges from 28% for small engines (less than 100 kW) to 40% for large engines (above 3 MW). Waste heat can be recovered from four sources in reciprocating engines: exhaust gas, engine jacket cooling water, lube oil cooling water, and turbocharger cooling. High- and low-pressure steam can be produced from reciprocating engines for combined heat and power applications. The overall efficiency for a CHP system using a reciprocating engine fueled by natural gas can exceed 70%.

Reciprocating engine technology has improved significantly over the last decades with increased fuel efficiency, reduced emissions, improved reliability, and low first cost. The use of reciprocating engines for combined heat and power generation applications is expected to continue to grow in the next decade. Currently, it is estimated that 1055 CHP systems operating in the U.S. use reciprocating engines with an overall power capacity of 800 MW. Table 75.10 provides typical cost and performance parameters for commercially available reciprocating engines suitable for cogeneration applications.

Gas Turbines

Gas turbines provide one of the cleanest means for electric power generation with very low emissions of carbon dioxide (CO₂) and oxides of nitrogen (NO_x). The available capacity of gas turbines ranges from 500 kW to 250 MW. Gas turbines are well suited for CHP applications because high-pressure steam (as high as 1200 psig) can be generated from their high-temperature exhaust using heat recovery steam generators (HRSGs). It is estimated that over 575 industrial and institutional facilities in the U.S. use gas turbines to generate power and heat with a total capacity of 40,000 MW [Energy Nexus Group, 2002c].

Table 75.11 lists typical cost and performance characteristics for selected commercially available gas turbine CHP systems. As indicated in Table 75.11, both the electrical efficiency and the overall CHP efficiency increase with the size of the gas turbine.

Packaged Cogeneration Systems

For cogeneration facilities requiring small systems ranging from less than 50 kW to about 1 MW, preengineered and factory-assembled cogeneration units are currently available with reduced construction, installation, and operation costs. In addition, small packaged systems with capacities ranging from 4 to 25 kW have been developed and can be installed in a short period of time with little interruption of service. Almost all packaged cogeneration systems are equipped with advanced controls to improve the reliability and the energy efficiency of the units.

Packaged cogeneration units are often sold as turn-key installations. In particular, manufacturers are generally responsible for the testing and installation of the complete cogeneration systems. The development of packaged systems has enlarged the appeal of cogeneration to a wide range of facilities including office buildings, restaurants, homes, and multifamily complexes. In addition, packaged cogeneration systems are now typically more cost-effective than conventional systems for small and medium hospitals, schools, and hotels. However, each facility has to be thoroughly evaluated to determine the economic feasibility of any packaged cogeneration system.

Packaged cogeneration systems typically use reciprocating engines. Recently, microturbines have been developed; they have been commercially available since 2000. Microturbines are small electricity generators that operate at very high speeds (over 60,000 rpm). They are available in sizes ranging from 30 to 350 kW. They have been promoted as ideal generators for distributed generation applications including cogeneration systems due to their connection flexibility (they can be stacked in parallel), their reliability, and their low emissions. Table 75.12 summarizes typical cost and performance characteristics for selected commercially available microturbines suitable for CHP applications.

Distributed Generation Technologies

Distributed generation is a relatively recent approach proposed to produce electricity using small and modular generators. The small generators with capacities in the range of 1 kW to 10 MW can be assembled and relocated in strategic locations (typically near customer sites) to improve power quality, reliability, and flexibility in order to meet a wide range of customer and distribution system needs. Some technologies have emerged in the last decade that allow generation of electricity with reduced waste, cost, and environmental impact, which may make the future of distributed generation promising especially in a competitive deregulated market. Among these technologies are renewable energy sources (wind and solar) and fuel cells, as well as microturbines, combustion turbines, gas engines, and diesel engines. Perhaps the recent developments in fuel cells represent the best opportunity for distributed generation

FIGURE 75.6 A basic operation of a fuel cell.

and CHP applications. It is expected that fuel cells will play a significant part in the twenty-first century electricity market.

The principle of the fuel cell was first demonstrated over 150 years ago. In its simplest form, the fuel cell is constructed similar to a battery with two electrodes in an electrolyte medium, which serves to carry electrons released at one electrode (anode) to the other electrode (cathode). Typical fuel cells use hydrogen (derived from hydrocarbons) and oxygen (from air) to produce electrical power with other byproducts (such as water, carbon dioxide, and heat). High efficiencies (up to 73%) can be achieved using fuel cells. Figure 75.6 illustrates the operation of a typical fuel cell.

Table 75.13 summarizes characteristics for various types of fuel cells that are commercially available or under development. Each fuel cell type is characterized by its electrolyte, fuel (source of hydrogen), oxidant (source of oxygen), and operating temperature range. CHP systems using fuel cells are available in sizes ranging from few to thousands of kW. Table 75.14 lists some cost and performance parameters for selected commercially available CHP systems using fuel cell technology.

TABLE 75.13 Types and Characteristics of Available Fuel Cell Technologies

| Fuel Cell Name | Electrolyte | Efficiency (%) | Fuel | Oxidant | Operating Temperatures (°C) |
|----------------|------------------|----------------|---------------|--------------------------------------|-----------------------------|

FIGURE 75.7 Input/output energy flows for a cogeneration system.

75.6 Evaluation of Cogeneration Systems

To evaluate the technical and economic feasibility of a cogeneration system for a given facility, it is important to collect accurate data about the facility and its energy consumption. In particular, information about current and projected future energy consumption and costs need to be available. For a detailed evaluation analysis, hourly electrical and thermal energy data are required. However, monthly and even yearly energy data can be sufficient for a preliminary feasibility analysis of cogeneration systems.

In this section, basic considerations involved in performing a feasibility analysis of cogeneration systems are discussed.

Efficiency of Cogeneration Systems

To account for the fact that a typical cogeneration system produces both electrical power, W_e , and useful thermal energy, Q_u , from fuel energy, FU , as illustrated in Figure 75.7, the overall efficiency, $\eta_{overall}$, of the cogeneration system is defined using the first law energy efficiency [refer to Equation (75.3)] as follows:

$$\eta_{overall} = \frac{W_e + Q_u}{FU} \quad (75.5)$$

It should be noted that for a cogeneration facility to meet the criteria specified by the PURPA, it has to comply with certain efficiency standards. These standards use a “PURPA efficiency,” η_{PURPA} , which is based on the second law efficiency defined by Equation (75.4). Using the energy flows of Figure 75.7, the PURPA efficiency is defined as follows:

$$\eta_{PURPA} = \frac{W_e + Q_u / 2}{FU} \quad (75.6)$$

PURPA states that to be a Qualified Facility (QF) for cogeneration, the efficiency, η_{PURPA} , has to be:

1. At least 45% for cogeneration facilities with a useful thermal energy fraction that is larger than 5%.
2. At least 42.5% for cogeneration facilities with a useful thermal fraction that is larger than 15%.

The main purpose of the PURPA efficiency is to ensure that a sufficient amount of thermal energy is produced so that the cogeneration facility is more efficient than the electric utility.

Example 75.1 illustrates how to estimate overall thermodynamic and PURPA efficiencies for conventional cogeneration systems [Karti, 2000].

Example 75.1

Consider a 20-MW cogeneration power plant in a campus complex. An energy balance analysis indicates the following energy fluxes for the power plant:

- Electricity generation 33%
- Condenser losses 30%
- Stack losses 30%

- Radiation losses 7%

It is estimated that all the condenser losses but only 12% of the stack losses can be recovered. Determine both the overall thermodynamic efficiency as well as the PURPA efficiency of the power plant.

Solution

First, the recovered thermal energy is determined:

$$E_t = \text{condenser losses} + \text{part of the stack losses}$$

This thermal energy output can be expressed in terms of the fuel use (FU) of the power plant:

$$E_t = 30\% * FU + 12\% * [30\%*FU] = 0.34*FU$$

The energy flow for the campus power plant is summarized in the diagram below:

Thus, the overall thermodynamic efficiency of the power plant can be easily determined using Equation (75.5):

$$\eta_{overall} = \frac{E_e + E_t}{FU} = \frac{0.33 * FU + 0.34 * FU}{FU} = 0.67$$

The PURPA efficiency can be calculated using Equation (75.6),

$$\eta_{PURPA} = \frac{E_e + E_t / 2}{FU} = \frac{0.33 * FU + 0.34 * FU / 2}{FU} = 0.50$$

Therefore, the campus power plant meets the PURPA criteria ($\eta_{PURPA} > 45\%$) and is thus a qualified cogeneration facility.

Feasibility Analysis Procedure

To determine if a cogeneration system is cost-effective, feasibility analysis should first be performed. A further evaluation with more detailed energy analysis tools may be warranted to determine the optimal design specifications of the cogeneration system.

A cogeneration feasibility analysis generally includes an evaluation of the facility electrical and thermal energy use, an assessment of client requirements, and a good understanding of the increasingly complex relationships between power purchase, fuel purchase, power sales, and the strategic benefits of combined heat and power generation. Specific tasks for a feasibility analysis study may include:

- Evaluate electricity and heat demand, profiles, and cost, including site shutdowns/holidays
- Determine possible system configurations and permutations to be considered
- Obtain information on the plant operation and needs for steam/hot water use on site

- Determine operation requirements for equipment such as waste incinerators, air compressors, and refrigeration systems
- Assess the availability of a heat sink where that surplus heat can be disposed of, such as a river or a lake

Ideally, the cogeneration system can be sized to match exactly both the electrical and thermal loads. Unfortunately, an exact match is almost never possible. Therefore, the cogeneration system has to be designed to meet specific load requirements such as the base-load thermal demand, base-load electrical demand, peak thermal demand, or peak electrical demand. The main features of each design scenario are briefly described below:

Base-load cogeneration systems produce only a portion of the facility's electrical and thermal requirements.

Thus, production of supplemental thermal energy (using a boiler for instance) and purchase of additional electrical energy are generally required. Base-load cogeneration systems are suitable for facilities characterized by variable thermal and electrical loads but not willing or able to sell electrical power.

Thermal-tracking cogeneration systems are those systems that produce all the thermal energy required by a facility. In case the generated electrical energy exceeds the electrical demand, the facility has to sell power to the utility. In case the generated electrical energy is lower than the electrical demand, additional power has to be purchased from the utility. Thermal-tracking cogeneration systems are increasingly becoming attractive to small buildings that have to pay higher utility rates than large industrial and commercial facilities do.

Electricity-tracking cogeneration systems are designed to match electrical loads. Any supplemental energy requirements are produced through boilers. These systems are typically suitable for large industrial facilities with fairly high and constant electrical loads and lower but variable thermal loads.

Peak-shaving cogeneration systems: In the case where the cost associated with peak electrical demand is high, it may be cost effective to design cogeneration systems specifically for peak shaving even though these systems may operate only few hours (less than 1000 hours per year).

Simplified calculation procedures as well as computer tools can be utilized to design cogeneration plants. Krarti [2000] provides a simplified analysis method to determine the optimum size for cogeneration systems. Simulation tools such as COGEN [Argonne National Laboratory, 1981; Fisher and Schmidt, 1983], CELCAP [Lee, 1988], and DOE 2 [LBL, 1984] can also be used for designing and assessing the cost-effectiveness of cogeneration systems. Example 75.2 illustrates a simplified calculation procedure to determine the cost-effectiveness of installing a cogeneration system for a hospital building [Krarti, 2000].

Example 75.2

Consider a 60-kW cogeneration system that produces electricity and hot water with the following efficiencies: (a) 26% for the electricity generation and (b) 83% for the combined heat and electricity generation. Determine the annual savings of operating the cogeneration system compared to a conventional system that consists of purchasing electricity at a rate of \$0.08/kWh and producing heat from a boiler with 70% efficiency. The cost of fuel is \$5/MMBtu. The maintenance cost of the cogeneration system is estimated at \$1.00 per hour of operation. Assume that all the generated thermal energy and electricity are utilized during 6500 h/year. *Determine the payback period of the cogeneration system if the installation cost is \$2,500/kW.*

Solution

First, the cost of operating the cogeneration system is compared to that of the conventional system on an hourly basis:

1. *Cogeneration System:* For each hour, 60 kW of electricity is generated (at an efficiency of 26%) with fuel requirements of 0.787 MMBtu [=60 kW*0.003413 MMBtu/kW/0.26]. In the same time,

a thermal energy of 0.449 MMBtu [=0.787 MMBtu *(0.83 – 0.26)] is obtained. The hourly flow of energy for the cogeneration system is summarized in the diagram below:

Thus, the cost of operating the cogeneration on an hourly basis can be estimated as follows:

Fuel Cost: 0.787 MMBtu/h * \$5/MMBtu = \$3.93/h

Maintenance Cost: \$1.00/h

Total Cost: \$4.93/h

2. *Conventional System:* For this system, the 60 kW electricity is directly purchased from the utility, while the 0.449 MMBtu of hot water is generated using a boiler with an efficiency of 0.65. Thus the costs associated with utilizing a conventional system are as follows:

Electricity Cost: 60 kWh/h * 0.08 = \$4.80/h

Fuel Cost (Boiler): (0.449 MMBtu/h)/0.65 * \$ 5/MMBtu \$3.45/h

Total Cost: \$8.25/h

Therefore, the annual savings associated with using the cogeneration system are:

$$\Delta Cost = (\$8.25 / hr - \$4.93 / hr) * 6500 hr / yr = \$21,580 / yr$$

Thus, the simple payback period for the cogeneration system:

$$SPB = \frac{\$2500 / kW * 60kW}{\$21,580} = 7.0 years$$

A Life Cycle Cost analysis may be required to determine if the investment in the cogeneration system is really warranted.

Financing Options

To finance a cogeneration system, several options are generally available. Selecting the most favorable financial arrangement is critical to the success of a cogeneration project. A number of factors affect the selection of the most appropriate financial arrangement for a given cogeneration project. These factors include ownership arrangements, risk tolerance, tax laws, credit markets, and cogeneration regulations. In the U.S., the most common financial approaches for cogeneration facilities include the following [Krarti, 2000]:

1. *Conventional ownership and operation:* In this financing structure, the owner of the cogeneration facility funds either totally or partially the project from internal sources. In the case of partial funding, the owner can borrow the remaining funds from a conventional lending institution. Operation and maintenance of the cogeneration system can be performed by an external contractor.
2. *Joint venture partnership:* This structure is an alternative to the conventional ownership and operation with a shared financing and ownership with a second partner such as an electric utility. Indeed, PURPA regulations provide the option for an electric utility to own up to 50% of a cogeneration facility. The joint venture financing structure reduces the risks for both partners but may increase the complexity of the various contracts between all the involved parties including

the owner and its partner, gas provider, electric utility, lending institution, and possible operation and maintenance contractor.

3. *Leasing*: In this financing option, a company builds the cogeneration facility with a leasing agreement from the owner to use part or all of the thermal and electrical energy output of the cogeneration plant. The construction of the cogeneration system by the lessor (i.e., the builder of the facility) can be financed through funds from lenders and/or investors. The owner is generally heavily involved in the construction phase of the cogeneration facility.
4. *Third-party ownership*: This financing structure is similar to that described for the leasing case. However, in third-party ownership, the owner is not involved in either financing or construction of the cogeneration facility. Instead, a third party or a lessee develops the project and arranges for gas/fuel supply, electrical power and heat sales, and operation and maintenance agreements. The finances can be arranged by a lessor through funds from investors and/or lenders.
5. *Guaranteed savings contracts*: In this financing option, a developer first builds and maintains the cogeneration facility. Then, the developer enters in a guaranteed savings contract with the energy consumer (the owner). This contract is typically made for a period ranging from 5 to 10 years with a guaranteed fixed savings per year. This type of financial structure is common for small cogeneration systems (i.e., packaged units) since it shifts all the financing and operation risks from the owner to the facility developer (i.e., the guaranteed savings contractor).

75.7 Case Study: Cogeneration System at the University of Colorado

The Power House at the University of Colorado was constructed in 1909. Coal was the original fuel source for the plant and was delivered to the site on railroad cars. The plant was converted to clean-burning natural gas in 1950, with the addition of No. 6 fuel oil stored in underground tanks on-site beginning in the early 1960s as backup fuel. Due to increasing demands in electricity and steam use, the university retrofitted the Power House in 1992 to build a cogeneration plant. The specifications of the components for the cogeneration systems are summarized in Table 75.15. Figure 75.8 provides a top view of the cogeneration plant.

The operation of the University of Colorado (CU) cogeneration system is outlined in the schematics provided in Figure 75.9. The primary systems of the CU cogeneration plant include two combustion gas turbines, two heat recovery steam generators (HRSGs), high-pressure steam boilers, and low-pressure

TABLE 75.15 Equipment Used for the Cogeneration Plant at the University of Colorado

| Utility | Quantity | Equipment | Description |
|----------------|----------|--|---|
| Electric power | 2 | Mitsubishi industrial gas turbine sets | 16 MW each; each includes a dual-fuel Mitsubishi Heavy Industries MF-111AB gas turbine driving a RENK single reduction gearbox coupled to a Brush two pole synchronous generator; operates with a shaft speed of 9645 rpm |
| Electric power | 1 | Dresser rand steam turbine set | 1 MW induction generator double-ended low- and high-pressure steam |
| Steam | 2 | Zurn (HRSG) heat recovery steam generators | Supplemental fire capability— Davis duct burners 80,000 lb/h, maximum steam output 300 psig |
| Steam | 1 | Erie City 1966 boiler | Front-fired 150,000 lb/h, maximum steam output 130 psig |
| Steam | 1 | Combustion Engineering 1957 boiler | Tangentially fired 115,000 lb/hr maximum steam output 130 psig |
| Chilled water | 3 | Steam absorption chillers | 1 Trane 1470 tons cooling; 2 York 900 tons cooling; each utilizes 10 psig steam lithium bromide |

FIGURE 75.8 Outside view of the Power House where the cogeneration plant is located at the University of Colorado.

absorption chillers. The two gas turbines are each capable of producing 16 MW of power while providing sufficient hot exhaust gas to generate 80,000 lb/h of 300 psig steam in each heat recovery steam generator (HRSG). The steam turbine generator consists of dual topping turbines driving a common generator. The turbine reduces the incoming steam pressure by expanding it through the turbines which, in turn, drive the generator. The exhaust steam is then exported to either the 130-psig or the 10-psig steam header. The 130-psig steam is delivered to various buildings in the campus for heating purposes. The 10-psig steam is utilized to operate three absorption chillers that deliver chiller water to the campus. The high pressure steam boilers deliver 300 psig steam to the gas turbines for NO_x control and steam injection for power augmentation [CU, 2002].

The CU cogeneration plant was designed to deliver over 30 MW of electrical power. Absorption chillers with over 3000-ton capacity were added to increase the thermal load on the plant especially during summer months. A large portion of the cogenerated electricity is generally sold to the local utility. As stipulated by PURPA, the plant can purchase electricity from the same utility in case of maintenance or

FIGURE 75.10 Monthly energy input and output of the CU cogeneration during 2002.

emergency periods. A typical monthly performance of the CO cogeneration plant is outlined in Table 75.16 and Figure 75.10.

As indicated in Table 75.16, the University used about 63% of the electricity produced by the cogeneration plant while the remaining 37% was sold to the local utility. In 1992, the cogeneration sold more than 50% of its electric power. Due to the ever-increasing electricity demands at the University (associated with new buildings and additional research laboratories), the cogeneration plant may not be able to meet the University load in the near future. The University is currently investigating plans to add a new cogeneration plant.

From the data provided in Table 75.16 and Figure 75.10, the electrical efficiency and the overall efficiency of the CU cogeneration plant during 2002 are estimated to be 33 and 80%, respectively. The PURPA efficiency [refer to Equation (75.5)] of the plant is over 56%, well above the requirements set by PURPA.

Over the last two decades, electricity and steam consumption have increased substantially at the University of Colorado with a growth rate of about 5%. Table 75.17 illustrates the progression of energy use and carbon emissions at the University of Colorado between 1990 (before the construction of the cogeneration plant) and 2000 (after the construction of the cogeneration plant). As indicated in Table 75.17, the cogeneration plant has substantially decreased the carbon output per unit of energy consumed.

TABLE 75.17 Comparison of Annual Energy Use and Carbon Emissions in 1990 and 2000 at the University of Colorado

| | Year 1990 | | Year 2000 | |
|--------------------------------|--------------------------|-------------------------|--------------------------|-------------------------|
| | Energy Purchased or Sold | Carbon Emissions (tons) | Energy Purchased or Sold | Carbon Emissions (tons) |
| Natural Gas Purchases | | | | |
| Central Plant/Cogeneration | 634,159 MMBtu | 10,115 | 1,936,341 MMBtu | 30,885 |
| Individual Buildings | 116,500 MMBtu | 1,849 | 632,419 MMBtu | 10,080 |
| Electricity Purchases | | | | |
| Central Plant/Cogeneration | 66,024,000 kWh | 18,476 | 39,937,364 kWh | 10,637 |
| Individual Buildings | 20,782,510 kWh | 5,816 | 9,970,008 kWh | 2,656 |
| Electricity Sales | | | | |
| Cogeneration Plant | 0 kWh | — | 74,893,631 kWh | (19,947) |
| Total Natural Gas Purchased | 750,659 MMBtu | 11,994 | 2,568,760 MMBtu | 40,965 |
| Net Electricity Purchased/Sold | 86,806,510 | 24,292 | (24,986,259 kWh) | (6,655) |
| Net Carbon Emissions | — | 36,296 | — | 34,310 |

Even though natural gas use has tripled between 1990 and 2000, the net carbon emissions have been actually reduced by 5%.

75.8 Summary and Conclusions

Cogeneration systems are suited for facilities that utilize electrical power and have significant and continuous thermal energy needs. With advances in combined heat and power technology, several facilities are able to benefit from cogeneration in the industrial, institutional, and commercial sectors. The components and operation procedures for conventional cogeneration plants are well developed and well established. New technologies such as microturbines and fuel cells are now commercially available and are making cogeneration cost effective for small applications such as commercial and residential buildings.

This chapter has provided an overview of the fundamentals and the applications of cogeneration systems. In particular this chapter has presented historical background, technical design issues, regulatory considerations, and financial options for cogeneration systems. Moreover, the chapter included one case study to illustrate the operation of a typical cogeneration system in an institutional facility.

In the future, cogeneration is expected to become more attractive for small buildings, especially with new developments in fuel cell technologies and microprocessor-based control systems. These developments will make small cogeneration systems cost effective, reliable, and efficient for even nontraditional cogeneration applications such as residential buildings. With market conditions and trends favoring distributed generation and with involvement of ESCOs, combined heat and power technology is expected to have a promising future in the U.S. over the next few decades.

The University of Akron

A significant percentage of the world's energy is associated with electromechanical energy conversion processes for both efficient energy transportation and mechanical work done at the receiving end. The ease of transmitting energy with exceptional control over long distances in electrical form is the primary motivation for converting the world's available energy from chemical, mechanical, or nuclear form into electrical form. Again, from a user's perspective, the electrical energy needs to be converted to mechanical energy for useful work. Electric machines accomplish the task of converting electrical energy to mechanical form and vice versa. The term "motor" is used for the electric machine when energy is converted from electrical to mechanical and the term "generator" is used when power flow is in the opposite direction with the machine converting mechanical energy into electrical energy. The term braking or regeneration is used to describe the generating mode when electric machines convert residual mechanical or magnetic energy into electrical energy. The goal of this chapter is to introduce the different types of machines available for electromechanical energy conversion.

The torque in electric machines is produced utilizing one of two basic principles of electromagnetic theory:

1. The Lorentz force principle, where torque is produced by the mutual interaction of two orthogonal magnetomotive forces (mmf)
 2. The reluctance principle, where the rotor produces torque while moving towards the minimum reluctance position in a varying reluctance path.
-

Direct current (DC) and alternating current (AC) machines, including permanent magnet machines work on the first principle, while reluctance machines work on the latter principle.

76.1 DC Machines

DC machines have two sets of windings, one in the rotor and the other in the stator, which establish the two fluxes needed to produce the torque. The orthogonality of the two magnetomotive forces, which is essential for maximum torque production, is maintained by a set of mechanical components called commutators and brushes. The winding in the rotor is called the armature winding, while the winding in the stationary part of the machine is called the field windings. Both the armature and the field windings are supplied with DC currents. The armature windings carry the bulk of the current, while the field windings carry a small field excitation current. The armature and the field currents in the respective windings establish the armature and field mmf. The magnitude of the mmf is the product of the number of turns in the windings and the current.

The advantage of a DC machine is the ease of control due to linearity, which makes it amenable to independent torque and flux control. The manufacturing technology is also well established. The disadvantage of DC machines is the brush wear that leads to high maintenance. The machines have a low power-to-weight ratio.

DC Generator

In a DC generator, a prime mover supplies power to rotate the shaft in the direction of applied shaft torque T_s , and voltage is induced in the armature windings. The induced or generated voltage can deliver power to an electrical load. The electromagnetic torque T_e is in a direction opposite to the rotational direction, as shown in Figure 76.1.

The armature equivalent circuit of a DC machine consists of the armature winding resistance R_A , the self-inductance of armature winding L_{AA} and the back-emf E_A . Figure 76.1 shows the armature circuit for a DC generator with armature current i_A flowing out of the circuit. In the figure, V_A is the armature voltage, ω_m is the shaft speed, and ϕ is the armature linking flux (primarily from field current). Applying KVL around the armature circuit, the voltage balance equation is

$$V_A = -R_A i_A - L_{AA} \frac{di_A}{dt} + E_A \quad (76.1)$$

where

$$\begin{aligned} E_A &= K\phi\omega_m \\ T_e &= K\phi i_A \end{aligned} \quad (76.2)$$

K is a machine constant that depends on the machine construction, number of windings, and core material properties. The field equivalent circuit of the DC machine is shown in Figure 76.2. The field

FIGURE 76.4 Magnetization characteristics of DC machines. (From Husain, I. 2003. *Electric and Hybrid Vehicles: Design Fundamentals*, CRC Press, Boca Raton, FL.)

circuit consists of the field winding resistance R_F and the self inductance of the field winding L_{FF} . V_F is the voltage applied to the field. The field circuit equation is

$$V_F = R_F i_F + L_{FF} \frac{di_F}{dt}$$

The transient response in the field circuit is much faster than the armature circuit. The field voltage is also typically not adjusted frequently, and for all practical purposes, a simple resistor fed from a DC source characterizes the electrical unit of the field circuit. The field current establishes the mutual flux or field flux, which is responsible for torque production in the machine. The field flux is a nonlinear function of field current and can be described by $\phi = f(i_F)$. The electromagnetic properties of the machine core materials are defined by the relationship

$$B = \mu H$$

where B is the magnetic flux density in Tesla or weber/m², H is the magnetic field intensity in Ampere-turn/m, and μ is the permeability of the material. The permeability in turn is given by $\mu = \mu_0 \mu_r$, where $\mu_0 = 4\pi \times 10^{-7}$. H/m is the permeability of free space and μ_r is the relative permeability. The relative permeability of air is 1. The B - H relationship of magnetic materials is nonlinear and is difficult to describe by a mathematical function. The properties of core materials are often described graphically in terms of the B - H characteristics as shown in Figure 76.3. The nonlinearity in the characteristics is due to the saturation of flux for higher currents and the hysteresis effects. The hysteresis causes magnetic flux density B to be a multivalued function that depends on the direction of magnetization. The magnetic effect that remains in the core after the complete removal of magnetization force is known as the residual magnetism (denoted by B_r in Figure 76.3). The direction of the residual flux, as mentioned previously, depends on the direction of field current change. The B - H characteristics can also be interpreted as the ϕ - i_F characteristics, since B is proportional to ϕ and H is proportional to i_F for a given motor. The energy required to cause change in the magnetic orientations is wasted in the core material and is referred to as hysteresis loss. The area of the hysteresis loop in the magnetization characteristics is proportional to the hysteresis loss.

For most applications, it is sufficient to show the magnetic properties of core materials through a single-valued yet nonlinear function, which is known as the DC magnetization curve. The magnetization curve of a DC machine is typically shown as a curve of open-circuit induced voltage (which is essentially the back-emf E_A) versus field current i_F at a particular speed. Therefore, the shape of this characteristic, shown in Figure 76.4, is similar to that of the magnetic characteristics of the core material.

DC Motor

The principles of electromagnetic operation of a DC motor are the same as that of a DC generator, but the power and energy flow is in the opposite direction. The armature equivalent circuit is the same as

FIGURE 76.5 Different types of DC machines: (a) separately excited, (b) shunt, (c) series, and (d) compound.

in Figure 76.1 except that the current flows into the windings when the armature is connected to a DC voltage supply. In the case of a DC motor, the voltage balance equation is

$$V_A = R_A i_A + L_{AA} \frac{di_A}{dt} + E_A \quad (76.3)$$

The back-emf E_A and torque T_e expressions are the same as those in Equation (76.2).

Types of DC Machines

Depending on the number of supply sources and the type of connection between the armature and field windings, there can be several types of DC machines (Figure 76.5) [Sen, 1997]. When the armature and field windings are connected to independent DC voltages, then it is known as a separately excited DC machine. The separately excited DC machine offers the maximum flexibility of torque and speed control through independent control of the armature and field currents. The DC shunt machine has the similar parallel configuration of armature and field windings, but the same DC source supplies both the windings. In another type of DC machine, known as the series DC machine, the armature and the series windings are connected in series and the machine is connected to a single terminal DC voltage. Since the two windings carry the same current, the field is wound with a few turns of heavy gauge wires to deliver the same mmf or ampere-turns as in the separately excited machine. A machine may have both a series winding and a shunt winding, in which case the machines are called compound machines. The series field may be assisting the shunt field or they may be opposing the shunt field, giving rise to cumulatively compound or differentially compound DC machines.

In the case of DC generators, the terminal voltage-current characteristics are important for performance evaluation. The terminal characteristics of several types of DC generators are shown in Figure 76.6. The speed–torque characteristics of DC motors are of interest for performance evaluation. The speed–torque relationship of a DC motor can be derived from Equation (76.2) and Equation (76.3) and is given by

$$\omega_m = \frac{V_A}{K\phi} - \frac{R_A}{(K\phi)^2} T_e \quad (76.4)$$

FIGURE 76.6 Terminal voltage-current characteristics of DC generators.

FIGURE 76.7 Speed-torque characteristics of DC motors.

The speed-torque characteristics of three types of DC motors are shown in Figure 76.7. The greatest advantage of the series machine is the very high starting torque that helps achieve rapid acceleration. However, the control flexibility is lost due to the series connection of armature and field windings.

76.2 Induction Machines

AC Machines

The primary difference between AC machines and DC machines is that the armature circuit of the former is located in the stationary piece of the structure. The major advantage of this arrangement is the elimination of the commutator and brushes of the DC machines. The machines are fed from AC sources and can be of single phase or multiple phase type. Single phase AC machines are used for low-power appliance applications, while higher power machines are always of three-phase configuration. The second mmf required for torque production in AC machines (equivalent to the field mmf of DC machines) comes from the rotor circuit. The method through which the rotor mmf is established differentiates the different types of AC machines. Broadly, the AC machines can be classified into two categories, synchronous machines and asynchronous machines. In synchronous machines, the rotor always rotates at synchronous speed. The rotor mmf is established by using either a permanent magnet or an electromagnet created by feeding DC currents in a rotor coil. The latter type synchronous machines are typically the large machines used in electric power generating systems. In the asynchronous-type AC machine, the rotor rotates at a speed that is different but close to the synchronous speed. These machines are known as induction machines, which in the more common configurations are fed only from the stator. The stator windings common to all AC machines will be presented first before discussing induction machines.

Sinusoidal Stator Windings

The three-phase stator windings of AC machines are distributed spatially around the stator circumference to produce a sinusoidal radial magnetic field along the stator circumference. The windings for the three phases are 120° shifted with respect to each other as shown in Figure 76.8. In practice, the phase windings are not concentrated in one location as shown but distributed in slots to produce a sinusoidal mmf.

The current i_a flowing through the phase- a stator windings will result in a sinusoidal phase- a mmf as shown in Figure 76.9. The sinusoidal conductor-density distribution in phase- a winding can theoretically be represented as [Krasue and Wasynchuk, 1986]

$$n_s(\theta) = \frac{N_s}{2} \sin \theta, \quad 0 \leq \theta \leq \pi \quad (76.5)$$

FIGURE 76.8 Three-phase winding and magnetic axes of an AC machine. (From Husain, I. 2003. *Electric and Hybrid Vehicles: Design Fundamentals*, CRC Press, Boca Raton, FL.)

FIGURE 76.9 Mmf distribution of phase a. (From Husain, I. 2003. *Electric and Hybrid Vehicles: Design Fundamentals*, CRC Press, Boca Raton, FL.)

The resulting phase-*a* stator mmf when current flows through the phase-*a* windings, derived using Ampere's Law is

$$F_a(\theta) = \frac{N_s}{2} i_a \cos\theta \quad (76.6)$$

The mmf, flux intensity and field intensity are all 90 degrees phase shifted in space with respect to the winding distribution. The angle θ is measured in the counterclockwise direction with respect to the phase-*a* magnetic axis. The field distribution in Figure 76.9 is for positive current. Irrespective of the direction of current, the peak of the mmf (positive or negative) will always appear along the phase-*a* magnetic axis, which is the characteristic of mmf produced by a single phase winding.

The resulting mmf due to currents in phases *b* and *c* can be expressed as

$$F_b(\theta) = \frac{N_s}{2} i_b \cos\left(\theta - \frac{2\pi}{3}\right) \quad \text{and} \quad F_c(\theta) = \frac{N_s}{2} i_c \cos\left(\theta + \frac{2\pi}{3}\right) \quad (76.7)$$

Number of Poles

The two equivalent phase-*a* conductors in Figure 76.8 represent two poles of the machines. Electric machines are designed with multiple pairs of poles for efficient utilization of the stator and rotor magnetic core material. In multiple pole pair machines, the electrical and magnetic variables (such as induced voltages, mmf, and flux density) complete more cycles during one mechanical revolution of the motor. The electrical and mechanical angles of revolution and the corresponding speeds are related by

$$\theta_e = \frac{P}{2} \theta_m \quad \text{and} \quad \omega_e = \frac{P}{2} \omega_m \quad (76.8)$$

where *P* is the number of poles. The phase *a* mmf of a *P* pole machine is mathematically represented as

$$F_a(\theta_e) = \frac{N_s}{P} i_a \cos(\theta_e) \quad (76.9)$$

Resultant Mmf in a Balanced System

Let us consider only the stator circuit and assume that all the current that is flowing through the stator winding is the magnetizing current required to establish the stator mmf. The 3-phase currents have the same magnitude and frequency, but are 120 degrees shifted in time with respect to each other. The currents in the time domain can be expressed as

$$\begin{aligned}
i_a(t) &= \hat{I}_M \cos \omega t \\
i_b(t) &= \hat{I}_M \cos(\omega t - 120^\circ) \\
i_c(t) &= \hat{I}_M \cos(\omega t - 240^\circ).
\end{aligned} \tag{76.10}$$

For the above three-phase variables, the space vector method can be used where a compact expression is derived from the individual phase variables as follows

$$\vec{i}_M(t) = i_a(t) + i_b(t) \angle 120^\circ + i_c(t) \angle 240^\circ \tag{76.11}$$

The resulting space vector for the balanced set of currents is

$$\vec{i}_M(t) = \frac{3}{2} \hat{I}_M \angle \omega t \tag{76.12}$$

The *space vector representation* is a convenient method of expressing the equivalent resultant effect of the sinusoidally space distributed electrical and magnetic variables in AC machines. The space vectors provide a very useful and compact form of representing the machine equations, which not only simplifies the representation of three-phase variables but also facilitates the transformation between three-phase and two-phase variables. The space vectors are similar but more complex than the phasors, since they represent time variation as well as space variation. The space vectors, just like any other vectors, have a magnitude and an angle, but the magnitude can be time varying.

The resultant stator mmf space vector is

$$\vec{F}_{ms}(t) = \frac{N_s}{2} \vec{i}_M(t) = \frac{3}{2} \frac{N_s}{2} \hat{I}_M \angle \omega t = \hat{F}_{ms} \angle \omega t \tag{76.13}$$

The result shows that the stator mmf has a constant peak amplitude \hat{F}_{ms} (since N_s and \hat{I}_M are constants) that rotates around the stator circumference at a constant speed equal to the angular speed of the applied stator voltages. This speed is known as the synchronous speed. Unlike the single-phase stator mmf, the peak of the stator mmf resulting in the three-phase AC machine is rotating synchronously along the stator circumference with the peak always located at $\theta = \omega t$. The mmf wave is a sinusoidal function of the space angle θ . The wave has a constant amplitude and a space-angle ωt , which is a linear function of time. The angle ωt provides rotation of the entire wave around the air-gap at a constant angular velocity ω . The three-phase stator mmf is known as the rotating mmf, which can be equivalently viewed as a permanent magnet rotating around the stator circumference at a constant speed.

Mutual Inductance L_m and Induced Stator Voltage

In an ideal situation, the equivalent electrical circuit for the stator windings with no rotor existing consists of the applied stator voltage source and a set of winding that is represented by an inductance known as magnetizing or mutual inductance. The practical circuit extends on this ideal circuit by adding the stator winding resistance and the stator leakage inductance in series with the magnetizing inductance. The magnetizing inductance for the three-phase AC machine including the effects of mutual coupling among the three phases can be shown to be [Novotny and Lipo, 1996]

$$L_m = \frac{3}{2} \left[\frac{\pi \mu_0 r l}{l_g} \left(\frac{N_s}{2} \right)^2 \right] \tag{76.14}$$

where r is the radius to the air gap, l is the rotor axial length and l_g is the air gap length. The voltage induced in the stator windings due to the magnetizing current flowing through L_m in space vector form is

FIGURE 76.10 The squirrel cage of an induction motor. (From Husain, I. 2003. *Electric and Hybrid Vehicles: Design Fundamentals*, CRC Press, Boca Raton, FL.)

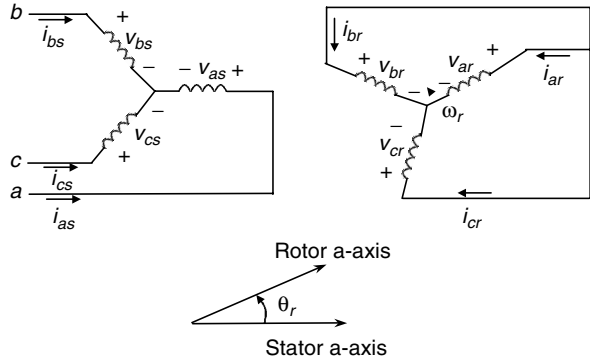

FIGURE 76.11 Stator and rotor electric circuit and magnetic axes of a three-phase induction machine. (From Husain, I. 2003. *Electric and Hybrid Vehicles: Design Fundamentals*, CRC Press, Boca Raton, FL.)

$$\vec{e}_{ms}(t) = j\omega L_m \vec{i}_M(t) \quad (76.15)$$

Types of Induction Machines

The low-cost, rugged construction and almost maintenance-free operation of three-phase induction machines have made them the workhorse of the industry in numerous motor drive applications. The three-phase stator windings of an induction machine are fed from a balanced three-phase supply, which creates a rotating magnetomotive force in the stator field.

The two types of induction machines are the squirrel cage machine and the wound rotor machine. Squirrel cage induction motors are widely used because of their rugged construction and low cost. The rotor, usually made of stacked laminations, has copper or aluminum rotor bars molded around the periphery in the axial direction. The bars are short-circuited at the ends through electrically conducting end rings forming the shape of a squirrel cage. The squirrel cage of an induction motor is shown in Figure 76.10. The rotor winding terminals of wound rotor induction machines are brought outside with the help of slip rings for external connections, which are used for speed control. Squirrel cage induction motors are of greater interest, and hence, will be discussed further.

The electrical equivalent circuit of a three-phase induction machine, along with the direction of phase-*a* stator and rotor magnetic axes, is shown in Figure 76.11. When a balanced set of voltages is applied to the stator windings, a magnetic field is established, which rotates at synchronous speed as described earlier in this chapter. By Faraday's Law, ($e = Blv$), as long as the rotor rotates at a speed other than the synchronous speed (even at zero rotor speed), the rotor conductor is cutting the stator magnetic field and there is a rate of change of flux in the rotor circuit, which will induce a voltage in the rotor bars. This is also analogous to transformer action, where a time-varying AC flux established by the primary winding induces voltage in the secondary set of windings. The induced voltage will cause rotor currents to flow in the rotor circuit, since the rotor windings or bars are short-circuited in the induction machine. The rotor induced voltages and the current have a sinusoidal space distribution, since these are created by the sinusoidally varying (space sinuoids) stator magnetic field. The resultant effect of the rotor bar currents is to produce a sinusoidally distributed rotor mmf acting on the air gap. The interaction of the stator and rotor mmfs produces the electromagnetic torque.

The difference between the rotor speed and the stator synchronous speed is the speed by which the rotor is slipping from the stator magnetic field, and is known as the slip speed

$$\omega_{slip} = \omega_e - \omega_m \quad (76.16)$$

where ω_e is the synchronous speed and ω_m is the motor or rotor speed. The slip speed expressed as a fraction of the synchronous speed is known as the slip

$$s = \frac{\omega_e - \omega_m}{\omega_e} \quad (76.17)$$

The rotor bar voltages, current and magnetic field are of the slip speed or slip frequency with respect to the rotor. The slip frequency is given by

$$f_{slip} = \frac{\omega_e - \omega_m}{2\pi} = sf, \text{ where } f = \frac{\omega_e}{2\pi}. \quad (76.18)$$

From the stator perspective, the rotor voltages, currents and rotor mmf all have the synchronous frequency, since the rotor speed of ω_m is superimposed on the rotor variables' speed of ω_{slip} .

Per-phase Equivalent Circuit

The steady-state analysis of induction motors is often carried out using the per-phase equivalent circuit. A single phase equivalent circuit is used for the three-phase induction machine assuming a balanced set as shown in Figure 76.12. The per-phase equivalent circuit consists of the stator loop and the rotor loop with the magnetic circuit parameters in the middle. For the stator and rotor electrical parameters, the circuit includes the stator winding resistance and leakage reactance and the rotor winding resistance and leakage reactance. A slip dependent equivalent resistance represents the mechanical power delivered at the shaft due to the energy conversion in the air gap coupled electromagnetic circuit. The electrical input power supplied at the stator terminals converts to magnetic power and crosses the air gap. The air gap power P_{ag} is converted to mechanical power delivered at the shaft after overcoming the losses in the rotor circuit. Note that the voltages and currents described here in relation to the per-phase equivalent circuit are phasors and not space vectors.

Although the per-phase equivalent circuit is not enough to develop controllers that demand good dynamic performance, the circuit provides the basic understanding of induction machines. The vast majority of applications of induction motors are for adjustable speed drives where controllers designed for good steady-state performance are adequate. The circuit does allow the analysis of a number of steady-state performance features.

The power and torque relations are

$$P_{ag} = \text{Air gap power} = 3|I_r'|^2 \frac{R_r'}{s}$$

$$P_{dev} = \text{Developed mechanical power} = 3|I_r'|^2 \frac{(1-s)R_r'}{s} = (1-s)P_{ag} = T_e \omega_m \quad (76.19)$$

FIGURE 76.12 Steady-state per-phase equivalent circuit of an induction motor. (From Husain, I. 2003. *Electric and Hybrid Vehicles: Design Fundamentals*, CRC Press, Boca Raton, FL.)

FIGURE 76.13 Steady-state torque speed characteristics of an induction motor. (From Husain, I. 2003. *Electric and Hybrid Vehicles: Design Fundamentals*, CRC Press, Boca Raton, FL.)

The electromagnetic torque with the assumption that $(R_c \parallel dx_m) \gg (R_s + jX_s)$ is given by

$$T_e = 3|I_r'|^2 \frac{(1-s)R_r'}{s\omega_m} = \frac{3R_r'}{s\omega_s} \frac{V_s^2}{(R_{ls} + R_r'/s)^2 + (X_{ls} + X_{lr}')^2} \quad (76.20)$$

The steady-state torque-speed characteristics of the machine are as shown in Figure 76.13. The torque produced by the motor depends on the slip and the stator currents among other variables. The induction motor starting torque, while depending on the design, is lower than the peak torque achievable from the motor. The motor is always operated in the linear region of the torque-speed curve to avoid the higher losses associated with the high slip operation.

The value of the rotor circuit resistance determines the speed at which the maximum torque will occur. In general, the starting torque is low and the maximum torque occurs close to the synchronous speed when the slip is small. The motor draws a large current during line starting from a fixed AC source, which gradually subsides as the motor reaches the steady-state speed. If the load requires a high starting torque, the motor will accelerate slowly. This will make a large current flow for a longer time, thereby creating a heating problem.

The speed of an induction motor can be controlled by varying either the stator terminal voltage or stator frequency. Changing the terminal voltage changes the torque output of the machine as is evident from Equation (76.20). Note that changing the applied voltage does not change the slip for maximum torque. The speed control through changing the applied frequency is based on the frequency and synchronous speed relation

$$\omega_e = \frac{4\pi f}{p}$$

Changing f changes ω_e . The adjustable speed drives consist of a variable voltage, variable frequency power electronics drive that adjusts the supply voltage and frequency of the induction motor.

Induction Generators

The induction machine works as a generator when it is operated with a negative slip, i.e., the synchronous speed is less than the motor speed $\omega_e < \omega_m$. The negative slip makes the electromagnetic torque negative during regeneration or generating mode. In the negative slip mode of operation, the voltages and currents induced in the rotor bars are of opposite polarity compared to those in the positive slip mode.

When operated as a generator, the external mechanical torque applied to the rotor drives the machine beyond the synchronous speed. In order to generate power into the power grid or any electrical network, the machine requires reactive power for its excitation. The excitation power can be provided by external capacitors connected to the generator terminal, and no separate AC supply is needed. In the case of a

grid-connected generator, the reactive power is supplied from the infinite bus. The advantage of induction generators is the absence of a separate field circuit and flexibility in speed. These advantages make the induction generator attractive for wind power generating systems.

Regenerative Braking

In the regenerative braking mode, the kinetic energy of the motor drive system is processed by the electric machine and returned to the energy source. From the machine perspective, this is no different than operating the machine in the generator mode. The electric machine converts the mechanical power available from the system kinetic energy and converts it to electrical energy. The electromagnetic torque acts on the rotor to oppose the rotor rotation, thereby decelerating the rotor. Induction motor drives are often used for four-quadrant drives, meaning that the electric motor is controlled by the drive to deliver positive or negative torque at positive or negative speed. Traction drives are examples of such applications.

dq Modeling

dq modeling relates to the transformation of three-phase variables in the *abc* coordinate system into an equivalent two-phase coordinate system that has an arbitrary speed in a given reference frame [Krasue and Wasynchuk, 1986; Lyon, 1954]. In the *dq* coordinate system, the *d*-axis is along the direct magnetic axis of the resultant mmf, while the *q*-axis is in quadrature to the direct axis. The *dq* modeling of AC machines enables the development of an electric machine controller, which operates in the inner loop with respect to the outer loop of the system level controller. The *dq* modeling analysis provides the necessary transformation equations required to implement the inner loop controller. Furthermore, the electromagnetic torque expression in terms of machine variables (current, flux linkage, etc.) in the *dq* model is often used to estimate the torque for closed loop control.

The space vector approach is retained in the *dq* reference frame, since these vectors help express the complex three-phase equations of AC machines in a compact form and also provide a simple relation for transformation between *abc* and *dq* reference frames. Several choices exist to define the relation between the *abc*-axes variables and the *dq*-axes variables. One choice is to take the *dq*-variables to be $2/3$ times the projection of *a*, *b* and *c* variables on the *d* and *q* axes. The $2/3^{\text{rd}}$ factor gives the same space vector magnitude as the peak value of the individual phase time-phasor variables. Another possible choice is to take the *dq*-variables to be $\sqrt{2/3}$ times the projection of *a*, *b* and *c* variables on the *d* and *q* axes. The $\sqrt{2/3}$ ratio between the *dq*-variables and the *abc*-variables conserves power without any multiplying factor in the *dq* and *abc* reference frames, and hence, is known as the power invariant transformation. The transformation matrices between the *abc* and *dq* variables for a multiplying factor of $2/3$ are

$$\begin{bmatrix} f_d(t) \\ f_q(t) \\ 0 \end{bmatrix} = T_{abc \rightarrow dq} \begin{bmatrix} f_a(t) \\ f_b(t) \\ f_c(t) \end{bmatrix}, \text{ where } T_{abc \rightarrow dq} = \frac{2}{3} \begin{bmatrix} \cos(\theta) & \cos(\theta - 2\pi/3) & \cos(\theta + 2\pi/3) \\ \sin(\theta) & \sin(\theta - 2\pi/3) & \sin(\theta + 2\pi/3) \\ 0.5 & 0.5 & 0.5 \end{bmatrix} \quad (76.21)$$

$$T_{dq \rightarrow abc} = \begin{bmatrix} \cos(\theta) & \sin(\theta) & 1 \\ \cos(\theta - 2\pi/3) & \sin(\theta - 2\pi/3) & 1 \\ \cos(\theta + 2\pi/3) & \sin(\theta + 2\pi/3) & 1 \end{bmatrix} \quad (76.22)$$

f is used to represent voltage, current, or flux linkages. These transformations are known as Park's transformations [Park, 1929].

The projections from both the *abc* frame and the *dq* frame to form the same space vector for a three-phase AC machine current variable are shown in Figure 76.14. The orientation of the *dq*-axes with respect to the *abc*-axes is at an arbitrary angle θ . The *dq*-reference frame can be stationary with respect to the stator or rotating at an arbitrary speed, such as at rotor speed or at synchronous speed. Again, when a

FIGURE 76.14 Transformation from three-phase variables to dq -axes variables. (From Husain, I. 2003. *Electric and Hybrid Vehicles: Design Fundamentals*, CRC Press, Boca Raton, FL.)

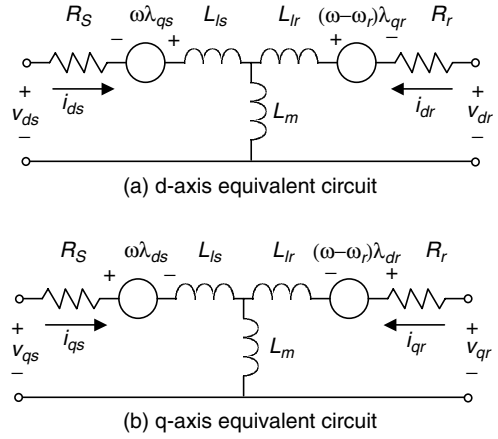

FIGURE 76.15 d and q -axes circuits of the induction machine. (From Husain, I. 2003. *Electric and Hybrid Vehicles: Design Fundamentals*, CRC Press, Boca Raton, FL.)

stationary dq reference frame is used, the dq -axes may be at any arbitrary angle with respect to our chosen reference phase a -axis.

The three speeds of dq windings commonly used for transformation are 0 , ω_m , and ω_e . The zero speed is known as the stationary reference frame where, typically, the stationary d -axis is aligned with the phase- a axis of the stator. The d and q axes variables oscillate at the synchronous frequency in the balanced sinusoidal steady state. When ω_e is chosen as the speed of the reference dq frame, all the associated variables in the stator and in the rotor dq windings appear as DC variables in the balanced sinusoidal steady state. For an arbitrary speed of reference dq windings, the angle of transformation is

$$\theta = \int_0^t \omega(\xi) d\xi + \theta_0 \quad (76.23)$$

The dq -equivalent circuit model for the induction machine in circuit schematic form is shown in Figure 76.15.

Power and Electromagnetic Torque

The power into the induction machine is the product of the phase voltage and phase currents given as

$$P_{in} = (v_{as} i_{as} + v_{bs} i_{bs} + v_{cs} i_{cs}) + (v_{ar} i_{ar} + v_{br} i_{br} + v_{cr} i_{cr}) \quad (76.24)$$

The input power expression in terms of dq components in scalar form is

$$P_{in} = \frac{3}{2} (v_{ds} i_{ds} + v_{qs} i_{qs} + v_{dr} i_{dr} + v_{qr} i_{qr}) \quad (76.25)$$

The multiplying factor $3/2$ is due to our choice of the factor $2/3$ for the ratio of dq and abc variables.

The electromagnetic torque for a P -pole machine is

$$T_e = \frac{3}{2} \frac{P}{2} \text{Im} \left[\bar{i}_{qds} \tilde{\lambda}_{qds}^* \right] = \frac{3}{2} \frac{P}{2} (\lambda_{ds} i_{qs} - \lambda_{qs} i_{ds}) \quad (76.26)$$

Several alternative forms of the electromagnetic torque can be derived using the stator and rotor flux linkage expressions [Novotny and Lipo, 1996]. The torque expressions in terms of dq variables are used in the vector control of induction motor drives. Vector control implementations are accomplished in one of the several available choices of reference frames, such as rotor flux oriented reference frame, stator flux oriented reference frame, or air gap flux oriented reference frame. The abc variables at the input of the controller are converted to dq variables in the chosen reference frame at the input of the controller. The control computations take place in terms of dq variables, and the generated command outputs are again converted back to abc variables. The inverter controller executes the commands to establish the desired currents or voltages in the drive system.

76.3 Synchronous Machines

The synchronous machine is an AC machine with a separate field circuit to supply the magnetizing flux [Sen, 1997; Krasue and Wasynchuk, 1986; Novotny and Lipo, 1996]. The stator has three-phase windings sinusoidally distributed around the stator circumference similar to induction machine windings. DC current is fed to the rotor field windings through slip rings and brushes. The flux produced by the separate field circuit generates an induced voltage in the armature, the peak value of which can be approximated at low levels of flux by the relationship

$$E_{af} = \omega_e L_m I_f$$

where E_{af} is the induced voltage, ω_e is the angular electrical frequency, L_m is the mutual coupling inductance and I_f is the field current. At larger field currents, the mutual inductance changes due to saturation. This causes the relationship between the field current and the induced voltage to be nonlinear.

Let us consider synchronous generator operation first. When the generator supplies a load connected to the terminal, stator currents flowing through the armature or stator windings produce a synchronously rotating field at the same angular speed as the rotor magnetic field. The stator magnetic field induces a second voltage in the stator windings. The stator winding voltage is also known as the armature reaction voltage, since it is directly proportional to the amount of stator current flowing. The three-phase synchronous machine is conveniently analyzed using the single phase equivalent circuit representing the steady state characteristics. Let I_a be the phasor representation of the stator current in the single phase equivalent circuit. The armature reaction voltage drop can be expressed as

$$E_{ar} = -jX_{ar}I_a$$

where X_{ar} is an equivalent armature reaction impedance. The leakage reactance (X_{al}) caused by fluxes linking the stator conductors only is added to X_{ar} to form what is commonly referred to as synchronous reactance $X_s = X_{ar} + X_{al}$. The per-phase equivalent circuit of a synchronous generator can be drawn as shown in Figure 76.16. In the figure, V_t is the terminal voltage of the synchronous generator, R_a is the per-phase stator winding resistance, θ is the power factor angle at the terminal, and δ is the power angle between the terminal and the internal voltage. The generated internal voltage obtained by applying Kirchoff's voltage law is

$$E_a \angle \delta = V_t \angle 0 + I_a \angle \theta * (R_a + jX_s) \quad (76.27)$$

The power and torque characteristics of a synchronous machine are analyzed neglecting the stator phase winding resistance R_a . The synchronous generators used in power systems are normally connected to the infinite (fixed voltage) bus of a power grid. The maximum power that the machine can deliver depends on the maximum mechanical torque that the prime mover can apply without loss of synchro-

FIGURE 76.16 Single-phase armature equivalent circuit of a synchronous generator.

FIGURE 76.17 Power and torque angle characteristics of three-phase synchronous generators.

nism. The real and reactive three-phase powers for the synchronous generator can be derived from the equivalent circuit of Figure 76.16 as follows:

$$P = 3 \frac{E_a V_t}{X_s} \sin \delta \quad (76.28)$$

$$Q = 3 \frac{V_t}{X_s} (E_a \cos \delta - V_t) \quad (76.29)$$

The torque applied by the prime mover is given by

$$T_e = 3 \frac{E_a V_t}{\omega_e X_s} \sin \delta \quad (76.30)$$

The power and torque angle characteristics are shown in Figure 76.17. The maximum power is obtained when the power angle is 90 degrees, which is also the static stability limit. The machine will lose synchronism if $\delta > 90^\circ$. The torque is also maximum at $\delta > 90^\circ$. The maximum torque is known as pull-out torque. In most cases, the angle δ is small (15° or less) and $\cos \delta$ is approximately 1.0. Thus, $E_a \cos \delta - V_t \approx E_a - V_t$. Note that, if $E_a > V_t$, $Q > 0$ (overexcited generator operating with leading power factor) and if $E_a < V_t$, $Q < 0$ (underexcited generator operating with lagging power factor).

In the case of synchronous motor, the current flows into the machine (opposite to the direction shown in Figure 76.16), and the terminal voltage equation becomes

$$V_t \angle 0 = E_a \angle \delta + I_a \angle \theta * (R_a + jX_s)$$

The real power of the synchronous motor can be expressed by Equation (76.28) or alternatively by $P = 3V_t I_a \cos \theta$.

The round rotor synchronous machines discussed so far have uniform air-gap, and the armature reaction mmf produces the same flux irrespective of the rotor position. Low-speed, multipolar machines have saliency in the rotor, which causes the reactance measured at the stator terminal to vary as a function of the rotor position. The magnetic reluctance is low along the pole axis or d -axis and high between the poles which is known as quadrature or q -axis. The armature reaction mmf will produce more flux if it is acting along the d -axis and less flux if it is acting along the q -axis.

76.4 Permanent Magnet Machines

The machines that use magnets to produce air-gap magnetic flux instead of field coils as in DC machines or magnetizing component of stator current as in induction machines are the permanent magnet or PM

FIGURE 76.18 Characteristics of commonly used permanent magnets. (From Husain, I. 2003. *Electric and Hybrid Vehicles: Design Fundamentals*, CRC Press, Boca Raton, FL.)

machines [Miller, 1989]. This configuration eliminates the rotor copper loss as well as the need for maintenance of the field exciting circuit. PM machines can be broadly classified into PM synchronous machines and trapezoidal or squarewave machines.

The permanent magnets provide a loss-free excitation in a compact way without complications of connections to external stationary electric circuits. This is especially true for smaller machines, since there is always an excitation penalty associated with providing the rotor field through electrical circuits. For smaller machines, the mmf required is small and the resistive effects often become comparable and dominating resulting in lower efficiency.

The permanent magnets are a source of mmf much like a constant current source with relative permeability μ_r , just greater than air, i.e., $\mu_r \approx 1.05$ to 1.07 . The PM characteristics are displayed in the second quadrant of the B - H plot as shown in Figure 76.18, conforming with the fact that these are sources of mmf. The common type of magnets used in PM machines are the ferrites, samarium cobalt (SmCo) and neodymium-iron-boron (NdFeB). The magnets remain permanent as long as the operating point is within the linear region of its B - H characteristics. However, if the flux density is reduced beyond the knee-point of the characteristics (B_d), some magnetism will be lost permanently. On removal of the demagnetizing field greater than the limit, the new characteristics will be another straight line parallel to, but lower than, the original.

Permanent magnets machines are not only expensive, but also sensitive to temperature and load conditions, which constitutes the major drawback of PM machines. Most of the PM machines are found in small- to medium-power applications, although such machines are used in some high-power applications.

PM Synchronous Motors

The PMSM has a stator with a set of three-phase sinusoidally distributed copper windings similar to the windings described earlier for AC machines. A balanced set of applied three-phase voltages forces a balanced set of sinusoidal currents in the three-phase stator windings, which in turn establishes the constant amplitude rotating mmf in the air gap. The stator currents are regulated using rotor position feedback so that the applied current frequency is always in synchronism with the rotor. The permanent magnets in the rotor are appropriately shaped, and their magnetization directions are controlled such that the rotor flux linkage created is sinusoidal. The electromagnetic torque is produced at the shaft by the interaction of these two stator and rotor magnetic fields.

The PMSM has a high efficiency and a cooling system that is easier to design. The use of rare earth magnet materials increases the flux density in the air gap and accordingly increases the motor power density and torque-to-inertia ratio. In high-performance motion control systems that require servo-type operation, the PMSM can provide fast response, high power density, and high efficiency. The PMSM, similar to induction and DC machines, is fed from a power electronic inverter for operation of the system. Smooth torque output is maintained in these machines by shaping the motor currents, which necessitates a high-resolution position sensor and current sensors. A flux-weakening operation that enables a constant

FIGURE 76.19 Permanent magnet machine: (a) surface-mounted and (b) interior. (From Husain, I. 2003. *Electric and Hybrid Vehicles: Design Fundamentals*, CRC Press, Boca Raton, FL.)

power mode of operation is possible in PMSM by applying a stator flux in opposition to the rotor magnet flux. The motor high speed limit depends on the motor parameters, its current rating, the back-emf waveform, and the maximum output voltage of the inverter.

PMSMs are classified according to the position and shape of the permanent magnets in the rotors. The three common arrangements of the rotors are surface mounted, inset, and interior or buried. The surface mounted and interior PM machine configurations are shown in Figure 76.19. The direct and quadrature-axis inductances of surface-mounted PMSM are approximately equal, since permeability of the path that the flux crosses between the stator and the rotor is equal all around the stator circumference. The space needed to mount the magnets increases the radial distance of the effective air gap, making the self-inductance relatively smaller in PMSMs. The interior PMSM has its magnets buried inside the rotor. The manufacturing process is complicated and expensive for the interior PMSM. The quadrature axis inductance L_q in the interior PMSMs can be much larger than the direct axis inductance L_d . The larger differences in the d and q -axes inductances make the interior PM more suitable for flux weakening operation delivering a wider constant power region compared to the other type of PMSMs. The extended constant power range capability is extremely important for applications requiring wide speed range operation. Because of the unequal reluctance paths in the direct and quadrature axes, a reluctance torque exists in buried and inset PMSMs.

The modeling of a PMSM can be accomplished either in the stationary reference frame or in the synchronous reference frame. In the synchronous reference frame, the dq reference frame is locked to the rotor frame. The d -axis is aligned with the magnet flux direction, while the q -axis lags the d -axis by 90 degrees of space angle. The stator applied voltage is balanced by the stator winding resistance drop and the induced voltage in the winding. The dq model of a PMSM in the rotor reference frame is

$$\begin{aligned}
 v_q &= R_s i_q + \frac{d}{dt} \lambda_q + \omega_r \lambda_d, & \text{with } \lambda_q &= L_q i_q \\
 v_d &= R_s i_d + \frac{d}{dt} \lambda_d - \omega_r \lambda_q, & \text{with } \lambda_d &= L_d i_d + \lambda_f
 \end{aligned}
 \tag{76.31}$$

where i_d , i_q are the dq axis stator currents, v_d , v_q are the dq axis stator voltages, R_s is the stator phase resistance, $L_d = L_s + L_{md}$ and $L_q = L_s + L_{mq}$ are the dq axis phase inductances, λ_f is the amplitude of the flux linkage established by the PM, λ_d , λ_q are dq axis flux linkages and ω_r is the rotor speed in electrical radians/sec. L_s is the leakage inductance. The electromagnetic torque for a P pole machine is

$$T_e = \frac{3P}{2} \left[\lambda_f i_q + (L_d - L_q) i_d i_q \right] \quad (76.32)$$

The rotor position information gives the position of d and q -axes. The control objective is to regulate the voltages v_d and v_q or the currents i_d and i_q by controlling the firing angles of the inverter switches. The rotor position is given by

$$\theta_r = \int_0^t \omega_r(\xi) d\xi + \theta_r(0)$$

PM Brushless DC Motors

Permanent magnet AC machines with trapezoidal back-emf waveforms are known as PM brushless DC machines or electronically commutated machines (ECMs). PM brushless DC motors are widely used in a range of applications starting from computer drives to sophisticated medical equipment. The reason behind the popularity of these machines is the simplicity of control. Only six discrete rotor positions per electrical revolution are needed in a three-phase machine to synchronize the phase currents with the phase back-emfs for effective torque production. A set of three Hall sensors mounted on the stator facing a magnet wheel fixed to the rotor and placed 120 degrees apart can easily give this position information. This eliminates the need for a high-resolution encoder or position sensor required in PM synchronous machines, but the penalty paid for position sensor simplification is in the performance. Vector control is not possible in PM brushless DC machines because of the trapezoidal shape of back-emfs.

The three-phase back-emf waveforms and the ideal phase currents of a PM brushless DC motor are shown in [Figure 76.20](#). Square wave phase currents are supplied such that they are synchronized with the back-emf peak of the respective phase. The three stator windings for the three phases are identical with 120 degrees (electrical) phase displacement among them. Therefore, the stator winding resistances and the self-inductance of each of the three phases can be assumed to be identical. Let R_s = stator phase winding resistance, $L_{aa} = L_{bb} = L_{cc} = L$ = stator phase self inductance, and $L_{ab} = L_{ac} = L_{bc} = M$ = stator mutual inductance.

FIGURE 76.20 Back-emf and ideal phase currents in the three phases of a PM brushless DC motor. (From Husain, I. 2003. *Electric and Hybrid Vehicles: Design Fundamentals*, CRC Press, Boca Raton, FL.)

The voltage balance equation for the three-phase PM brushless DC motor is

$$\begin{bmatrix} v_a \\ v_b \\ v_c \end{bmatrix} = R \cdot \begin{bmatrix} i_a \\ i_b \\ i_c \end{bmatrix} + \begin{bmatrix} L & M & M \\ M & L & M \\ M & M & L \end{bmatrix} \cdot p \cdot \begin{bmatrix} i_a \\ i_b \\ i_c \end{bmatrix} + \begin{bmatrix} e_a \\ e_b \\ e_c \end{bmatrix} \quad (76.33)$$

where p is the operator d/dt , and e_a , e_b , and e_c are the back-emfs in the three phases.

The electrical power transferred to the rotor is equal to the mechanical power $T_e \omega_r$ available at the shaft. Using this equality, the electromagnetic torque for the PM brushless DC motor is

$$T_e = \frac{e_a \cdot i_a + e_b \cdot i_b + e_c \cdot i_c}{\omega_r} \quad (76.34)$$

For the control strategy where only two phase-currents are active at one time, the torque expression for equal currents in two phases simplifies to

$$T_e = \frac{2 \cdot e_{\max} \cdot I}{\omega_r} \quad (76.35)$$

Since the currents are controlled to synchronize with the maximum back-emf only, e_{\max} has been used in Equation (76.35) instead of e as a function of time or rotor position. For a peak phase flux of ϕ_{\max} , e_{\max} can be shown to be

$$e_{\max} = K \cdot \phi_{\max} \cdot \omega_r \quad (76.36)$$

where K is a machine constant. The torque expression of Equation (76.34) can also be written as

$$T_e = K \cdot \phi_{\max} \cdot I \quad (76.37)$$

Equation (73.36) and Equation (76.37) are very similar to the back-emf and torque equations [Equation (76.2)] for conventional DC machines. Therefore, with the position feedback-based inverter control strategy, the PM brushless DC motors can be considered to behave like that of a DC machine.

76.5 Switched Reluctance Machines

The switched reluctance machine or motor (SRM) is a doubly salient, singly excited reluctance machine with independent phase windings on the stator [Lawrenson et al., 1980; Miller, 1993]. The stator and the rotor are made of magnetic steel laminations, with the latter having no windings or magnets. Cross-sectional diagrams of a four-phase, 8-6 SRM and a three-phase, 12-8 SRM are shown in [Figure 76.21](#). The three-phase, 12-8 machine is a two-repetition version of the basic 6-4 structure within the single stator geometry. The two-repetition machine can alternately be labeled as a four-poles/phase machine, compared to the 6-4 structure with two poles/phase. The stator windings on diametrically opposite poles are connected either in series or in parallel to form one phase of the motor. When a stator phase is energized, the most adjacent rotor pole-pair is attracted towards the energized stator to minimize the reluctance of the magnetic path. Therefore, it is possible to develop constant torque in either direction of rotation by energizing consecutive phases in succession.

Several other combinations of the number of stator and rotor poles exist, such as 10-4, 12-8, etc. A 4-2 or a 2-2 configuration is also possible, but they have the disadvantage that if the stator and rotor poles are aligned exactly, then it would be impossible to develop a starting torque. Configurations with

FIGURE 76.21 Cross-sections of three-phase SR machines: (a) four-phase 8/6 structure; (b) 12/8, two-repetition structure. (From Husain, I. 2002. Switched reluctance machines, in *Power Electronics Handbook*, Skvarenina, T. L., Ed., CRC Press, Boca Raton, FL.)

higher numbers of stator/rotor pole combinations have less torque ripple and do not have the problem of starting torque.

Advantages and Drawbacks

The SRM possesses a few unique features that make it a strong competitor to existing AC and DC motors in various adjustable speed drive and servo applications. The major advantage of an SRM is the simple and low-cost machine construction due to the absence of rotor winding and permanent magnets. The fault tolerance capability in SRM because of the phase independence and natural protection against shoot-through faults in the converter is also an extremely attractive feature. In SRM, the bulk of the losses appears in the stator, which is relatively easier to cool. The maximum permissible rotor temperature is higher, since there is no permanent magnet. The rotor inertia is low, enabling extremely high speeds with a wide constant power region operation.

Among the disadvantages of SRM are the higher torque ripple and higher acoustic noise compared to other machines. The absence of permanent magnets imposes the burden of excitation on the stator windings and converter, which increases the converter kVA requirement. However, the maximum speed at constant power is not limited by the fixed magnet flux as in the PM machine, and hence, an extended constant power region of operation is possible in SRMs. The control can be simpler than the field-oriented control of induction machines, although for torque ripple minimization, significant computations may be required for an SRM drive.

Basic Principle of Operation

The general equation governing the flow of stator current in one phase of an SRM can be written as

$$V_{ph} = i_{ph}R_s + \frac{d\lambda_{ph}}{dt} = i_{ph}R_s + \frac{\partial\lambda_{ph}}{\partial i_{ph}} \frac{di_{ph}}{dt} + \frac{\partial\lambda_{ph}}{\partial\theta} \frac{d\theta}{dt} \quad (76.39)$$

where V_{ph} is the DC bus voltage, i_{ph} is the instantaneous phase current, R_s is the winding resistance and λ_{ph} is the flux linking the coil. The SRM is always driven into saturation to maximize the utilization of the magnetic circuit; hence, the flux-linkage λ_{ph} is a nonlinear function of stator current and rotor position

$$\lambda_{ph} = \lambda_{ph}(i_{ph}, \theta)$$

The electromagnetic profile of an SRM is defined by the $\lambda - i - \theta$ characteristics shown in [Figure 76.22](#).

FIGURE 76.22 Flux-angle-current characteristics of a four-phase SRM. (From Husain, I. 2002. Switched reluctance machines, in *Power Electronics Handbook*, Skvarenina, T. L., Ed., CRC Press, Boca Raton, FL.)

The last term in Equation (76.38) is the “back-emf” or “motional-emf” and has the same effect on SRM as the back-emf has on DC motors or electronically commutated motors. However, the back-emf in SRM is generated in a different way from the DC machines or ECMs where it is caused by a rotating magnetic field. In an SRM, there is no rotor field and back-emf depends on the instantaneous rate of change of phase flux-linkage.

Assuming magnetic linearity [where $\lambda_{ph} = L_{ph}(\theta)i_{ph}$] for simplifying the analysis, the instantaneous input power can be expressed as

$$P_m = V_{ph}i_{ph} = i_{ph}^2 R + \frac{d}{dt} \left(\frac{1}{2} L_{ph} i_{ph}^2 \right) + \frac{1}{2} i_{ph}^2 \frac{dL_{ph}}{d\theta} \omega \quad (76.39)$$

The first term represents the stator winding loss, the second term denotes the rate of change of magnetic stored energy, and the third term is the mechanical output power. The rate of change of magnetic stored energy always exceeds the electromechanical energy conversion term. The supplied energy is used most effectively when the current is maintained constant during the positive $dL_{ph}/d\theta$ slope. The magnetic stored energy is not necessarily lost but can be retrieved by the electrical source if an appropriate converter topology is used. In the case of a linear SRM, the energy conversion effectiveness can be at most 50%. The drawback of lower effectiveness is the increase in converter volt-amp rating for a given power conversion of the SRM. The division of input energy increases in favor of energy conversion if the motor operates under magnetic saturation, which is the primary reason for operating the SRM always under saturation.

Torque Production

The general expression for instantaneous phase torque for a device operating under the reluctance principle is

$$T_{ph}(\theta, i_{ph}) = \left. \frac{\partial W'(\theta, i_{ph})}{\partial \theta} \right|_{i_{ph}=\text{constant}} \quad \text{with co-energy} \quad W' = \int_0^i \lambda_{ph}(\theta, i_{ph}) di \quad (76.40)$$

Obviously, the instantaneous torque is not constant. The total instantaneous torque of the machine is given by the sum of the individual phase torques

FIGURE 76.23 Torque-angle-current characteristics of a four-phase SRM for four constant current levels. (From Husain, I. 2002. Switched reluctance machines, in *Power Electronics Handbook*, Skvarenina, T. L., Ed., CRC Press, Boca Raton, FL.)

$$T_{inst}(\theta, i) = \sum_{phases} T_{ph}(\theta, i_{ph}). \quad (76.41)$$

The SRM electromechanical properties are defined by the static $T-i-\theta$ characteristics of a phase, an example of which is shown in Figure 76.23.

When magnetic saturation can be neglected, the instantaneous phase torque expression becomes

$$T_{ph}(\theta, i) = \frac{1}{2} i_{ph}^2 \frac{dL_{ph}(\theta)}{d\theta} \quad (76.42)$$

The linear torque expression also follows from the energy conversion term (last term) in Equation (76.39).

The phase current needs to be synchronized with the rotor position for effective torque production. For positive or motoring torque, the phase current is switched such that the rotor moves from the unaligned position towards the aligned position. The linear SRM model is very insightful in understanding these situations. Equation (76.42) clearly shows that for motoring torque, the phase current must coincide with the rising inductance region. On the other hand, the phase current must coincide with the decreasing inductance region for braking or generating torque. The phase currents for motoring and generating modes of operation are shown in Figure 76.24 with respect to the phase inductance profiles.

The power electronic circuits for SRM drives are quite different from those of AC motor drives. The torque developed in an SRM is independent of the direction of current flow. Therefore, unipolar converters are sufficient to serve as the power converter circuit for the SRM, unlike the situation with induction motors or synchronous motors, which require bidirectional currents. This unique feature of the SRM, together with the fact that the stator phases are electrically isolated from one another, generates a wide variety of power circuit configurations. The type of converter required for a particular SRM drive is intimately related to motor construction and the number of phases. The choice also depends on the specific application. The most flexible and the most versatile four-quadrant SRM converter is the bridge converter shown in Figure 76.25, which requires two switches and two diodes per phase.

Appropriate positioning of the phase excitation pulses relative to the rotor position is the key in obtaining effective performance out of an SRM drive system. Therefore, a rotor position transducer is essential to provide the position feedback signal to the controller. The turn-on time, the total conduction period, and the magnitude of the phase current determine torque, efficiency, and other performance parameters.

76.6 Synchronous Reluctance Machine

The variable reluctance type synchronous machine is a viable alternative for variable speed drives for applications where rated torque at low speed is required [Lipo et al., 1992]. For such applications, the low-speed rotor losses of the induction machine make it a suboptimal choice. The synchronous reluctance machine (abbreviated as SynRM) rotor is constructed with saliency to employ the principle of reluctance torque production for electromechanical energy conversion. The machine retains many of the advantages of a switched reluctance motor, but at the same time overcomes some of its disadvantages. For example, the SynRM can be operated with unipolar currents in the same manner as in a SRM. Alternatively, the stator can be wound conventionally as in an induction or synchronous machine to produce the sinusoidal uniformly rotating air gap mmf to overcome the acoustic noise and torque ripple problems of SRM. The three-phase machine is fed from an inverter with a balanced set of three-phase AC voltages.

The SynRM are characterized by the absence of rotor windings or currents and special salient pole rotor configurations. The modern axially laminated rotor [Figure 76.26(a)] has high L_d/L_q ratio providing high torque density (Nm/kg), power factor, and efficiency that are comparable or superior to those of induction motors. The conventionally laminated anisotropic rotor [Figure 76.26(b)] has $L_d/L_q < 3$ leading to lower-power-factor (0.45 to 0.5) operation. The major difficulty with the axially laminated SynRM is the high manufacturing cost of the rotor, which could be eliminated or minimized only through mass production. The absence of rotor currents and ideally zero rotor core losses (in reality there are some losses due to harmonic flux currents) eliminates the need for cooling the rotor, which enables the motor to operate at very low speeds and high torque provided the stator is adequately cooled.

The d - q axes transformation theory can be used for the analysis of the SynRM. The torque produced by the machine can be expressed as

$$T_e = \frac{3}{2} \cdot \frac{P}{2} \cdot (\lambda_{ds} i_{qs} - \lambda_{qs} i_{ds}) \quad (76.43)$$

FIGURE 76.26 SynRM rotors: (a) rotor with multiple flux barrier, (b) modern axially laminated, and (c) conventional. (From Boldea, I. and Nasar, S. A. 1999. *Electric Drives*, CRC Press, Boca Raton, FL.)

FIGURE 76.27 Mmf angle ϵ and dq currents in a synchronous reluctance machine.

In normal steady-state conditions when the rotor currents are zero, the d and q -axes flux linkages are given by $\lambda_{ds} = L_{ds} i_{ds}$ and $\lambda_{qs} = L_{qs} i_{qs}$. L_{ds} and L_{qs} are the d and q axes inductances with $L_{ds} \neq L_{qs}$. In general, L_{ds} and L_{qs} both have a leakage component and a magnetizing component, i.e.,

$$\begin{aligned} L_{ds} &= L_{ls} + L_{md} \\ L_{qs} &= L_{ls} + L_{mq} \end{aligned} \quad (76.44)$$

Therefore, the torque expression in terms of the magnetizing component is

$$T_e = \frac{3}{2} \cdot \frac{P}{2} \cdot (L_{md} - L_{mq}) i_{qs} i_{ds} \quad (76.45)$$

Expressing the d and q axes currents in terms of the stator current amplitude and the mmf angle ϵ (see Figure 76.27)

$$\begin{aligned} i_{ds} &= I_s \cos \epsilon \\ i_{qs} &= I_s \sin \epsilon \end{aligned} \quad (76.46)$$

The electromagnetic torque in terms of the stator current amplitude and mmf angle ϵ is

$$T_r = \frac{3}{2} \cdot \frac{P}{2} \cdot (L_{md} - L_{mq}) I_s^2 \frac{\sin 2\epsilon}{2} \quad (76.47)$$

Clearly, the torque is maximized when $\epsilon = 45^\circ$. For loads less than and up to rated conditions, the angle ϵ is maintained at 45° , while the current amplitude is varied, minimizing the I^2R loss as well as the converter loss.

76.7 Small Electric Motors

Motors for small loads are often single-phase as opposed to the three-phase machines used in industrial applications [Sen, 1997]. Although the three-phase motors use the majority of power generated, there are a large number of smaller machines used to move small loads in residential application and in servo applications. Small electric motors are available in a wide variety of designs in order to meet the available power supply and cost requirements. Some of these motors require electronics to start and operate, while others can run directly from a single-phase AC source without any electronics. A large number of fractional power applications use PM brushless DC motors, which have already been discussed. This section will cover some of the other available low-cost small electric motors. Single-phase motors operate with slightly higher slips and losses, but this is acceptable in many small load applications, especially when only single-phase power is readily available.

Single-Phase Induction Machines

Single-phase induction motors do not have a rotating flux wave, which is essential to develop a starting torque. The machines are built with an auxiliary mechanism to provide a second current that is out of phase with the main winding so that the interaction of the windings produces a rotating mmf to start the motor.

One method of providing starting torque to single-phase induction machines is to place a capacitor in series with the auxiliary winding of the motor. These motors are known as capacitor motors. The mmf of the starting current in the auxiliary winding can be adjusted to be equal to the current in the main winding, and the phase angle of the auxiliary winding current can be made to lead the main phase winding current by 90° by proper selection of the capacitor size. The 90° phase difference in the two currents results in a rotating mmf, which is required for the starting torque. A centrifugal switch in series with the capacitor circuit disconnects the capacitor once the motor starts running (Figure 76.28). Alternately, the capacitor can be kept permanently connected in the circuit, eliminating the need for the centrifugal switch. These permanent split capacitor motors tend to run more smoothly with higher efficiency and power factor. However, the starting torque is lower, since the capacitor is sized to balance the currents during operation with normal loads. In a more complex two-capacitor motor, known as capacitor-start, capacitor-run motor, a larger capacitor value is used for starting to ensure a high starting torque. Once the motor attains sufficient speed, the centrifugal switch opens, lowering the capacitor value to balance currents for normal loads.

Split-phase induction motors use a main winding and an auxiliary winding without a capacitor with their axes displaced by 90° in space. The auxiliary winding has a large R/X ratio, which is accomplished by using smaller wire-gauge for the winding. The centrifugal switch in series with the auxiliary winding opens at some set speed leaving only the main winding for operation. Split-phase motors have a moderate starting torque with very low starting current. The direction of rotation of any split phase motor or capacitor-start motor can be reversed by switching the connections of the auxiliary winding.

Another method of providing the starting torque for single-phase induction machines is to employ a separate short-circuited coil (called a shading coil) on one side of the main winding coil (Figure 76.29).

FIGURE 76.28 Connections for single-phase capacitor start motors.

FIGURE 76.29 Shaded-pole induction motor.

These motors are known as shaded pole motors. The shading coils induce a current that resists a change of flux, therefore effectively delaying the flux buildup in the part of the pole with the coil. This creates a small rotating flux that can generate enough starting torque to start a motor that is lightly loaded. The direction of rotation of these motors cannot be reversed. The torque and rotation are in the direction from the unshaded to the shaded portion of the pole face. These are also less efficient and have much higher slip.

Universal Motors

Universal motors are essentially DC motors with series windings. The motors can be operated from either a DC or an AC source. Since the torque in a DC motor is proportional to both the armature and the field currents, connecting the windings in series ensures that the polarity of both the armature and field windings reverses simultaneously producing unidirectional torque.

Universal motors can operate at up to 20,000 rpm and are widely used for vacuum cleaners, portable drills, food mixers, and fans. These motors tend to be noisy when supplied from an AC source with high torque ripples and are also not very efficient. A triac connected in series with the supply can be used to regulate the supply voltage, thereby enabling the use of these machines for low-cost variable-speed applications.

Stepper Motors

The stepper motor is an electromagnetic actuator used for positioning of the rotor without any feedback. The motor converts digital pulse inputs designating a certain degree of rotation to an actual rotation of the rotor shaft. The machines have zero steady-state error and high torque density. The stepper motors develop a holding torque rather than a rotating torque when one phase is activated, thereby accurately retaining the position with load. Typical applications of stepper motors are printers, plotters, machine tools, and robotics.

Stepper motors are designed on the concept of either the variable (switched) reluctance motor or the PM synchronous motor. In the variable reluctance-type stepper motor, a large number of teeth is used in the rotor to create saliency. When one phase is aligned, the other phases are unaligned, similar to the switched reluctance machine. Permanent magnet stepper motors use permanent magnets in the rotor. There also exist hybrid stepper motors, where the rotor has an axial permanent magnet in the middle and ferromagnetic teeth at the outer sections.

76.8 Transverse Flux Machines

Conventional motor drive systems typically use a high-speed motor with a speed reduction gearbox. The drawbacks of gearing mechanisms are additional space, elasticity, backlash, and efficiency. A direct-drive system can eliminate the gearing mechanism in applications where the tip speed and other speed-related effects are not important. The direct-drive systems make sense functionally as well as economically only when a high-torque density machine is available. The concept of transverse flux (TF) machines with permanent magnets (PM) emerged about 12 years ago as a result of the search for optimized magnet

paths in electric machines. The potentials for high efficiency and high torque density in TF machines have been demonstrated to be high in early research [Kruse et al., 1998].

Let us first discuss the torque density factor of electric machines to understand how TF machines are designed to achieve a high value of such. The torque per unit volume can be generally expressed as [Beaty and Kirtley, 1998]

$$\frac{T}{V_a} = \frac{\tau}{2} \frac{r}{h_s + t_b} \frac{l}{l + 2\Delta l} \quad (76.48)$$

where τ is the average shear stress producing the electromagnetic interaction, r is the rotor radius, l is the axial length of the machine, h_s is the radial length extension to accommodate stator windings, t_b is the radial length extension for the back iron and Δl is the axial length extension for the end windings. It can be concluded from Equation (76.48) that torque density increases directly with rotor radius, and large pole numbers reduce the impact of both t_b and h_s . The value of large pole numbers hits a point of diminishing return when $t_b < h_s$.

High-torque machines must be designed with short pole-pitch that has the advantage of reducing the required end-turn length and back-iron depth, especially for low-speed machines. However, short pole-pitch machines require relatively large magnetizing mmf, since every pole must be excited. Furthermore, low-speed machines are typically inefficient, because conduction losses are normally associated with torque, while power is torque times speed.

The TF machine uses a topology with a toroidal armature coil, where the current flows parallel to the direction of rotation. The winding arrangement gives an extremely short current path in the machine, thereby reducing conduction losses. The high specific torque in these machines is obtained by increasing the current loading through simply increasing the pole pairs without increasing the armature ampere-turns. The decoupled structure of flux-paths and armature coils enables such a design. The stator core is essentially salient with a large number of poles.

In PM TF machines, the magnets provide for the relatively large mmf requirements in these machines. In direct drive motors, the amount of magnet material is also proportionately high due to the high torque, which works against PM TF machines for economic reasons in the face of high magnet costs. The basic operating principle is the same for all PM TF machine variants. A stator phase winding having a ring or circular form produces a homopolar mmf distribution in the air-gap. This mmf is modulated by a pattern of stator poles or teeth to interact with a heteropolar pattern of PMs placed on the rotor. The basic structure of a PM TFM is shown in Figure 76.30. The number of stator poles is usually half of the number of rotor PMs, but much greater than for conventional machines with heteropolar topology. The machine thus obtained is capable of producing power densities up to three times greater than conventional machines. The PM TF machine must have two or more phases to produce continuous rotation and to

FIGURE 76.30 Transverse flux machines: (a) PM type, (b) reluctance type. (Figure 76.30(a) is from Henneberger, G. and Viorel, I. A. 2001. *Variable Reluctance Electric Machines*, Shaker Verlag, Aachen, Germany.)

avoid the starting difficulties. In contrast to conventional machines, there is no common rotating field in the three-phase structure of the TF machine, only three independent alternating fields, which are electrically shifted by 120° . The necessary mechanical shift of 120° for the prototype is obtained in the rotor by shifting the magnets. The PM TF machine stator windings must be supplied from an electronic power converter, which is controlled with respect to the rotor position. The control of the TF machines with PMs on the rotor is similar to that of the conventional synchronous machines.

The rotor in TF machines can also be made of salient poles instead of using permanent magnets [Kruse et al., 1998]. This type of machine is known as the reluctance TFM and is shown in [Figure 76.31](#). The reluctance TF machine has quite the same features as a switched reluctance machine, the main difference being the homopolar type ring winding placed on the stator. The reluctance TF machine has the same number of poles on both stator and rotor. The phases are placed axially as is usual for TF machines. A reluctance TF machine can have three or more than three independent phases, which are fed independently as in a switched reluctance machine.

The TF machine has an outstanding torque-to-volume ratio compared to all other types of machines but has a lower power factor due to its homopolar feature. The constructional difficulty is the other main drawback of these machines.

Gregor Hoogers

University of Applied Sciences Trier

As early as 1838/1839 Friedrich Wilhelm Schönbein and William Grove discovered the basic operating principle of fuel cells by reversing water electrolysis to generate electricity from hydrogen and oxygen [Bossel, 2000]. This has not changed since:

A fuel cell is an electrochemical device that continuously converts chemical energy into electric energy — and heat — for as long as fuel and oxidant are supplied.

Fuel cells therefore bear similarities both to batteries, with which they share the electrochemical nature of the power generation process, and with engines which, unlike batteries, will work continuously consuming a fuel of some sort. When hydrogen is used as fuel, they generate only power and pure water: they are therefore called zero-emission engines. Thermodynamically, the most striking difference is that thermal engines are limited by the well-known Carnot efficiency, while fuel cells are not. This is an advantage at low-temperature operation — if one considers, for example, the speculative Carnot efficiency of a biological system working, instead, as a heat engine. At high temperatures, the Carnot efficiency theoretically surpasses the electrochemical process efficiency. Therefore, one has to look in detail at the actual efficiencies achieved in working thermal and fuel cell systems where, in both cases, losses rather than thermodynamics dominate the actual performance.

Fuel cells are currently being developed for three main markets: automotive propulsion, electric power generation, and portable systems. Each main application is dominated by specific systems requirements and even different types of fuel cells, while the underlying operating principle remains the same.

77.1 Fundamentals

Operating Principle

The underlying principle of fuel cell operation is the same for all types that have emerged over the past 160 years: a so-called redox reaction is carried out in two half-reactions located at two electrodes separated by an electrolyte. The purpose of the electrolyte is electronic separation of and ionic connection between the two electrodes, which will assume different electrochemical potentials. The advantage of carrying out

the reaction in two parts is direct electrochemical conversion of chemical energy into electric energy by employing the resulting potential difference between the two electrodes, anode and cathode. The simplest and most relevant reaction in this context is the formation of water from the elements,

Rather than carrying out reaction (77.1) as a gas phase reaction, i.e., thermally after supplying activation energy (ignition) or, more gently, by passing the two reactants over an oxidizing catalyst such as platinum and generating merely heat, the electrochemical reaction requires the half-reactions

and

to take place at an anode (77.2) and cathode (77.3), respectively. Therefore, the two electrodes assume their electrochemical potentials at — theoretically — 0 and 1.23 V, respectively, and an electronic current will flow when the electrodes are connected through an external circuit. The anode reaction is the hydrogen oxidation reaction (HOR); the cathode reaction is the oxygen reduction reaction (ORR). In this specific case, the electrolyte is an acidic medium which only allows the passage of protons, H^+ , from anode to cathode. Water is formed at the cathode.

Fuel Cell Types

The different fuel cells differ from each other by and are named after the choice of electrolyte. The electrolyte will also determine the nature of the ionic charge carrier and whether it flows from anode to cathode or cathode to anode. Electrode reactions and electrolytes are listed in [Table 77.1](#).

Grove's fuel cell operating in dilute sulfuric acid electrolyte, but also the phosphoric acid fuel cell (PAFC, operating at around 200°C) and the proton exchange membrane fuel cell (PEMFC or PEFC, operating at 80°C, also called solid polymer fuel cell, SPFC) are examples for cells with acidic, proton-conducting electrolytes as in reactions (77.2) and (77.3).

In contrast, when using an alkaline electrolyte, the primary charge carrier is the OH^- ion, which flows in the opposite direction, so water is formed at the anode. The overall reaction (77.1) does not change. The resulting fuel cell is called an alkaline fuel cell or AFC and leads a very successful niche existence in supplying electric power to space craft such as Apollo and the Shuttle.

TABLE 77.1 Fuel Cell Types, Electrolytes, and Electrode Reactions

| Fuel Cell Type | Electrolyte | Charge Carrier | Anode Reaction | Cathode Reaction | Operating Temperature |
|---|---|--------------------|--|---|-----------------------|
| Alkaline FC (AFC) | KOH | OH^- | $\text{H}_2 + 2\text{OH}^- = 2\text{H}_2\text{O} + 2\text{e}^-$ | $\frac{1}{2}\text{O}_2 + \text{H}_2\text{O} + 2\text{e}^- = 2\text{OH}^-$ | 60–120°C |
| Proton exchange membrane FC (PEMFC, SPFC) | Solid polymer (such as Nafion) | H^+ | $\text{H}_2 = 2\text{H}^+ + 2\text{e}^-$ | $\frac{1}{2}\text{O}_2 + 2\text{H}^+ + 2\text{e}^- = \text{H}_2\text{O}$ | 50–100°C |
| Phosphoric acid FC (PAFC) | Phosphoric acid | H^+ | $\text{H}_2 = 2\text{H}^+ + 2\text{e}^-$ | $\frac{1}{2}\text{O}_2 + 2\text{H}^+ + 2\text{e}^- = \text{H}_2\text{O}$ | ~220°C |
| Molten carbonate FC (MCFC) | Lithium and potassium carbonate | CO_3^{2-} | $\text{H}_2 + \text{CO}_3^{2-} = \text{H}_2\text{O} + \text{CO}_2 + 2\text{e}^-$ | $\frac{1}{2}\text{O}_2 + \text{CO}_2 + 2\text{e}^- = \text{CO}_3^{2-}$ | ~650°C |
| Solid oxide FC (SOFC) | Solid oxide electrolyte (yttria stabilized zirconia, YSZ) | O^{2-} | $\text{H}_2 + \text{O}^{2-} = \text{H}_2\text{O} + 2\text{e}^-$ | $\frac{1}{2}\text{O}_2 + 2\text{e}^- = \text{O}^{2-}$ | ~1000°C |

FIGURE 77.1 Fuel cell stack made up of flow field plates (or bipolar plates) and MEAs (shown in the insert).

Phosphoric acid fuel cells (PAFCs) use molten H_3PO_4 as an electrolyte. The PAFC has been mainly developed for the medium-scale power generation market, and 200 kW demonstration units have now clocked up many thousands of hours of operation. However, in comparison with the two low-temperature fuel cells, alkaline and proton exchange membrane fuel cells (AFCs, PEMFCs), PAFCs achieve only moderate current densities.

The proton exchange membrane fuel cell, PEMFC, takes its name from the special plastic membrane that it uses as its electrolyte. Robust cation exchange membranes were originally developed for the chlor-alkali industry by Du Pont and have proven instrumental in combining all the key parts of a fuel cell, anode and cathode electrodes and the electrolyte, in a very compact unit. This membrane electrode assembly (MEA), not thicker than a few hundred microns, is the heart of a PEMFC and, when supplied with fuel and air, generates electric power at cell voltages up to 1 V and power densities of up to about 1Wcm^{-2} .

The membrane relies on the presence of liquid water to be able to conduct protons effectively, and this limits the temperature up to which a PEMFC can be operated. Even when operated under pressure, operating temperatures are limited to below 100°C . Therefore, to achieve good performance, effective electrocatalyst technology is required. The catalysts form thin (several microns to several tens of microns) gas-porous electrode layers on either side of the membrane. Ionic contact with the membrane is often enhanced by coating the electrode layers using a liquid form of the membrane ionomer.

The MEA is typically located between a pair of current collector plates with machined flow fields for distributing fuel and oxidant to anode and cathode, respectively (compare [Figure 77.1](#)). A water jacket for cooling may be inserted at the back of each reactant flow field followed by a metallic current collector plate. The cell can also contain a humidification section for the reactant gases, which helps to keep the membrane electrolyte in a hydrated, proton-conduction form. The technology is given a more thorough discussion in the following chapter.

Another type of fuel cell is already built into most cars today: the lambda sensor measuring the oxygen concentration in the exhaust of four-stroke spark ignition engines is based on high temperature oxygen ion, O^{2-} , conductors. Typically, this is yttria stabilized zirconia or YSZ, which is also used as solid electrolyte in high temperature (up to 1100°C or 1850°F) solid oxide fuel cells (SOFC). In fact, a lambda sensor works rather well as a high-temperature fuel cell when a hydrogen or a hydrocarbon is used instead of exhaust gas. [Table 77.1](#) shows the electrode reactions.

The second high-temperature fuel cell uses molten carbonate salts at 650°C (1200°F) as electrolyte which conducts carbonate ions, CO_3^{2-} . It is unique that in this type of fuel cell, the ions are formed not

from the reactants but from CO₂ that is injected into the cathode gas stream, and usually recycled from the anode exhaust — compare Table 77.1.

The two high-temperature fuel cells, solid oxide and molten carbonate (SOFC and MCFC), have mainly been considered for large scale (MW) stationary power generation. In these systems, the electrolytes consist of anionic transport materials, as O²⁻ and CO₃⁻ are the charge carriers. These two fuel cells have two major advantages over low-temperature types. They can achieve high electric efficiencies — prototypes have achieved over 45% — with over 60% currently targeted. This makes them particularly attractive for fuel-efficient stationary power generation.

The high operating temperatures also allow direct, internal processing of fuels such as natural gas. This reduces the system complexity compared with low-temperature power plants, which require hydrogen generation in an additional process step. The fact that high-temperature fuel cells cannot easily be turned off is acceptable in the stationary sector, but most likely only there.

Thermodynamics and Efficiency of Fuel Cells

Thermodynamics [Atkins, 1994] teaches that the right thermodynamic potential to use for processes with nonmechanical work is ΔG , the Gibbs free energy. The Gibbs free energy determines the maximum of the nonmechanical work that can be expected from such a reaction, for example, a biological or electrochemical reaction. Another useful quantity in this context is the standard potential of an electrochemical reaction, E_0 . E_0 is related to the Gibbs free energy of the reaction by

$$\Delta G = nFE_0 \quad (77.4)$$

where n is the number of charges in the reaction, and $F = 96485 \text{ C mol}^{-1}$ is the Faraday constant. ΔG essentially determines the upper limit of the electric work coming out of a fuel cell. Both Gibbs free energies and standard reaction potentials are tabulated. So are standard reaction enthalpies, ΔH .

In order to derive the highest possible cell voltage and the cell efficiency, let us consider reaction (77.1). The reaction Gibbs free energy is determined in the usual way from the Gibbs free energies of formation, ΔG_f , of the product side minus ΔG_f on the reactant side.

$$\Delta G = \Delta G_f(\text{H}_2\text{O}) - \Delta G_f(\text{H}_2) - 1/2 \Delta G_f(\text{O}_2) = \Delta G_f(\text{H}_2\text{O}) = -237.13 \text{ kJ mol}^{-1} \quad (77.5)$$

(The Gibbs free energies of elements in their standard states are zero.)

From (77.4) we can now calculate the maximum cell voltage for a cell based on reaction (77.1):

$$E_0 = \Delta G(\text{H}_2\text{O})/nF = 237.13 \text{ kJ mol}^{-1}/(2 \cdot 96485 \text{ C mol}^{-1}) = 1.23 \text{ V} \quad (77.6)$$

Here, $n = 2$ because reaction (77.3) shows that two electrons are exchanged for the formation of one mol of water.

The higher heating value (HHV) of the same reaction is simply ΔH , the reaction enthalpy for reaction (77.1) with liquid product water. In analogy with reaction (77.5), we can calculate the reaction enthalpy from the tabulated enthalpies of formation. Again:

$$\Delta H = \Delta H_f(\text{H}_2\text{O}, l) = -285.83 \text{ kJ mol}^{-1} \quad (77.7)$$

Comparison with (77.5) shows that an electrochemical cell based on reaction (77.1) can at best achieve an electric efficiency of

$$\eta_{el}^{max} = \Delta G/\Delta H = 0.83 = 83\%$$

based on the HHV of the fuel.

Measuring the actual electric efficiency of a fuel cell is extremely simple: A measurement of the operating cell voltage E is sufficient:

$$\eta_{el} = E/E_0 \cdot \Delta G/\Delta H = (nF/\Delta H) \cdot E = 0.68 \text{ V}^{-1} E \quad (77.8)$$

For example, a hydrogen/air fuel cell achieving a cell voltage of 0.7 V under operation converts $0.68 \text{ V}^{-1} \cdot 0.7 \text{ V} = 0.47 = 47\%$ of the chemical energy supplied into electric energy.

Effects of Pressure and Temperature

Everything that has been said so far was based on standard values for pressure and temperature, i.e., $T = 298 \text{ K}$ and $P = 1 \text{ bar}$. In practice, fuel cells usually operate at elevated temperatures and, often, above ambient pressure.

Generally, for a chemical reaction of the type

the effect of the partial pressures (strictly speaking: activities) of the reactants and products on the change in Gibbs free energy is given as

$$\Delta G = \Delta G^\circ + RT \ln \frac{P_M^m P_N^n}{P_A^a P_B^b} \quad (77.10)$$

When converted to potentials, using Equation 77.4, this turns into the well-known Nernst equation. It is clear from (77.1), (77.9), and (77.10) that an increase in either $P(\text{H}_2)$ or $P(\text{O}_2)$ will lead to a higher cell potential.

The temperature dependence is given by the temperature dependence of the Gibbs free energy, $\Delta G(T)$.

Since $\Delta G = \Delta H - T\Delta S$, and ΔH depends only weakly on T , the temperature derivative of ΔG is given by:

$$dG/dT = -\Delta S \text{ or, using (77.4)}$$

$$dE_0/dT = -\Delta S/nF \quad (77.11)$$

System Efficiency

The *system efficiency* in this case will, of course, be lower due to the consumption of the power system itself and due to wastage of hydrogen fuel or air. The reason for this is often system related, i.e., a certain amount of hydrogen is passing through the cell unused in order to remove continuously water or contaminants from the anode. The hydrogen leaving the cell is either recycled or burned. The hydrogen excess is quantified by two terms used by different authors, stoichiometry and the fuel utilization. A 50% excess of hydrogen feed is expressed in a fuel stoichiometry of 1.5 or in a fuel utilization of $1/1.5 = 2/3$. An air surplus is also used routinely. This will affect the system efficiency through the energy lost on compressor power.

Another consideration is linked to the method of providing hydrogen. When hydrogen is made from another chemical that is more apt for storage (for example, on board a vehicle) or for supply from the natural gas grid, the fuel processor or *reformer* will also have a certain efficiency.

Finally, the DC power generated by a fuel cell is often converted into AC, either for an electric motor or for supplying mains current. The alternator, again, affects the overall system efficiency by a load-dependent loss factor.

Kinetics of Fuel Cell Reactions

As may be expected, the treatment of the kinetics of fuel cell reactions is harder than the thermodynamics but nonetheless much simpler than the details of the energy conversion in thermal engines.

A full treatment of the electrochemical kinetics (Butler–Volmer Equation) is beyond the scope of this chapter and can be found in the general electrochemical [Hamann, 1998] or dedicated fuel cell literature

[Hoogers, 2003]. It is a striking result of the kinetic work on fuel cells that anode reaction kinetics are far superior to cathode kinetics and that the anode potential — with the cell operating on clean hydrogen — is close to the reversible hydrogen potential at 0 V. The cell performance is therefore dominated by the cathode potential, i.e., $E_{cell} = E_c$.

Essentially, the kinetic description of electrode kinetics predicts an exponential dependence of the cell current on the cell voltage. For practical purposes, it is often more desirable to express the cell potential as a function of current drawn from the cell, i.e.,

$$E_c = E_r - b \log_{10}(i/i_o) - i r \quad (77.12)$$

where E_r = reversible potential for the cell; i_o = exchange current density for oxygen reduction; b = Tafel slope for oxygen reduction; r = (area specific) ohmic resistance; and i = current density, in which ohmic losses have been included by adding the term $(-ir)$.

This is the so called *Tafel equation* (with addition of the ir -dependence). The *Tafel slope* b is determined by the nature of the electrochemical process. b can be expressed as

$$b = RT/\beta F \quad (77.13)$$

where $R = 8.314 \text{ J mol}^{-1} \text{ K}^{-1}$ denotes the universal gas constant, F is again the Faraday constant, T is the temperature (in K), and β is the transfer coefficient, a parameter related to the symmetry of the chemical transition state, usually taken to be 0.5, when no first principle information is available. For the oxygen reduction reaction in practical proton exchange membrane fuel cells, b is usually experimentally determined with values between 40 and 80 mV.

The main factor controlling the activation overpotential and hence the cell potential, $E_{cell} = E_c$, is the (apparent) exchange current density i_o . Equation. (77.12) demonstrates that, due to the logarithm, a tenfold increase in i_o leads to an increase in cell potential at the given current by one unit of b , or typically 60 mV. It is important to dwell on this point. While the reversible potential E_r is given by thermodynamics and the Tafel slope b is dictated by the chemical reaction (and the temperature), the value for i_o depends entirely on reaction kinetics. Ultimately, it depends on the skill of the MEA and electrocatalyst producer to increase this figure.

For doing so there are, in principle, the following possible approaches:

- The magnitude of i_o can be increased (within limits) by adding more electrocatalyst to the cathode. As today's electrocatalysts (used in low temperature fuel cells) contain platinum, there are economic reasons why MEA makers do not just put more platinum inside their products.
- Clearly, there have been many attempts to do away with platinum as the leading cathode catalyst for low-temperature fuel cells altogether. Unfortunately, to date, there appears to be no convincing alternative to platinum or related noble metals. This is not merely due to the lack of catalytic activity of other catalyst systems but often is a result of insufficient chemical stability of the materials considered.
- A logical and very successful approach is the more effective use of platinum in fuel cell electrodes. A technique borrowed from gas phase catalysis is the use of supported catalysts with small, highly dispersed platinum particles. Of course, electrocatalysts have to use electrically conducting substrate materials, usually specialized carbons.
- Of course, it is not sufficient to improve the surface area of the catalyst employed; there has to be good electrochemical contact between the membrane and the catalyst layer. *In-situ* measurement of the effective platinum surface area (EPSA) is a critical test for the quality of an electrode structure. The EPSA may be measured by electronic methods or, more commonly, by carbon monoxide adsorption and subsequent electrooxidation to carbon dioxide with charge measurement. For more information see Chapter 6 in [Hoogers, 2003]. Impedance measurements under practical loads can give valuable information on the catalyst utilization under operating conditions.

77.2 Fueling and Fuel Cell Systems

Not all fuel cells require these two reactants, but all fuel cells will function well with hydrogen and oxygen or air. In stationary power systems, the most convenient fuel is usually natural gas from the national grid. This has to be converted into the right fuel for the fuel cell — see below. In automotive systems, but also for portable power fuel, storage is an issue.

Hydrogen Storage

Pressure Cylinders

The need for lighter gas storage has led to the development of lightweight composite rather than steel cylinders. Carbon-wrapped aluminum cylinders can store hydrogen at pressures of up to 55 MPa (550 bar/8000 PSI). In most countries, gas cylinders are typically filled up to a maximum of 24.8 or 30 MPa (248 bar/3600 PSI and 300 bar/4350 PSI, respectively). At the higher pressure, a modern composite tank reaches a hydrogen mass fraction of approximately 3%, i.e., only 3% of the weight of the full cylinder consists of hydrogen. In a further development, so called “conformable” tanks have been produced in order to give a better space filling than packed cylinders.

General Motors’ current compressed hydrogen gas storage systems typically hold 2.1 kg of hydrogen in a 140 liter/65 kg tank at 350 bar, which is good for 170 km (106 miles). The target here is a 230 liter/110 kg tank that would hold 7 kg of hydrogen at 700 bar, giving the same range as liquid hydrogen (see below), 700 km (438 miles) (H&FC, 2001).

Californian Quantum Technologies WorldWide has demonstrated a composite hydrogen pressure storage tank with a nominal operating pressure of almost 700 bar (10,000 PSI) giving an 80% capacity increase over tanks operating at 350 bar. The new tank underwent a hydrostatic burst test at which it failed under 1620 bar (23,500 psi). This test was done along the lines given in the draft regulations by the European Integrated Hydrogen Project (EIHP). The tank has an in-tank regulator that provides a gas supply under no more than 10 bar (150 PSI).

Liquid Hydrogen

It is unfortunate that the critical temperature of hydrogen, i.e., the temperature below which the gas can be liquefied, is at 33 K. Storage in cryogenic tanks at the boiling point of hydrogen, 20.39 K (−252.76°C/−422.97°F) at 1 atm (981 hPa), allows higher storage densities at the expense of the energy required for the liquefaction process. Lowering the temperature of hydrogen to its boiling point at 20.39 K (−252.76°C/−422.97°F) at atmospheric pressure requires approximately 39.1 kJ/g or 79 kJ mol^{−1}. To put this figure into perspective, this energy amounts to over a quarter of the higher heating value (286 kJ mol^{−1}) of hydrogen.

Another problem with cryogenic storage is hydrogen boil-off. Despite good thermal insulation, the heat influx into the cryogenic tank is continuously compensated by boiling off quantities of the liquid (heat of evaporation). In cryogenic storage systems on-board cars, the boil-off rate is estimated by most developers at approximately 1% per day, which results in further efficiency losses.

Cryogenic tanks consist of a multi-layered aluminum foil insulation. A typical tank stores 120 l of cryogenic hydrogen or 8.5 kg, which corresponds to an extremely low (liquid) density of 0.071 kg dm^{−3}. The empty tank has a volume of approximately 200 l and weighs 51.5 kg [Larminie, 2000]. This corresponds to a hydrogen mass fraction of 14.2%.

In General Motors’ HydroGen1, 5 kg of hydrogen are stored in a 130 l/50 kg tank that gives the vehicle a 400 km (250 mile) drive range. The future target is a 150-l tank that is lighter yet, holding 7 kg for a range of 700 km (438 miles), as well as reduced boil-off time via an additional liquefied/dried air cooling shield developed by Linde.

The actual handling of cryogenic hydrogen poses a problem to the filling station, requiring special procedures such as fully automated, robotic filling stations.

Metal Hydrides

Most elements form ionic, metallic, covalent, or polymeric hydrides or mixtures thereof [Greenwood, 1984]. Ionic and metallic types are of particular interest, as they allow reversible storage of hydrogen [Sandrock, 1994].

The formation of the hydride is an exothermal process. Important parameters in this context are the enthalpy of formation of the hydride, which may range between several kJ and several hundred kJ per mol of hydrogen stored, and the resulting temperature and pressure to release the hydrogen from the hydride. In order to adjust these figures to technically acceptable levels, intermetallic compounds have been developed. Depending on the hydride used, the mass fraction of hydrogen ranges between 1.4 and 7.7% of total mass. Many hydrides actually store more hydrogen by volume than liquid hydrogen does. However, the storage process itself is exothermal and may amount to 25 to 45% of the hydrogen HHV (for full details, see Chapter 5 in [Hoogers, 2003]). Clearly, for large storage capacities such as the typical automotive tank, this is entirely unacceptable. Yet, for small, hydrogen-based portable systems, metal hydrides may form a convenient method of energy storage if cartridges are made universally available for purchase and recycling.

Sodium Borohydride

Sodium borohydride, NaBH_4 , has recently received much attention through the work of Millenium Cell and DaimlerChrysler. Millennium Cell has patented a process that releases hydrogen from an aqueous solution of sodium borohydride, NaBH_4 , in an exothermal reaction. (Sodium borohydride is usually made from borax using diborane, a highly reactive, highly toxic gas.) Hydrogen is only produced when the liquid fuel is in direct contact with a catalyst. The only other reaction product, sodium metaborate (analogous to borax), is water soluble and environmentally benign. The 35 wt% solution (35 wt% NaBH_4 , 3 wt% NaOH , 62 wt% H_2O) will store 7.7 wt% of hydrogen or 77 g/921 standard liters of hydrogen in one liter of solution.

DaimlerChrysler has presented a fuel cell vehicle, the *Natrium*, that incorporates a sodium borohydride tank of about the size of a regular gas tank, which can power the concept vehicle about 300 miles.

There are numerous questions regarding production, energy efficiency, infrastructure, and stability of the solutions (Millenium quotes a half-life of 450 days, equivalent to 0.15% decomposition per day — this would be far less than the liquid hydrogen boil-off). The technique may well have its merits for special applications, particularly if an environmentally benign production process can be developed.

Fuel Reforming

Hydrogen is currently produced in large quantities for mainly two applications. Roughly 50% of the world hydrogen production is consumed for the hydro-formulation of oil in refineries producing mainly automotive fuels. Approximately 40% is produced for subsequent reaction with nitrogen to ammonia, the only industrial process known to bind atmospheric nitrogen. Ammonia is used in a number of applications, with fertilizer production playing a key role.

Storage of some hydrocarbon-derived liquid fuel followed by hydrogen generation on-board vehicles has been one option for chemical storage of hydrogen. So far, practical prototype cars have only been produced with methanol reformers (DaimlerChrysler). In contrast, the work on gasoline reformers by GM/Toyota/Exxon on the one hand and HydrogenSource (Shell Hydrogen and UTC Fuel Cells) on the other has not yet led to working fuel cell prototype cars.

Fortunately, there is no dispute about natural gas reforming for stationary power generation. An exhaustive discussion of the catalysis involved in fuel processing is presented in [Trimm, 2001].

The main techniques are briefly described in the following.

Steam Reforming (SR)

Steam reforming, SR, of methanol is given by the following chemical reaction equation:

Methanol and water are evaporated and react in a catalytic reactor to carbon dioxide and hydrogen, the desired product. Methanol steam reforming is currently performed at temperatures between 200 and 300°C (390 and 570°F) over copper catalysts supported by zinc oxide [Emonts, 1998]. One mole of methanol reacts to three moles of dihydrogen. This means that an extra mole of hydrogen originates from the added water.

In practice, reaction (77.14) is only one of a whole series, and the raw reformer output consists of hydrogen, carbon dioxide, and carbon monoxide. Carbon monoxide is converted to carbon dioxide and more hydrogen in a high temperature shift, HTS, stage followed by a low temperature shift, LTS, stage. In both stages, the *water-gas shift reaction*

takes place.

As water-gas shift is an exothermal reaction, if too much heat is generated, it will eventually drive the reaction towards the reactant side (Le Chatelier's principle). Therefore, multiple stages with interstage cooling are used in practice. The best catalyst for the HTS reaction is a mixture of iron and chromium oxides (Fe_3O_4 and Cr_2O_3) with good activity between 400 and 550°C (750 and 1020°F). LTS uses copper catalysts similar to and under similar operating conditions to those used in methanol steam reforming (77.14).

Steam reforming of methane from natural gas is the standard way of producing hydrogen on an industrial scale. It is therefore of general importance to a hydrogen economy. In addition, smaller-scale methane steam reformers have been developed to provide hydrogen for stationary power systems based on low-temperature fuel cells, PEMFC and PAFC.

The methane steam reforming reaction is described by

It is again followed by the shift reactions (77.15).

Methane steam reforming is usually catalyzed by nickel [Ridler, 1996] at temperatures between 750 and 1000°C (1380 and 1830°F), with excess steam to prevent carbon deposition ("coking") on the nickel catalyst [Trimm, 2001].

Partial Oxidation (POX)

The second important reaction for generating hydrogen on an industrial scale is partial oxidation. It is generally employed with heavier hydrocarbons or when there are special preferences because certain reactants (for example, pure oxygen) are available within a plant.

It can be seen as oxidation with less than the stoichiometric amount of oxygen for full oxidation to the stable end products, carbon dioxide and water. For example, for methane

and/or

While the methanol reformers used in fuel cell vehicles presented by DaimlerChrysler are based on steam reforming, Epyx (a subsidiary of Arthur D. Little, now part of Nuvera) and Shell (now incorporated into HydrogenSource) are developing partial oxidation reactors for processing gasoline.

Autothermal Reforming (ATR)

Attempts have been made to combine the advantages of both concepts, steam reforming and partial oxidation. Ideally, the exothermic reaction (77.17) would be used for startup and for providing heat to the endothermic process (77.16) during steady-state operation. The reactions can either be run in separate reactors that are in good thermal contact or in a single catalytic reactor.

Comparison of Reforming Technologies

So, when does one use which technique for reforming? The first consideration is the ease by which the chosen fuel can be reformed using the respective method. Generally speaking, methanol is most readily reformed at low temperatures and can be treated well in any type of reformer. Methane and, similarly, LPG (liquefied petroleum gas) require much higher temperatures but again can be processed by any of the methods discussed. With higher hydrocarbons, the current standard fuels used in the automotive sector, one usually resorts to POX reactors.

Table 77.2 compares the theoretical (thermodynamic) efficiencies for proton exchange membrane fuel cells operating directly (DMFC) or indirectly on methanol (using one of the reformers discussed). The efficiencies currently achieved are labeled $\eta_{el}(tech)-typ$, while the technical limits are estimated by the author at $\eta_{el}(tech)-max$.

Table 77.3 and Table 77.4 show gas compositions from methanol reformers calculated as upper limit (by the author) and determined experimentally, respectively. Table 77.3 also includes information on the feed mix, i.e., X, the molar percentage, and wt%, the weight percentage of methanol in the methanol/water feed. A disadvantage of the POX reactors is the presence of nitrogen (from partial oxidation with ambient air) in the reformer output. This leads to lower hydrogen concentrations.

TABLE 77.2 Thermodynamics of PEM Fuel Cell Systems Operating on Methanol

| | ΔH [kJ/mol] | ΔG [kJ/mol] | η_{el} (theor.) | η_{el} (tech) – typ | η_{el} (tech) – max |
|----------------------------|---------------------|---------------------|----------------------|--------------------------|--------------------------|
| DMFC | | -702,35 | 0,97 | 0,27 | 0,40 |
| SR + H ₂ – PEM | 130,98 | -711,39 | 0,83 | 0,32 | 0,54 |
| POX + H ₂ – PEM | -154,85 | -474,26 | 0,65 | 0,25 | 0,42 |
| ATR + H ₂ – PEM | 0 | -602,73 | 0,83 | 0,32 | 0,54 |

Note: The DMFC is a fuel cell that can electro-oxidize methanol directly while the other systems are based on hydrogen fuel cells with reformer: Steam-reformer (SR), partial oxidation reformer (POX), and autothermal (ATR) reformer. The efficiencies have been determined by thermodynamics (theo.) or estimated by the author (typ./max.).

TABLE 77.3 Stoichiometric Input Feed and Output Gas Compositions for Different Concepts of Methanol Reforming

| | X (MeOH) | wt% MeOH | H ₂ | CO ₂ | N ₂ |
|----------------------------|----------|----------|----------------|-----------------|----------------|
| DMFC | 0,5 | 64 | | | |
| SR + H ₂ – PEM | 0,5 | 64 | 75% | 25% | 0% |
| POX + H ₂ – PEM | 1,0 | 100 | 41% | 20% | 39% |
| ATR + H ₂ – PEM | 0,65 | 77 | 58% | 23% | 20% |

TABLE 77.4 Experimental Gas Compositions Obtained as Reformer Outputs

| | H ₂ | CO ₂ | N ₂ | CO |
|---------------|----------------|-----------------|----------------|----|
| SR [PASE 00] | 67% | 22% | – | |
| POX [PASE 00] | 45% | 20% | 22% | |
| ATR [GOLU 98] | 55% | 22% | 21% | 2% |

Steam reforming gives the highest hydrogen concentration. At the same time, a system relying entirely on steam reforming operates best under steady-state conditions because it does not lend itself to rapid dynamic response. This also applies to startup. Partial oxidation, in contrast, offers compactness, fast startup, and rapid dynamic response, while producing lower concentrations of hydrogen. In addition to differences in product stoichiometries between SR and POX reformers, the output of a POX reformer is necessarily further diluted by nitrogen. Nitrogen is introduced into the system from air, which is usually the only economical source of oxygen, and carried through as an inert. Autothermal reforming offers a compromise.

Yet, the fuel processor cannot be seen on its own. Steam reforming is highly endothermic. Heat is usually supplied to the reactor, for example, by burning extra fuel. In a fuel cell system, (catalytic) oxidation of excess hydrogen exiting from the anode provides a convenient way of generating the required thermal energy. In stationary power generation, it is worth considering that the PAFC fuel cell stack operates at a high enough temperature to allow generating steam and feeding it to the fuel processor. Steam reforming may be appropriate here whereas autothermal reforming could be considered in a PEMFC system, which has only low-grade heat available.

Fuel efficiency also deserves careful attention. Though always important, the cost of fuel is the most important factor in stationary power generation (on a par with plant availability). Hence, the method offering the highest overall hydrogen output from the chosen fuel, usually natural gas, is selected. Steam reforming delivers the highest hydrogen concentrations. Therefore, the fuel cell stack efficiency at the higher hydrogen content may offset the higher fuel demand for steam generation. This is probably the reason why steam reforming is currently also the preferred method for reforming natural gas in stationary power plants based on PEM fuel cells.

In automotive applications, the dynamic behavior of the reformer system may control the whole drive train, depending on whether backup batteries, super-capacitors or other techniques are used for providing peak power. A POX reformer offers the required dynamic behavior and fast startup and is likely to be the best choice with higher hydrocarbons. For other fuels, in particular, methanol, an ATR should work best. Yet, the reformers used by DaimlerChrysler in their NECAR 3 and 5 vehicles are steam reformers. This perhaps surprising choice can be reconciled when one considers that during startup, additional air is supplied to the reformer system to do a certain degree of partial oxidation. During steady-state operation, the reformer operates solely as SR with heat supplied from excess hydrogen. Clearly, it is not always possible to draw clear borderlines between different types of reformers.

Striking advantages of liquid fuels are their high energy storage densities and their ease of transport and handling. Liquid fuel tanks are readily available, and their weight and volume are essentially dominated by the fuel itself. LPG is widely applied in transportation in some countries, and storage is comparably straightforward since LPG is readily liquefied under moderate pressures (several bar).

CO Removal/Pd-Membrane Technology

As was noted in the introduction to this chapter, different fuel cells put different demands on gas purity. CO removal is of particular concern to the operation of the PEMFC, less so with fuel cells operating at higher temperatures.

After reforming and water gas shift, the CO concentration in the reformer gas is usually reduced to 1 to 2%. A PEMFC will require further cleanup down to levels in the lower ppm range. Another reason for having further CO cleanup stages is the risk of CO spikes, which may result from rapid load changes of the reformer system as can be expected from automotive applications.

There are a number of ways to clean the raw reformer gas of CO. Alternatively, ultra-pure hydrogen void of any contaminant can be produced using Pd membrane technology.

We will discuss these methods in turn.

Preferential Oxidation

Oxidative removal of CO is one option often applied in fuel cell systems working with hydrocarbon reformers. Unfortunately, this increases the system complexity because well-measured concentrations of air have to be added to the fuel stream.

The reaction

works surprisingly well despite the presence of CO_2 and H_2 in the fuel gas. This is due to the choice of catalyst, which is typically a noble metal such as platinum, ruthenium, or rhodium supported on alumina. Gold catalysts supported on reducible metal oxides have also shown some benefit, particularly at temperatures below 100°C [Plzak, 1999]. CO bonds very strongly to noble metal surfaces at low to moderate temperatures. So, the addition reaction (77.18) takes place on the catalytic surface, in preference to the undesirable direct catalytic oxidation of hydrogen. Therefore, this technique is referred to as preferential oxidation, or PROX. The selectivity of the process has been defined as the ratio of oxygen consumed for oxidizing CO divided by the total consumption of oxygen.

The term selective oxidation, or SELOX, is also used. But this should better be reserved for the case where CO removal takes place *within* the fuel cell.

An elegant way of making the fuel cell more carbon monoxide-tolerant is the development of CO-tolerant anode catalysts and electrodes [Cooper, 1997]. A standard technique is the use of alloys of platinum and ruthenium. Another, rather crude, way of overcoming anode poisoning by CO is the direct oxidation of CO by air in the anode itself [Gottesfeld, 1988]. One may see this as an internal form of the preferential oxidation discussed above. In order to discriminate the terminology, this method is often referred to as selective oxidation or SELOX. The air for oxidizing CO is “bled” into the fuel gas stream at concentrations of around 1%. Therefore, this technique has been termed *air bleed*. It is a widely accepted way of operating fuel cells on reformer gases.

Bauman et al. have also shown that anode performance after degradation due to CO “spikes,” which are likely to appear in a reformer-based fuel cell system upon rapid load changes, recovers much more rapidly when an air bleed is applied [Bauman, 1999].

Pd-Membranes

In some industries, such as the semiconductor industry, there is a demand for ultra-pure hydrogen. Since purchase of higher-grade gases multiplies the cost, hydrogen is either generated on site or low-grade hydrogen is further purified.

A well-established method for hydrogen purification (and only applicable to hydrogen) is permeation through palladium membranes [McCabe, 1997], and plug-and-play hydrogen purifiers are commercially available. Palladium only allows hydrogen to permeate and retains any other gas components, such as nitrogen, carbon dioxide, carbon monoxide, and any trace impurities, on the upstream side. As carbon monoxide adsorbs strongly onto the noble metal, concentrations in the lower percent range may hamper hydrogen permeation through the membrane, unless membrane operating temperatures high enough to oxidize carbon monoxide (in the presence of some added air) to carbon dioxide are employed. In a practical test, operating temperatures in excess of 350°C and operating pressures above 20 hPa (20 bar or 290 PSI) had to be used [Emonts, 1998].

For economic reasons, thin film membranes consisting of palladium/silver layers deposited on a ceramic support are being developed. Thin film membranes allow reducing the amount of palladium employed and improve the permeation rate. Silver serves to stabilize the desired metallic phase of palladium under the operation conditions. Yet, thermal cycling and hydrogen embrittlement pose potential risks to the integrity of membranes no thicker than a few microns [Emonts, 1998].

The main problems with palladium membranes in automotive systems appear to be the required high pressure differential, which takes its toll from overall systems efficiency, the cost of the noble metal, and/or membrane lifetime. Other applications, in particular compact power generators, may benefit from reduced system complexity.

A number of companies, including Misubishi Heavy Industries [Kuroda, 1996] and IdaTech [Edlund, 2000], have developed reformers based on Pd membranes. Here, the reforming process takes place inside a membrane tube or in close contact with the Pd membrane. IdaTech achieved CO and CO_2

levels of less than 1 ppm with a SR operating inside the actual cleanup membrane unit using a variety of fuels.

Methanation

Methanation,

is another option for removing CO in the presence of large quantities of H₂.

Unfortunately, due to current lack of selective catalysts, the methanation of CO₂ is usually also catalyzed. Therefore, for cleaning up small concentrations of CO in the presence of large concentrations of CO₂, methanation is not possible. IdaTech uses methanation in conjunction with Pd-membranes as second cleanup stage. This is possible in this particular instance because the membrane removes both CO and CO₂ down to ppm levels.

Other System Components

Fuel Cell Stack

Figure 77.1 demonstrates how MEAs are supplied with reactant gases and put together to form a fuel cell stack. The gas supply is a compromise between the flat design necessary for reducing ohmic losses and sufficient access of reactants. Therefore, so-called flow field plates are employed to feed hydrogen to the anodes and air/oxygen to the cathodes present in a fuel cell stack. Other stack components include cooling elements, current collector plates for attaching power cables, end plates, and, possibly, humidifiers. End plates give the fuel cell stack mechanical stability and enable sealing of the different components by compression. A number of designs have been presented. Ballard Power Systems has used both threaded rods running along the whole length of the stack and metal bands tied around the central section of the stack for compression.

Bipolar Plates

Flow field plates in early fuel cell designs — and still in use in the laboratory — were usually made of graphite into which flow channels were conveniently machined. These plates have high electronic and good thermal conductivity and are stable in the chemical environment inside a fuel cell. Raw bulk graphite is made in a high-temperature sintering process that takes several weeks and leads to shape distortions and the introduction of some porosity in the plates. Hence, making flow field plates is a lengthy and labor-intensive process, involving sawing blocks of raw material into slabs of the required thickness, vacuum-impregnating the blocks or the cut slabs with some resin filler for gas-tightness, and grinding and polishing to the desired surface finish. Only then can the gas flow fields be machined into the blank plates by a standard milling and engraving process. The material is easily machined but abrasive. Flow field plates made in this way are usually several millimeters (1 mm = 0.04 inch) thick, mainly to give them mechanical strength and allow the engraving of flow channels. This approach allows the greatest possible flexibility with respect to designing and optimizing the flow field.

When building stacks, flow fields can be machined on either side of the flow field plate such that it forms the cathode plate on one and the anode plate on the other side. Therefore, the term *bipolar plate* is often used in this context. The reactant gases are then passed through sections of the plates and essentially the whole fuel cell stack — compare Figure 77.1.

Graphite-Based Materials

The choice of materials for producing bipolar plates in commercial fuel cell stacks is not only dictated by performance considerations but also cost. Present blank graphite plates cost between US\$20 and US\$50 apiece in small quantities, i.e., up to US\$1000/m², or perhaps over US\$100 per kW assuming one plate per MEA plus cooling plates at an MEA power density of 1 Wcm⁻². Again, automotive cost targets are well beyond reach, even ignoring additional machining and tooling time.

This dilemma has sparked off several alternative approaches. Ballard Power Systems has developed plates based on (laminated) graphite foil, which can be cut, molded, or carved in relief in order to generate a flow field pattern. This may open up a route to low-cost volume production of bipolar plates. Potential concerns are perhaps the uncertain cost and the availability of the graphite sheet material in large volumes.

Another cost-effective volume production technique is injection or compression molding. Difficulties with molded plates lie in finding the right composition of the material, which is usually a composite of graphite powder in a polymer matrix. While good electronic conductivity requires a high graphite fill, this hampers the flow and hence the moldability of the composite. Thermal stability and resistance towards chemical attack of the polymers limit the choice of materials.

Plug Power has patented flow field plates that consist of conducting parts framed by nonconducting material, which may form part of the flow field systems.

Metallic Bipolar Plates

Metals are very good electronic and thermal conductors and exhibit excellent mechanical properties. Undesired properties include their limited corrosion resistance and the difficulty and cost of machining.

The metals contained in the plates bear the risk of leaching in the harsh electrochemical environment inside a fuel cell stack; leached metal may form damaging deposits on the electrocatalyst layers or could be ion-exchanged into the membrane or the ionomer, thereby decreasing the conductivity. Corrosion is believed to be more serious at the anode, probably due to weakening of the protective oxide layer in the hydrogen atmosphere.

Several grades of stainless steel (310, 316, 904L) have been reported to survive the highly corroding environment inside a fuel cell stack for 3000 h without significant degradation [Davies, 2000] by forming a protective passivation layer.

Clearly, the formation of oxide layers reduces the conductivity of the materials employed. Therefore, coatings have been applied in some cases. In the simplest case, this may be a thin layer of gold or titanium. Titanium nitride layers are another possibility and have been applied to lightweight plates made of aluminum or titanium cores with corrosion-resistant spacer layers. Whether these approaches are commercially viable depends on the balance between materials and processing costs.

Meanwhile, mechanical machining of flow fields into solid stainless steel plates is difficult. A number of companies such as Microponents (Birmingham, U.K.) and PEM (Germany) are attempting to achieve volume production of flow field plates by employing chemical etching techniques. Yet, etching is a slow process and generates slurries containing heavy metals, and it is hence of limited use for mass production.

Another solution to the problem of creating a (serpentine) flow field is using well-known metal stamping techniques. To date, there appear to be no published data on flow fields successfully produced in this fashion.

Humidifiers and Cooling Plates

A fuel cell stack may contain other components. The most prominent ones are cooling plates or other devices and techniques for removing reaction heat and, possibly, humidifiers.

Cooling is vital to maintain the required point of operation for a given fuel cell stack. This may either be an isothermal condition, or perhaps a temperature gradient may be deliberately superimposed in order to help water removal. Relatively simple calculations show that for very high power densities such as those attained in automotive stacks, liquid cooling is mandatory. This is traditionally done by introducing dedicated cooling plates into the stack, through which water is circulated.

In less demanding applications, such as portable systems, where the system has to be reduced to a bare minimum of components, air cooling is sometimes applied. In the simplest case, the cathode flow fields are open to ambient, and reactant air is supplied by a fan, at the same time providing cooling. No long-term performance data have been reported for this type of air-cooled stack.

A second function sometimes integrated into the stack is reactant humidification. It is currently unknown whether innovative membrane concepts will ever allow unhumidified operation in high-performance fuel cell stacks. In most automotive stacks to date, both fuel gas and air are most likely

humidified because maximum power is required, which is only achieved with the lowest possible membrane resistance.

The literature knows several types of humidifiers, bubblers, membrane, or fiber-bundle humidifiers and water evaporators. The simplest humidifier is the well-known “bubbler,” essentially the wash bottle design with gas directly passing through the liquid. Clearly, this approach allows only poor control of humidification, is less suited within a complex fuel cell system, and may cause a potential safety hazard due to the direct contact of the fluids. Another approach is using a membrane humidifier. A semipermeable membrane separates a compartment filled with water from a compartment with the reactant gas. Ideally, the gas is conducted along the membrane and continually increases its humidity up to or close to saturation as it passes from the gas inlet to the gas outlet. Some concepts combine humidification and cooling [Vitale, 2000].

This concludes the list of the most important functional components of a fuel cell stack. The fuel cell system contains a large number of other components for fuel generation, pumping, compression, etc., which are usually just summarized under the term balance-of-plant, BOP.

Direct Methanol Fuel Cells

No doubt one of the most elegant solutions would be to make fuel cells operate on a liquid fuel. This is particularly so for the transportation and portable sectors. The direct methanol fuel cell (DMFC), a liquid- or vapor-fed PEM fuel cell operating on a methanol/water mix and air, therefore deserves careful consideration. The main technological challenges are the formulation of better anode catalysts, which lower the anode overpotentials (currently several hundred millivolts at practical current densities), and the improvement of membranes and cathode catalysts in order to overcome cathode poisoning and fuel losses by migration of methanol from anode to cathode. Current prototype DMFCs generate up to 0.2 Wcm^{-2} (based on the MEA area) of electric power, but not yet under practical operating conditions or with acceptable platinum loadings.

Therefore, there is currently little hope that DMFCs will ever be able to power a commercially viable car. The strength of the DMFC lies in the inherent simplicity of the entire system and the fact that the liquid fuel holds considerably more energy than do conventional electrochemical storage devices such as primary and secondary batteries. Therefore, DMFCs are likely to find a range of applications in supplying electric power to portable or grid-independent systems with small power consumption but long, service-free operation.

Applications

It now looks as though fuel cells are eventually coming into widespread commercial use. Before starting a fuel cell development project, one should consider the benefits to be expected in the respective application.

[Table 77.5](#) lists a range of applications for each type of fuel cell.

Transportation

In the transportation sector, fuel cells are probably the most serious contenders as competitors to internal combustion engines. They are highly efficient as they are electrochemical rather than thermal engines. Hence they can help to reduce the consumption of primary energy and the emission of CO_2 .

What makes them most attractive for transport applications, though, is the fact that they emit zero or ultra-low emissions. And this is what mainly inspired automotive companies and other fuel cell developers in the 1980s and 1990s to start developing fuel cell-powered cars and buses. Leading developers realized that although the introduction of the three-way catalytic converter had been a milestone, keeping up the pace in cleaning up car emissions further was going to be very tough indeed. Legislation such as California's Zero Emission Mandate has come in and initially, only battery-powered vehicles were seen as a solution to the problem of building zero-emission vehicles. Meanwhile, it has turned out that the storage capacity of batteries is unacceptable for practical use because customers ask for the same drive range they are used to from internal combustion engines (ICEs). In addition, the battery solution is

TABLE 77.5 Currently Developed Types of Fuel Cells and Their Characteristics and Applications

| Fuel Cell Type | Electrolyte | Charge Carrier | Operating Temperature | Fuel | Electric Efficiency (System) | Power Range/ Application |
|-------------------------------------|--|-------------------------------|-----------------------|---|------------------------------|--|
| Alkaline FC (AFC) | KOH | OH | 60–120°C | Pure H ₂ | 35–55% | <5 kW, niche markets (military, space) |
| Proton exchange membrane FC (PEMFC) | Solid polymer (such as Nafion) | H ⁺ | 50–100°C | Pure H ₂ (tolerates CO ₂) | 35–45% | Automotive, CHP (5–250 kW), portable |
| Phosphoric acid FC (PAFC) | Phosphoric acid | H ⁺ | ~220°C | Pure H ₂ (tolerates CO ₂ , approx. 1% CO) | 40% | CHP (200 kW) |
| Molten carbonate FC (MCFC) | Lithium and potassium carbonate | CO ₃ ²⁻ | ~650°C | H ₂ , CO, CH ₄ , other hydrocarbons tolerates CO ₂ | >50% | 200 kW-MW range, CHP and standalone |
| Solid oxide FC (SOFC) | Solid oxide electrolyte (yttria, zirconia) | O ²⁻ | ~1000°C | H ₂ , CO, CH ₄ , other hydrocarbons tolerates CO ₂ | >50% | 2 kW-MW range, CHP and standalone |

unsatisfactory for yet another reason: with battery-powered cars the point where air pollution takes place is only shifted back to the electric power plant providing the electricity for charging. This is the point where fuel cells were first seen as the only viable technical solution to the problem of car-related pollution.

It has now become clear that buses will make the fastest entry into the market because the hydrogen storage problem has been solved with roof-top pressure tanks. Also, fueling is not an issue due to the fleet nature of buses. For individual passenger cars, the future remains unclear. Most developers have now moved away from on-board reforming and promote direct hydrogen storage. Yet, this will require a new fuel infrastructure, which is not easy to establish.

Another automotive application is auxiliary power units (APUs). APUs are designed not to drive the main power train but to supply electric power to all devices on-board conventional internal combustion engines, even when the main engine is not operating. A typical example for a consumer requiring large amounts of power (several kW) is an air-conditioning system. Currently, due to the difficulties with reforming gasoline, high-temperature fuel cells are considered a good option.

Stationary Power

Cost targets were first seen as an opportunity: The reasoning went that, when fuel cells were going to meet automotive cost targets, other applications, including stationary power, would benefit from this development, and a cheap multipurpose power source would become available.

Meanwhile, stationary power generation, in addition to buses, is viewed as the leading market for fuel cell technology. The reduction of CO₂ emissions is an important argument for the use of fuel cells in small stationary power systems, particularly in combined heat and power generation. In fact, fuel cells are currently the only practical engines for micro-CHP systems in the domestic environment at less than, say, 5 kW of electric power output. The higher capital investment for a CHP system would be offset against savings in domestic energy supplies and — in more remote locations — against power distribution cost and complexity. It is important to note that due to the use of CHP, the electrical efficiency is less critical than in other applications. Therefore, in principle all fuel cell types are applicable. In particular, PEMFC systems and SOFC systems are currently being developed in this market segment. PEMFC systems offer the advantage that they can be easily turned off when not required. SOFC systems, with their higher operating temperature, are usually operated continuously. They offer more high-grade heat and provide simpler technology for turning the main feed — natural gas, sometimes propane — into electric power than the more poison-sensitive PEMFC technology.

In the 50 to 500 kW range there will be competition with spark or compression ignition engines modified to run on natural gas. So far, several hundred 200-kW phosphoric acid fuel cell plants manufactured by ONSI (IFC) have been installed worldwide. Yet, in this larger power range, high-temperature fuel cells offer distinct advantages. They allow simpler gas pretreatment than low-temperature fuel cells do and achieve higher electrical efficiencies. This is important when one considers that a standard motor CHP unit at several hundred kilowatts of electric power output will generally achieve close to 40% electrical efficiency — at a fraction of the cost of a fuel cell. High-temperature fuel cells also offer process heat in the form of steam rather than just hot water. Both MCFC and SOFC are currently being developed for industrial CHP systems.

Portable Power

The portable market is less well defined, but a potential for quiet fuel cell power generation is seen in the sub-1kW portable range. The term “portable fuel cells” often includes grid-independent applications such as camping, yachting, and traffic monitoring. Fuels considered vary from one application to another. And fuels are not the only aspect that varies. Different fuel cells may be needed for each subsector in the portable market.

It is currently not clear whether DMFC systems will ever be able to compete with lithium ion batteries in mass markets such as cellular phones or portable computers. But in applications where size does not matter and long, unattended service at low power levels is required, DMFCs are the ideal power source.

There may also be room for hydrogen-fueled PEMFC systems where higher peak power demand is needed for short durations. Storage of hydrogen and the implementation of a supply infrastructure remain problems to be solved.

At more than several hundred watts of electric power, reformer-based systems remain the only option to date. This is the range of the APU (see Transportation, above), and it is likely that similar systems will provide power to yachts and motor homes, mountaineering huts, etc. They may be fueled by propane or perhaps some liquid fuel — compare the following section.

Choice of Fuel

Before even deciding which fuel cell type to use, one needs to identify the best fuel base and the allowable size and complexity of the resulting fuel cell system.

Of the three key applications for fuel cells — automotive propulsion, stationary power generation and portable power — the automotive case is most readily dealt with. For generating the propulsion power of a car, bus, or truck, only PEMFCs are currently being considered for their superior volumetric power density with operation on hydrogen. Leading developers originally favored hydrogen generation from methanol on board and, more recently, either hydrogen generation from reformulated gasoline on board or hydrogen storage on board. As hydrogen generation from gasoline is technically difficult, questionable for energy efficiency reasons, and methanol as a fuel base has been demonstrated but is unwanted by most developers, hydrogen storage on board appears to emerge as the overall compromise. Moreover, automotive propulsion is still at least 10 years away from widespread market introduction; it is a highly challenging, specialist job that is well underway at the leading developers’ laboratories — and it should be left there.

The other extreme is portable power, where again the PEMFC is the only fuel cell seriously considered. In this case, there are two options for fuel, hydrogen or direct methanol, i.e., without prior conversion to hydrogen. The latter type of PEMFC is usually referred to as DMFC. For systems larger than, say, 1 kW that operate continuously, direct methanol is not an option because of the expense of the fuel cell. Direct hydrogen is not an option because of the lack of storage capacity. Therefore, one may consider converting a chemical such as LPG, propane, butane, methanol, gasoline, or diesel into hydrogen. Such larger systems will be considered among the stationary power systems.

Stationary power generation, at the first glance, is the least clear application in terms of the technology base: four types of fuel cell are currently being developed for stationary power generation.

In contrast, the fuel base is rather clear in this particular case: for residential and small combined heat and power generation, natural gas is the usual source of energy, and fuel cell systems have to adapt to this fuel. In areas without a gas — and electricity — grid, LPG may be an option and is being actively pursued by a number of developers.

[Table 77.6](#) summarizes the most likely applications and fueling options for all types of fuel cells.

Defining Terms

AFC — Alkaline fuel cell.

APU — Auxiliary power unit — supplying electric power to cars independent of the main engine.

Bipolar plate — Metal, graphite or composite plate separating two adjacent cells in planar PEMFC, AFC, PAFC, and MCFC stacks (possibly also planar SOFC). One side consequently acts as positive electrode (cathode), while the opposite side acts as negative electrode (anode) to the following cell. The two sides contain channels to distribute the reactants, usually hydrogen-rich gas (anode) and air (cathode).

CHP — Combined heat and power generation.

DMFC — Direct methanol fuel cell. Liquid or vaporized methanol/water fueled version of PEMFC.

Humidifier — Unit required for providing high water vapor concentration in inlet gas streams of PEMFC.

MCFC — Molten carbonate fuel cell.

MEA — Membrane electrode assembly — central electrochemical part of a PEMFC. Consists of anode, cathode and membrane electrolyte.

PAFC — Phosphoric acid fuel cell.

PEMFC — Proton exchange membrane fuel cell — also called SPFC.

Reformer — Gas or liquid processing unit providing hydrogen-rich gas to run fuel cells off readily available hydrocarbon fuels such as methane, methanol, propane, gasoline, or diesel.

SPFC — Solid polymer fuel cell — see PEMFC.

SOFC — Solid oxide fuel cell.

Stack — Serial combination (pile) of alternating planar cells and bipolar plates in order to increase the overall voltage.

TABLE 77.6 Fuel Cell Applications and Likely Fueling Options

| Fuel Cell | Automotive | | Portable | | Stationary | | |
|-----------|--|--|---|---|--|---|--|
| | Main Drive Train | Auxiliary Power | Battery Replacement Long Operation, Low Power | Battery Replacement Short Operation, High Power | Residential Remote Power or Residential Heat and Power (few kW range) | Small-Scale Heat and Power (100 kW to several MW) | Large Central Power Station (many MW) |
| PEMFC | 50 to 100 kW hydrogen powered (liquid or compressed) other fuels less likely | Less likely | 0.1 to 500 W direct methanol powered = DMFC | 100 W to few kW hydrogen (compressed or metal hydride) | 1 to 10 kW natural gas or LPG powered (possibly methanol or fuel oil) | 100 kW to 10 MW natural gas powered less likely | |
| MCFC | | Less likely | | | Less likely | 100 kW to 10 MW natural gas powered | Perhaps, in combination with gas turbine coal gas fired |
| SOFC | | Several kW gasoline or diesel powered | | | 1 to 10 kW natural gas or LPG powered | 100 kW to 10 MW natural gas powered | Perhaps, in combination with gas turbine coal gas fired |
| PAFC | | | | | | 100 kW to 10 MW natural gas powered less likely | |

Oak Ridge National Laboratory

This chapter presents a brief overview of reaction kinetics primarily for engineers who are not directly involved in the investigation of reaction kinetics or in the design of chemical reactors. For a comprehensive treatise on reaction kinetics, the reader should consult the references at the end of the chapter.

In contrast to the static and equilibrium concept of thermodynamics, reaction kinetics is concerned with dynamics of chemical changes. Thus, reaction kinetics is the science that investigates the rate of such chemical changes as influenced by various process parameters and attempts to understand the mechanism of the chemical changes. For any reaction system to change from an initial state to a final state, it must overcome an energy barrier. The presence of such an energy barrier is commonly manifested in the observed relationship between the reaction rate and temperature, which will be discussed in some detail in the sections that follow.

78.1 Fundamentals

Basic Terms and Equations

One of the key terms in reaction kinetics is the **rate of reaction**, r_A , the general definition of which is given by

$$r_A = \frac{1}{y} \frac{dN_A}{dt} \quad (78.1)$$

which expresses the rate r_A as the amount of a chemical component of interest being converted or produced per unit time per unit quantity of a reference variable y [e.g., volume of reacting mixture (V) or of reactor (V_R), mass (W), surface area (S), etc.]. It delineates the time dependence of chemical changes involving component A as a derivative. In homogeneous fluid reactions, y is normally represented by V or V_R , whereas the mass (W) or the surface area (S) of the solid reactant may be taken as y in heterogeneous solid–fluid reactions. Here, N_A refers to the amount of component A , and t is time. By convention, r_A is negative when A is a reactant and positive when A is a product. Molal units are commonly used as the

amount of N_A , but other units such as mass, radioactivity, pressure, and optical property are also used. When V remains constant (as in a liquid-phase batch reactor), Equation (78.1) is simplified to

$$r_A = dC_A / dt \quad (78.2)$$

where C_A represents the concentration of component A.

Rate Constant and Elementary Reactions

In general, the rate of reaction in terms of component i is a function of the concentration of all components participating in the reaction, C ; the temperature, T ; the pressure, P ; and other parameters, m :

$$r_i = \text{function}(C, T, P, m) \quad (78.3)$$

Thus, the rate expression for a simple irreversible reaction in terms of the reacting components may assume the following form:

$$-r_A = k(C_A)^{n_1}(C_B)^{n_2} \dots (C_i)^{n_i} \quad (78.4)$$

The proportionality constant, k , is the **rate constant** that is markedly influenced by the temperature and may be subject to the influence of pressure, pH, kinetic isotopes, and so on, and the presence of catalysts. The exponents n_1, n_2, \dots, n_i are *orders of reaction* with respect to individual reacting components A, B, ..., i. The *overall order of reaction* refers to the sum of n_1, n_2, \dots, n_i , which does not have to be an integer and may be determined empirically.

The units and value of rate constant k vary with the units of C , the specific component that k refers to, and the reaction order. The effect of temperature on k was first described by Arrhenius through the following equation:

$$k = A e^{-\frac{E}{RT}} \quad (78.5)$$

where A , termed the *frequency factor*, has the same units as k , E is **activation energy**, and R is the gas law constant. E was considered by Arrhenius as the amount of energy that a reacting system must have in excess of the average initial energy level of reactants to enable the reaction to proceed.

A *simple or elementary* reaction is one in which the order of reaction is identical to the *molecularity* (the number of molecules actually participating in the reaction). Under these circumstances, the chemical stoichiometric equation represents the true reaction mechanism, and the rate equation may therefore be derived directly from the stoichiometric equation. Thus, for an elementary reaction $n_1 A + n_2 B = n_3 D$, the rate equation in terms of disappearance of A would be $-r_A = k(C_A)^{n_1}(C_B)^{n_2}$. The values of n_1 and n_2 in this equation are positive integers.

Complex (or Multiple) Reactions

A reaction that proceeds by a mechanism involving more than a single reaction path or step is termed a *complex reaction*. Unlike elementary reactions, the mechanisms of complex reactions differ considerably from their stoichiometric equations. Most industrially important reactions are complex reactions, the mechanisms of which can often be determined by assuming that the overall reaction consists of several elementary reaction steps. The resulting overall rate expression is then compared with the experimental data, and the procedure is repeated until a desired degree of agreement is obtained. Each of the elementary reaction steps may proceed *reversibly, concurrently, or consecutively*.

A *reversible reaction* is one in which conversion of reactants to products is incomplete at equilibrium because of an increasing influence of the reverse reaction as the forward reaction approaches equilibrium. For a reversible reaction of the type

the net forward rate of reaction in terms of disappearance of A is

$$-r_A = k_f C_A C_B - k_r C_D C_E \quad (78.6)$$

which assumes both forward and reverse reactions to be elementary.

A simple example of *consecutive reaction* is illustrated by

Again, assuming an elementary reaction for each reaction step, the following rate equations result:

$$-r_A = k_1 C_A \quad (78.8)$$

$$r_D = k_2 C_B \quad (78.9)$$

$$r_B = k_1 C_A - k_2 C_B \quad (78.10)$$

Parallel or *simultaneous reactions* are those involving one or more reactants undergoing reactions of more than one scheme, as in

The rate equation may assume the following forms:

$$-r_A = k_1 (C_A)^a + k_2 (C_A)^b \quad (78.11)$$

$$r_B = k_1 (C_A)^a \quad (78.12)$$

$$r_D = k_2 (C_A)^b \quad (78.13)$$

Under a constant-volume condition, $r_B = dC_B/dt$ and $r_D = dC_D/dt$. Therefore, the relative rate of formation of B and D is derived from Equation (78.12) and Equation (78.13) as

$$dC_B/dC_D = (k_1/k_2)(C_A)^{a-b} \quad (78.14)$$

The ratio dC_B/dC_D is termed the *point selectivity*, which is the ratio of the *rate* of formation of product B to the *rate* for product D . The *overall* (or *integrated*) *selectivity* is obtained by integration of this ratio, and it represents the ratio of the overall *amount* of product B to that of product D . Equation (78.14) implies that the relative rate of formation of B is proportional to C_A when $a > b$, whereas it is inversely proportional to C_A when $a < b$.

In a chemical process involving complex reactions that consist of several reaction steps, one or more steps may represent major factors in governing the overall rate of reaction. Such reaction steps are termed the **rate-controlling steps**. The rate-controlling reaction steps are observed in homogeneous complex reactions and heterogeneous reactions.

Uncatalyzed Heterogeneous Reactions

Heterogeneous reactions involve more than one phase (e.g., gas–liquid, gas–solid, liquid–solid, and gas–liquid–solid) and are generally more complicated than homogeneous reactions are due to interaction between physical and chemical processes; that is, reactants in one phase have to be transported (physical process) to the other phase, containing other reactants where the reactions take place.

In a gas–solid reaction, for example, the reaction may proceed in several steps, as follows:

1. Reactants in the gas phase diffuse to the gas–solid interface.
2. When there is a layer of solid product and/or inert material at the interface (e.g., ash), the reactants from the gas phase would have to diffuse through this layer before they can reach the unreacted solid core containing other reactants.
3. The chemical reaction takes place between the reactants from the gas phase and those in the unreacted solid core.
4. The reaction products diffuse within the solid phase and/or diffuse out of the solid phase into the bulk of gas phase.

The step that controls the overall reaction rate will be determined by the nature of the phases and specific reactions involved and by process conditions. Thus, the overall reaction rate is subject to the influence of parameters that affect both the physical and chemical processes, including (a) patterns of phase contact, (b) the reactor geometry, (c) fluid dynamic factors (e.g., velocity and degree of turbulence), (d) interfacial surface area, (e) mass transfer factors, (f) chemical kinetics of reactions involved, and (g) process parameters (e.g., temperature and pressure). Some of these parameters may interact with one another. For example, in a reaction involving two distinct fluid phases (e.g., gas–liquid or liquid–liquid), parameters (d) and (e) would be affected by parameter (c).

The overall reaction rate expression of a heterogeneous reaction is fairly complex, since it considers all of these parameters. Further, the form of rate equation varies with the type of heterogeneous reaction system and with the nature of the controlling step. Some examples of the industrially significant uncatalyzed heterogeneous reactions are given in [Table 78.1](#).

Homogeneous and Heterogeneous Catalytic Reactions

A catalytic reaction is a chemical reaction, the rate of which is modified in the presence of a catalyst. A **catalyst** is a substance that may or may not change chemically during the reaction and is regenerated at the end of the reaction. The catalytic reaction proceeds appreciably faster than does an uncatalyzed reaction, presumably because an intermediate compound, formed between the catalyst and some reactants, reacts with other reactants by a mechanism that requires a lower activation energy to form desired products. In *homogeneous catalysis* the catalyst forms a homogeneous phase with the reaction mixture. In *heterogeneous catalysis*, however, the catalyst is present in a phase different from that of the reaction mixture.

Homogeneous Catalysis

Most homogeneous catalysis takes place in the liquid phase. Perhaps the most widely studied type of liquid-phase catalysis is the acid-base catalysis that exerts influence on the rates of many important organic reactions, including (a) esterification of alcohols, (b) hydrolysis of esters, and (c) inversion of sugars. One of the industrially important gas-phase catalytic reactions is the oxidation of SO_2 to SO_3 in the production of sulfuric acid, catalyzed by nitric oxide in the lead chamber.

TABLE 78.1 Examples of Uncatalyzed Heterogeneous Reactions

| Gas-Liquid Reactions | Liquid-Solid Reactions |
|--|---|
| Production of ammonium nitrate by reaction between ammonia gas and nitric acid | Reaction of aqueous sulfuric acid with phosphate rock |
| Hydrogenation of vegetable oil with hydrogen gas | Ion exchange process |
| Production of nitric acid by absorption of nitric oxide in water | Recovery of uranium by leaching of uranium ores with sulfuric acid |
| Gas-Solid Reactions | Solid-Solid Reactions |
| Gasification of coal | Production of calcium carbide by reaction of carbon with lime |
| Production of hydrogen gas by reaction of steam with iron | Production of Portland cement by reaction of limestone with clay |
| Production of volatile uranium chloride by reaction of uranium oxide with chlorine gas | Production of glass by melting a mixture of calcium carbonate, sodium carbonate, and silica |
| Liquid-Liquid reactions | Gas-Liquid-Solid Reaction |
| Aqueous sulfuric acid treatment of petroleum liquid | Liquefaction of coal by reaction of hydrogen with coaloil slurry |
| Nitration of organic solvents with aqueous nitric acid | |
| Production of soaps by reaction of aqueous alkalies and fatty acids | |

Solid-Catalyzed Reaction

This reaction, the most common type of heterogeneous catalysis, finds extensive applications in many important industrial processes that produce inorganic and organic chemicals. Well-known examples of such chemicals include HNO_3 , HCl , ammonia, aniline, butadiene, ethanol, formaldehyde, methanol, organic polymers, and petrochemicals. The generally accepted, simplified mechanism of solid-catalyzed fluid (gas or liquid) phase reactions is outlined as follows:

1. Reactants diffuse from the main body of the fluid phase to the exterior surface of catalyst pellets and subsequently into catalyst pores.
2. Reactants are adsorbed onto both the catalyst exterior and pore surfaces.
3. Products are formed from interaction of the reactants on the surfaces (catalyst exterior and pore).
4. Products thus formed are desorbed (or released) from the surfaces; those formed on the pore surface are released to the fluid phase within the pores and then diffuse out of pores to the exterior surface of the catalyst pellet.
5. Products then diffuse from the exterior surfaces into the bulk of the fluid phase.

The relative importance of these steps in influencing the overall reaction rate depends upon a variety of factors, among which are thermal factors, fluid dynamic factors, properties of the catalyst, and diffusion characteristics of the reactants and products. Besides the process steps described earlier, there are various deactivation processes that cause loss of catalytic efficiency, such as fouling and poisoning.

78.2 Analysis of Kinetic Data

Data Acquisition

Because chemical reactions involved in most industrial processes are complex, development of the database for the design of the chemical reactor facility can be quite time consuming. Accordingly, selection of experimental methods and equipment for acquisition of kinetic data is crucial in determining the development cost as well as the accuracy and reliability of the data obtained. In essence, the selection process is concerned with both the methods and the equipment to conduct the reactions and to monitor the progress of the reactions. The type of equipment to be used is generally determined by the experi-

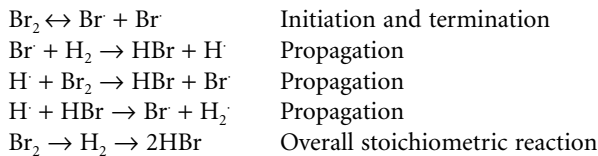

mental method for data acquisition. Acquisition of the kinetic data for homogeneous reactions is frequently carried out using a batch reactor because of its relatively simple design and versatility. In heterogeneous reactions, a flow reactor is often utilized for the data acquisition. For detailed discussion on various methods and equipment for obtaining the experimental kinetic data, the reader is referred to the references at the end of the chapter.

Evaluation of Reaction Mechanism

Understanding of the reaction mechanism is important in the selection and design of an industrial reactor for a specific reaction. Full elucidation of the mechanism, however, is not always possible, in which case derivation of the rate equation may have to resort to the empirical method (see the following subsection). No simple standardized method is available for evaluation of the reaction mechanism. Nevertheless, a trial-and-error method is often used based on the experimental kinetic data acquired — including analysis of the reaction mixture to determine the distribution of the residual reactants, intermediates, and final products — following these steps:

1. Assume a simple elementary reaction mechanism and a corresponding stoichiometry and derive a rate equation from the assumed mechanism.
2. Evaluate the experimental data based on the proposed reaction mechanism and the corresponding rate equation using the integral method (described in the section to follow) first since it is relatively easy to use.
3. If the experimental data do not agree with the proposed mechanism, possibly suggesting a non-elementary reaction, propose a new mechanism that consists of several elementary reaction steps with formation of intermediate compounds.
4. Develop rate equations for individual elementary reaction steps and combine the individual rate equations to represent the overall rate expression.
5. If the experimental kinetic data do not fit into the rate equation developed above, assume an alternate mechanism, and repeat step 4. Continue this process until a desired degree of agreement is reached between the experimental data and the rate expression.
6. Evaluation of the reaction mechanism may also be accomplished using the differential method (see the next subsection), especially for complicated reactions. The method of approach is similar to that using the integral method, but it requires more accurate and extensive experimental data.

An example of a nonelementary complex reaction consisting of several elementary reaction steps is the formation of hydrogen bromide from hydrogen and bromine:

Based on the above reaction mechanism, the following rate equation has been derived:

$$r_{\text{HBr}} = \frac{k_1 C_{\text{H}_2} C_{\text{Br}_2}^{0.5}}{1 + k_2 (C_{\text{HBr}} / C_{\text{Br}_2})} \quad (78.15)$$

Development of Rate Equation

For reactions with simple mechanisms under isothermal conditions, either the integral method or the differential method (discussed in a later section) may be used in the derivation of rate equations. It is

assumed that the data representing the extent of an isothermal reaction are available in terms of the time variation of a selected component A .

Integral Method

An elementary reaction mechanism is first assumed; for example, a second-order isothermal homogeneous reaction under *constant-volume* conditions, $A + B \rightarrow C + D$, results in the rate equation of the form

$$-r_A = \frac{dC_A}{dt} = kC_A C_B \quad (78.16)$$

and the integrated rate equation becomes

$$kt = \frac{1}{C_{B_0} - C_{A_0}} \ln \frac{C_{A_0}(C_A + C_{B_0} - C_{A_0})}{C_A C_{B_0}} \quad (78.17)$$

where C_{A_0} and C_{B_0} represent the initial concentrations of reactants A and B , respectively. One way to confirm the proposed reaction mechanism is to compute values of k at various values of C_A and t . If the values of k remain nearly constant, the proposed mechanism is accepted. Otherwise, another mechanism is assumed, and the process is repeated until a desired degree of agreement is reached.

When the volume of the reaction mixture varies with the extent of reaction, the rate equation becomes more complicated. In this case, if it is assumed that the volume varies linearly with the extent of reaction, derivation of the rate equation could be simplified. Using the fractional conversion x_A to replace C_A as the variable, the volume V is expressed as

$$V = V_0(1 + f_A x_A) \quad (78.18)$$

Here, V_0 represents the initial volume of the reaction mixture and f_A is the fractional change in V between no conversion and complete conversion with respect to reactant A , as defined by

$$f_A = (V_{x_A=1} - V_{x_A=0}) / V_{x_A=0} \quad (78.19)$$

Thus, for a *variable-volume* reaction, the reaction rate defined by Equation (78.1) assumes the following form,

$$-r_A = -\frac{1}{V} \frac{dN_A}{dt} = -\frac{1}{V_0(1 + f_A x_A)} \frac{d}{dt} N_{A_0}(1 - x_A) \quad (78.20)$$

which simplifies to

$$-r_A = \frac{C_{A_0}}{1 + f_A x_A} \frac{dx_A}{dt} \quad (78.21)$$

and the integrated rate equation is

$$t = C_{A_0} \int_0^{x_A} \frac{dx_A}{(1 + f_A x_A)(-r_A)} \quad (78.22)$$

where $-r_A$ stands for the rate expression for the assumed reaction mechanism to be evaluated. For example, for a first-order homogeneous reaction,

$$-r_A = kC_A = kC_{A_0} \frac{1-x_A}{1+f_A x_A} \quad (78.23)$$

Introducing this expression for $-r_A$ into Equation (78.22),

$$Kt = -\ln(1 - x_A) \quad (78.24)$$

The steps to be taken to evaluate the assumed reaction mechanism for the variable-volume case are identical to those for the constant-volume case.

Differential Method

This approach is based on the direct application of the differential rate equation in the analysis of the experimental kinetic data to determine the reaction mechanism. The method requires more accurate and extensive experimental data than the integral method. The basic principle of the method is illustrated by an example of assumed n th-order reaction under the isothermal and constant-volume condition:

With initially equimolar concentrations of A and B (i.e., $C_A = C_B$), the rate equation may take the following form,

$$-r_A = kC_A^a C_B^b = kC_A^{a+b} = kC_A^n \quad (78.25)$$

which is rearranged into

$$\log(-r_A) = \log(-dC_A/dt) = \log k + n \log C_A \quad (78.26)$$

The assumption of the n th-order reaction mechanism is confirmed if a log-log plot of (dC_A/dt) versus C_A results in a straight line.

The next step is to evaluate the values of the rate constant k and the overall order of reaction n from the plot. With the known values of k and n , the reaction orders with respect to A and B can be determined by the method that follows. Rearranging Equation (78.25),

$$-r_A = kC_A^a C_B^{n-a} = kC_B^n (C_A/C_B)^a \quad (78.27)$$

On further rearrangement,

$$\log\left(-\frac{r_A}{kC_B^n}\right) = a \log(C_A/C_B) \quad (78.28)$$

A log-log plot of Equation (78.28) yields the reaction order a with respect to A , whereas the reaction order b is obtained as the difference between n and a .

Empirical Method

This method, which finds uses when the reaction mechanism appears to be complex, is often based on a mathematical approach using the curve-fitting procedure. The method involves a trial-and-error technique to fit the experimental data to a relatively simple form of the empirical equation, including (a) linear form, $y = a + bx$, (b) semilogarithmic form, $y = ae^{bx}$, (c) logarithmic form, $y = c + ax^n$, and so forth. The initial step usually consists of plotting the experimental data on graph papers of different

coordinates that may produce a straight line. Upon selection of a proper form of the empirical equation, the constants in the empirical equation are determined either by the graphic means or by the analytical technique using the method of averages or the method of least squares. Computer software is available for performing the curve-fitting procedure.

Determination of Rate Constant and Arrhenius Parameters

The rate constant k can be obtained by using either a differential form [e.g., Equation (78.16)] or an integrated form [e.g., Equation (78.17)] of the rate equation. It is an average of values calculated at various experimental kinetic data points (i.e., reactant concentrations at various reaction times).

Arrhenius parameters consist of the activation energy E and the frequency factor A . The value of E may be calculated from the rate constants at two distinct but adjacent temperatures, T_1 and T_2 , as follows:

$$k_1 = Ae^{-E/RT_1}; \quad k_2 = Ae^{-E/RT_2}$$

Combining the above two equations,

$$E = R \frac{\ln(k_2/k_1)}{1/T_1 - 1/T_2} \quad (78.29)$$

The value of A is calculated from one of the Arrhenius equations shown above.

Defining Terms

Activation energy — A parameter associated with the Arrhenius equation and considered by Arrhenius as the energy in excess of the average energy level of reactants required to enable the reaction to proceed.

Catalyst — A substance that accelerates the reaction, presumably by making available a reaction path that requires a lower activation energy. The catalyst may or may not change chemically during the reaction and is regenerated at the end of the reaction.

Rate constant — A proportionality constant in the rate equation. The rate constant is markedly influenced by temperature and, to a lesser degree, by pressure and the presence of catalysts. The units and value of the rate constant depend on the specific chemical component to which it refers, the units for concentration (or other quantity) of the component, and the reaction order.

Rate-controlling step — The slow steps that tend to control the overall rate of reaction. In a complex reaction consisting of several chemical reaction steps (and physical process steps in heterogeneous reaction), the reaction rate (and physical process rate) of one or more steps may be much slower than other steps.

Rate equation — A functional expression describing the relationship between the rate of reaction and the amounts (e.g., concentrations) of selected chemical components participating in the reaction at any time under isothermal condition.

Rate of reaction — The amount of a chemical component of concern being converted or produced per unit time per unit quantity of a reference variable. Examples of the reference variable include the volume of reacting mixture, the reactor volume, the mass of solid (solid–fluid reaction), and the surface area of solid.

H. Scott Fogler
University of Michigan

Chemical reaction engineering (CRE) sets chemical engineers apart from other engineers. Students and professionals can easily learn the elements of CRE because it has a very logical structure. The six basic pillars that hold up what you might call the “temple” of chemical reaction engineering are shown in [Figure 79.1](#).

The pillar structure shown in [Figure 79.1](#) allows one to develop a few basic concepts and then to arrange the parameters (equations) associated with each concept in a variety of ways. Without such a structure, one is faced with the possibility of choosing or perhaps memorizing the correct equation from a multitude of equations that can arise for a variety of reactions, reactors, and sets of conditions. This chapter shall focus on five types of chemical reactors commonly used in industry: **batch**, **semibatch**, **CSTR**, **plug flow**, and **packed bed reactors**. [Table 79.1](#) describes each of these reactors.

By using an algorithm to formulate CRE problems, we can formulate and solve CRE problems in a very logical manner. Step 1 in the CRE algorithm is to begin by choosing the mole balance for one of the five types of reactors shown. In step 2 we choose the rate law and in step 3 we specify whether the reaction is gas or liquid phase. Finally, in step 4 we combine steps 1, 2, and 3 and obtain an analytical solution or solve the equations using an *ordinary differential equation (ODE) solver* [Sacham and Cutlip, 1988].

79.1 The Algorithm

We now address each of the individual steps in the algorithm to design isothermal reactors: (1) mole balances, (2) rate laws, (3) stoichiometry, and (4) combine.

Mole Balances

The general mole balance equation (GBE) on species j in a system volume V is:

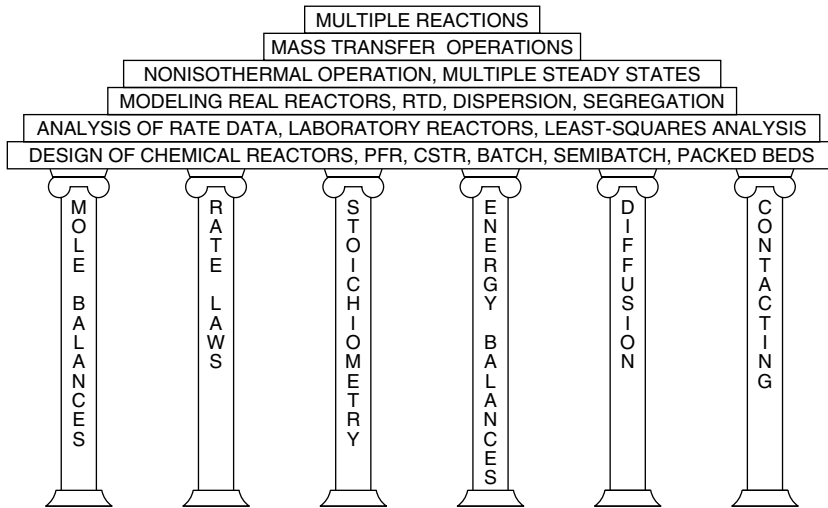

FIGURE 79.1 Pillars of the temple of chemical reaction engineering. (Source: Fogler, H. S. 1992. *The Elements of Chemical Reaction Engineering*, 2nd ed. Prentice Hall, Englewood Cliffs, NJ.)

$$\left[\begin{array}{c} \text{Molar flow} \\ \text{rate} \\ \text{IN} \end{array} \right] - \left[\begin{array}{c} \text{Molar flow} \\ \text{rate} \\ \text{OUT} \end{array} \right] + \left[\begin{array}{c} \text{Molar rate} \\ \text{of} \\ \text{GENERATION} \end{array} \right] = \left[\begin{array}{c} \text{Molar rate} \\ \text{of} \\ \text{ACCUMULATION} \end{array} \right]$$

$$F_{j0} - F_j + \int_0^V r_j dV = \frac{dN_j}{dt} \quad (79.1)$$

We now make use of the definition of conversion, X , with respect to the limiting reactant, which we shall call species A ,

$$X = (N_{A0} - N_A) / N_{A0} \quad \text{Batch} \quad X = (F_{A0} - F_A) / F_{A0} \quad \text{Flow}$$

and apply the GME to each of the following reactors: batch, continuous stirred tank reactors (CSTR), plug flow reactor (PER), and packed bed reactor (PBR). The CSTR, PER, and PBR are all operated as steady state (i.e., $dN_j/dt = 0$) and it is assumed that the PBR and PFR are in plug flow (no radial gradients or dispersion) and that the contents of the CSTR are well mixed. There is no in-flow or out-flow ($F_{j0} = F_j = 0$) in the batch reactor. When these conditions and the definition of conversion are applied to the general mole balance, the design equations [(Equation (79.2) to Equation (79.8)] in [Table 79.2](#) result.

In order to evaluate the design equations given in [Table 79.2](#), we must determine the form of the rate of formation, r_A . We do this with the aid of a rate law.

Rate Laws

The power law model is one of the most commonly used forms for the rate law. It expresses the rate of reaction as a function of the concentrations of the species involved in the reaction.

For the irreversible reaction in which A is the limiting reactant,

TABLE 79.1 Comparison of Five Types of Chemical Reactors

| Type of Reactor | Characteristics | Usage | Advantages | Disadvantages |
|--|---|---|---|--|
| Batch | Reactor is charged (filled) via two holes in the top of the tank; while reaction is carried out, nothing else is put in or taken out until reaction is done; tank easily cooled or heated by jacket | Small-scale production Intermediate or one-shot productions Pharmaceuticals Fermentations | High conversion per unit volume for one pass Same reactor can be used to produce one product one time and a different product the next | High operating cost (labor) Product quality more variable than with continuous operation |
| Semibatch | Either one reactant is charged and the other is fed continuously (at small concentrations) or else one of the products can be removed continuously (to avoid side reactions) | Small-scale production Competing reactions | Good selectivity; feed can be controlled so as to minimize side runs. | High operating labor cost Product quality more variable than with continuous operation |
| Continuously stirred tank reactor (CSTR) | Run at steady state with continuous flow of reactants and products; the feed assumes a uniform composition throughout the reactor, exit stream has the same composition as in the tank | When agitation is required Series configuration for different concentration streams | Continuous operation Good temperature control Good control Simplicity of construction Low operating (labor) cost | Lowest conversion per unit volume Bypassing and channeling possible with poor agitation |
| Plug flow reactor (PFR) | Arranged as one long reactor or many short reactors in a tube bank; no radial variation in reaction rate (concentration); concentration changes with length down the reactor | Large-scale production Homogeneous reactions Heterogeneous reactions Continuous production High temperature | Highest conversion per unit volume Low operating labor cost Continuous operation Good heat transfer | Undesired thermal gradients may exist Poor temperature control Shutdown, cleaning may be expensive |
| Tubular packed bed reactor (PBR) | Tubular reactor that is packed with solid catalyst particles | Used primarily in heterogeneous gas phase reactions with a catalyst | Highest conversion per unit mass of catalyst Low operating cost Continuous operation | Undesired thermal gradients may exist Poor temperature control Channeling may occur |

TABLE 79.2 Design Equations

| Reactor | Differential | Algebraic | Integral |
|---------|--|--|--|
| Batch | $N_{A0} \frac{dX}{dt} = -r_A V$ (79.2) | | $t = N_{A0} \int_0^x \frac{dX}{-r_A V}$ (79.3) |
| CSTR | | $t = N_{A0} \int_0^x \frac{dX}{-r_A V}$ (79.3) | |
| PFR | $F_{A0} \frac{dX}{dV} = -r_A$ (79.5) | | $V = F_{A0} \int_0^x \frac{dX}{-r_A}$ (79.6) |
| PBR | $F_{A0} \frac{dX}{dW} = -r'_A$ (79.7) | | $W = F_{A0} \int_0^x \frac{dX}{-r'_A}$ (79.8) |

the rate law is

$$-r_A = kC_A^\alpha C_B^\beta \quad (79.10)$$

We say the reaction is α order in A, β order in B, and overall order = $\alpha + \beta$. For example, if the reaction $A + B \rightarrow C + D$ is said to be second order in A and first order in B and overall third order, then the rate law is

$$-r_A = kC_A^2 C_B \quad (79.11)$$

The temperature dependence of specific reaction rate, k , is given by the Arrhenius equation,

$$k = A e^{-E/RT} \quad (79.12)$$

where A is the frequency factor and E the activation energy. Taking the natural log of both sides of Equation (79.12),

$$\ln k = \ln A - \frac{E}{R} \left(\frac{1}{T} \right) \quad (79.13)$$

we see the slope of a plot of $\ln k$ versus $(1/T)$ will be a straight line equal to $(-E/R)$.

The specific reaction rate at temperature T is commonly written in terms of the specific reaction rate, k_1 , at a reference temperature T_1 and the activation energy E . That is,

$$k = k_1(T_1) \exp \left[\frac{E}{R} \left(\frac{1}{T_1} - \frac{1}{T} \right) \right] \quad (79.14)$$

Example

The following reaction is carried out in a constant volume batch reactor:

Determine the appropriate linearized concentration-time plots for zero-, first-, and second-order reactions.

Solution

Use the algorithm to determine the concentration of A as a function of time.

Mole balance:
$$\frac{dN_A}{dt} = r_A V \quad (79.15)$$

Rate law:
$$-r_A = kC_A^\alpha \quad (79.16)$$

Stoichiometry:
$$V = V_0 \quad \therefore C_A = N_A / V_0 \quad (79.17)$$

Combine:
$$-\frac{dC_A}{dt} = kC_A^\alpha \quad (79.18)$$

Solving Equation (79.18) for a first-, second-, and third-order rate law, we can arrive at the following linearized concentration-time plots.

For reversible reactions at equilibrium the rate law must reduce to a thermodynamically consistent equation for the equilibrium constant.

Stoichiometry

Now that we have the rate law as a function of concentration (i.e., $-r_A = kC_A^\alpha C_B^\beta$), we need to express the concentrations of the reacting species as functions of conversion in order to evaluate any one of the reactor design equations.

Concentration

We start by defining concentration for a flow system and a batch system. For a flow system,

$$C_i = \frac{F_i}{v} \quad (79.19)$$

where v is the volumetric flow rate. For a batch system,

$$C_i = \frac{N_i}{V} \quad (79.20)$$

The next step is to express N_i and F_i as a function of conversion using a stoichiometric table.

The Stoichiometry Table

Using our definition of conversion we can construct the following stoichiometric table.

| Stoichiometry | | $A + \frac{b}{a}B \rightarrow \frac{c}{a}C + \frac{d}{a}D$ | | |
|---------------|--------|--|-----------------------|--|
| Batch Systems | | | | |
| Species | Symbol | Initial | Change | Remaining |
| A | A | N_{A0} | $-NA_0X$ | $N_A = N_{A0}(1-X)$ |
| B | B | $N_{A0}\Theta_B$ | $-\frac{b}{a}N_{A0}X$ | $N_B = N_{A0}\left(\Theta_B - \frac{b}{a}X\right)$ |
| C | C | $N_{A0}\Theta_C$ | $+\frac{c}{a}N_{A0}X$ | $N_C = N_{A0}\left(\Theta_C + \frac{c}{a}X\right)$ |
| D | D | $N_{A0}\Theta_D$ | $+\frac{d}{a}N_{A0}X$ | $N_D = N_{A0}\left(\Theta_D + \frac{d}{a}X\right)$ |
| Inert | I | $\frac{N_{A0}\Theta_I}{N_{T0}}$ | — | $\frac{N_I = N_{A0}\Theta_I}{N_T = N_{T0} + \delta N_{A0}X}$ |

where $\delta = \frac{d}{a} + \frac{c}{a} - \frac{b}{a} - 1$, $\epsilon = y_{A0}\delta$, and $\Theta_i = \frac{N_{i0}}{N_{A0}} = \frac{y_{i0}}{y_{A0}} = \frac{C_{i0}}{C_{A0}}$

For flow systems the number of moles of species i , N_i in this table, is simply replaced by the molar flow rates of species i , F_i .

Expressing Concentration as a Function of Conversion in Batch System

Constant volume batch: $V = V_0$.

$$C_B = \frac{N_B}{V} = \frac{N_B}{V_0} = \frac{N_{A0}}{V_0} \left(\Theta_B - \frac{b}{a}X \right)$$

$$C_B = C_{A0} \left(\Theta_B - \frac{b}{a}X \right) \quad (79.21)$$

Expressing Concentration as a Function of Conversion in Flow System

For flow systems, the stoichiometric table is the same, except replace N_i by F_i . Because there is hardly ever a volume change with reaction, the concentration of A in a *liquid* flow system is as follows. For liquid systems,

$$C_A = \frac{F_A}{v_0} = \frac{F_{A0}}{v_0}(1-X) = C_{A0}(1-X) \quad (79.22)$$

For gas systems,

$$C_A = \frac{F_A}{\nu} \quad (79.23)$$

In ideal gas systems the gas volumetric flow rate, ν , can change with conversion, temperature, and pressure according to the following equation:

$$\nu = \nu_0 \left(\frac{F_T}{F_{T0}} \right) \frac{P_0}{P} \frac{T}{T_0} \quad (79.24)$$

Taking the ratio of F_T/F_{T0} and then using the stoichiometric table, we arrive at the following equation for the volumetric flow rate at any point in the reactor.

$$\nu = \nu_0 (1 + \epsilon X) \frac{P_0}{P} \frac{T}{T_0} \quad (79.25)$$

Substituting this result and Equation (79.22) into Equation (79.23) gives

$$C_A = \frac{C_{A0}(1-X)}{(1+\epsilon X)} \frac{P}{P_0} \frac{T_0}{T} \quad (79.26)$$

We now will apply the algorithm described earlier to a specific situation. Suppose we have, as shown in Figure 79.2, mole balances for three reactors, three rate laws, and the equations for concentrations for both liquid and gas phases. In Figure 79.3, the algorithm is used to formulate the equation to calculate the PFR reactor volume for a first-order gas-phase reaction. The pathway to arrive at this equation is shown by the ovals connected to the dark lines through the algorithm. The dashed lines and the boxes represent other pathways for other solutions. For the reactor and reaction specified, we follow these steps:

1. Choose the *mole balance* on species A for a PFR.
2. Choose the *rate law* for an irreversible first-order reaction.
3. Choose the equation for the concentration of A in the gas phase (*stoichiometry*).
4. Finally, *combine* to calculate the volume necessary to achieve a given conversion or calculate the conversion that can be achieved in a specified reaction volume.

For the case of isothermal operation with no pressure drop, we were able to obtain an analytical solution, given by equation (A) in Figure 79.2, which gives reactor volume necessary to achieve a conversion X for a gas phase reaction carried out isothermally in a PFR. However, in the majority of situations, analytical solutions to the ordinary differential equations appearing in the combine step are not possible. By using this structure, one should be able to solve reactor engineering problems through reasoning rather than memorization of numerous equations together with the various restrictions and conditions under which each equation applies (i.e., whether there is a change in the total number of moles, etc.). In perhaps no other area of engineering is mere formula plugging more hazardous; the number of physical situations that can arise appears infinite, and the chances of a simple formula being sufficient for the adequate design of a real reactor are vanishingly small.

Example

The elementary gas phase reaction

$$-r_A = k_A C_A^2 C_B$$

1. MOLE BALANCES

PFR: $\frac{dX}{dV} = \frac{-r_A}{F_{A0}}$
 CSTR: $V = \frac{F_{A0}X}{-r_A}$
 BATCH: $\frac{dX}{dt} = \frac{-r_A V}{N_{A0}}$

2. RATE LAWS

PFR: $-r_A = kC_A$
 CSTR: $-r_A = \frac{kC_A}{1 + K_A C_A}$
 BATCH: $-r_A = k \left[C_A - \frac{C_B C_C}{K_e} \right]$

3. STOICHIOMETRY

FLOW
 $C_A = \frac{F_A}{v}$
 $F_A = F_{A0}(1 - X)$

BATCH
 $C_A = \frac{N_A}{V}$
 $N_A = N_{A0}(1 - X)$

LIQUID Constant flowrate
 $v = v_0$
 $C_A = C_{A0}(1 - X)$

GAS Variable flow rate
 $v = v_0(1 + \epsilon X) \frac{P_0}{P} \frac{T}{T_0}$
 $C_A = \frac{C_{A0}(1 - X) \frac{P}{P_0} \frac{T_0}{T}}{(1 + \epsilon X)}$

GAS Variable volume
 $V = V_0(1 + \epsilon X) \frac{P_0}{P} \frac{T}{T_0}$
 $C_A = \frac{C_{A0}(1 - X) \frac{P}{P_0} \frac{T_0}{T}}{(1 + \epsilon X)}$

LIQUID OR GAS Constant volume
 $V = V_0$
 $C_A = C_{A0}(1 - X)$

4. COMBINE (1st order Gas Phase Reaction in a PFR)

From mole balance: $\frac{dX}{dV} = \frac{-r_A}{F_{A0}}$
 From rate law: $\frac{-r_A}{F_{A0}} = \frac{kC_A}{F_{A0}}$
 From stoichiometry: $\frac{kC_A}{F_{A0}} = \frac{k}{F_{A0}} \left(C_{A0} \frac{(1 - X)}{(1 + \epsilon X)} \right) \frac{P}{P_0} \frac{T_0}{T}$

$\frac{dX}{dV} = \frac{k}{v_0} \frac{(1 - X)}{(1 + \epsilon X)} y \frac{T_0}{T}$, where $y = \frac{P}{P_0}$ (A)

Integrating for the case of constant temperature and pressure

$V = \frac{v_0}{k} \left[(1 + \epsilon X) \ln \frac{1}{1 - X} - \epsilon X \right]$

FIGURE 79.2 Algorithm for isothermal reactors. (Source: Fogler, H. S. 1996. *Elements of Chemical Reaction Engineering*, 3rd ed. Prentice Hall, Englewood Cliffs, NJ.)

is carried out at constant T (500 K) and P (16.4 atm) with $k_A = 10 \text{ dm}^6/\text{mol}^2\cdot\text{sec}$. Determine the CSTR reactor volume necessary to achieve 90% conversion when the feed is 50% mole A and 50% B.

Solution

The feed is equal molar in A and B; therefore, A is the limiting reactor and taken as our basis of calculation:

Algorithm

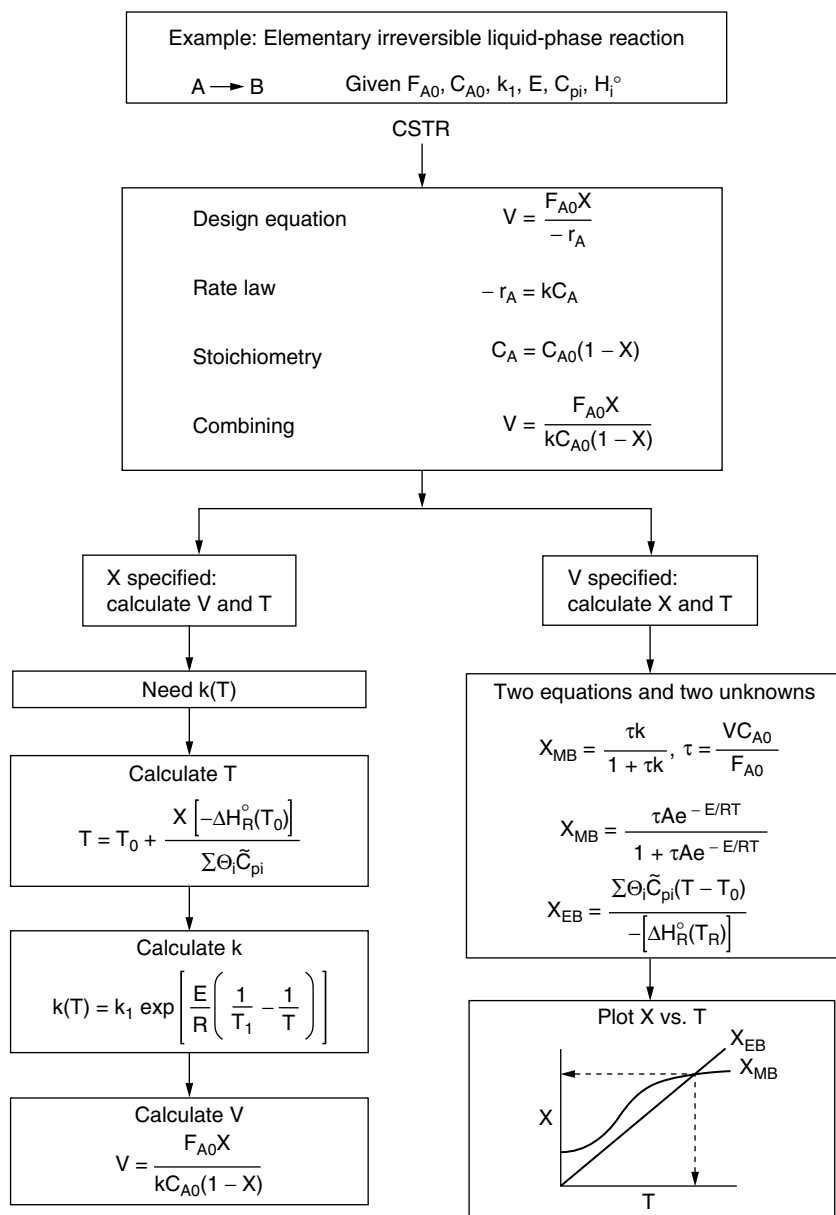

FIGURE 79.3 Algorithm for nonisothermal CSTR design. (Source: Fogler, H. S. 1992. *The Elements of Chemical Reaction Engineering*, 2nd ed. Prentice Hall, Englewood Cliffs, NJ.)

Mole balance is given as:

$$V = \frac{F_{A0}X}{-r_A} \tag{79.27}$$

Rate law is given as:

$$-r_A = k_A C_A^2 C_B \quad (79.28)$$

Stoichiometry is found as follows:

$$C_A = C_{A0} \cdot \frac{(1-X)}{(1+\epsilon X)} \frac{P}{P_0} \frac{T_0}{T} = C_{A0} \frac{(1-X)}{(1+\epsilon X)}$$

$$\epsilon = y_{A0} \delta = 0.5 \left[\frac{1}{2} - \frac{1}{2} - 1 \right] = -0.5 \quad (79.29)$$

$$C_A = C_{A0} (1-X) / (1-0.5X)$$

$$C_{A0} = \frac{y_{A0} P_0}{RT_0} = \frac{(0.5)(16.4 \text{ atm})}{\frac{0.082 \text{ atm m}^3}{\text{kmol K}} \cdot 500 \text{ K}} = 0.2 \frac{\text{kmol}}{\text{m}^3} = 0.2 \frac{\text{mol}}{\text{dm}^3} \quad (79.30)$$

$$C_B = C_{A0} \frac{\Theta_B - \frac{1}{2}X}{(1+\epsilon X)} = C_{A0} \frac{(1-0.5X)}{(1-0.5X)} = C_{A0} \quad (79.31)$$

For the combine step,

$$\begin{aligned} -r_A &= k_A C_A^2 C_B = k_A C_{A0}^3 \frac{(1-X)^2}{(1-0.5X)^2} \\ &= 0.08 \frac{\text{mol}}{\text{dm}^3 \cdot \text{s}} \frac{(1-X)^2}{(1-0.5X)^2} \end{aligned} \quad (79.32)$$

For a CSTR,

$$\begin{aligned} V &= \frac{F_{A0} X}{-r_A} = \frac{(5 \text{ mol/s})(0.9)[1-0.5(0.9)]^2}{(0.08) \frac{\text{mol}}{\text{dm}^3 \cdot \text{s}} (1-0.9)^2} \\ &= 1701 \text{ dm}^3 \end{aligned} \quad (79.33)$$

79.2 Pressure Drop in Reactors

If pressure drop is not accounted for in gas phase reactions, significant underdesign of the reactor size can result. This variation is handled in the stoichiometry step, in which concentration is expressed as a function of conversion, temperature, and total pressure. The change in total pressure is given by the Ergun equation [Fogler, 1992]:

$$\frac{dP}{dL} = - \frac{G(1-\phi)}{\rho g_c D_p \phi^3} \left[\frac{150(1-\phi)\mu}{D_p} + 1.75 G \right] \quad (79.34)$$

For isothermal operation the density is (assuming ideal gas)

$$\rho = \frac{\rho_0}{(1 + \epsilon X)} \frac{P}{P_0} \quad (79.35)$$

The catalyst weight, W , and length down the reactor, L , are related by the equation

$$W = LA_c(1 - \Phi)\rho_{\text{cat}}$$

Substituting back in the Ergun equation,

$$\frac{dP}{dW} = -\frac{\alpha_p (1 + \epsilon X)}{2 \frac{1}{\frac{P}{P_0}}} \quad (79.36)$$

where

$$\alpha_p = \frac{G(1 - \Phi)}{\rho_0 g_c D_p \Phi^3} \left[\frac{150(1 - \Phi)\mu}{D_p} + 1.75 G \right]$$

$$A_c(1 - \Phi)\rho_{\text{cat}} P_0$$

We now need to solve this differential equation to obtain the pressure as a function of the weight of catalyst the gas has passed over. We can obtain an analytical solution of $\epsilon = 0$. Otherwise, we must solve the equation numerically and simultaneously with the mole balance. For an analytical solution,

$$\frac{d(P/P_0)^2}{dW} = -\alpha_p(1 + \epsilon X) \quad (79.37)$$

For POLYMATH solution, letting $y = P/P_0$,

$$\frac{dy}{dW} = -\frac{\alpha_p(1 + \epsilon X)}{2y} \quad (79.38)$$

Example

To understand the effect pressure drop has on gas phase reaction in a packed bed, we analyze the reaction $A \rightarrow B$ carried out in a packed bed reactor (PBR). Mole balance (PBR) is

$$F_{A0} \frac{dX}{dW} = -r'_A$$

Wherever pressure drop occurs in a PBR, we must use the differential form of the mole balance to separate variables. Pressure drop only affects C_A , C_B , and so on, as well as $-r'_A$.

Rate law is second order in A and irreversible, according to the formula $-r'_A = kC_A^2$.

Stoichiometry is given by

$$C_A = C_{A0} \frac{(1-X) P T_0}{(1+\epsilon X) P_0 T}$$

For $\epsilon = 0$ and isothermal operation,

$$\frac{P}{P_0} = (1 - \alpha_p W)^{1/2}$$

$$C_A = C_{A0} (1-X) \frac{P}{P_0} = C_{A0} (1-X) (1 - \alpha_p W)^{1/2}$$

combining,

$$F_{A0} \frac{dX}{dW} = -r'_A = k C_{A0}^2 (1-X)^2 (1 - \alpha_p W)$$

By integrating with limits $W = 0, X = 0$ we obtain the desired relationship between conversion and catalyst weight.

$$\frac{X}{1-X} = \frac{k C_{A0}^2}{F_{A0}} \left[W - \frac{\alpha_p W^2}{2} \right]$$

79.3 Multiple Reactions

There are three basic types of multiple reactions: series, parallel, and independent. In *parallel reactions* (also called *competing reactions*) the reactant is consumed by two different reactions to form different products:

In *series reactions*, also called *consecutive reactions*, the reactant forms an intermediate product, which reacts further to form another product:

Multiple reactions involve a combination of both series and parallel reactions, such as

Independent reactions are of the type

and occur in feed stocks containing many reactants. The cracking of crude oil to form gasoline is an example of an independent reaction.

To describe selectivity and yield we consider the following competing reactions.

The rate laws are

$$r_D = k_D C_A^{\alpha_1} C_B^{\beta_1} \quad (79.39)$$

$$r_U = k_U C_A^{\alpha_2} C_B^{\beta_2} \quad (79.40)$$

We want the rate of D , r_D , to be high with respect to the rate of formation U , r_U . Taking the ratio of these rates, we obtain a rate *selectivity parameter*, S , which is to be maximized:

$$S_{DU} = \frac{r_D}{r_U} \quad (79.41)$$

Substituting Equation (79.39) and Equation (79.40) into Equation (79.41) and letting $a = \alpha_1 - \alpha_2$ and $b = \beta_2 - \beta_1$, where a and b are both positive numbers, we have

$$S_{DU} = \frac{r_D}{r_U} = \frac{k_1 C_A^a}{k_2 C_B^b}$$

To make S_{DU} as large as possible, we want to make the concentration of A high and the concentration of B low. To achieve this result, use the following:

A semibatch reactor in which B is fed slowly into a large amount of A

A tubular reactor with side streams of B continually fed to the reactor

A series of small CSTRs with A fed only to the first reactor and B fed to each reactor

Another definition of selectivity used in the current literature is given in terms of the flow rates leaving the reactor:

$$\tilde{S}_{DU} = \text{Selectivity} = \frac{F_D}{F_U} = \frac{\text{Exit molar flow rate of desired product}}{\text{Exit molar flow rate of undesired product}} \quad (79.42)$$

For a batch reactor, the selectivity is given in terms of the number of moles of D and U at the end of the reaction time:

$$\tilde{S}_{DU} = \frac{N_D}{N_U} \quad (79.43)$$

One also finds that the reaction yield, like the selectivity, has two definitions: one based on the ratio of reaction rates and one based on the ratio of molar flow rates. In the first case the yield at a point can be defined as the ratio of the reaction rate of a given product to the reaction rate of the key reactant A [Carbery, 1967]:

$$Y_D = \frac{r_D}{-r_A} \quad (79.44)$$

In the case of reaction yield based on molar flow rates, the yield is defined as the ratio of moles of product formed at the end of the reaction to the number of moles of the key reactant, A , that have been consumed. For a batch system,

$$\tilde{Y}_D = \frac{N_D}{N_{A0} - N_A} \quad (79.45)$$

For a flow system,

$$\tilde{Y}_D = \frac{F_D}{F_{A0} - F_A} \quad (79.46)$$

Because of the various definitions for selectivity and yield, when reading literature dealing with multiple reactions, check carefully to ascertain the definition intended by the author.

79.4 Heat Effects

For nonisothermal reaction in CRE we must choose which form of the energy balance to use (e.g., PFR, CSTR) and which terms to eliminate (e.g., $Q = 0$ for adiabatic operation). The structure introduced to study these reactors builds on the isothermal algorithm by introducing the Arrhenius equation, $k = Ae^{-E/RT}$ in the **rate law** step, which results in one equation with two unknowns, X and T , when we finish with the combine step. For example, using again the PFR mole balance and conditions in [Figure 79.2](#) [Equation (A)], we have, for constant pressure,

$$\frac{dX}{dV} = \frac{k(1-X)}{v_0(1+\epsilon X)} \frac{T_0}{T} \quad (79.47)$$

$$\frac{dX}{dV} = \frac{Ae^{-E/RT}(1-X)}{v_0(1+\epsilon X)} \left(\frac{T_0}{T} \right) \quad (79.48)$$

We can now see the necessity of performing an energy balance on the reactor to obtain a second equation relating X and T . We will use energy balance to relate X and T .

$$\begin{array}{c}
 \left[\begin{array}{c} \text{Rate of} \\ \text{accumulation} \\ \text{of energy} \\ \text{within the} \\ \text{system} \end{array} \right] = \left[\begin{array}{c} \text{Rate of flow} \\ \text{of heat to} \\ \text{the system} \\ \text{from the} \\ \text{surroundings} \end{array} \right] - \left[\begin{array}{c} \text{Rate of work} \\ \text{done by} \\ \text{the system} \\ \text{on the} \\ \text{surroundings} \end{array} \right] \\
 \\
 + \left[\begin{array}{c} \text{Rate of energy} \\ \text{added to the} \\ \text{system by mass} \\ \text{flow into the} \\ \text{system} \end{array} \right] - \left[\begin{array}{c} \text{Rate of} \\ \text{energy leaving} \\ \text{system by mass} \\ \text{flow out of} \\ \text{the system} \end{array} \right]
 \end{array}$$

$$\frac{dE}{dt} = \dot{Q} - \dot{W} + \sum F_{in} E_{in} - \sum F_{out} E_{out}$$

Neglecting potential and kinetic energy, the energy E_i is just the internal energy of species i , substituting for W in terms of the flow work and the shaft work, W_s , and using the definition of enthalpy gives for steady-state operation

$$\dot{Q} - \dot{W}_s + \sum F_{i0} H_{i0} - \sum F_i H_i = 0 \quad (79.49)$$

For adiabatic operation, no work done on the system and constant heat capacity and $\Delta C_p = 0$, the energy balance reduces to

$$T = T_0 + \frac{(-\Delta H_R)X}{\sum \theta_i C_{pi} + \Delta C_p X} \quad (76.50)$$

We now use this relationship to solve adiabatic reactor design problems.

The procedure for nonisothermal reactor design can be illustrated by considering the first-order irreversible liquid-phase reaction $A \rightarrow B$. The CSTR design equation is

$$V = \frac{F_{A0} X}{-r_A}$$

Rate law is found by

$$-r_A = kC_A \quad (79.51)$$

with the Arrhenius equation:

$$k = A e^{-E/RT}$$

Stoichiometry for the liquid phase (i.e., $v = v_0$) is given by

$$C_A = C_{A0}(1 - X)$$

Combining yields

$$V = \frac{\nu_0}{Ae^{-E/RT}} \left(\frac{X}{1 - X} \right) \quad (79.52)$$

Continuing from this point requires two distinct cases. For the first case, the variables X , ν_0 , C_{A0} , and F_{i0} are specified and the reactor volume, V , must be determined. The procedure is as follows:

1. Evaluate Equation (79.50) to find the temperature, T , for the conditions specified.
2. Calculate k from the Arrhenius equation.
3. Calculate the reactor volume, V , from Equation (79.52).

For the second case, the variables ν_0 , C_{A0} , V , and F_{i0} are specified and the exit temperature, T , and conversion, X , are unknown quantities. The procedure is as follows:

1. Solve the energy balance for X as a function of T . If adiabatic, Equation (79.50) becomes

$$X_{EB} = \frac{\sum \Theta_i \tilde{C}_{pi} (T - T_0)}{-[\Delta H_R^\circ(T_R)]} \quad (79.53)$$

2. Solve the mole balance [Equation (79.52)] for X as a function of T .

$$X_{MB} = \frac{\tau A e^{-E/RT}}{1 + \tau A e^{-E/RT}} \quad (79.53)$$

where $\tau = V/\nu_0$

3. Plot the previous two steps on the same graph to determine the intersection. At this point the values of X and T satisfy both the energy balance and mole balance. As an alternative, one may equate the equations for X from the previous two steps and solve numerically.

An energy balance on a PFR with heat exchange yields the second equation we need relating our independent variables X and T :

$$\frac{dT}{dV} = \frac{[UA_c(T_a - T) + (r_A)(\Delta H_R)]}{F_{A0} C_{pA}} \quad (79.54)$$

The differential equation describing the change of temperature with volume (i.e., distance) down the reactor,

$$\frac{dT}{dV} = g(X, T) \quad (79.55)$$

must be coupled with the mole balance, Equation (79.5),

$$\frac{dX}{dV} = \frac{-r_A}{F_{A0}} f(X, T) \quad (79.56)$$

and solved simultaneously. A variety of numerical integration schemes and ODE solvers can be used to solve these two equations simultaneously.

79.5 Summary

By arranging chemical reaction engineering in a structure analogous to a French menu, we can study a multitude of reaction systems with very little effort. This structure is extremely compatible with a number of user-friendly ordinary differential equation (ODE) solvers. Using **ODE solvers** such as POLYMATH, the student is able to focus on exploring reaction engineering problems rather than crunching numbers. Thus, the teacher is able to assign problems that are more open ended and give students practice at developing their creativity. Practicing creativity is extremely important, not only in CRE, but in every course in the curriculum if students are to compete in the world arena and succeed in solving the relevant problems that they will be faced with in the future.

Nomenclature

| | | | |
|-----------|--|--------------|---|
| A | frequency factor (appropriate units) | V | volume, dm^3 |
| A_c | cross-sectional area, m^2 | W | catalyst weight, g |
| C_i | concentration of species i ($i = A, B, C, D$), mol/dm^3 | X | conversion |
| C_{p_i} | heat capacity of species i , $\text{J}/\text{g}/\text{K}$ | y | pressure drop parameter (P/P_o) |
| D_p | particle diameter, m | y_A | mole fraction of A |
| E | activation energy, J/mol | a | ambient temperature |
| F_i | entering molar flow rate of species i , mol/sec | A | refers to species A |
| G | superficial gas velocity $\text{g}/\text{m}^2/\text{sec}$ | cat | catalyst density kg/m^3 |
| g_c | conversion factor | EB | energy balance |
| k | specific reaction rate (constant), appropriate units | MB | mole balance |
| K_A | adsorption equilibrium constant (dm^3/mol) | T | total number of moles |
| K_c | equilibrium constant, appropriate units | 0 | entering or initial condition |
| L | length down the reactor, m | a | reaction order |
| N_i | number of moles of species i , mol | α_p | pressure drop parameter, g^{-1} |
| P | pressure, kPa | β | reaction order |
| r_i | rate of formation of species i per unit volume, $\text{mol}/\text{sec}/\text{dm}^3$ | ΔH_R | heat of reaction, $\text{J}/\text{mole } A$ |
| r_i' | rate of formation of species i per unit mass of catalyst, $\text{mol}/\text{sec}/\text{g}$ | δ | change in the total number of moles per mole of A reacted |
| R | ideal gas constant, $\text{J}/\text{mol}/\text{K}$ | ϵ | bolome change parameter = $y_{A0}\delta$ |
| t | time, sec | ϕ | porosity |
| T | temperature, K | μ | viscosity, cp |
| U | overall heat transfer coefficient, $\text{J}/(\text{dm}^3\text{sec K})$ | ρ | density, g/dm^3 |
| | | ν | volumetric flow rate, dm^3/sec |
| | | Θ_i | N_i/N_{A0} |

Defining Terms

Batch reactor — A closed vessel (tank) in which there is no flow in or out of the vessel during the time the reaction is taking place.

Continuous stirred tank reactor (CSTR) — A reactor in which the reactant and products flow continuous into and out of (respectively) the tank. A reactor where the contents are well mixed.

ODE solver — A user-friendly software package that solves ordinary differential equations, for example, Mathematica, POLYMATH, Matlab.

Packed bed reactor — Usually a tubular reactor packed with solid catalyst pellets.

Plug flow reactor — Usually a tubular reactor used for gas phase reactions in which it is assumed there are no radial gradients in temperature or concentration as well as no dispersion of reactants.

Semibatch reactor — A reactor (vessel) in which one of the reactants is placed in the reactor and a second reactant is slowly added to the reactor.

Scaleup is one of those overworked terms that has come to mean almost anything and everything, depending on who is using it. In this article we will use it very little, and then only to indicate the generic process of commercializing new chemical technology. The alternative to scaleup is rational design, which utilizes mathematical relationships and computer simulation to develop the best design for the reactor. The mathematical relationships describe both the reaction kinetics and the attributes of the reactor and its associated auxiliary equipment.

Geometric scaleup was practiced routinely in the chemical industry as a design protocol until a few decades ago, but, today, rational design — based on laboratory data and correlations — has largely replaced it for most types of industrial chemical reaction systems. To understand why this is so, it is necessary to note how the chemical industry has changed over the years.

Forty or 50 years ago, merely producing a chemical on an industrial scale was usually sufficient to ensure a profit for the manufacturer. Chemical processes were labor intensive, but capital and energy were cheap and the selling price of a pound of finished product was typically several times the raw material cost. Furthermore, the environment had not yet been discovered either by industry or by the public at large.

It was really unnecessary to design reactors rationally for most kinds of processes in that era, because any questions about productive capacity could be addressed simply by making the reactor larger, raw material selectivities usually were not economically critical, and the large quantities of energy that were expended in complex distillation trains to remove byproducts and impurities were both practicable and inexpensive.

In contrast, the petrochemical industry today utilizes chemical reactions that produce the desired products much more directly and cleanly, with as little waste as possible. Raw material cost is frequently the largest component of the final product cost, and the crude product must not contain unexpected byproducts that the refining system cannot remove adequately and efficiently. The failure to meet tight product specifications can produce chemicals that either cannot be sold at all without expensive reprocessing or can be sold only for little more than their value as fuel.

In any case, both today's marketplace and concerns for the environment demand that chemical reaction systems produce no more than extremely small amounts of waste or off-specification product per pound of refined salable product. Reactors must be accurately designed and operated because today's chemistry frequently is strongly dependent upon carrying out just the desired amount of reaction in order to avoid the production of unwanted byproducts by over-reaction. The energy efficiencies of refining systems strongly depend upon their receiving crude product of uniform and predictable composition, because product specifications are usually tight and must be met at minimum cost. Simply put, today's chemical reaction systems must operate as intended.

80.1 General Considerations in the Rational Design of Chemical Reactors

Reaction Kinetics Models and Reactor Models

The rational design of any type of reactor involves the marriage of one or more reaction kinetics models and a reactor model. It is important to recognize exactly what these two kinds of models describe:

- *Reaction kinetics models* describe the response of reaction rates to the reaction environment — that is, to temperature and the concentrations of virtually everything in the system — reactants, products, byproducts, catalysts, and contaminants. For design purposes, it is necessary and sufficient that the kinetic model reflect the reaction stoichiometry accurately and that it predict reaction rates accurately. It is not important that it reflect the actual reaction mechanism.
- *Reactor models* describe how the reaction environment is shaped by the geometry of the reactor, by physical processes such as fluid dynamics and heat and mass transport, and by process variables and conditions such as mean reactor residence time and residence time distribution, flow rate, pressure, and temperature.

These distinctions are subtle but important. It is sufficient to remember that kinetics models contain *only* temperature and concentration terms, whereas reactor models may contain these as well as everything else that influences the conduct of the reaction.

Kinetics of a Simple Hypothetical System of Reactions

Real systems will have their own individual structures and characteristics and will reflect the particular stoichiometry of the reaction system at hand. In this chapter, we will use a general, somewhat simplified set of reactions and reactor equations for illustration. Consider the general group of n_r reactions presented below, in which chemical species A and B react to produce several products P_k according to the following scheme:

Kinetic models for the rational design of reaction systems will usually be of one of two basic mathematical forms, each given in moles/volume/time and describing the response of the reaction rates r_j to temperature and concentration. For exponential models,

$$r_j = K_{oj} e^{-\frac{E_{aj}}{RT}} C_A^{a_j} C_B^{b_j} C_{P_1}^{p_{1j}} \dots C_{P_n}^{p_{nj}} \quad (80.1)$$

For hyperbolic models,

$$r_j = \frac{K_{oj} e^{-\frac{E_{aj}}{RT}} C_A C_B}{1 + K_{A_j} C_A + K_{B_j} C_B + \sum_1^{n_c} (K_{P_{kj}} C_{P_k})} \quad (80.2)$$

Each of these two types of kinetic models has its own preferred uses. Their development will be discussed in a later section of this chapter. For now, assume that either of these types is to be used in a combined kinetics and reactor model to predict reaction rates, as described in the following section.

Combined Kinetics and Reactor Models: The General Continuity Equation

Virtually all combined reaction kinetics and reactor models utilize some form of the general continuity equation for flow and reaction in an element of volume of some kind of reactor, such as that shown in Figure 80.1. In its simplest form, this equation states that the quantity of each component k that enters the volume element of the reactor must either leave, react, or accumulate:

FIGURE 80.1 Flow and concentration in a volume element of a chemical reactor.

$$F_{e_{in}} C_{k_{in}} = F_{e_{out}} C_{k_{out}} - V_e \sum_1^{n_r} (\alpha_{kj} r_j) + \frac{d(V_e C_{k_e})}{dt} \text{ mol/time} \quad (80.3)$$

Different types of idealized reactors can be represented by this equation, simply by noting what terms are not appropriate and eliminating them. Thus, a simple *batch reactor* has no flow in or out, and therefore terms containing F drop out. So, for a simple batch reactor,

$$\frac{d(V_e C_{k_e})}{dt} = \sum_1^{n_r} (\alpha_{kj} r_j) V_e \quad (80.4)$$

which may be further simplified by canceling the V_e terms as well if the reaction volume is constant. Note that the volume element in this case is simply the entire filled volume of the reactor, because the concentration is assumed to be uniform throughout.

A steady-state *continuous stirred tank reactor (CSTR)* may have the same flow rate in and out, and the entire contents of the reactor comprise the volume element, as in the batch reactor. The time-derivative term is absent because the reactor is at steady state. The concentrations of all species in the reactor are the same as in the outlet. Thus we have, for the CSTR,

$$F C_{k_{in}} = F C_{k_{out}} - V \sum_1^{n_r} (\alpha_{kj} r_j) \quad (80.5)$$

which can be rearranged to

$$\sum_1^{n_r} \alpha_{kj} r_j = \frac{F(C_{k_{out}} - C_{k_{in}})}{V} \text{ mol/volume/time} \quad (80.6)$$

Weight of catalyst, W_c , replaces reactor volume, V , for a catalytic reaction:

$$\sum_1^{n_r} \alpha_{kj} r_j = \frac{F(C_{k_{out}} - C_{k_{in}})}{W_c} \text{ mol/wt. catalyst/time} \quad (80.7)$$

This simple relationship makes the CSTR the preferred type of reactor for many kinds of kinetics studies, in which the net rates of formation or disappearance [that is, $\sum_1^{n_r} (\alpha_{kj} r_j)$] for each individual component can be observed directly.

For design purposes, it is more convenient to integrate the unsteady-state form of the general continuity equation for the CSTR until the steady-state concentrations are attained. (The model will behave very much as the real reactor would in this respect.) This procedure avoids the need to use constrained nonlinear estimation to predict the reactor outlet concentrations. Again, assuming that flows in and out of the reactor are the same and that volume is constant,

$$\frac{d(C_k)}{dt} = \frac{F(C_{k_{in}} - C_{k_{out}})}{V} + \sum_1^{n_r} (\alpha_{kj} r_j) \text{ mol/h} \quad (80.8)$$

The reactor model will comprise an equation like Equation (80.8) for each component k in the CSTR. Another advantage of the unsteady-state model is that stoichiometry is automatically preserved without the need for any constraints. It may be used readily to simulate a system comprising a large number of

components and reactions in a multistage system of CSTRs, which is otherwise mathematically intractable. And, of course, it may be used to study the dynamic behavior of the system as well. Therefore, it is the preferred design approach for multistage CSTR systems.

In the *ideal steady-state plug flow reactor*, all elements of fluid that enter the reactor together travel down its length and exit together, having thus stayed in the reactor for identical lengths of time. The volume element will be only a differential slice of the reactor cross-section, denoted by dV . There will be no accumulation term, since the reactor is at steady state. The differential concentration difference across the differential volume element will be denoted by dC . Thus, Equation (80.3) is once again applicable and simplifies to

$$F_e dC_k = \sum_1^{n_r} (\alpha_{kj} r_j) dV_e \quad (80.9)$$

If F changes as the reaction proceeds (as with many gas-phase reactions), then this can be accommodated down the length of the plug flow reactor by modifying the above equation to

$$d(F_e C_k) = \sum_1^{n_r} (\alpha_{kj} r_j) dV_e$$

whence

$$F_e \frac{dC_k}{dV_e} + C_k \frac{dF_e}{dV_e} = \sum_1^{n_r} (\alpha_{kj} r_j) dV_e \quad (80.10)$$

$$\frac{dC_k}{dV_e} = \frac{\sum_1^{n_r} (\alpha_{kj} r_j)}{F_e} - \frac{C_k}{F_e} \frac{dF_e}{dV_e}$$

Equation (80.10) describes the rate of change of concentration C of species k with volume down a plug flow reactor as a function of the reaction rates, concentration, and flow. It also reflects the change in molar flow as the reaction proceeds.

A complete *isothermal* plug flow reactor model can readily be constructed using as many Equations (80.10) as there are components k , and as many kinetic models as there are reactions j . For *nonisothermal* reactors, differential equations that describe the temperature changes down the length of the reactor can be constructed in an analogous fashion, using the molar heat generation for each reaction j and its corresponding reaction rate r_j and heat transfer terms appropriate to the reactor type and geometry. For a multitube plug flow reactor with coolant on the outside of the tubes, the equation for reaction temperature (in degrees/volume) is as follows:

$$\frac{dT_r}{dV_e} = \frac{\sum_1^{n_r} (r_j \Delta H_j) - \frac{4U}{D_t} (T_r - T_c)}{F_e \rho_p c_p} \quad (80.11)$$

For coolant temperature,

$$\frac{dT_c}{dV_e} = \frac{\frac{4U}{D_t} (T_r - T_c) (\text{Mode})}{F_c \rho_c c_c} \quad (80.12)$$

Combined model equations like these are simplified in the sense that they do not account for departures from ideality because of nonideal mixing patterns in the case of stirred reactors, radial and axial diffusion effects in the case of tubular catalytic reactors, or the very specialized phenomena in fluidized beds and fixed-bed multiphase reactors. Yet they are surprisingly applicable in many industrial applications — and will certainly be preferred to geometric scaleup in almost all cases.

80.2 Protocol for the Rational Design of Chemical Reactors

Given the distinctions between kinetics models and reactor models, as well as the characteristics of combined reaction and reactor models, we can now establish a general protocol for rational design that will apply to many types of chemical reactors in industrial situations. The protocol comprises several steps, each of which is discussed in the following sections.

Step 1: Select the Type of Reactor for the Commercial Process

First, select one or more potentially useful types of reactors for the commercial process. In many instances, the preferred reactor type will be known from past experience with the same or similar reactions. Even so, the scaleup characteristics and requirements for two important types of reaction — batch reactions and solid-catalyzed reactions — merit special attention here. The reader is referred to the large open literature for additional information. Texts by Froment and Bischoff [1979] and Levenspiel [1972] are classic and are particularly recommended.

Scaleup of Laboratory Batch Reactions

Plant-Size Batch Reactors — Many reactions are conveniently studied in laboratory batch reactors, but batch reactors often are not preferred for full-scale operations, particularly if the reaction is rapid or if the planned plant will be quite large. Plant-size batch reactors are costly to operate, simply because they must be shut down, emptied, and recharged after a fairly short time — typically after only a few hours. This means that each reactor produces chemicals only on a part-time basis. As a consequence, batch reactors are usually preferred only for fairly high-priced specialty chemicals such as pharmaceuticals that are produced at fairly low volumes — say, under 50 million pounds per year — so that the required number and size of batch reactors are reasonable.

Ideal Plug Flow Reactors (PFRs) — PFRs have the same residence-time distribution as ideal batch reactors — that is, each element of feed is exposed to reaction conditions for exactly the same length of time. They are particularly useful for high-volume, low-priced commodity chemicals, for which the laboratory batch reactor is preferred. If the reaction time is short — say, under an hour — it may be practicable to use some type of large-scale plug flow reactor (PFR) for the plant. A baffled column is a common example. More often than not, however, batch times are at least several hours, and a plug flow continuous reactor would be too large and too costly for full-scale plant use. However, PFRs are routinely used in industry for solid-catalyzed reactions, as discussed later. The difference here is that the catalyst dramatically accelerates the reaction so that large-scale plug flow reactors are quite practicable.

Single and Multistage CSTRs — The single-stage continuous stirred tank reactor (CSTR) is relatively inexpensive and provides good temperature control, but it has a broad residence-time distribution. This means that some of the feed may be under reaction for a very short time and some may be in the reactor for an extended time. Also, concentrations of reactants and products throughout a CSTR will be the same as their exit concentrations, so that the reactions are conducted at minimum reactant concentration and maximum product concentration. This will mean a relatively slow reaction rate with maximum exposure of products to further reaction, which may lead to relatively low production rates and relatively high by-product formation rates.

Residence-Time Distribution and the Effects of Staging — To overcome some of the disadvantages of both the PFR and CSTR reactors for reactions that are ideally carried out by batch in the laboratory, several CSTRs are frequently connected in series. Their residence-time distributions will be intermediate

FIGURE 80.2 Effects of residence-time distribution.

between the very narrow distributions of the batch reactor or PFR and the very broad distributions of the CSTR. Such a multistage reactor may be a good compromise, but it will not operate identically to the laboratory batch reactor.

The effect of staging on a chemical reaction may be inferred from Figure 80.2, in which a simple sequential reaction of A going to B (desired) and then to C (undesired) is assumed. The figure shows that the batch reactor has the highest conversion of A and the highest yield of B , and that the CSTR has the lowest. The three- and five-stage CSTRs are intermediate between the batch and CSTR reactors. In practice, multistage systems of two to five CSTRs are common. Froment and Bischoff [1979], Levenspiel [1972], and others have written extensively on residence-time distribution and its impact on product yields and selectivities. These concepts are important to the successful commercialization of batchwise laboratory reaction technology.

Scaleup of Solid-Catalyzed Reactions

Solid catalysts are widely used in the chemical industry in several types of packed-bed reactors, slurry reactors, and fluidized bed reactors. Commercial processes frequently utilize solid-catalyzed gas-phase reactions, but it is not uncommon for them to use both gas and liquid streams, which greatly complicates the hydrodynamics. Reactors for solid-catalyzed reactions are all subject to scaleup problems because of differences in mass and heat transport between large-scale equipment and laboratory equipment.

Packed-bed reactors are probably used more than any other type for solid-catalyzed reactions. They tend to have residence-time distributions that closely approach plug flow, especially for plant-scale single-phase systems in which the bed length is at least 5 to 10 meters. Their narrow residence-time distribution makes them preferred from the standpoint of being able to control product distribution in systems of sequential reactions. Equation (80.10) through Equation (80.12) are appropriate here.

Shell-and-tube packed-bed reactors have excellent heat removal characteristics, particularly if the tube diameters are fairly small — say, 1 to 1.5 in. A schematic of a typical plant-scale shell-and-tube reactor is shown in Figure 80.3. Although relatively expensive, such reactors can usually be designed rationally with confidence.

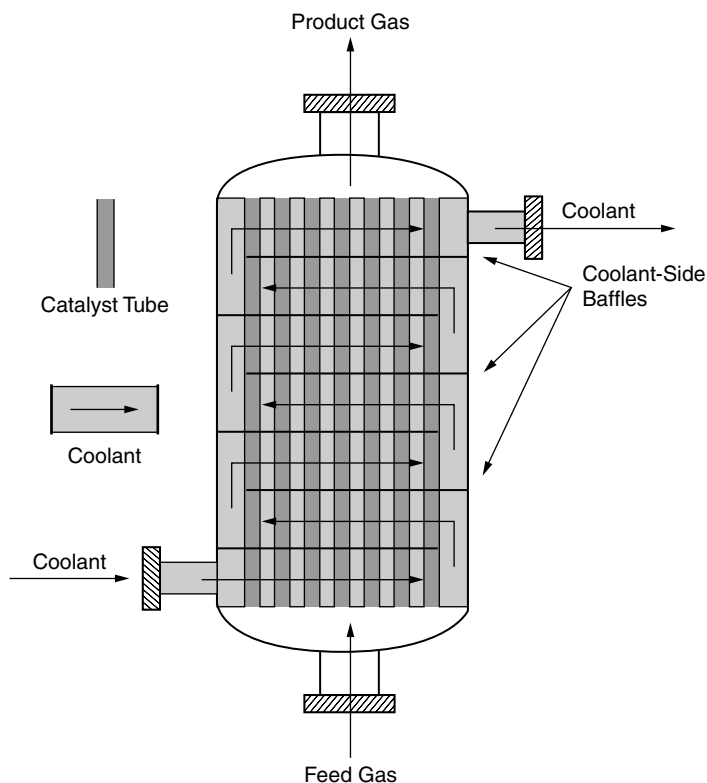

FIGURE 80.3 Conceptual shell-and-tube fixed-bed reactor. (Source: Reproduced with permission of the American Institute of Chemical Engineers from Cropley, J. B. 1990. *Chemical Engineering Progress* 86(2):32–39. Copyright 1990 AIChE. All rights reserved.)

Adiabatic packed-bed reactors are attractive because of their relatively low cost. (At their simplest, they can be little more than an empty tank filled with catalyst pellets.) However, they suffer from the effects of an uncontrolled reaction temperature and tend to drift towards the maximum possible attainable temperature, which usually means that the limiting reactant is completely consumed or that equilibrium has been reached. This is a desirable property for some reactions (e.g., hydrogenations), but usually the chemical selectivity suffers as a result. Unwanted byproducts may result, even in hydrogenation systems. The adiabatic reactor usually is not recommended where temperature control is important.

Multiphase packed-bed reactors (e.g., trickle beds) are widely used, but the transport of reactants and products between the flowing gas and liquid and the solid catalyst is a major uncertainty. A lot of work remains to be done before the rational design of these reactors can be undertaken with confidence. Instead, back-and-forth experimentation and mathematical analysis of the hydrodynamics is necessary. Suffice it to note here that the transport characteristics of multiphase reactors are different in each of the several hydrodynamic regimes that may be experienced (e.g., trickle flow, bubbling flow, pulsing flow, slug flow, mist flow). A priori calculations using relationships from the open literature can often predict whether reaction kinetics or mass transfer will limit the reactor's performance, and the preliminary design sometimes can be developed rationally thereafter. Pilot-scale experimental verification of the performance of the final design in the *same hydrodynamic region* as the plant reactor is nonetheless essential to avoid surprises. There is an abundant literature on this type of reactor, and the excellent text by Ramachandran and Chaudhari [1983] is a good place to obtain an introduction to this complex technology.

Fluidized-bed reactors are widely used in fluidized catalytic cracking, the manufacture of polyethylene and polypropylene, the manufacture of silicones from silicon, and some other commercial reactions. The

fluid and solid dynamics of these systems are extremely complex, and available models are best described as learning models, rather than predictive models for reaction system design. Scaleup is typically done incrementally in a series of pilot-plant reactors. Despite the well-known advantages of these systems for some purposes (excellent temperature control, absence of diffusional and transport restrictions), the decision to use fluidized systems for new applications must not be taken lightly. Although the solid phase may usually be assumed to be well mixed, the residence-time distribution of the fluid phase is complex and largely unpredictable. It follows that the performance of a scaled-up reactor is also largely unpredictable if the fluid-phase residence-time distribution is important.

It is worth noting that, with few exceptions, all successful commercial fluidized bed reaction systems involve a solid phase that is always in some kind of rapid transition. Fluidized catalytic-cracking catalyst becomes coked and inactive in only 3 to 5 sec and is continuously removed from the fluidized riser reactor and regenerated by burning in dilute oxygen. The solid phase is in fact the product polyolefin in fluidized systems such as Union Carbide's Unipol™ polyolefins process. Dimethyldichloro silane (an intermediate in the manufacture of silicone oils and other products) is manufactured by reacting silicon metal and methyl chloride in a fluidized-bed reactor. Here, the silicon reactant is in the form of a fine metal powder that is continually consumed by the reaction and that comprises the solid phase in the reactor. An exception to the above observation is the Badger process for the manufacture of phthalic anhydride in a fluidized-bed reactor, in which the solid is a catalyst that is not undergoing any rapid change. It is carried out in a fluidized bed because the temperature control is important to the process.

The technology of fluidization has been studied in depth since before World War II and continues to be studied still because of its importance in those industries that depend upon it. AIChE has published several volumes on fluidization in its symposium series, and more appear periodically. Some excellent texts exist on fluidization phenomena; that by Kunii and Levenspiel [1969] is considered a classic.

Slurry reactors are attractive for many gas-liquid systems that are catalyzed by solid catalysts, but their design is nearly as complicated as for fluidized-bed systems. There is an extensive open literature on this type of reactor. The Air Products Company has published a number of reports on work done under contract for the U.S. Department of Energy and has a large pilot plant at LaPorte, Texas, for the manufacture of methanol and higher alcohols from CO and hydrogen. These reports and the text on multiphase reactors by Ramachandran and Chaudhari [1983] are recommended.

Step 2: Design the Laboratory to Generate Reaction Kinetics Data

The second step in the protocol for rational design is to design the laboratory reaction system specifically to generate kinetics rate data. By now it should be clear that the kinetic model is the link between the laboratory operations and the large-scale plant design. The experimental reactor for kinetics studies will ordinarily not look at all like the final plant reactor. Rather, it will be designed to obtain the kinetic data necessary for kinetic model development. Three primary types of laboratory reactor are suitable for design-quality kinetics studies:

- The batch reactor
- The long-tube reactor with sample points along its length
- The continuous stirred tank reactor, or CSTR

The following paragraphs discuss each of these types, with the emphasis upon what kinds of reactions are suitable for each and any special considerations that may apply.

Laboratory batch reactors are found in virtually limitless variety in most industrial chemical laboratories. For kinetics studies it is imperative that chemical analyses be obtained at several times during the reaction period. This sometimes poses problems if the reaction starts before the desired reaction temperature has been reached or if the reaction proceeds so quickly that multiple samples are not practical. Likewise, the loss of reacting volume due to sampling may be important, particularly if a solid catalyst is involved. Both of these problems are best handled during mathematical analysis of the data by forcing the simulated time-temperature and time-reacting volume profiles to be the same as the observed ones.

FIGURE 80.4 The Bertly reactor for experimental catalyst testing and kinetics. (Source: Reproduced with permission of the American Institute of Chemical Engineers from Cropley, J. B. 1990. *Chemical Engineering Progress* 86(2):32–39. Copyright 1990 AIChE. All rights reserved.)

Batch laboratory reactors are suitable for either uncatalyzed or catalyzed liquid-phase or gas-liquid reactions. In special situations they may be useful for gas-phase reactions as well. They are especially useful for slurry-catalyzed reactions, but they can also be used with pelleted catalysts, provided that provision is made to retain the pellets in a basket or container through which the fluid passes. Both the Bertly reactor (see Figure 80.4 and [Berty, 1974]) and the Carberry rotating basket reactor [Levenspiel, 1972] have been widely used for batchwise kinetic studies of catalytic reactions, although their best use is probably in continuous gas-phase kinetics studies.

Long-tube reactors for kinetics studies will typically be of a length to promote both plug flow characteristics and good mass and heat transfer so that these physical processes do not mask the chemical reaction rates. Tube length per se is not critical, although it is highly desirable that the length-to-diameter ratio be at least 100:1 to avoid the effects of axial mixing and departure from plug flow behavior. Tube diameter is not particularly important but should be small enough to ensure good heat transfer. If solid-catalyst pellets are to be used, the tube diameter should be no more than four or five pellet diameters to avoid radial temperature gradients. It is important that provision be made for samples to be taken at multiple points down the tube length. Reactors such as these are particularly well suited for kinetics studies using plant-scale catalyst pellets and for the study of the kinetics of sequential byproduct formation, in which the desired product reacts to form unwanted byproducts.

Perhaps the most difficult requirement from the standpoint of experimental reactor design is to provide for multiple sampling points down the length of the tube. It is relatively easy to make such a reactor using lengths of stainless steel tubing connected by tubing tees, which can then be used simultaneously as sample taps and for the insertion of thermocouples. Tubing diameter will typically be between 0.25 and 0.50 in., and the length will be 5 to 6 feet. Sample taps at 12-in. intervals will provide good composition and temperature profiles. Excellent temperature control can be attained in such a reactor if it is immersed in a thermostated heat transfer fluid or fluidized sand-bath heater.

Continuous stirred tank reactors (CSTRs) are ideally suited for kinetics studies for many types of reactions, owing largely to the ease with which reaction rates can be measured directly. Kinetics models are readily

developed from CSTR data, as discussed by Cropley [1978]. The Berty and Carberry reactors cited previously are especially useful for continuous studies of catalytic kinetics, using real catalyst pellets. An abundant literature on their use exists; Cropley [1990] describes an overall strategy for their use in catalytic reactor design.

Step 3: Use Statistically Valid Experimental Programs and Models

The third element of the protocol is to utilize statistically valid experimental programs and data analysis for kinetic model development. Usually, kinetic data should be generated from statistically designed experimental programs, such as the factorial or central composite design, for which an abundant literature is available. The writings of Hendrix [1979] are recommended. Cropley [1978] describes the heuristic development of both exponential and hyperbolic kinetic models from a statistically designed data set. Table I from that article is an example of a central composite statistical design for the study of the kinetics of a fictitious catalytic reaction (the oxidation of Dammitol to Valualdehyde). The experimental reactor was assumed to be a CSTR like the Berty reactor, which permitted kinetic rates to be observed directly, as in Equation (80.7). The synthetic data in that table were developed from the following “true” model, with the incorporation of 20% normally distributed random error [reproduced with permission of the American Chemical Society from (Cropley, 1978)].

$$r_{\text{Val}} = \frac{4.67(10^{11})e^{-20000/RT}(P_{\text{O}_2})^{0.5}(P_{\text{Dam}})^{1.0}}{1 + 5.52(10^{-4})e^{5000/RT}(P_{\text{O}_2})^{0.5} + 7.64(10^{-4})e^{5000/RT}(P_{\text{Val}})^2} \text{ Gmols/Kgcat/H} \quad (80.13)$$

If a CSTR is used as the experimental reactor, the experimental design should include the independent control of any product species that might influence the reaction rates to avoid systematic bias in the kinetic parameters, as discussed by Cropley [1987].

In the heuristic study cited above, log-linear multiple regression was used for the development of exponential models, and the Nelder–Mead nonlinear search algorithm [Nelder and Mead, 1965] was used for estimation of the nonlinear parameters in the hyperbolic models. (Although Nelder–Mead tends to converge more slowly than some other algorithms, it is robust, stable, and reliable for nonlinear estimation and optimization studies.)

Step 4: Develop Computer Programs for Reactor Simulation and Design

The fourth element of the protocol is to develop computer programs for reactor simulation and design. The typical reaction system design model will comprise several dozen differential equations and a number of nonlinear constraints as well. Consider very carefully just how complex the final models should be. The determination of the true economic optimum may require that the reactor be simulated iteratively many thousands of times, and the model at this point should be no more complex than necessary in order to minimize computer time. Therefore, simulation models for reactor design and optimization should in most cases be based primarily upon the kind of simple idealized reactors represented by Equation (80.3) through Equation (80.12), as discussed earlier. Even so, simulation models can become unwieldy. For example, a five-stage CSTR model for a system of four chemical components and temperature will comprise 25 nonlinear differential equations similar to Equation (80.8). Any of a number of numerical integration techniques may be used for the solution of the differential equations; the fourth-order Runge–Kutta algorithm is perhaps the most common.

Step 5: Develop the Economically Optimum Reactor Design

The fifth protocol for rational design is to develop economically optimum reactor designs. The potentially useful reactor types should be compared to one another at their individual economic optimum design and operating conditions. Arrive at these for each type by varying the simulated reactor size and geometry

FIGURE 80.5 Elements of product cost. (Source: Reproduced with permission of the American Institute of Chemical Engineers from Cropley, J. B. 1990. *Chemical Engineering Progress* 86(2):32–39. Copyright 1990 AIChE. All rights reserved.)

(e.g., diameter, length and number of tubes, or agitator horsepower and vessel diameter and height) and operating conditions (like pressure, flow rate, reactant concentration, coolant temperature, and so on). A suitable optimization procedure, such as the Nelder–Mead algorithm cited previously [Nelder and Mead, 1965], should be used.

The Objective Function for Optimization

The design process will include the computation of objective economic or reactor performance criteria for the comparison of optimized design alternatives. This objective function must be reasonably accurate, yet simple enough to be evaluated easily and quickly for each iteration. It is convenient and quite accurate to use simple linear relationships for optimization criteria like that in Figure 80.5, which illustrates the dependence of incremental product cost on cycle gas flow rate and catalyst bed pressure drop for a hypothetical process. Several similar relationships can comprise an easily used objective function for optimization. Relationships like this can be developed easily from detailed economic analyses of a small number of base case designs. Their development was discussed by Cropley [1990].

Explicit and Implicit Constraints

The optimization package will normally utilize both explicit and implicit constraints to relate the reactor to the rest of the process. In a typical design, for example, reactor inlet pressure and reactor gas flow rate might be *explicitly* constrained to reasonable ranges. Likewise, the maximum reactor temperature might be *implicitly* constrained not to exceed a stipulated maximum. Constraints like these are at the very heart of the optimization process. At the same time, their formulation is both esoteric and beyond the scope of this article, and they are not extensively treated in the open literature. It is recommended that an optimization or numerical analysis specialist be consulted in their development.

Step 6: Validate the Design in a Pilot Plant Reactor

The final step in the protocol for rational design is to validate the overall optimum design by operation of a pilot reactor system. This is the *only time* that scaleup, per se, will be considered in the design. Here again, this may not necessarily involve a pilot reactor that is geometrically similar to the final plant design, although it may be in some cases. It will be important to design the pilot reactor to be able to confirm the predicted reaction yields and selectivities under design conditions. It is vital that all important recycle

streams be incorporated into the pilot plant system — which will then be, to the extent possible, a scaled-down version of the integrated commercial process. Typically, recycle streams include previously unreacted raw materials, byproducts that can be reverted to useful product, or potential pollutants that can simply be destroyed by further reaction in the reactor. But trace components and minor species can build up in recycle systems to many times their single-pass concentrations, and they may have adverse effects on catalyst life, equilibrium conversion, crude product quality, and so on. It is important that the effects of recycled species be incorporated into the kinetics model for operational monitoring and control. Unanticipated effects of recycle streams probably account for a significant fraction of scaleup problems in commercial systems.

Finally, please note that this chapter has not discussed the *size* of the pilot plant reactor — size per se really is not an issue. What *is* important is that it function in such a way as to test the rational design before it is built. More discussion of process optimization and validation can be found in Cropley [1990].

Nomenclature

Uppercase Symbols

| | |
|-----------------------------|--|
| A, B | Reactants |
| C_k | Concentration of k th chemical component, in mols/volume units |
| D_t | Tube diameter, in linear units |
| Dam | Fictitious component Dammitol |
| F_e, F_c | Flow rate of process fluid (e) or of coolant (c) through the volume element, in volume/time units |
| ΔH_j | Heat of reaction of j th reaction in heat/mol units |
| K_{0j}, E_{a_j} | Arrhenius kinetic parameters for reaction j |
| $K_{A_j}, K_{B_j}, K_{P_k}$ | Kinetic parameters associated with reactants A and B and products P_k for reaction j |
| Mode | (-1) if coolant flows countercurrent to process stream flow (+1) if flows are cocurrent (0) if coolant is isothermal (infinite flow, boiling, etc.) |
| P_k | Reaction products |
| R | Gas constant, typically 1.987 cal/Gmol/K for kinetics models |
| T_p, T_c | Reaction and coolant temperature, respectively |
| U | Overall heat transfer coefficient, in heat/area/time/temperature units |
| Val | Fictitious component Valualdehyde |
| V_c | An element of volume of any reactor |
| W_c | Weight of catalyst in the reactor, in weight units |

Lowercase and Greek Symbols

| | |
|------------------|---|
| α_{kj} | Stoichiometric coefficient for species k in reaction j |
| c_c | Heat capacity of coolant stream, in heat/mass/temperature units |
| c_p | Heat capacity of flowing process stream, in heat/mass/temperature units |
| n_c | Total number of products k in the kinetic model |
| n_r | Number of reactions j in the kinetic model |
| n_t | Number of tubes in a tubular reactor |
| ρ_p, ρ_c | Density of process stream (p) or coolant (c), mass/volume units |
| r | Kinetic reaction rate, mols/volume/time (or mols/wt. catalyst/time for catalytic reactions) |
| t | Time, in units consistent with F, r, U |

Defining Terms

Chemical reaction — The chemical transformation of one or more reactant species into one or more chemical products, usually with the evolution or absorption of heat.

Chemical reactor — The vessel in which a chemical reaction is conducted.

Continuous stirred tank reactor — A well-mixed continuous reactor, characterized by a broad residence time distribution.

Conversion — The fraction of a feed component that undergoes chemical transformation in the reactor.

Plug flow reactor — A type of reactor in which all entering elements of fluid have the same residence time. The residence time distribution is thus extremely narrow.

Residence time — The amount of time that a reactive mixture spends in a chemical reactor.

Residence-time distribution (RTD) — The spread of residence times that different elements entering a reactor spend in it. RTD is one of the distinguishing characteristics of different reactor types.

Selectivity — The fraction of all of a feed component that is converted to form a specified product.

Yield — The fraction of all of a feed component entering a reactor that is converted to a specified product.
Yield = (Selectivity) (Conversion).

81.3 Effective Stress

81.4 Consolidation

Time Rate of Consolidation

81.5 Shear Strength

Soil mechanics is the branch of science that deals with the study of the physical properties of soil and the behavior of soil masses while being subjected to various types of forces. Soils engineering is the application of the principles of soil mechanics to practical problems.

81.1 Weight–Volume Relationship

The three phases of a soil sample are solid, water, and air, as shown in [Figure 81.1](#). Thus, a given soil sample of weight W can be expressed as

$$W = W_s + W_w + W_a \quad (81.1)$$

where W_s is the weight of the soil solids, W_w is the weight of the water, and W_a is the weight of air. Assuming that $W_a \approx 0$,

$$W = W_s + W_w \quad (81.2)$$

As shown in [Figure 81.1](#), the total volume of the soil sample is V . The volumes occupied by solid, water, and air are, respectively, V_s , V_w , and V_a . Thus, the volume of void, V_v , is

$$V_v = V_w + V_a \quad (81.3)$$

Common weight and volume relationships are given in [Table 81.1](#).

81.2 Hydraulic Conductivity

In 1856, Darcy published a relationship for the discharge velocity of water through saturated soil (usually referred to as Darcy's law), according to which

$$v = ki \quad (81.4)$$

where v is the discharge velocity, i is the **hydraulic gradient**, and k is the *coefficient of permeability or hydraulic conductivity*. The unit of hydraulic conductivity is LT^{-1} . See [Table 81.2](#).

FIGURE 81.1 Weight–volume relationship.

TABLE 81.1 Weight–Volume Relationships

Volume Relationships

$$\text{Void ratio, } e = \frac{V_v}{V_s} = \frac{n}{1-n}$$

$$\text{Porosity, } n = \frac{V_v}{V} = \frac{e}{1+e}$$

$$\text{Degree of saturation, } S = \frac{V_w}{V_v} = \frac{wG_s}{e}$$

Weight Relationships

$$\text{Moisture content, } w = \frac{W_w}{W_s}$$

$$\text{Moist unit weight, } \gamma = \frac{W}{V}$$

$$\gamma = \frac{(1+w)G_s\gamma_w}{1+e}$$

$$\gamma = \frac{(G_s + Se)\gamma_w}{1+e}$$

$$\gamma = G_s\gamma_w(1-n)(1+w)$$

$$\text{Dry unit weight, } \gamma_d = \frac{\gamma}{1+w}$$

$$\gamma_d = \frac{G_s\gamma_w}{1+e}$$

$$\gamma_d = G_s\gamma_w(1-n)$$

$$\gamma_d = \frac{G_s\gamma_w}{1+wG_s/S}$$

$$\text{Saturated unit weight, } \gamma_{\text{sat}} = \frac{(G_s + e)\gamma_w}{1+e}$$

$$\gamma_{\text{sat}} = [(1-n)G_s + n]\gamma_w$$

$$\gamma_{\text{sat}} = \gamma_d + n\gamma_w$$

Note: G_s = Specific gravity of soil solids; γ_w = Unit weight of water (62.4 lb/ft³; 9.81 kN/m³)

TABLE 81.2 Typical Range of Hydraulic Conductivity

| Soil Type | k (cm/sec) | Relative Hydraulic Conductivity |
|--------------|------------------------|---------------------------------|
| Clean gravel | 10^2 to 10^0 | High |
| Coarse sand | 10^0 to 10^{-2} | High to medium |
| Fine sand | 10^{-2} to 10^{-3} | Medium |
| Silt | 10^{-3} to 10^{-5} | Low |
| Clay | Less than 10^{-6} | Very low |

One of the most well-known relationships for hydraulic conductivity is the Kozeny–Carman equation, which is of the form

$$k = \frac{1}{\eta} \frac{1}{s_p t^2 s_s^2} \frac{n^3}{(1-n)^2} \quad (81.5)$$

where η is viscosity, s_p is pore shape factor, t is tortuosity, s_s is specific surface per unit volume, and n is porosity. Table 81.2 gives the general magnitude of the hydraulic conductivity.

81.3 Effective Stress

In saturated soil the **total stress** in a given soil mass can be divided into two parts — a part that is carried by water present in continuous void spaces, which is called *pore water pressure*, and the remainder that is carried by the soil solids at their points of contact, which is called the *effective stress*. Or

$$\sigma = \sigma' + u \quad (81.6)$$

where σ is total stress, σ' is effective stress, and u is pore water pressure.

In partially saturated soil, water in the void space is not continuous, and the soil is a three-phase system — that is, solid, pore water, and pore air. In that case,

$$\sigma = \sigma' + u_a - \chi(u_a - u_w) \quad (81.7)$$

where u_a is pore air pressure and u_w is pore water pressure.

81.4 Consolidation

Consolidation is the *time-dependent* volume change of saturated clayey soil due to the expulsion of water occupying the void spaces. When a load is applied to a saturated compressible soil mass, the increase in stress is initially carried by the water in the void spaces (that is, increase in pore water pressure) due to its relative incompressibility. With time, the water is squeezed out, and the stress increase is gradually transferred to effective stress. The effective stress increase results in consolidation settlement of the clayey soil layer(s).

A clay is said to be *normally consolidated* when the present *effective* overburden pressure (p_o) is the maximum pressure to which the soil has been subjected in the past. When the present effective overburden pressure of a clay is less than that which it experienced in the past, it is referred to as an *overconsolidated* clay. The maximum past effective overburden pressure is called the *preconsolidation pressure* (p_c).

The *primary consolidation* settlement (S) of a saturated clay layer of thickness H (Figure 81.2) due to a load application can be calculated by the following relationships. In Figure 81.2, for the clay layer, p_o is the effective overburden pressure before the load application, Δp is the increase in stress at the middle

FIGURE 81.2 Consolidation settlement of a clay layer.

of the clay layer due to the load application, and e_o is the initial void ratio. For normally consolidated clay ($p_o = p_c$),

$$S = \frac{C_c H}{1 + e_o} \log \left(\frac{p_o + \Delta p}{p_o} \right) \quad (81.8)$$

For overconsolidated clay with $p_o + \Delta p \leq p_c$,

$$S = \frac{C_s H}{1 + e_o} \log \left(\frac{p_o + \Delta p}{p_o} \right) \quad (81.9)$$

For overconsolidated clay with $p_o < p_c < p_o + \Delta p$,

$$S = \frac{C_s H}{1 + e_o} \log \left(\frac{p_c}{p_o} \right) + \frac{C_c H}{1 + e_o} \log \left(\frac{p_o + \Delta p}{p_c} \right) \quad (81.10)$$

where C_c is the compression index and C_s is the swelling index. The magnitudes of C_c and C_s can be obtained from laboratory consolidation tests. In the absence of the laboratory results the following empirical approximations can be used. From Skempton [1944],

$$C_c = 0.009(LL - 10) \quad (81.11)$$

where LL is liquid limit, in percent. From Nishida [1956],

$$C_c = 1.15(e_o - 0.27) \quad (81.12)$$

And, finally, from Rendon-Herrero [1980],

$$C_c = 0.156 e_o + 0.0107 \quad (81.13)$$

$$C_s \approx 0.1 - 0.2 C_c \quad (81.14)$$

Time Rate of Consolidation

The average degree of consolidation (U) of a clay layer due to an applied load can be defined as

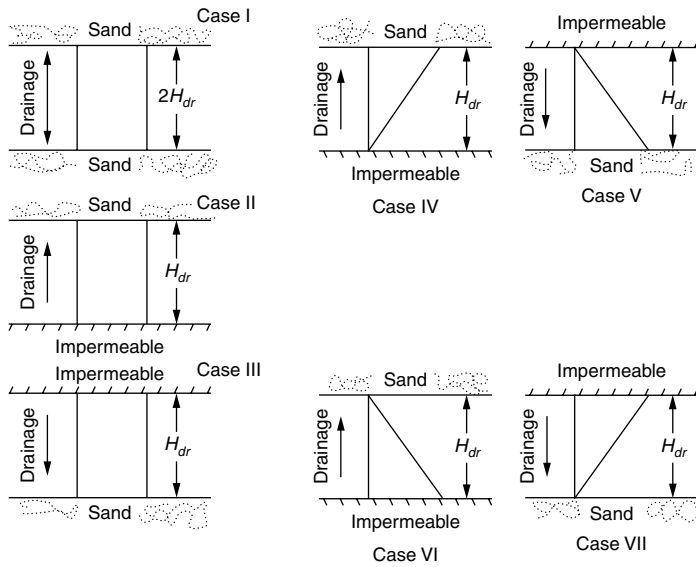

FIGURE 81.3 Definition of H_{dr} .

$$U = \frac{S_t}{S} \quad (81.15)$$

where S_t is primary consolidation settlement after time t of load application, and S is the ultimate consolidation settlement. The degree of consolidation is a function of time factor T_v , which is a nondimensional quantity. Or

$$U = f(T_v) \quad (81.16)$$

$$T_v = \frac{C_v t}{H_{dr}^2} \quad (81.17)$$

where C_v is the **coefficient of consolidation**, t is the time after load application, and H_{dr} is the length of the smallest drainage path. Figure 81.3 shows the definitions of H_{dr} and the initial excess pore water pressure (u_o) distribution for seven possible cases. The variations of U with T_v for these cases are shown in Table 81.3.

81.5 Shear Strength

Shear strength of a soil mass is the internal resistance per unit area that the soil mass can offer to resist failure and sliding along any plane inside it. For most soil mechanics problems, it is sufficient to approximate the shear strength by the *Mohr–Coulombe failure criteria*, or

$$s = c + \sigma' \tan \phi \quad (81.18)$$

where c is the cohesion, σ' is the effective normal stress, and ϕ is the drained friction angle. For normally consolidated clays and sands, $c \approx 0$.

Figure 81.4 shows an approximate correlation for ϕ with porosity and **relative density** for coarse-grained soils. Table 81.4 gives typical values of ϕ for sand and silt.

TABLE 81.3 Variation of Average Degree of Consolidation with Time Factor

| Average Degree of Consolidation, U (%) | Time Factor, T_v | | |
|--|--------------------|------------|--------------|
| | Case I, II, III | Case IV, V | Case VI, VII |
| 0 | 0 | 0 | 0 |
| 10 | 0.008 | 0.003 | 0.0047 |
| 20 | 0.031 | 0.009 | 0.100 |
| 30 | 0.071 | 0.025 | 0.158 |
| 40 | 0.126 | 0.048 | 0.221 |
| 50 | 0.197 | 0.092 | 0.294 |
| 60 | 0.287 | 0.160 | 0.383 |
| 70 | 0.403 | 0.271 | 0.500 |
| 80 | 0.567 | 0.440 | 0.665 |
| 90 | 0.848 | 0.720 | 0.940 |
| 100 | ∞ | ∞ | ∞ |

FIGURE 81.4 Approximate correlation for ϕ of coarse-grained soil with porosity and relative density. Note: GW = well-graded gravel, GP = poorly graded gravel, SW = well-graded sand, SP = poorly graded sand, SM = silt sand, ML = silt with low plasticity. (After Department of the Navy, 1971. *Soil Mechanics, Foundations, and Earth Structures* — NAVFAC DM-7, U. S. Government Printing Office, Washington, DC.)

TABLE 81.4 Typical Values of ϕ for Sand and Silt

| Soil | ϕ (deg) |
|--------|--------------|
| Sand | |
| Loose | 28–35 |
| Medium | 30–40 |
| Dense | 35–45 |
| Silt | 25–35 |

Defining Terms

Coefficient of consolidation — The coefficient of consolidation is defined by the relationship

$$C_v = \frac{k}{\gamma_w \left(\frac{\Delta e}{\Delta p} \frac{1}{1 + e_o} \right)}$$

where Δe is the change in void ratio due to a pressure increase in Δp .

Hydraulic gradient — The ratio of the loss of head to the length of flow over which the loss occurred.

Relative density — Relative density is defined as $(e_{\max} - e)/(e_{\max} - e_{\min})$, where e_{\max} and e_{\min} are, respectively, the maximum and minimum possible void ratios for a soil, and e is the *in situ* void ratio.

Total stress — The total stress at a given elevation is the force per unit gross cross-sectional area due to soil solids, water, and surcharge.

Michael D. Meyer

Georgia Institute of Technology

Transportation planning is undertaken for a variety of reasons. With the provision of much of the world's transportation infrastructure the responsibility of governments, transportation planning is undertaken primarily to support public officials in their choice of most cost-effective investments. Because transportation investment has a strong influence on how a community evolves, transportation planning must necessarily consider a variety of factors when assessing the cost effectiveness of alternative investment options. For example, transportation investment can strongly influence land use patterns, the attractiveness of different parts of a region for economic development, the equitable distribution of mobility benefits among different population groups, and the environmental consequences of both the construction and operation of transportation facilities. Transportation planning must therefore be forward-looking, as well as give attention to current problems in the transportation system.

82.1 Basic Framework of Transportation Planning

The basic framework for transportation planning that could be applied at any scale of application is shown in [Figure 82.1](#). The steps shown in this framework are discussed in the following sections.

Define a Vision

The transportation system can impact society in a variety of ways — providing mobility and accessibility, promoting economic development, contributing to quality of life, as well as negatively affecting the natural environment. The first step in transportation planning thus usually consists of defining what it is that the nation, state or region desires in terms of its future characteristics.

Identify Goals and Objectives

Once a desired vision is articulated, *goals* can be identified that relate the vision to the ultimate achievement of a transportation plan. *Objectives* are more specific statements that indicate the means by which these goals will be achieved. Goals and objectives not only provide overall direction to the transportation planning process, but they also help define the criteria, known as *measures of effectiveness*, that are used later in the process for evaluating alternative courses of action.

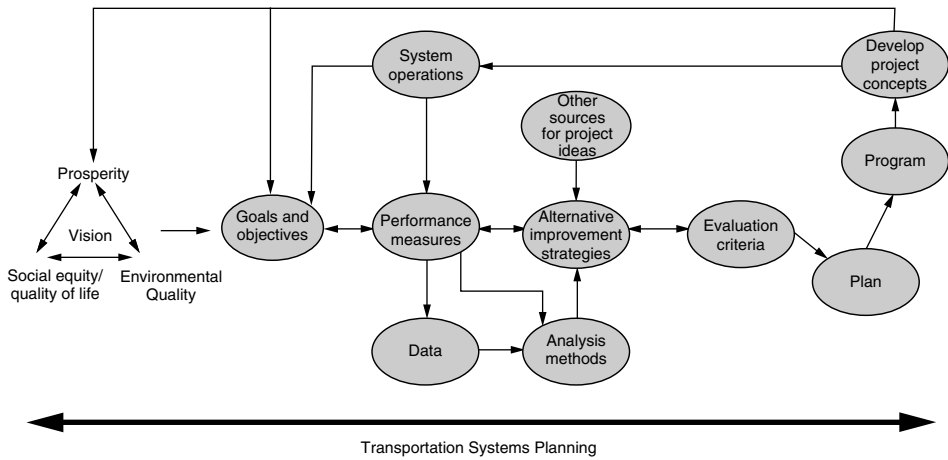

FIGURE 82.1 Transportation planning process.

Identify Performance Measures

An important aspect of a continuing transportation planning process is the monitoring of system performance. This monitoring systematically identifies areas where improvements might occur, and, in addition, helps transportation officials assess the effectiveness of previously implemented actions. Performance measures can focus explicitly on transportation system operations, e.g., the level of freeway delay during the morning peak travel hours, or on other issues of importance to transportation officials, e.g., the level of transportation-related air pollutants emitted during specified periods of time.

Collect Data

Given that transportation investment is usually aimed at upgrading the *physical condition* of a facility (e.g., repaving a road or building a new bridge) or at improving its *performance* (e.g., providing new person-carrying capacity by setting aside highway lanes for multi-occupant vehicles or by building a new road), engineers are continually collecting data on the many different components of the transportation system. The base condition or performance of all the different facilities or services that make up a transportation system is called an *inventory*.

Forecasting future demand for transportation requires engineers and planners to characterize the current and likely future states of the factors that influence this demand. Thus, for example, the type of data that is collected includes such things as current land use and socioeconomic characteristics of the traveling population. Current land use is readily attained through land use inventories. The methods of estimating future land use range from trends analysis to large-scale land use models that predict household and employment sites decades into the future. Important socioeconomic characteristics include level of household income, number of members of the household, number of autos in the household, number of children, age of the head of household, and highest level of education achieved. Each of these factors has been shown through research to influence the amount and type of travel associated with a typical household.

Use Analysis Tools to Identify System Deficiencies or Opportunities

The analysis tools and methods used to identify transportation deficiencies and improvement opportunities can vary widely. In some cases, computer-based transportation network models are used to estimate future traffic volumes and transit ridership, with the results then compared to existing system capacity to handle such volumes. This comparison relies on one of the more popular performance measures used in transportation planning today, the volume-to-capacity (V/C) ratio. However, given the many different

goals and objectives that can characterize a transportation planning process, a wide variety of measures are often used for determining system deficiencies. Other types of analysis tools include time–distance diagrams, queuing models, fluid-flow approximation methods, macro- and micro-simulation models, and mathematical programming techniques.

Develop and Analyze Alternatives

Various types of strategies can result from the planning process:

1. Improving the *physical infrastructure* of the transportation system — for example, adding new highway lanes or extending an existing subway line
2. Improving *system operations* — for example, coordinating traffic signals, improving traffic flow through improved geometric design of intersections, or making transit operations more efficient through schedule coordination
3. Reducing *travel demand* so that the transportation system can handle peak loads more effectively — for example, flexible working hours, increasing average vehicle occupancy through such measures as carpools or transit use, or raising the “price” of travel through the use of tolls

In the past 10 years, the application of advanced transportation technologies to the operation of the transportation system, known as *intelligent transportation systems* (ITS), has become an important type of strategy in many cities. Thus, it is not uncommon for major cities to now have a centralized traffic management center, with a regional surveillance and traveler communication system that permits transportation system managers to communicate to travelers the best times for travel and which routes are least congested.

Evaluate Alternatives

Evaluation brings together all of the information gathered on individual alternatives/plans and provides a systematic framework to compare the relative worth of each. This evaluation process most often relies on the various measures of effectiveness that link to the goals and objectives defined at the beginning of the process. Different types of evaluation methods include use of benefit/cost ratios, cost-effectiveness indices, goals matrix analysis, and subjective assessment of the merits of individual alternatives.

Develop Transportation Plan

One of the most important products of the transportation planning process is the *transportation plan*. The plan outlines the many different strategies and projects that are necessary to meet the challenges and opportunities facing a state or region. In the U.S., federal law requires that every state and every metropolitan area over 50,000 population have a transportation plan. The state department of transportation (DOT) is responsible for preparing the state transportation plan; an agency called the metropolitan planning organization (MPO) is responsible for preparing the metropolitan transportation plan.

Implement Plan

Another major product of the transportation planning process is a strategy for implementing all of the actions identified in the plan. In the U.S., federal law requires each state and every metropolitan area over 50,000 population to produce a *transportation improvement program* that lists the projects that will be implemented over the next 3 to 5 years, identifies which agency is responsible for each project, and describes the source of project funding.

The implemented projects will affect the performance of the transportation system. Through a continuing monitoring process, linked directly to important performance measures, the performance of individual projects or of the entire transportation system can be fed back into the planning process as a means of identifying new problems.

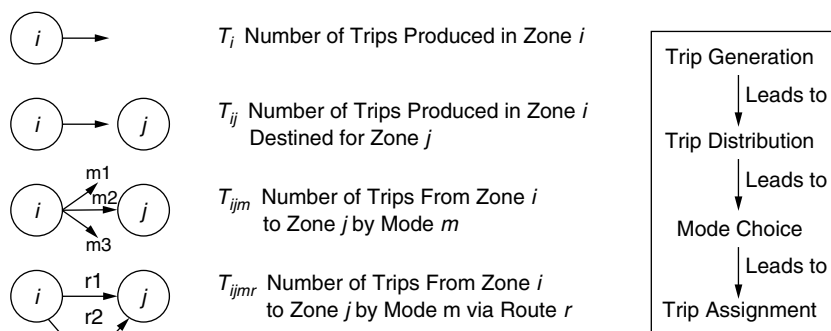

FIGURE 82.2 Transportation modeling framework.

82.2 Transportation Modeling

The level of transportation analysis can vary according to the level of complexity and scale of application of potential solution strategies. Thus, for example, the consideration of a new subway system would necessarily have to be examined from a metropolitan level, while the transportation impacts of a new development site would likely be analyzed at a subregional level. In most cases, however, the modeling process consists of four major steps — trip generation, trip distribution, mode split, and trip assignment. Even though recent models combine some of these steps together during the analysis process, the concept of the “trip” consisting of these four stages still holds. Each study area (whether a nation, state, metropolitan area, or community) is divided into *zones* of homogeneous characteristics (e.g., similar household incomes) that can then be used as the basic foundation for estimating trips from or attracted to that zone. Most planning studies define these zones to be similar to those used in other data collection activities (e.g., the U.S. census tracts) so that data useful to the transportation study collected by others can be readily linked to the transportation analysis. The transportation system is represented in models as a network of links and nodes. Links represent line-haul facilities, such as roads or transit lines, and nodes represent points of connection, such as an intersection or transit terminal. Given the complex nature of transportation systems, the typical transportation network consists of links representing only highly used facilities or other facilities that are critical to the overall performance of the transportation system.

The steps in a typical modeling exercise are shown in Figure 82.2. Basic to this approach is the concept of *derived demand*. Derived demand means that a trip is taken to accomplish some activity at a destination, and that the trip itself is simply a means of reaching this activity. There is no intrinsic value of the trip itself. Thus, modeling trip-making requires linking travel behavior to the characteristics of the trip-maker and to the activities at the origin and destination ends of the trip that will influence the way the trips are made.

Trip generation is the process of analytically deriving the number of trips that will be generated from a location or zone based on socioeconomic characteristics of the household, or in the case of freight movement, the zonal economic characteristics. Trip generation also includes predicting the number of trips that will be attracted to each zone in the study area.

Number of trips produced in a zone = f (Population socio-economic characteristics, land use, transportation mode availability)

Number of trips attracted to a zone = f (Attractiveness of the zone)

Two approaches are often used to estimate the number of trips generated. The first uses trip rate models that are based on trip-making behavior as compared to important variables. For example, see Table 82.1. The other approach is to use regression models that are estimated either from survey data

TABLE 82.1 Cross-Classification Analysis, Trips per Day, by Household Size and Income

| | Number of People in Households | | |
|---------------|--------------------------------|-----|-----|
| | 1 | 2 | 3+ |
| Low income | 2.4 | 3.3 | 4.5 |
| Medium income | 3.5 | 3.8 | 4.8 |
| High income | 3.9 | 4.2 | 5.4 |

collected throughout the study area or from some other data source, such as the U.S. Census. The following regression equations illustrate this approach.

Zone Trip Productions: $T_i = 184.2 + 120.6 (\text{Workers}_i) + 34.5 (\text{Autos}_i)$

Household Trip Productions: $T_{ih} = 0.64 + 2.3 + (\text{Employee}_i) + 1.5 (\text{HHAuto}_i)$

Zonal Attractions: $T_j = 54.2 + 0.23 (\text{Office}_j) + 0.43 (\text{Retail}_j)$

where T_i = total number of trips generated in zone i ; T_{ih} = total trips generated per household in zone i ; T_j = total trips attracted to zone j ; Workers_i = number of workers in zone i ; Autos_i = number of autos in zone i ; Employee_i = number of employees per household in zone i ; HHAuto_i = number of autos per household in zone i ; Office_j = number of office employees in zone j ; and Retail_j = number of retail employees in zone j .

Trip distribution is the process of estimating the number of trips that travel from each zone to every other zone in the study area. The results of the trip distribution process is a matrix called the *trip table*, which shows the number of trips traveling between each origin–destination (O-D) pair for the time period being examined. A common method for distributing trips in a zonal system is the gravity model, which is of the following form:

$$T_{ij} = P_i \times \frac{A_i \times F_{ij} \times K_{ij}}{\sum (A_j \times F_{ij} \times K_{ij})}$$

where T_{ij} = total trips originating in zone i and destined to zone j ; P_i = number of trips produced in zone i ; A_j = level of attractiveness of zone j (e.g., number of retail employees); F_{ij} = friction or impedance factor between zones i and j (a value usually a function of travel time); and K_{ij} = socioeconomic adjustment factors for trips between zones i and j (a value that represents variables that influence trip making not accounted for by other variables).

Mode choice is the process of estimating the percentage of travelers who will use one mode of transportation versus the others available for a given trip. The basic approach in making this estimation is that each mode has associated with it some empirically known characteristics that, when combined with characteristics of the traveler in a mathematical equation, can define that mode's *utility*. Variables such as travel time, travel cost, modal reliability, and so on are often incorporated into a mode's *utility function*, along with socioeconomic characteristics of the traveler. Freight models use a similar concept in estimating commodity flows by mode. One of the most familiar forms of mode choice models, based on the concept of consumer choice, is the logit model, which predicts mode shares based on the following equation:

$$P_{ik} = \frac{e^{U_k}}{\sum e^U_m} \text{ for all modes } n$$

where P_{ik} = probability of individual i choosing mode k ; U_k = utility of mode k ; U_m = utility of mode m ; n = number of modes available for trip.

The utility of each mode is often represented as a linear function of those variables found to influence an individual's choice of mode. For example, a utility function for the automobile mode might be of the form,

$$U_a = 6.3 - 0.21 (X_1) - 0.43 (X_2) - 0.005 (X_3)$$

where U_a = utility of automobile; X_1 = access and egress time when automobile is chosen; X_2 = line-haul travel time; and X_3 = cost of travel.

The utility functions of other modes available for a specific trip would be similarly specified. The respective probabilities would then be multiplied by the total number of trips between an origin and destination to obtain the number of trips made by mode.

Trip assignment is the process of estimating the trip paths through a transportation network based on a trip table (which is produced in trip distribution). The basic concept found in all trip assignment methods is that travelers choose modes that will minimize travel time, that is, they will choose the shortest path through a network (once again, the assumption of derived demand influencing the analysis approach). Link performance functions that relate travel time to the number of vehicles or riders on that link are used to iteratively update estimated link travel times so that minimum path travel times reflect the effect of congestion (see [Figure 82.3](#)). A portion of the total O-D travel demand is assigned to the network, with travel times then updated based on the link performance function, given the volume on each link. An additional portion of the O-D travel is next assigned given the updated travel times, still following the minimum travel time path through the network. This process continues until all estimated trips have been assigned to a link path in the network. Stochastic assignment is also used in many planning studies. This assignment recognizes that, in certain cases, some subset of trip routes will have associated with them some characteristics that attract specific types of travelers, even if the travel time is longer. A probabilistic approach takes these characteristics into account.

In order to develop more behaviorally based travel models, researchers in recent years have focused on the fact that travel arises out of the need to participate in out-of-home activities (work, shopping, school, etc.). This directly leads to the conclusion that what one should study in the first instance is not travel per se, but rather the participation in the *activities* that ultimately generate travel. This approach has been referred to as “activity-based modeling.” [Figure 82.4](#) shows the difference in the traditional approach toward modeling and the activity-based approach. Many activity-based models are being implemented within a *micro-simulation* framework, within which the behavior of each individual is dynamically simulated over time.

FIGURE 82.3 Link performance function.

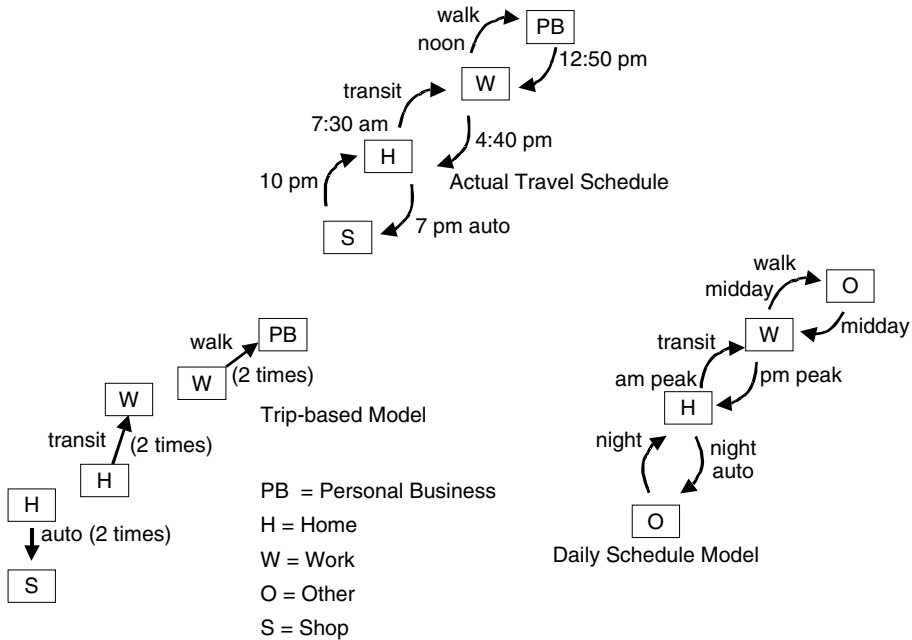

FIGURE 82.4 Difference between trip-based modeling and activity-based modeling.

Defining Terms

Demand management — Reducing the demand for travel during specific time periods by shifting trips to other times, diverting trips to other routes or modes, or reducing the need for trip-making to begin with.

Derived demand — An assumption that travelers make a trip to accomplish some objective at the destination and that the trip itself is simply a means of reaching that activity.

Intelligent transportation systems — Application of surveillance, communication, and control technologies to the management of the transportation system, and in some cases, to the control of individual vehicles.

Transportation network — A transportation system is represented in models as a network of links and nodes. Links represent line-haul facilities, such as roads and transit lines, and nodes represent points of connection.

Utility function — A mathematical formulation that assigns a numerical value to the attractiveness of individual modes of transportation based primarily on that mode's characteristics.

Zonal system — Each study area (whether nation, state, metropolitan region, or community) is divided into zones of homogeneous characteristics that can then be used as the basic foundation for estimating trips from, or attracted to, that zone.

Georgia Institute of Technology

The efficient movement of people and goods requires transportation systems and facilities that are designed to provide sufficient capacity for the demands they face in as safe a manner as possible. In addition, in most modern societies, the design of transportation facilities must explicitly minimize harm to the natural and human-made environment while providing for mitigation measures that relate to those impacts that are unavoidable. In many ways the critical challenge to today's designers of transportation projects is successfully designing a facility that minimally harms the environment.

The design of a transportation facility almost always takes place within the context of a much broader **project development process**. This process can vary in complexity with the type of project under design and with the scale of implementation. The importance of the project development process to the designer is that it:

- Establishes the key characteristics of the project that must be considered in the design
 - Indicates the time frame that will be followed for project design
 - Establishes which agencies and groups will be involved in the process and when this involvement will likely occur
 - Links the specific elements of the project design with other tasks that must be accomplished for the project to be constructed
-

- Satisfies legal requirements for a design process that is open for public review and comment
- Indicates the specific products that must be produced by the designers to complete the project design process

In most cases the project development process consists of a well-defined set of tasks that must be accomplished before the next task can occur. These tasks include both technical activities and public involvement efforts that are necessary for successful project development.

83.1 Components of the Project Development Process

Identify Project Need

A project need can be identified through a formal planning process or from a variety of other sources, including suggestions from elected officials, agency managers, transportation system users, and citizens. Important in this early portion of project development is an indication of what type of improvement is likely to be initiated. For example, a project could relate to one or more of the following types of improvement strategies:

- *New construction.* A transportation facility constructed at a new location
- *Major reconstruction.* Addition of new capacity or significant changes to the existing design of a facility, but usually occurring within the area where the current facility is located
- *Rehabilitation/restoration.* Improvements to a facility usually as it is currently designed and focusing on improving the physical condition of the facility or making minor improvements to enhance safety
- *Resurfacing.* Providing new pavement surface to a transportation facility that prolongs its useful life
- *Spot improvements.* Correction of a problem or hazard at an isolated or specific location

Establish Project Limits and Context

One of the very first steps in the design process is to define the boundaries or limits of the project. This implies establishing how far the project will extend beyond the area being targeted for improvement and the necessary steps to ensure smooth connections to the existing transportation system. Project boundaries also have important influence on the amount of right-of-way that might have to be purchased by an agency to construct a project.

Establish Environmental Impact Requirements

The design of a project will most likely be influenced by environmental laws or regulations that require design compliance with environmental mandates. These mandates could relate to such things as wetland protection, preservation of historic properties, use of public park lands, maintaining or enhancing water quality, preserving navigable waterways, protecting fish and wildlife, reducing air pollutants and noise levels, and protecting archaeological resources. One of the first steps in project development is to determine whether the likely project impacts are significant enough to require a detailed environmental study.

Develop Strategy for Interagency Coordination and Public Involvement

Depending on the complexity and potential impact of a project, the project designer could spend a great deal of time interacting with agencies having some role in or jurisdictional control over areas directly related to the project. These agencies could have jurisdiction by law (e.g., wetlands) or have special expertise that is important to project design (e.g., historic preservation). In addition to interagency coordination, transportation project development is often subject to requirements for public outreach and/or public hearings. An important aspect of recent project development efforts is to develop very early in the process a consensus among involved agencies on what environmental impacts will have to be carefully studied and on the definition of the project purpose and need.

Initiate Project Design and Preliminary Engineering

Topographic data of the study area and forecasted vehicular volumes expected to use the facility in the design year are used as input into the preliminary design of the horizontal and vertical alignment of the facility, that is, the physical space the facility will occupy once finished. This preliminary engineering step also includes the preparation of initial right-of-way (ROW) plans, which indicate the amount of land that must be available to construct the facility. Preliminary engineering is a critical step for environmental analysis in that it provides the first detailed examination of the scope and extent of potential environmental impacts.

Project Engineering

Once preliminary engineering has provided the basic engineering information for the project, the more detailed project design begins. This entails specific layouts of horizontal and vertical geometry, soils/subsurface examination and design, design of utility location, drainage design, more detailed ROW plans, and initial construction drawings. Concurrent with this design process, the environmental process continues with updated information on project changes that might cause additional environmental harm, the initiation of any permitting process that might be needed to construct the project (e.g., environmental agency permission to affect wetlands), and public hearings/meetings to keep the public involved with project development.

Final Engineering

The final engineering step is the culmination of the design process, which completes the previous design plans to the greatest level of detail. This step includes finalizing ROW plans, cost estimates, construction plans, utility relocation plans, and any agreements with other agencies or jurisdictions that might be necessary to complete the project. Environmental permits are received and final project review for environmental impacts is completed.

Context-Sensitive Design

One of the important characteristics of transportation facility design is the potentially negative impact that new facilities could have on the surrounding community and natural environment. Engineers and planners have begun to consider such impacts earlier in the project development process so that the context within which a facility is constructed is incorporated into the design itself. This process is called **context-sensitive design**.

83.2 Basic Concepts of Project Design

Human Factors

Human factors have a great deal of influence on the design of transportation facilities in such things as width of facility, length and location of access/egress points, vehicle braking distance, location of information/guidance aids such as signs, and geometric characteristics of the facility's alignment. The driver-vehicle-roadway interface is shown in [Figure 83.1](#).

Vehicle or User Performance Factors

The dynamics of vehicle motion play an important role in determining effective and safe design. The key vehicle characteristics that relate to facility design criteria include:

- *Vehicle size*. Influences vertical and horizontal clearances, turning radii, alignment width, and width of vehicle storage berths.
- *Vehicle weight*. Influences strength of material needed to support vehicle operations.

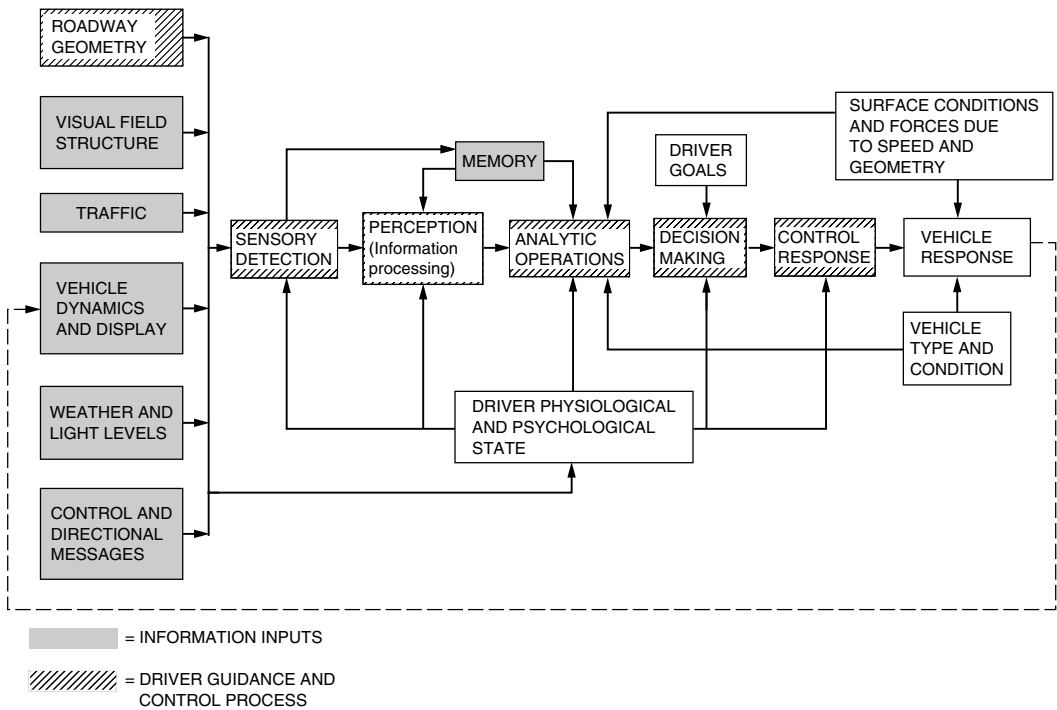

FIGURE 83.1 Driver-vehicle-roadway interface.

- *Vehicle or user performance.* Influences specifications for horizontal and vertical geometry, braking distances, operational performance and needed capacity to allow passing and successful maneuvering (e.g., assumed walking speed of pedestrians crossing a road that dictates how long a traffic signal must remain red).

Classification Schemes

The transportation system serves many functions, ranging from providing access to specific locations to providing high-speed, high-capacity movement over longer distances. Classification schemes are used to represent these various roles and influence the design criteria that are associated with the facilities in each classification category. A common **functional classification** scheme for highways is shown in Figure 83.2.

Capacity and Level of Service

Every design usually begins with some estimation of the demand for the transportation facility that will likely occur if the facility is built. The key design question then becomes, what facility capacity (e.g., number of road lanes, runways, transit lines, or vehicle departures) is necessary if a certain level of performance is desired? These different levels of performance are referred to as **level of service (LOS)**. Level of service is a critical element in establishing important design factors (see Figure 83.3).

FIGURE 83.2 Relationship of functionally classified systems in relation to traffic mobility and land access. FREEWAYS

| Level of Service | Maximum Density (pc/mi/ln) | Minimum Speed (mph) | Max Service Flow Rate (pcphpl) | Maximum v/c Ratio |
|--------------------------|----------------------------|---------------------|--------------------------------|-------------------|
| Free-Flow Speed = 70 mph | | | | |
| A | 10.0 | 70.0 | 700 | 0.318/0.304 |
| B | 16.0 | 70.0 | 1120 | 0.509/0.487 |
| C | 24.0 | 68.5 | 1644 | 0.747/0.715 |
| D | 32.0 | 63.0 | 2015 | 0.916/0.876 |
| E | 36.7/39.7 | 60.0/58.0 | 2200/2300 | 1.000 |
| F | var | var | var | var |
| Free-Flow Speed = 65 mph | | | | |
| A | 10.0 | 65.0 | 650 | 0.295/0.283 |
| B | 16.0 | 65.0 | 1040 | 0.473/0.452 |
| C | 24.0 | 64.5 | 1548 | 0.704/0.673 |
| D | 32.0 | 61.0 | 1952 | 0.887/0.849 |
| E | 39.3/43.4 | 56.0/53.0 | 2200/2300 | 1.000 |
| F | var | var | var | var |
| Free-Flow Speed = 60 mph | | | | |
| A | 10.0 | 60.0 | 600 | 0.272/0.261 |
| B | 16.0 | 60.0 | 960 | 0.436/0.417 |
| C | 24.0 | 60.0 | 1440 | 0.655/0.626 |
| D | 32.0 | 57.0 | 1824 | 0.829/0.793 |
| E | 41.5/46.0 | 53.0/50.0 | 2200/2300 | 1.000 |
| F | var | var | var | var |
| Free-Flow Speed = 55 mph | | | | |
| A | 10.0 | 55.0 | 550 | 0.250/0.239 |
| B | 16.0 | 55.0 | 880 | 0.400/0.383 |
| C | 24.0 | 55.0 | 1320 | 0.600/0.574 |
| D | 32.0 | 54.8 | 1760 | 0.800/0.765 |
| E | 44.0/47.9 | 50.0/48.0 | 2200/2300 | 1.000 |
| F | var | var | var | var |

Note: In table entries with split values, the first value is for four-lane freeways, and the second is for six- and eight-lane freeways.

PEDESTRIAN WALKWAYS

| Level of Service | Space (sq ft/ped) | Expected flows and Speeds | | |
|------------------|-------------------|---------------------------|---------------------------|--------------------|
| | | Ave. Speed, S (ft/min) | Flow Rate, v (ped/min/ft) | Vol/Cap Ratio, v/c |
| A | ≥130 | ≥260 | ≤2 | ≤0.08 |
| B | ≥40 | ≥250 | ≤7 | ≤0.28 |
| C | ≥24 | ≥240 | ≤10 | ≤0.40 |
| D | ≥15 | ≥225 | ≤15 | ≤0.60 |
| E | ≥6 | ≥150 | ≤25 | ≤1.000 |
| F | <6 | <150 | —Variable— | |

*Average conditions for 15 min.

SIGNALIZED INTERSECTIONS

| Level of Service | Stopped Delay per Vehicle (sec) |
|------------------|---------------------------------------|
| A | ≤5.0 |
| B | 5.1 to 15.0 |
| C | 15.1 to 25.0 |
| D | 25.1 to 40.0 |
| E | 40.1 to 60.0 |
| F | >60.0 |

ARTERIAL ROADS

| Arterial Class | I | II | III |
|------------------------------------|----------------------------|----------|----------|
| Range of Free Flow Speeds (mph) | 45 to 35 | 35 to 30 | 35 to 25 |
| Typical Free Flow Speed (mph) | 40 mph | 33 mph | 27 mph |
| Level of Service | Average Travel Speed (mph) | | |
| A | ≥35 | ≥30 | ≥25 |
| B | ≥28 | ≥24 | ≥19 |
| C | ≥22 | ≥18 | ≥13 |
| D | ≥17 | ≥14 | ≥ 9 |
| E | ≥13 | ≥10 | ≥ 7 |
| F | <13 | <10 | < 7 |

FIGURE 83.3 *Continued.*

Design Standards

Design standards dictate minimum or maximum values of project characteristics that are associated with a particular facility type. Design standards usually result from extensive study of the relationship between various facility characteristics, vehicle performance, and the safe handling of the vehicles by human operators. Design standards often vary by the “design speed” of the facility (and thus the importance of the facility classification) and by the “design vehicle.” Design standards are often the basis for developing typical cross-sections (see [Figures 83.4](#) and [83.5](#)).

83.3 Intermodal Transportation Terminals or Transfer Facilities

Terminals or transfer facilities are locations where users of the transportation system change from one mode of travel to another. The effective design of such facilities is a critical element of successful transportation system performance, given the potential bottlenecks they represent if not designed appropriately. The design of terminals and transfer facilities must pay special attention to the needs of the users of the facility, in that they serve to establish the effective capacity of the facility, for example:

1. Internal pedestrian movement facilities and areas (stairs, ramps, escalators, elevators, corridors, etc.)
2. Line-haul transit access area (entry control, fare collection, loading, and unloading)
3. Components that facilitate movements between access modes and the station (ramps or electric doors)

RECOMMENDED ROADWAY SECTION WIDTHS

| Functional Class | U/R | Number of Lanes | Travel Lane | Shoulder | |
|------------------|-------|--------------------------|-------------|-------------------|-------------------|
| | | | | Right | Left ¹ |
| Freeway | Urban | 4–8 | 12 | 10 | 4 ² |
| | Rural | 4–8 | 12 | 10 | 4 ² |
| Arterial | Urban | Multilane with median | 12 | 10 | 4 |
| | Urban | Multilane without median | 11–12 | 8–10 ³ | N/A |
| | Rural | 2 lane | 12 | See Table 5.2 | N/A |
| | Rural | Multilane with median | 12 | 8–10 | 4 |

**WIDTH OF USABLE SHOULDER—EACH SIDE OF TRAVEL WAY
RURAL TWO-LANE ARTERIAL**

| Design Traffic Volume | | | | | |
|-----------------------|-----------------------|----------------------|-------------|-------------|--------------|
| | Current ADT Under 400 | Current ADT Over 400 | DHV 100–200 | DHV 200–400 | DHV Over 400 |
| All design speeds | 4 ft | 6 ft | 6 ft | 8 ft | 10 ft |

**RECOMMENDED WIDTH OF TRAVEL WAY AND GRADED SHOULDER
RURAL COLLECTOR**

| Design Traffic Volume | | | | | |
|------------------------------|-----------------------|----------------------|-------------|-------------|--------------|
| Design Speed (mph) | Current ADT Under 400 | Current ADT Over 400 | DHV 100–200 | DHV 200–400 | DHV Over 400 |
| 30 | 20 ft | 20 ft | 20 ft | 22 ft | 24 ft |
| 40 | 20 ft | 22 ft | 22 ft | 22 ft | 24 ft |
| 50 | 20 ft | 22 ft | 22 ft | 24 ft | 24 ft |
| 60 | 22 ft | 22 ft | 22 ft | 24 ft | 24 ft |
| Graded Shoulder (Each Side)* | | | | | |
| All speeds | 2 ft | 4 ft | 6 ft | 8 ft | 8 ft |

*If right-of-way permits

FIGURE 83.4 Example design criteria. (Source: Massachusetts Department of Public Works, 1988. *Highway Design Manual*, Boston, MA.)

4. Communications (public address systems and signage)
5. Special provisions for disabled patrons (elevators and ramps)

The criteria that could relate to the design of such a facility include threshold values for pedestrian level of service, delay at access points, connectivity from one area of the facility to another, and low-cost maintenance. For the vehicle side of such terminals, special consideration must be given to the performance of the design vehicle (e.g., turning radii of buses or semitrailer trucks) and the vehicle storage requirements (e.g., the number, size, and orientation of loading/unloading berths).

83.4 Advanced Technology Projects

One of the characteristics of transportation system development in recent years has been the increased application of advanced (usually electronic) technologies to improve system performance. Known as **intelligent transportation systems (ITS)**, the following steps apply in their design.

Typical Freeway/Expressway Section

Typical Urban Collector and Local Road

FIGURE 83.5 Example cross-sections.

Define Problems and Needs

Typical problems or needs might relate to congestion, excessively high accident rates, or improving current system capabilities and levels of service.

Define System

A system definition should include a mission statement, listing of physical components (e.g., roads, travelers, buses, rolling stock, existing rail lines, control centers, and communication links), and the physical relationship between those components.

Define Users

System users is a rather broad description of all individuals, organizations, and other systems that might interact or have a stake in the fully implemented transportation system under study.

Establish Institutional Framework and Partnerships

Various organizations possess differing missions, priorities, and policies — sometimes in conflict. Strong emphasis on coalition building during the early stages of project planning and engineering can help diffuse potential project-stopping disagreements later in the process.

Develop User Service Plan

The development of a user service plan consists of the following steps: (1) establish user services, (2) identify technology areas, and (3) map user services to technology areas. User services might include:

- Traveler information services
- Freight and fleet management services
- Emergency vehicle management services
- Traffic management services
- Public transport services

Available technologies fall within one of the following functional areas: (1) surveillance, (2) communications, (3) traveler interface, (4) control strategies, (5) navigation/guidance, (6) data processing, and (7) in-vehicle sensors.

Define System Architecture

A logical architecture consists of a *block diagram* identifying the major systems and subsystems, the participating agencies, and users. Through the use of arrows, the flow of information between these elements is identified. A logical architecture also shows the allocation of responsibilities throughout the transportation system.

Evaluate Alternative Technologies

Some of the factors to be considered in this evaluation include (1) cost, (2) performance, (3) reliability, (4) compatibility, (5) environmental impacts, and (6) compliance to standards.

Defining Terms

Context-sensitive design — A design process in which the community and environmental context is considered very early in the project development process. Mitigation and avoidance of significant impacts are proposed at this stage.

Design standard — Physical characteristics of a proposed facility that are professionally accepted and often based on safety considerations.

Functional classification — Classifying a transportation facility based on the function it serves in the transportation system. Such classification becomes important in that design standards are often directly related to the functional classification of a facility.

Intelligent transportation systems — Use of information and surveillance technologies to monitor and control the operation of the transportation system. Many of these systems are targeted at specific travel markets.

Level of service — An assessment of the performance of a transportation facility based on measurable physical characteristics (e.g., vehicular speed, average delay, density, flow rate). Level of service is usually subjectively defined as ranging from level of service A (good performance) to level of service F (bad or heavily congested performance).

Project development process — The steps that are followed to take a project from initial concept to final engineering. This process includes not only the detailed engineering associated with a project design but also the interaction with the general public and with agencies having jurisdiction over some aspect of project design.

- 84.2 Flow, Speed, and Density Relationships
- 84.3 Level of Service (LOS)
- 84.4 Highway Capacity
- 84.5 Intersection Capacity
- 84.6 Traffic Control Devices
- 84.7 Coordinated System Operations
- 84.8 Environmental Impacts

The safe and efficient movement of vehicles and people are the two most important goals of highway design. This is accomplished through careful geometric design of the layout and physical features of the roads, and through operational procedures and devices designed to guide, advise, and regulate vehicle operators in their use of the road. Proper design is based on a thorough understanding of the complex interactions among driver, vehicle, and roadway characteristics. For example, the design of a highway passing lane reflects the performance characteristics of the vehicle, the reaction time of the driver, and the ability of the road itself to provide sufficient distance that allows safe vehicle passing.

The following sections present the fundamental equations of vehicle flow and engineering principles upon which good highway design is based.

84.1 Fundamental Equations

Flow, q , is given by the following formula:

$$q = \frac{n \times 3600}{T} \quad \text{vehicles per hour} \quad (84.1)$$

where n = number of vehicles passing a point in T seconds.

Density, k , is given by

$$k = \frac{n}{L} \times 5280 \quad \text{vehicles per mile} \quad (84.2)$$

where n = number of vehicles occupying a length of road, L , and L is in feet, or by

$$k = \frac{n}{L} \times 1000 \quad \text{vehicles per kilometer} \quad (84.3)$$

where n = number of vehicles occupying a length of road, L , and L is in meters.

Average speed, \bar{u} , is given by

$$\bar{u}_t = \frac{1}{n} \sum_{i=1}^n u_i \quad (84.4)$$

where u_i = speed of the i th vehicle, termed the *time mean speed*, and by

$$\bar{u}_s = \frac{n \cdot s}{\sum_{i=1}^n t_i} \quad (84.5)$$

where t_i = time for the i th vehicle to traverse distance s , termed the *space mean speed*. The values \bar{u}_s and \bar{u}_t usually differ very slightly from one another unless there are wide variations among the speeds of individual vehicles.

84.2 Flow, Speed, and Density Relationships

The fundamental equation relating flow, density, and speed can be formulated as follows:

$$q = k \times \bar{u}_s \quad (84.6)$$

For simplicity, it is often assumed that average speed, u , decreases linearly as density, k , increases. Given this assumption and the dimensional identity expressed in Equation (84.6), it follows that flow, density, and speed are related as shown in Figure 84.1. It may be seen from Figure 84.1 that

1. When density on the highway is zero, there are no vehicles on the highway and the flow is zero.
2. As density goes to its maximum, flow goes to zero as vehicles line up — essentially bumper to bumper.

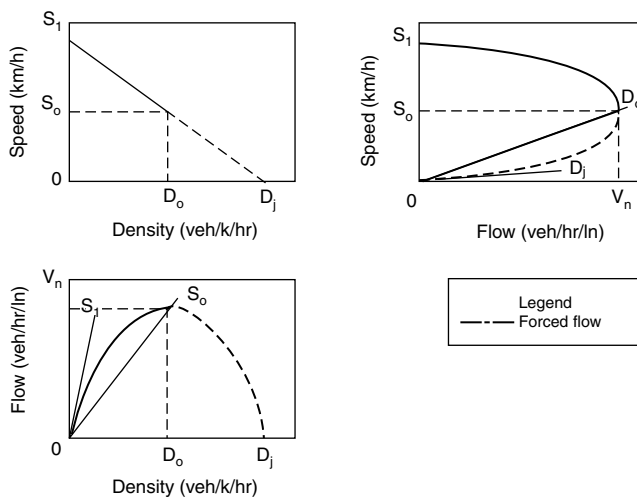

FIGURE 84.1 Relationships among flow, density, and speed.

3. As density increases, flow also increases — up to the point where $k = kj/2$ — and then decreases as density increases.
4. As flow increases from zero to a maximum (the capacity of the roadway), speed also decreases. Once the flow approaches capacity, any impediment to the steady movement of traffic will reduce both flow and speed abruptly, with a concomitant rapid increase in density.

84.3 Level of Service (LOS)

Level of service is a measure of how freely a given transportation system is operating. It is affected primarily by traffic **volume**, but other factors such as proportion of heavy vehicles, roadway geometrics, and incidents also affect the level of service. LOS is designated by letters A through F. LOS A is characterized as *free flow* and is applied to conditions of very low traffic volume in which there is little or no restriction to traffic flow. LOS F is characterized as *forced flow* with congested, stop-and-go movement. LOS C involves some restriction to free movement of traffic and is the level of service commonly used as the target for road design. The maximum flow along a facility occurs at LOS E.

Different elements of the road system emphasize different LOS measures. For example, the following measures are the key determinants in the LOS for the identified element of the road network.

| | |
|--------------------------|---|
| Urban street: | Average travel speed for through vehicles |
| Freeway: | Average speed, freedom to maneuver, and proximity of other vehicles |
| Freeway ramp: | Vehicle density |
| Signalized intersection: | Average traffic control delay per vehicle |
| Two-lane highways: | Percent time spent following other vehicles, and average speed |
| Pedestrian walkways: | Space per pedestrian, flow rate, and average speed |

The calculation of road level of service varies by type of road. For example, the *Highway Capacity Manual*, the manual that defines how level of service should be calculated, describes different methodologies for the following transportation facilities: urban streets, signalized intersections, unsignalized intersections, pedestrian walkways, bicycle facilities, two-lane highways, multi-lane highways, freeway facilities, basic freeway segments, freeway weaving sections, ramps, interchange ramp terminals, and transit services.

As an example, the LOS for a freeway segment is calculated with the following two equations:

$$FFS = BFFS - f_{LW} - f_{LC} - f_N - f_{ID} \quad (84.7)$$

where FFS = free flow speed (mi/h); BFFS = base free flow speed (70 mi/h for urban and 75 mi/h for rural); f_{LW} = adjustment for lane width; f_{LC} = adjustment for right-shoulder lateral clearance; f_N = adjustment for number of lanes; and f_{ID} = adjustment for interchange density.

$$D = \frac{V}{S \times (PHF \times N \times f_{HV} \times f_p)} \quad (84.8)$$

where D = density (pc/mi/ln); S = average passenger car speed (mi/h); V = hourly volume (veh/h); PHF = peak hour factor (variation in traffic low within hour); N = number of lanes; f_{HV} = heavy vehicle adjustment factor; and f_p = driver population factor.

The results of these two equations for the circumstances of a specific freeway segment are then entered into a table that defines a corresponding level of service.

84.4 Highway Capacity

The **capacity** of a highway, that is the maximum flow of vehicles or passengers, depends on many geometric and traffic characteristics. The capacity of a road occurs at LOS E. Equation 84.7 and Equation

84.8 indicate that the most important of these factors include number of lanes, width of lanes, lateral clearance to obstructions, percentage of the traffic stream made up of trucks and buses, characteristics of the driver population and percent grade of the roadway (incorporated into the heavy vehicle adjustment factor). Lane widths will vary according to the type of road; however, for high-capacity, high-speed roads such as freeways, the lane width should be at least 12 ft. Obstructions should be a minimum of 6 ft from the edge of pavement. Vertical grades of 3% or more that are one-half mile long or longer will reduce the capacity of a highway, especially where commercial vehicles are present. For freeways, maximum lane capacity under ideal conditions is generally assumed to be 2400 vehicles/hr per lane. Ideal conditions, however, are seldom achieved.

84.5 Intersection Capacity

The *Highway Capacity Manual* provides a detailed method for estimating the capacity of a signalized intersection. This method examines the geometric, traffic and signalization conditions for each lane approach to the intersection. Similar to Equation 84.7 and Equation 84.8, the following equation is used to determine the saturation flow rate for each group of lanes entering an intersection.

$$S = s_0 \times N \times f_w \times f_{HV} \times f_g \times f_p \times f_{bb} \times f_a \times f_{LU} \times f_{LT} \times f_{RT} \times f_{Lpb} \times f_{Rpb} \quad (84.9)$$

where S = saturation flow rate for each group of lanes (veh/h); s_0 = base saturation flow rate per lane (pc/h/ln); N = number of lanes in lane group; f_w = adjustment for lane width; f_{HV} = adjustment for heavy vehicles (trucks and buses); f_g = adjustment for approach grade; f_p = adjustment for existence of parking lane and parking activity adjacent to lane group; f_{bb} = adjustment for blocking effect of local buses that stop within intersection area; f_a = adjustment for area type; f_{LU} = adjustment for lane utilization; f_{LT} = adjustment for left turns in lane group; f_{RT} = adjustment for right turns in lane group; f_{Lpb} = pedestrian–bicycle adjustment factor for left-turn movements; and f_{Rpb} = pedestrian–bicycle adjustment factor for right-turn movements.

The result of Equation 84.9 is then multiplied by the amount of green time per total signal cycle time for the lane group being analyzed to obtain the capacity of the lane group. As shown, Equation 84.9 illustrates the basic concept of first starting with an “ideal” capacity or saturation flow and then modifying this value with adjustments that reflect physical characteristics of the existing facility and area.

84.6 Traffic Control Devices

Traffic signs, signals, and pavement markings (**traffic control devices**) are used to regulate, warn, and guide the users of the road. The effectiveness of such devices is greatly enhanced through the uniformity of their design — including shape, color, and message — and through their use and placement on the roadway. Uniformity is ensured by adherence to the standards promulgated in the *Manual of Uniform Traffic Control Devices* [U.S. DOT and FHWA, 2000] or an equivalent manual adopted by each state highway agency. As stated in the **Manual**, to be effective, a traffic control device should meet five basic requirements: fulfill a need, command attention, convey a simple and clear meaning, command respect from road users, and give adequate time for proper response.

One of the ways that traffic control devices gain respect from road users is by using them in situations where such devices are clearly warranted. Experience over many decades and engineering judgement have become the basis for “warrants,” guidelines that are used by engineers to justify the use of particular traffic control devices. Two examples of how this principle is used by engineers are provided below for STOP signs and traffic signals.

STOP signs should be used only where one or more of the following conditions or warrants hold:

1. At an intersection of a less important road with a main road where application of the normal right-of-way rule would not be expected to provide reasonably safe operation

2. Where a street enters a through highway or street
3. At an unsignalized intersection in a signalized area
4. At other intersections where a combination of high speed, restricted view, and crash records indicate a need for control by a STOP sign

Traffic control signals should not be installed unless at least one of several signal warrants is met (the *Manual* defines eight warrants). Eleven signal warrants are used to account for such factors as traffic volume, crash experience, school crossings, and pedestrian volumes. In addition to a review of these warrants, an engineering study should be conducted to show that the installation of such a signal would improve the overall safety and operation of the intersection.

Consideration should be given to other, less restrictive measures before these warrants are applied.

84.7 Coordinated System Operations

The efficient operation of a road network requires more than simply placing traffic control devices at warranted locations. A regional road network for a modern metropolitan area consists of many different road types, whose jurisdiction is shared by numerous different organizations. One of the key challenges facing many metropolitan areas today is coordinating the many different responsibilities for operating a regional road network. This can be accomplished through ad hoc working groups focusing on specific operations strategies (e.g., coordinating traffic signals across jurisdictions) or by the creation of a regional entity with a legislative mandate to operate all transportation services in a region (much more common in countries other than the U.S.). In the U.S., some of the strategies used to coordinate system operations include:

1. Standardized strategies to be implemented in response to expected incidents or events
2. Shared databases and information retrieval
3. Corridor teams that focus on network operations
4. Regional programs, e.g., incident management efforts or traffic signal coordination, which target key determinants of system performance
5. Regional traffic management centers that collect data on system performance and provide information and guidance to road network users
6. Formal information and technological systems architecture that specifies protocols and processes for computer-supported approaches to system operations

With the advent of more powerful computers and improved sensors, it seems likely that future developments in coordinated system operations will to a large extent rely on the application of advanced technology.

84.8 Environmental Impacts

One of the most important characteristics of transportation system performance is the corresponding impact on the natural and human environment. This impact occurs not only during the construction of transportation facilities themselves but also from the resulting operations. For example, automobile travel in many urban areas is a primary source of many air pollutants. In terms of energy consumption, total auto travel accounts for approximately 25% of U.S. oil consumption, with about two-thirds of this consumption occurring in urban areas. [Table 84.1](#) shows the environmental impacts that are of concern to transportation officials. Of those shown, the impacts that are directly linked to the operations of a facility or transportation system include air quality, noise, vibration, stormwater, energy consumption, and ecological effects.

It is often difficult to determine the best operations strategy for minimizing these impacts. For example, the air quality impacts of motor vehicles are a function of the number, type, and condition of vehicles on the highway and of the speed and efficiency with which these vehicles operate. Carbon monoxide, hydrocarbons, and oxides of nitrogen are the primary pollutants emitted by vehicular traffic. The level

TABLE 84.1 Transportation System Impacts of Concern to Transportation Officials

| |
|---|
| Natural System Impacts |
| Terrestrial ecology (habitats and animals) |
| Aquatic ecology (habitats and animals) |
| Physical Impacts |
| Air quality |
| Noise |
| Vibration |
| Water quality |
| Hazardous wastes |
| Stormwater |
| Energy consumption |
| Erosion and sedimentation |
| Farmland conversion |
| Social and Cultural Impacts |
| Historic and archaeological |
| Displacement of people |
| Community cohesion |
| Resource consumption |
| Land use |
| Aesthetics |
| Infrastructure effects |
| Accessibility of facilities, services, and jobs |
| Environmental justice |
| Employment, income, and business activity |

of emission of each pollutant is complicated and difficult to predict. In general, the emission of carbon monoxide and hydrocarbons is minimized at speeds between 35 and 45 mi/h, whereas the emission of oxides of nitrogen increases over this speed range. Therefore, there is no ideal speed at which the level of emission of all three pollutants will be minimized. Nevertheless, smoothly flowing traffic will tend to produce less pollution, and, therefore, whatever can be done to reduce delay and congestion — especially when combined with a reduction in total vehicle miles traveled — will result in an improvement in air quality.

The reader is referred to the following site for information on the many environmental impacts that are of concern to transportation officials: <http://www.fhwa.dot.gov/environment/index.htm>

Defining Terms

Capacity — A maximum flow of vehicles or persons at a specific location, given the characteristics of the facility.

Density (k) — Number of vehicles or persons occupying a given length of a facility at an instant in time; usually expressed as veh/mi or veh/km for vehicles and persons/ft² or persons/m² for individuals.

Flow (q) — Time rate of flow of facility users; usually expressed as veh/h or passenger/h.

Level of service (LOS) — The quality of movement experienced by the users of a facility in a traffic stream; usually expressed in terms of the freedom of movement of facility users, ranging from little or no restriction (LOS A) to stopped flow (LOS F).

Speed (u) — Average speed of vehicles in a traffic stream; usually expressed as miles per hour (mph) or kilometers per hour (kph).

Traffic control devices — Signs, signals, and pavement markings placed on streets or highways to guide, inform, or regulate the movement of vehicles on those facilities.

Paul Schonfeld
University of Maryland

The various forms of transportation that have been developed over time are called **modes**. The classification of modes may be very broad (e.g., highway transportation or air transportation) or more restrictive (e.g., chartered helicopter service). The major distinctions among transportation modes that help to classify them include:

1. Medium (e.g., air, space, surface, underground, water, underwater)
2. Users (e.g., passengers vs. cargo, general-purpose vs. special trips or commodities, common vs. private carrier)
3. Service type (scheduled vs. **demand responsive**, fixed vs. variable route, nonstop vs. express or local, mass vs. personal)
4. Right-of-way type (exclusive, semiexclusive, shared)
5. Technology:
 - A. Propulsion (e.g., electric motors, diesel engines, gas turbines, linear induction motors, powered cables)
 - B. Energy sources (e.g., petroleum fuels, natural gas, electric batteries, electric power from conducting cables)
 - C. Support (e.g., aerodynamic lift, flotation on water, steel wheels on two steel rails, monorails, air cushions, magnetic levitation, suspension from cables)
 - D. Flow type (e.g., discrete vehicles vs. continuous flow, as in pipelines, conveyor belts and escalators)
 - E. Local control (e.g., lateral control by steering wheels, wheel flanges on railroad vehicles, rudders, longitudinal control by humans or automatic devices)
 - F. Network guidance and control systems (with various degrees of automation and optimization)

A mode may be defined by its combination of such features. The number of conceivable combinations greatly exceeds the number of modes that have been actually tried, which, in turn, exceeds the number of successful modes. Success may be limited to relatively narrow markets and applications (e.g., for helicopters or aerial cablecars) or may be quite general. Thus, automobiles are successful in a very broad range of applications and have become the basis for distinct transportation modes such as taxis, carpools, or ambulances.

The relative success of various transportation modes depends on available technology and socioeconomic conditions at any particular time, as well as on geographic factors. As technology or socioeconomic conditions change, new transportation modes appear, develop, and may later decline as more effective competitors appear. For many centuries water transportation was considerably cheaper than overland transportation. Access to waterways was quite influential in the location of economic activities and cities. Access to good transportation is still very important to industries and communities. Technological developments have so drastically improved the relative effectiveness of air transportation that within a short period (approximately 1950 to 1965), aircraft almost totally replaced ships for transporting passengers across oceans. It is also notable that as economic prosperity grows, personal transportation tends to shift from the walking mode to bicycles, motorcycles, and then automobiles. Geography can significantly affect the relative attractiveness of transportation modes. Thus, natural waterways are highly valuable where they exist. Hilly terrain decreases the economic competitiveness of artificial waterways or conventional railroads while favoring highway modes. In very mountainous terrain, even highways may become uncompetitive compared to alternatives such as helicopters, pipelines, and aerial cablecars.

The relative shares of U.S. intercity passenger and freight traffic are shown in [Table 85.1](#). The table shows the relative growth since 1929 of airlines, private automobiles, and trucks and the relative decline of railroad traffic.

85.1 Transportation System Components

The major components of transportation systems are:

1. Links
2. Terminals
3. Vehicles
4. Control systems

Certain “continuous-flow” transportation systems, such as pipelines, conveyor belts, and escalators, have no discrete vehicles and, in effect, combine the vehicles with the link.

Transportation systems may be developed into extensive networks. The networks may have a hierarchical structure. Thus, highway networks may include freeways, arterials, collector streets, local streets, and driveways. Links and networks may be shared by several transportation modes (e.g., cars, buses, trucks, taxis, bicycles, and pedestrians on local streets). Exclusive lanes may be provided for particular modes (e.g., pedestrians or bicycles) or groups of modes (e.g., buses and carpools).

Transportation terminals provide interfaces among modes or among vehicles of the same mode. They may range from marked bus stops or truck loading zones on local streets to huge airports or ports.

85.2 Evaluation Measures

Transportation systems are evaluated in terms of their effects on their suppliers, users, and environment. Both their costs and benefits may be classified into supplier, user, and external components. Private transportation companies normally seek to maximize their profits (i.e., total revenues minus total supplier costs). Publicly owned transportation agencies should normally maximize net benefits to their jurisdictions, possibly subject to financial constraints.

From the supplier’s perspective, the major indicators of performance include measures of **capacity** (maximum throughput), speed, **utilization rate** (i.e., fraction of time in use), **load factor** (i.e., fraction of maximum payload actually used), energy efficiency (e.g., Btu per ton-mile or per passenger mile), and labor productivity (e.g., worker hours per passenger mile or per ton-mile). Measures of environmental impact (e.g., noise decibels or parts of pollutant per million) are also increasingly relevant. To users, price and service quality measures, including travel time, wait time, access time, reliability, safety, security, comfort (ride quality, roominess), simplicity of use, and privacy are relevant in selecting modes, routes, travel times, and suppliers.

85.3 Air Transportation

Air transportation is relatively recent, having become practical for transporting mail and passengers in the early 1920s. Until the 1970s, its growth was paced primarily by technological developments in propulsion, aerodynamics, materials, structures, and control systems. These developments improved its speed, load capacity, energy efficiency, labor productivity, reliability, and safety, to the point where it now dominates long-distance mass transportation of passengers overland and practically monopolizes it over oceans. Airliners have put ocean passenger liners out of business because they are much faster and also, remarkably, more fuel efficient and labor efficient when transporting passengers. However, despite this fast growth, the cargo share of air transportation is still small.

For cargoes that are perishable, high in value, or urgently needed, air transportation is preferred over long distances. For other cargo types, ships, trucks, and railroads provide more economic alternatives. In the 1990s, the nearest competitors to air cargo were containerships over oceans and trucks over land. For passengers, air transportation competes with private cars, trains, and intercity buses over land, with practically no competitors over oceans. The growth of air transportation has been restricted to some extent by the availability of adequate airports, by environmental concerns (especially noise), by security concerns, and by the fear of flying of some passengers.

There are approximately 10,000 commercial jet airliners in the world, of which the largest (as of 2003) are Boeing B-747 types, of approximately 800,000 lb gross takeoff weight, with a capacity of 550 passengers. The economic cruising speed of these and smaller “conventional” (i.e., **subsonic**) airliners has stayed at around 560 mph since the late 1950s. A few supersonic transports (SSTs) capable of cruising at approximately 1300 mph were built in the 1970s (the Anglo-French Concorde and the Soviet Tu-144) but, due to high capital and fuel costs, were unprofitable to operate.

The distance that an aircraft can fly depends on its payload, according to the following equation:

$$R = \frac{V}{c'} \left(\frac{L}{D} \right) \ln(W_{TO} / W_L) \quad (85.1)$$

where R = range (mi); c' = specific fuel consumption (lb fuel/lb thrust \times h); (L/D) = lift-to-drag ratio (dimensionless); W_{TO} = aircraft takeoff weight (lb) = $W_L + W_F$; W_L = aircraft landing weight (lb) = $W_E + W_R + P$; W_E = aircraft empty weight (lb); W_R = reserve fuel weight (lb); W_F = consumed fuel weight (lb); and P = payload (lb).

This equation assumes that the difference between the takeoff weight and landing weight is the fuel consumed. For example, suppose that for a Boeing B-747 the maximum payload carried (based on internal fuselage volume and structural limits) is 260,000 lb, maximum W_{TO} is 800,000 lb, $W_R = 15,000$ lb, $W_E = 370,000$, $L/D = 17$, $V = 580$ mph, and $c' = 0.65$ lb/lb thrust \times h. The resulting weight ratio [$W_{TO}/W_L = 800/(370 + 15 + 260)$] is 1.24 and the range R is 3267 mi. Payloads below 260,000 allow higher ranges.

Most airline companies fly scheduled routes, although charter services are common. U.S. airlines are largely free to fly whatever routes (i.e., origin–destination pairs) they prefer in the U.S. In much of the rest of the world, authority to serve particular routes is regulated or negotiated by international agreements. The major components of airline costs are direct operating costs (e.g., aircraft depreciation or rentals, aircrews, fuel, and aircraft maintenance) and indirect operating costs (e.g., reservations, advertising and other marketing costs, in-flight service, ground processing of passengers and bags, and administrations).

The efficiency and competitiveness of airline service is heavily dependent on efficient operational planning. Airline scheduling is a complex problem in which demand at various times and places, route authority, aircraft availability and maintenance schedules, crew availability and flying restrictions, availability of airport gates and other facilities, and various other factors must all be considered. Airline management problems are discussed in [Wells, 1984].

Airports range from small unmarked grass strips to major facilities requiring many thousands of acres and billions of dollars. Strictly speaking, an airport consists of an airfield (or “airside”) and terminal (or

“landside”). Airports are designed to accommodate specified traffic loads carried by aircraft up to a “design aircraft,” which is the most demanding aircraft to be accommodated. The design aircraft might determine such features as runway lengths, pavement strengths, or terminal gate dimensions at an airport. Detailed guidelines for most aspects of airport design (e.g., runway lengths and other airfield dimensions, pavement characteristics, drainage requirements, allowable noise and other environmental impacts, allowable obstruction heights, lighting, markings, and signing) are specified by the U.S. Federal Aviation Administration (FAA) in a series of circulars.

Airport master plans are prepared to guide airport growth, usually in stages, toward ultimate development. These master plans:

1. Specify the airport’s requirements
2. Indicate a site if a new airport is considered
3. Provide detailed plans for airport layout, land use around the airport, terminal areas, and access facilities
4. Provide financial plans, including economic and financial feasibility analysis

Major new airports tend to be very expensive and very difficult to locate. Desirable airport sites must be reasonably close to the urban areas they serve yet far enough away to ensure affordable land and acceptable noise impacts. Many other factors — including airspace interference with other airports, obstructions (e.g., hills, buildings), topography, soil, winds, visibility, and utilities — must be reconciled. Hence, few major new airports are being built, and most airport engineering and planning work in the U.S. is devoted to improving existing airports. Governments sometimes develop multiairport system plans for entire regions or countries.

National agencies (such as the FAA in the U.S.) are responsible for traffic control and airspace management. Experienced traffic controllers, computers, and specialized sensors and communication systems are required for this function. Increasingly sophisticated equipment has been developed to maintain safe operations even for crowded airspace and poor visibility conditions. For the future we can expect increasing automation in air traffic control, relying on precise aircraft location with global positioning satellite (GPS) systems and fully automated landings. Improvements in the precision and reliability of control systems are increasing (slowly) the capacity of individual runways as well as reducing the required separation among parallel runways, thus allowing capacity increases in restricted airport sites.

85.4 Railroad Transportation

The main advantages of railroad technology are low frictional resistance and automatic lateral guidance. The low friction reduces energy and power requirements but limits braking and hill-climbing abilities. The lateral guidance provided by wheel flanges allows railroad vehicles to be grouped into very long trains, yielding economies of scale and, with adequate control systems, high capacities per track. The potential energy efficiency and labor productivity of railroads is considerably higher than for highway modes, but is not necessarily realized due to regulations, managerial decisions, demand characteristics, or terrain.

The main competitors of railroads include automobiles, aircraft, and buses for passenger transportation, and trucks, ships, and pipelines for freight transportation. To take advantage of their scale economies, railroad operators usually seek to combine many shipments into large trains. Service frequency is thus necessarily reduced. Moreover, to concentrate many shipments, rail cars may be frequently re-sorted into different trains, rather than moving directly from origin to destination, which results in long periods spent waiting in classification yards, long delivery times, and poor vehicle utilization. An alternative operational concept relying on direct nonstop “unit trains” is feasible only when demand is sufficiently large between an origin–destination pair.

Substantial traffic is required to cover the relatively high fixed costs of railroad track. Moreover, U.S. railroads, which are privately owned, must pay property taxes on their tracks, unlike their highway

competitors. By 1920, highway developments had rendered low-traffic railroad branch lines noncompetitive in the U.S. Abandonment of such lines has greatly reduced the U.S. railroad network, even though the process was retarded by political regulation.

The alignment of railroad track is based on a compromise between initial costs and operating costs. The latter are reduced by a more straight and level alignment, which requires more expensive earthwork, bridges, or tunnels. Hay [1982] provides design guidelines for railroads.

In general, trains are especially sensitive to gradients. Thus, compared to highways, railroad tracks are more likely to go around rather than over terrain obstacles, which increases the **circuitry factors** for railroad transportation.

The resistance for railroad vehicles may be computed using the Davis equation [Hay, 1982]:

$$r = 1.3 + 29/w + bV + CAV^2 / wn + 20G + 0.8D \quad (85.2)$$

where G = gradient (%); D = degree of curvature; r = unit resistance (lb of force per ton of vehicle weight); w = weight (tons per axle of car or locomotive); n = number of axles; b = coefficient of flange friction, swaying, and concussion (0.045 for freight cars and motor cars in trains, 0.03 for locomotives and passenger cars, and 0.09 for single-rail cars); C = drag coefficient of air [0.0025 for locomotives (0.0017 for streamlined locomotives) and single- or head-end-rail cars, 0.0005 for freight cars, and 0.00034 for trailing passenger cars, including rapid transit]; A = cross-sectional area of locomotives and cars (usually 105 to 120 ft² for locomotives, 85 to 90 ft² for freight cars, 110 to 120 ft² for multiple-unit and passenger cars, and 70 to 110 ft² for single- or head-end-rail cars); and V = speed (mph).

The coefficients shown for this equation reflect relatively old railroad technology and can be significantly reduced for modern equipment [Hay, 1982]. The equation provides the unit resistance in pounds of force per ton of vehicle weight. The total resistance of a railroad vehicle (in lb) is

$$R_v = rwn \quad (85.3)$$

The total resistance of a train R is the sum of resistances for individual cars and locomotives. The rated horsepower (hp) required for a train is:

$$\text{hp} = \frac{RV}{375\eta} \quad (85.4)$$

where η = transmission efficiency (typically about 0.83 for a diesel electric locomotive).

The hourly fuel consumption for a train may be computed by multiplying hp by a specific fuel consumption rate (approximately 0.32 lb/hp × h for a diesel electric locomotive).

Diesel electric locomotives with powers up to 5,000 hp haul most trains in the U.S. Electric locomotion is widespread in other countries, especially those with low petroleum reserves. It is especially competitive on high-traffic routes (needed to amortize electrification costs) and for high-speed passenger trains. Steam engines have almost disappeared.

The main types of freight rail cars are box cars, flat cars (often used to carry truck trailers or intermodal containers), open-top gondola cars, and tank cars. Passenger trains may include restaurant cars and sleeping cars. Rail cars have tended toward increasing specialization for different commodities carried, a trend that reduces opportunities for back hauls. Recently, many “double-stack” container cars have been built to carry two tiers of containers. Such cars require a vertical clearance of nearly 20 ft, as well as reduced superelevation (banking) on horizontal curves. In the U.S., standard freight rail cars with gross weights up to 315,000 lb are used.

High-speed passenger trains have been developed intensively in Japan, France, Great Britain, Italy, Germany, and Sweden. Some of the most advanced French and Japanese trains (in 2003) have cruising speeds of 186 mph and double-deck cars. At such high speeds, trains can climb long, steep grades (e.g.,

3.5%) without slowing down much. Construction costs in hilly terrain can thus be significantly reduced. Even higher speeds are being tested in experimental railroad and magnetic levitation (MAGLEV) trains.

85.5 Highway Transportation

Highways provide very flexible and ubiquitous transportation for people and freight. A great variety of transportation modes, including automobiles, buses, trucks, motorcycles, bicycles, pedestrians, animal-drawn vehicles, taxis, and carpools, can share the same roads. From unpaved roads to multilane freeways, roads can vary enormously in their cost and performance. Some highway vehicles may even travel off the roads in some circumstances. The vehicles also range widely in cost and performance, and at their lower range (e.g., bicycles) are affordable for private use even in poor societies.

Flexibility, ubiquity, and affordability account for the great success of highway modes. Personal vehicles from bicycles to private automobiles offer their users great freedom and access to many economic and social opportunities. Trucks increase the freedom and opportunities available to farmers and small business. Motor vehicles are so desirable and affordable that in the U.S. the number of registered cars and trucks approximates the number of people of driving age. Other developed countries are approaching the same state despite strenuous efforts to discourage motor vehicle use.

The use of motor vehicles brings significant problems and costs. These include:

1. Road capacity and congestion. Motor vehicles require considerable road space, which is scarce in urban areas and costly elsewhere. Shortage of road capacity results in severe congestion and delays.
2. Parking availability and cost.
3. Fuel consumption. Motor vehicles consume vast amounts of petroleum fuels. Most countries have to import such fuels and are vulnerable to price increases and supply interruptions.
4. Safety. The numbers of people killed and injured and the property damages in motor vehicle accidents are very significant.
5. Air quality. Motor vehicles are major contributors to air pollution.
6. Regional development patterns. Many planners consider the low-density “sprawl” resulting from motor vehicle dominance to be inefficient and inferior to the more concentrated development produced by mass transportation and railroads.

In the U.S., trucks have steadily increased their share of the freight transportation market, mostly at the expense of railroads, as shown in [Table 85.1](#). They can usually provide more flexible, direct, and responsive service than railroads do, but at higher unit cost. They are intermediate between rail and air transportation in both cost and service quality. With one driver required per truck, the labor productivity is much lower than for railroads, and there are strong economic incentives to maximize the load capacity for each driver. Hence, the tendency has been to increase the number, dimensions, and weights allowed for trailers in truck-trailer combinations, which requires increased vertical clearances (e.g., bridge overpasses), geometric standards for roads, and pavement costs.

Various aspects of highway flow characteristics, design standards, and safety problems were presented in [Chapter 82](#) through [Chapter 84](#). The main reference for highway design is the AASHTO manual [AASHTO, 1990]. For capacity, the main reference is the Transportation Research Board *Highway Capacity Manual* [TRB, 1985]. Extensive software packages have been developed for planning, capacity analysis, geometric design, and traffic control.

Currently (2003), major research and development efforts are being devoted to exploiting advances in information technology to improve highway operations. The Intelligent Transportation Systems (ITS) program of the U.S. Department of Transportation includes, among other activities, an Advanced Traffic Management System (ATMS) program to greatly improve the control of vehicles through congested road networks, an Advanced Travelers Information System (ATIS) program to guide users through networks, and, most ambitiously, an Automated Highway System (AHS) program to replace human driving with hardware. Such automation, when it becomes feasible and safe, has the potential to

drastically improve lane capacity at high speeds by greatly reducing spacing between vehicles. Other potential benefits include reduced labor costs for trucks, buses, and taxis; higher and steadier speeds; improved routings through networks; remote self-parking vehicles; and use of vehicles by nondrivers such as children and handicapped persons. However, substantial technological, economical, and political problems will have to be surmounted.

Very elaborate traffic control and management systems are currently being developed to minimize traffic delays in transportation networks. These often use information from numerous distributed sensors to forecast, simulate, and optimize traffic flows. Since the demand for road trips may greatly exceed the available road capacity, transportation system management policies, such as pricing schemes, lane use priorities, parking controls, land use controls, and incentives for public transportation use, may be helpful in shifting some of the demand to less congested travel routes, modes, or times of day. As telecommunications improve over time, they may also replace some trips currently made by highways or other modes.

As the infrastructure for highways and other transportation modes matures, maintaining existing facilities without excessive costs or service disruptions becomes at least as challenging as building new facilities. Hence, considerable efforts are being devoted to materials research, to maintenance planning and scheduling, and to the development of efficient inspection, maintenance, and repair techniques.

85.6 Water Transportation

Water transportation may be classified into (1) marine transportation across seas and (2) inland waterway transportation; their characteristics differ very significantly. Inland waterways consist mostly of rivers, which may be substantially altered to aid transportation. Lakes and artificial canals may also be part of inland waterways. Rivers in their natural states are often too shallow, too fast, or too variable in their flows. All these problems may be alleviated by impounding water behind dams at various intervals. (This also helps generate electric power.) Boats can climb or descend across dams by using **locks** or other elevating systems [Hochstein, 1981]. In the U.S. inland waterway network, there are well over 100 major lock structures, with chambers up to 1200 ft long and 110 ft wide. Such chambers allow up to 18 large barges (35 × 195 ft) to be raised or lowered simultaneously.

In typical inland waterway operations, large diesel-powered “towboats” (which actually push barges) handle a rigidly tied group of barges (a “tow”). Tows with up to 48 barges (35 × 195 ft, or about 1300 tons/barge) are operated on the lower Mississippi, where there are no locks or dams. On other rivers, where locks are encountered at frequent intervals, tow sizes are adjusted to fit through locks. The locks constitute significant bottlenecks in the network, restricting capacity and causing significant delays.

Table 85.1 indicates that the waterway share of U.S. freight transportation has increased substantially in recent years. This is largely attributable to extensive improvements to the inland waterway system undertaken by the responsible agency, the U.S. Army Corps of Engineers.

The main advantage of both inland waterway and marine transportation is low cost. The main disadvantage is relatively low speed. Provided that sufficiently deep water is available, ships and barges can be built in much larger sizes than ground vehicles. Ship costs increase less than proportionally with ship size, for ship construction, crew, and fuel. Energy efficiency is very good at low speeds [e.g., 10 to 20 knots (nautical mi/h)]. However, at higher speeds the wave resistance of a conventional ship increases with the fourth power of speed (V^4). Hence, the fuel consumption increases with V^4 and the power required increases with V^5 . Therefore, conventional-displacement ships rarely exceed 30 knots in commercial operation. Higher practical speed may be obtained by lifting ships out of the water on hydrofoils or air cushions. However, such unconventional marine vehicles have relatively high costs and limited markets at this time. Over time, ships have increased in size and specialization. Crude oil tankers of up to 550,000 tons (of payload) have been built. Tankers carrying fluids are less restricted in size than other ships because they can pump their cargo from deep water offshore without entering harbors. Bulk carriers (e.g., for coal, minerals, or grains) have also been built in sizes exceeding 300,000 tons. They may also be loaded through conveyor belts built over long pier structures to reach deep water. General cargo ships and container ships are practically always handled at shoreline berths and require much storage space nearby.

The use of intermodal containers has revolutionized the transportation of many cargoes. Such containers greatly reduce the time and cost required to load and unload ships. Up to 8000 standard 20-ft containers (20 × 8 × 8 ft) can be carried at a speed of about 25 knots on the largest recently built (2003) container ships.

Port facilities for ships should provide shelter from waves and sufficiently deep water, including approach channels to the ports. In addition, ports should provide adequate terminal facilities, including loading and unloading equipment, storage capacity, and suitable connections to other transportation networks. Ports often compete strenuously with other ports and strive to have facilities that are at least equal to those of competitors. Since ports generate substantial employment and economic activities, they often receive financial and other support from governments.

Geography limits the availability of inland waterways and the directness of ship paths across oceans. Major expensive canals (e.g., Suez, Panama, Kiel, Welland) have been built to provide shortcuts in shipping routes. These canals may be so valuable that ship dimensions are sometimes compromised (i.e., reduced) to fit through these canals. In some parts of the world (e.g., Baltic, North Sea, most U.S. coasts) the waters are too shallow for the largest ships in existence. Less efficient, smaller ships must be used there. The dredging of deeper access channels and ports can increase the allowable ship size, if the costs and environmental impacts are considered acceptable.

85.7 Public Transportation

Public transportation is the term for ground passenger transportation modes available to the general public. It connotes public availability rather than ownership. “Conventional” public transportation modes have fixed routes and fixed schedules and include most bus and rail transit services. “Unconventional” modes (also labeled “paratransit”) include taxis, carpools and van pools, rented cars, dial-a-ride services, and subscription services.

The main purposes of public transportation services, especially conventional mass transportation services in developed countries, are to provide mobility for persons without automobiles (e.g., children, poor, nondrivers); to improve the efficiency of transportation in urban areas; to reduce congestion effects, pollution, accidents, and other negative impacts of automobiles; and to foster preferred urban development patterns (e.g., strong downtowns and concentrated rather than sprawled development).

Conventional services (i.e., bus and rail transit networks) are quite sensitive to demand density. Higher densities support higher service frequencies and higher network densities, which decrease user wait times and access times, respectively. Compared to automobile users, bus or rail transit users must spend extra time in access to and from stations and in waiting at stations (including transfer stations). Direct routes are much less likely to be available, and one or more transfers (with possible reliability problems) may be required. Thus, mass transit services tend to be slower than automobiles unless exclusive rights-of-way (e.g., bus lanes, rail tunnels) can favor them. Such exclusive rights-of-way can be quite expensive if placed on elevated structures or in tunnels. Even when unhindered by traffic, average speeds may be limited by frequent stops and allowable acceleration limits for standing passengers. Prices usually favor mass transit, especially if parking for automobiles is scarce and expensive.

The capacity of a transit route can be expressed as:

$$C = F L P \quad (85.5)$$

where C = one-way capacity (passengers/hour) past a certain point; F = service frequency (e.g., trains/hour); L = train length (cars/train); and P = passenger capacity of cars (spaces/car).

For rail transit lines where high capacity is needed in peak periods, C can reach 100,000 passengers/hour (i.e., 40 trains/hour × 10 cars/train × 250 passenger spaces/car). There are few places in the world where such capacities are required. For a bus line the train length L would usually be 1.0. If no on-line stops are allowed, an exclusive bus lane also has a large capacity (e.g., 1000 buses/hour × 90 passenger spaces/bus), but such demand levels for bus lanes have not been observed.

The average wait time of passengers on a rail or bus line depends on the headway, which is the interval between successive buses or trains. This can be approximated by:

$$\bar{W} = \bar{H} / 2 + \text{var}(H) / 2\bar{H} \quad (85.6)$$

where \bar{W} = average wait time (e.g., minutes); \bar{H} = average headway (e.g., minutes); $\text{var}(H)$ = variance of headway (e.g., minutes²).

It should be noted that the headway is the inverse of the service frequency.

The minimum number of vehicles N required to serve a route (before factoring reserve vehicles or those undergoing maintenance) is:

$$N = RFL \quad (85.7)$$

where R = vehicle round trip time on route (e.g., hours).

The effectiveness of a public transportation system depends on many factors, including demand distribution and density, network configuration, routing and scheduling of vehicles, fleet management, personnel management, pricing policies, and service reliability. Demand and economic viability of services also depend on automobile ownership and on how good and uncongested the road system is for automobile users.

Engineers can choose from a great variety of options for propulsion, support, guidance and control, vehicle configurations, facility designs, construction methods, and operating concepts. New information and control technology can significantly improve public transportation systems. It will probably foster increased automation and a trend toward more personalized (i.e., taxi-like) service rather than mass transportation.

Defining Terms

Capacity — The maximum flow rate that can be expected on a transportation facility. “Practical” capacity is sometimes limited by “acceptable” delay levels, utilization rates, and load factors.

Circuitry factor — Ratio of actual distance on network to shortest airline distance.

Delay — Increase in service time due to congestion or service interruptions.

Demand-responsive — A mode whose schedule or route is adjusted in the short term as demand varies, such as taxis, charter airlines, and “TRAMP” ships.

Load factor — Fraction of available space or weight-carrying capability that is used.

Lock — A structure with gates at both ends, which is used to lift or lower ships or other vessels.

Mode — A distinct form of transportation.

Subsonic — Flying below the speed of sound (Mach 1), which is approximately 700 mph at cruising altitudes of approximately 33,000 ft.

Utilization rate — Fraction of time that a vehicle, facility, or equipment unit is in productive use.

86.1 Introduction

Surface transportation systems in the United States today face a number of significant challenges. Congestion and safety continue to present serious problems in spite of the nation's superb roadway systems. Congestion imposes an exorbitant cost on productivity, costing the nation an estimated \$40 billion per year. Vehicle crashes cause another \$150 billion burden to the economy and result in the loss of 40,000 lives annually. Inefficient surface transportation, whether in privately owned vehicles, commercial motor carriers, or public transit vehicles, constitutes a burden on the nation's quality of life through wasted energy, increased emissions, and serious threats to public safety [41]. In addition, it directly impacts national economic growth and competitiveness.

Over the last two decades, demand for mobility has continued to increase, but the available capacity of the roadway system is nearly exhausted. Vehicle travel has increased 70%, while road capacity has increased only slightly more than 1% [47].

Except for fine-tuning and relatively modest additions, the road system cannot be expanded in many areas. The only means left for increasing available travel capacity is to use the available capacity more effectively, e.g., redirect traffic to avoid congestion, provide assistance to drivers and other travelers on planning and following optimal routes, increase the reliability of and access to public transportation, and refocus safety efforts on accident avoidance rather than merely minimizing the consequences of accidents [1].

Responding to this need, Intelligent Transportation Systems (ITS) is the integrated application of well-established technologies in advanced information processing and communications, sensing, control, electronics, and computer hardware and software to improve surface transportation performance, both in the vehicle and on the highway [1,2,32].

This simple definition underlies what has been a substantial change in surface transportation in the United States and around the world. Development of ITS was motivated by the increased difficulty — social, political, and economic — of expanding transportation capacity through conventional infrastructure building. ITS represents an effort to harness the capabilities of advanced technologies to improve transportation on many levels. ITS is intended to reduce congestion, enhance safety, mitigate the environmental impacts of transportation systems, enhance energy performance, and improve productivity [32].

Intelligent Transportation Systems, formerly Intelligent Vehicle–Highway Systems (IVHS), offers technology-based solutions to the compelling challenges confronting the nation's surface transportation systems while concurrently establishing the basis for dealing with future demands through a strategic, intermodal view of transportation. ITS applications offer proven and emerging technologies in fields such as data processing, communications, control, navigation, electronics, and the supporting hardware and software systems capable of addressing transportation challenges. Although ITS technology applications alone cannot completely satisfy growing transportation needs, they provide the means to revise current approaches to problem solving, and they improve the efficiency and effectiveness of existing systems. When deployed and integrated effectively, ITS technologies will enable the surface transportation system to operate as multimodal, multijurisdictional entities providing meaningful benefits, including more efficient use of infrastructure and energy resources, complemented by measurable improvements in safety, mobility, productivity, and accessibility [41].

Some of the effects that ITS could have in transportation operations, safety, and productivity are described next.

86.2 Role of ITS in Tomorrow's Transportation Systems

Operations

The essence of ITS as it relates to transportation operations is the improved ability to manage transportation services as a result of the availability of accurate, real-time information and to greatly enhance control of traffic flow and individual vehicles. With ITS, decisions that individuals make as to time, mode, and route choices can be influenced by information that currently is not available when it is needed or

is incomplete, inconvenient, or inaccurate. For example, ITS technology would enable operators to detect incidents more quickly; to provide information immediately to the public on where the incident is located, its severity, its effect on traffic flow, and its expected duration; to change traffic controls to accommodate changes in flow brought about by the incident; and to provide suggestions on better routes and information on alternative means of transportation [2].

The availability of this information would also enable the development of new transportation control strategies. For example, to obtain recommended routing information, drivers will have to specify their origins and destinations. Knowledge of origin and destination information in real time will enable the development of traffic assignment models that will be able to anticipate when and where congestion will occur (origins and destinations can also be estimated in real time). Control strategies that integrate the operation of freeway ramp metering systems, driver information systems, and arterial traffic signal control systems, and that meter flow into bottleneck areas, can be developed to improve traffic control. Eventually, perhaps toward the third decade of the 21st century, totally automated facilities may be built on which vehicles would be controlled by electronics in the highway [2].

Safety

Whereas many safety measures developed over the years have been aimed at reducing the consequences of accidents (such as vehicle crashworthiness and forgiving roadside features), many ITS functions are directed toward the *prevention* of accidents. A premise of the European PROMETHEUS program, for example, was that 50% of all rear-end collisions and accidents at crossroads and 30% of head-on collisions could be prevented if the driver was given another half-second of advance warning and reacted correctly. Over 90% of these accidents could be avoided if drivers took the appropriate countermeasures 1 second earlier. ITS technologies that involve sensing and vehicle-to-vehicle communications are initially designed to automatically warn the driver, providing enough lead time for him or her to take evasive actions. The technologies may also assume some of the control functions that are now totally the responsibility of drivers, compensating for some of their limitations and enabling them to operate their vehicles closer together but safer. Even before these crash-avoidance technologies become available to the public, ITS holds promise for improving safety by providing smoother traffic flow. For example, driver information systems provide warnings on incident blockages ahead, and this may soften the shock wave that propagates as a result of sudden and abrupt decelerations caused by unanticipated slowdowns [2].

Potential safety dangers must, however, also be acknowledged. A key issue involves driver distraction and information overload from the various warning and display devices in the vehicle. Other issues include dangers resulting from system unreliability (for example, a warning or driver-aid system that fails to operate) and the incentive for risky driving that ITS technologies may provide. These are important research issues that must be addressed before such systems are widely implemented [2].

Productivity

The availability of accurate, real-time information will be especially useful to operators of vehicle fleets, including transit, high-occupancy vehicle (HOV), emergency, fire, and police services, as well as truck fleets. Operators are able to know where their vehicles are and may receive an estimate on how long a trip can be expected to take; thus, they will be able to advise on best routes to take and will be able to manage their fleets better [2].

There is great potential for productivity improvements in the area of regulation of commercial vehicles. Automating and coordinating regulatory requirements through application of ITS technologies can, for example, reduce delays incurred at truck weigh stations, reduce labor costs to the regulators, and minimize the frustration and costs of red tape to long-distance commercial vehicle operators. There is also potential to improve coordination among freight transportation modes; as an example, if the maritime and trucking industries used the same electronic container identifiers, as has been the case in certain limited applications, freight-handling efficiencies would be greatly improved [2].

86.3 ITS Categories

At its early stages, by general agreement, IVHS (the precursor of ITS) had been subdivided into six interlocking system areas, three focused on technology and three on applications [1]:

Technology oriented:

- Advanced Traffic Management Systems (ATMS)
- Advanced Traveler Information Systems (ATIS)
- Advanced Vehicle Control Systems (AVCS)

Applications oriented:

- Advanced Public Transportation Systems (APTS)
- Commercial Vehicle Operations (CVO)
- Advanced Rural Transportation Systems (ARTS)

Advanced Traffic Management Systems

ATMS addresses technologies to monitor, control, and manage traffic on streets and highways. ATMS technologies include [1]:

- Traffic management centers (TMCs) in major metropolitan areas to gather and report traffic information, and to control traffic movement to enhance mobility and reduce congestion through ramp, signal, and lane management; vehicle route diversion; etc.
- Sensing instrumentation along the highway system, which consists of several types of sensors, including magnetic loops and machine vision systems, that provide current information on traffic flow to the TMC
- Variable message signs that provide current information on traffic conditions to highway users and suggest alternate routes
- Priority control systems to provide safe travel for emergency vehicles when needed
- Programmable, directional traffic signal control systems
- Automated dispatch of tow, service, and emergency vehicles to accident sites

Advanced traffic management systems have six primary characteristics differentiating them from the typical traffic management system of today [2]. In particular, ATMS:

- Work in real time.
- Respond to changes in traffic flow. In fact, an ATMS will be one step ahead, predicting where congestion will occur based on collected origin–destination information.
- Include areawide surveillance and detection systems.
- Integrate management of various functions, including transportation information, demand management, freeway ramp metering, and arterial signal control.
- Imply collaborative action on the part of the transportation management agencies and jurisdictions involved.
- Include rapid-response incident management strategies.

To implement ATMS, real-time traffic monitoring and data management capabilities are being developed, including advanced detection technology, such as image processing systems, automatic vehicle location and identification techniques, and the use of vehicles as probes. New traffic models are being created, including real-time dynamic traffic assignment models, real-time traffic simulation models, and corridor optimization techniques. The applicability of artificial intelligence and expert systems techniques is assessed, and applications such as rapid incident detection, congestion anticipation, and control strategy selection are being developed and tested [2].

Advanced Traveler Information Systems

ATIS address technologies to assist travelers with planning, perception, analysis, and decision making to improve the convenience and efficiency of travel. In the automobile, ATIS technologies include [1]:

- Onboard displays of maps and roadway signs (in-vehicle signing)
- Onboard navigation and route guidance systems
- Systems to interpret digital traffic information broadcasts
- Onboard traffic hazard warning systems (e.g., icy road warnings)

Outside the vehicle, ATIS technologies include [1]:

- Trip planning services
- Public transit route and schedule information available online at home, office, kiosks, and transit stops.

Advanced traveler information systems provide drivers with information about congestion and alternate routes, navigation and location, and roadway conditions through audio and visual means in the vehicle. This information can include incident location, location of fog or ice on the roadway, alternate routes, recommended speeds, and lane restrictions. ATIS provide information that assist in trip planning at home, at work, and by operators of vehicle fleets. ATIS also provide information on motorist services such as restaurants, tourist attractions, and the nearest service stations and truck and rest stops (this has been called the yellow pages function.) ATIS can include onboard displays that replicate warning or navigational roadside signs when they may be obscured during inclement weather or when the message should be changed, as when speed limits should be lowered on approaches to congested freeway segments or fog areas. An automatic Mayday feature may also be incorporated, which would provide the capability to automatically summon emergency assistance and provide vehicle location [2].

A substantial effort is required to define the communications technology, architecture, and interface standards that will enable two-way, real-time communication between vehicles and a management center. Possibilities include radio data communications, cellular systems, roadside beacons used in conjunction with infrared or microwave transmissions or low-powered radio signals, and satellite communications. Software methods to fuse the information collected at the management center and format it for effective use by various parties must also be developed. These parties include commuters, tourists, other trip makers, and commercial vehicle operators, both before they make a trip and en route; operators of transportation management systems; and police, fire, and emergency response services [2].

A number of critical human factors issues must also be investigated. These include identifying the critical pieces of information and the best way of conveying them to different individuals. The human factors issues also include a critical examination of in-vehicle display methods [2].

Advanced Vehicle Control Systems

AVCS address technologies to enhance the control of vehicles by facilitating and augmenting driver performance and, ultimately, relieving the driver of some tasks, through electronic, mechanical, and communications devices in the vehicle and on the roadway. AVCS technologies include [1]:

- Adaptive cruise control, which slows a cruise-controlled vehicle if it gets too close to a preceding vehicle
- Vision enhancement systems, which aid driver visibility in the dark or in adverse weather
- Lane departure warning systems, which help drivers avoid run-off-the-road crashes
- Automatic collision avoidance systems, i.e., automatic braking upon obstacle detection
- Automated Highway Systems (AHS), automatically controlling vehicles in special highway lanes to increase highway capacity and safety

Whereas the other categories of ITS primarily serve to make traveling more efficient by providing more timely and accurate information about transportation, AVCS serve to greatly improve safety and

potentially make dramatic improvements in highway capacity by providing information about changing conditions in the immediate environment of the vehicle, sounding warnings, and assuming partial or total control of the vehicle [2].

Early implementation of AVCS technologies may include a number of systems to aid with the driving task. These include hazard warning systems that sound an alarm or actuate a light when a vehicle moves dangerously close to an object, such as when backing up or when moving into the path of another vehicle when changing lanes. Infrared imaging systems may also be implemented that enhance driver visibility at night. AVCS technologies also include adaptive cruise control and lane-keeping systems that automatically adjust vehicle speed and position within a lane through, for example, radar systems that detect the position and speed of a lead vehicle, or possibly through electronic transmitters in the pavement that detect the position of vehicles within the lane and send messages to a computer in the vehicle that has responsibility for partial control functions. As technology advances, lanes of traffic may be set aside exclusively for automated operation, known as platooning highway systems. These automated facilities have the potential to greatly increase highway capacity while at the same time providing for safer operation [2].

Much research, development work, and testing are needed before such systems can be built and implemented, and much of it is taking place today. Perhaps the most important issues, though, relate to the role of humans in the system — that is, public acceptability and how it is likely to affect system effectiveness. Other human factors issues include driver reaction to partial or full control — whether it will cause them to lose alertness or drive more erratically. Another important area is AVCS reliability and the threat of liability [2].

The vision for the AHS program is to create a fully automated system that evolves from today's roads, beginning in selected corridors and routes; provides fully automated, “hands-off” operation at better levels of performance than there are today, in terms of safety, efficiency, and comfort; and allows equipped vehicles to operate in both urban and rural areas and on highways that are instrumented and not instrumented [7].

Although full deployment of an AHS is certainly a long-term goal, pursuit of this goal is extremely important. A new level of benefits could be realized with the complete automation of certain facilities. By eliminating human error, an automated highway could provide a nearly accident-free driving environment. In addition, the precise, automated control of vehicles on an automated vehicle–highway system could result in an increase of two to three times the capacity of present-day facilities while encouraging the use of more environmentally benign propulsion methods. Initial AHS deployments might be on heavily traveled urban or interstate highway segments, and the automated lanes might be comparable to the HOV vehicle lanes on today's highways. If successful, the AHS could evolve into a major advance of the nation's heavily traveled roadways or the interstate highway system [7].

Advanced Public Transportation Systems

APTS addresses applications of ITS technologies to enhance the effectiveness, availability, attractiveness, and economics of public transportation. APTS strives to improve performance of the public transportation system at the unit level (vehicle and operator) and at the system level (overall coordination of facilities and provision of better information to users). APTS technologies include [1]:

- Fleet monitoring and dispatch management
- Onboard displays for operators and passengers
- Real-time displays at bus stops
- Intelligent fare collection (e.g., using smart cards)
- Ride-share and HOV information systems

Applications of ITS technologies could lead to substantial improvements in bus and paratransit operations in urban and rural areas. Dynamic routing and scheduling could be accomplished through onboard devices, communications with a fleet management center, and public access to a transportation information system containing information on routes, schedules, and fares. Automated fare collection

systems could also be developed that would enable extremely flexible and dynamic fare structures and relieve drivers of fare collection duties [2].

Commercial Vehicle Operations

CVO addresses applications of ITS technologies to commercial roadway vehicles (trucks, commercial fleets, and intercity buses). Many CVO technologies, especially for interstate trucking, relate to the automated, no-stop-needed handling of the routine administrative tasks that have traditionally required stops and waiting in long lines: toll collection, road-use calculation, permit acquisition, vehicle weighing, etc. Such automation can save time, reduce air pollution (most, and the worst, emissions are produced during acceleration and deceleration), and increase the reliability of record keeping and fee collection. CVO technologies include [1]:

- Automatic vehicle identification (AVI)
- Weigh-in motion (WIM)
- Automatic vehicle classification (AVC)
- Electronic placarding or bill of lading
- Automatic vehicle location (AVL)
- Two-way communications between fleet operator and vehicles
- Automatic clearance sensing (ACS)

The application of ITS technologies holds great promise for improving the productivity, safety, and regulation of all commercial vehicle operations, including large trucks, local delivery vans, buses, taxis, and emergency vehicles. Faster dispatching, efficient routing, and more timely pickups and deliveries are possible, and this will have a direct effect on the quality and competitiveness of businesses and industries at both the national and international levels. ITS technologies can reduce the time spent at weigh stations, improve hazardous material tracking, reduce labor costs to administer government truck regulations, and minimize costs to commercial vehicle operators [2].

ITS technologies manifest themselves in numerous ways in commercial vehicle operations. For example, for long-distance freight operations, onboard computers not only will monitor the other systems of the vehicle but also can function to analyze driver fatigue and provide communications between the vehicle and external sources and recipients of information. Applications include automatic processing of truck regulations (for example, commercial driver license information, safety inspection data, and fuel tax and registration data), avoiding the need to prepare redundant paperwork and leading to “transparent borders”; provision of real-time traffic information through advanced traveler information systems; proof of satisfaction of truck weight laws using weigh-in motion scales, classification devices, and automated vehicle identification transponders; and two-way communication with fleet dispatchers using automatic vehicle location and tracking and in-vehicle text and map displays. Regulatory agencies would be able to take advantage of computerized record systems and target their weighing operations and safety inspections at those trucks that are most likely to be in violation [2].

Advanced Rural Transportation Systems

ARTS address applications of ITS technologies to rural needs, such as vehicle location, emergency signaling, and traveler information. The issues involved in implementing ITS in rural areas are significantly different from those in urban areas, even when services are similar. Rural conditions include low population density, fewer roads, low amount of congestion, sparse or unconventional street addresses, etc. Different technologies and communications techniques are needed in rural ITS to deal with those conditions. Safety is a major issue in ARTS; over half of all accidents occur on rural roads. ARTS technologies include [1]:

- Route guidance
- Two-way communications

- Automatic vehicle location
- Automatic emergency signaling
- Incident detection
- Roadway edge detection

Application of ARTS technologies can address the needs of rural motorists who require assistance either because they are not familiar with the area in which they travel (tourists) or because they face extreme conditions such as weather, public works, and special events. Provision of emergency services is particularly important in rural areas. A state study [28] has determined that notification of spot hazardous conditions and collision avoidance at nonsignalized intersections are highly important issues that ARTS could address in the short term; long-term issues include construction zone assistance, transit applications, inclement weather trip avoidance and assistance, tourist en route information and traffic control, and in-vehicle Mayday devices.

86.4 ITS Restructuring and Progress

With the enactment of the Intermodal Surface Transportation Efficiency Act (ISTEA) in 1991, Congress set a new course for transportation by mandating increased efficiency and safety on the existing highway and transit infrastructure through increased emphasis on intermodalism — the seamless integration of multiple modes of transportation. In response to ISTEA, the U.S. Department of Transportation (DOT) initiated a multifaceted ITS program involving research and field operational testing of promising ITS applications. With the passage of the Transportation Equity Act for the 21st Century (TEA-21) in June 1998, Congress reaffirmed the U.S. DOT's role in continuing the development of ITS technologies and launching the transition nationwide and the integrated deployment of ITS applications to foster the management of multiple transportation resources as unified systems delivering increased efficiency, safety, and customer satisfaction. We have thus witnessed the restructuring of the ITS program from the program areas established during the ISTEA era into the new organization reflecting congressional direction in TEA-21, which emphasizes deployment and integration of ITS. The advent of TEA-21 catalyzed a restructuring of ITS program activities into intelligent infrastructure categories and the Intelligent Vehicle Initiative (IVI) [41].

The program reorientation reflects the evolution of emphasis to deployment whose output is infrastructure or vehicles. Metropolitan ITS infrastructure inherits the research in Advanced Traffic Management Systems, Advanced Public Transportation Systems, and Advanced Traveler Information Systems. The Rural ITS infrastructure encompasses the activities of the Advanced Rural Transportation Systems (ARTS) program, including the application of technologies under development for metropolitan and commercial vehicle infrastructure that are adaptable to rural community needs. The commercial vehicle ITS infrastructure continues to build on the research endeavors of the Commercial Vehicle Operations program and is heavily focused on the deployment of Commercial Vehicle Information Systems and Networks (CVISN). The Intelligent Vehicle Initiative integrates the work accomplished in various facets of intelligent vehicle research and development to include the Advanced Vehicle Control and Safety Systems (AVCSS) program and the Automated Highway Systems [41].

The enabling research and technology program area continues to provide crosscutting support to each of the four functional components constituting the program's foundation. [Figure 86.1](#) provides a crosswalk depicting the dynamics of the realignment.

The restructured ITS program places emphasis in two major areas: deploying and integrating intelligent infrastructure, and testing and evaluating intelligent vehicles. Intelligent infrastructure and intelligent vehicles, working together, will provide the combinations of communications, control, and information management capabilities needed to improve mobility, safety, and traveler decision making in all modes of travel. Intelligent infrastructure comprises the family of technologies that enable the effective operation of ITS services in metropolitan areas, in rural and statewide settings, and in commercial vehicle applications. Intelligent vehicle technologies foster improvements in safety and mobility of vehicles. The

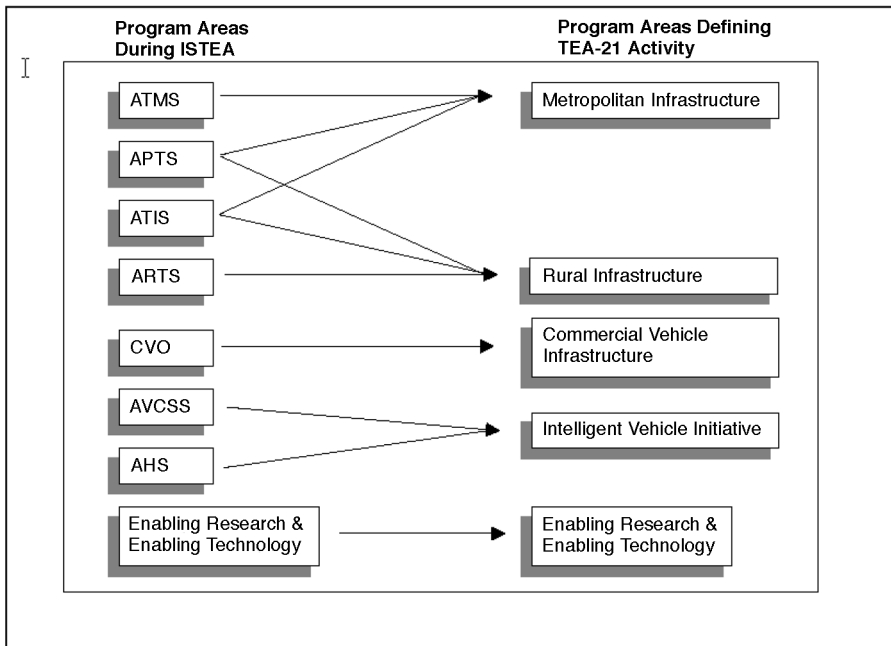

FIGURE 86.1 ITS program reorientation. (From ITS JPO, Department of Transportation's Intelligent Transportation Systems (ITS) Projects Book, U.S. DOT, FHWA Operations Core Business Unit, FTA Office of Mobility Innovation, National Highway Traffic Safety Administration, Washington, D.C., 2001.)

Intelligent Vehicle Initiative embraces four classes of vehicles: light vehicles (ranging from passenger automobiles and vans to light trucks), transit vehicles (buses), commercial vehicles (trucks and interstate buses), and specialty vehicles (emergency response, enforcement, and maintenance vehicles).

Within this restructuring, intelligent infrastructure and intelligent vehicle program development objectives are pursued through four program areas: metropolitan ITS infrastructure, rural ITS infrastructure, commercial vehicle ITS infrastructure, and the Intelligent Vehicle Initiative, as described below, which includes light vehicles, transit vehicles, trucks, and emergency and specialty vehicles.

The metropolitan ITS infrastructure program area is focused on deployment and integration of technologies in that setting. The rural ITS infrastructure program area emphasizes deployment of high-potential technologies in rural environments. Commercial vehicle ITS infrastructure program objectives are directed at safety and administrative regulation of interstate trucking. Intelligent vehicle program objectives are centered on in-vehicle safety systems for all classes of vehicles in all geographic environments.

There are no specific ITS applications that hold the potential for addressing all of the current or projected transportation system needs. The potential for success lies in developing a national transportation system incorporating integrated and interoperable ITS services. The ITS program envisions a gradual and growing interaction between infrastructure and vehicles to produce increased benefits in mobility and traveler safety.

The documents guiding ITS program direction are evolving. The U.S. DOT's goals, key activities, and milestones for fiscal years (FY) 1999 through 2003 are documented in the National Intelligent Transportation Systems Program 5-year horizon plan [38]. This plan was followed by a 10-year program plan [46] that presents the next generation research agenda for ITS. These two documents, coupled with the Intelligent Transportation Society of America's national deployment strategy, satisfy congressional direction in TEA-21 to update the National ITS Program Plan published in 1995 and address ITS deployment and research challenges for stakeholders at all levels of government and the private sector. Within the restructured framework, the ITS program is focused on activities impacting both near-term and long-term horizons.

Near Term

Through the end of FY 2003, the effective period of TEA-21, the program will focus on facilitating integrated deployment of ITS components in the defined infrastructure categories.

Metropolitan ITS infrastructure will integrate various components of advanced traffic management, traveler information, and public transportation systems to achieve improved efficiency and safety and to provide enhanced information and travel options for the public.

Commercial vehicle ITS infrastructure is oriented on integrating technology applications for improving commercial vehicle safety, enhancing efficiency, and facilitating regulatory processes for the trucking industry and government agencies. The principal instrument of this component is known as Commercial Vehicle Information Systems and Networks, a system of information systems that link the nodes supporting communications among carriers and agencies.

Rural ITS infrastructure is characterized by a framework of seven development tracks such as surface transportation weather and winter mobility and rural transit mobility. ITS technologies are demonstrating exceptional effectiveness and customer acceptance in such applications that are tailored to rural transportation settings.

The development of a robust market fueled by private sector investment is dependent on a critical mass of basic ITS infrastructure. In the era of ISTEA, the National ITS Program focused principally on research, technology development, and field testing; the focus of TEA-21 will continue this legacy by building on successes to deploy ITS infrastructure. A critical challenge in achieving a seamless, intermodal transportation system is ensuring interoperability through the use of an open, nonproprietary architecture and the adoption of ITS standards.

Long Term

The long-term focus will be directed at supporting research, development, and testing of advanced technologies demonstrating potential for deployment in the 5- to 20-year horizon. The in-vehicle component of this effort will be consolidated into a single Intelligent Vehicle Initiative centered heavily on applying driver assistance and control intervention systems to reduce vehicle crashes. A companion effort seeks to integrate driving assistance and motorist information functions to facilitate information processing, decision making, and more effective vehicle operation.

A summary of ITS projects, tests, and studies initiated through September 2000 that have been partially or totally financed from federal ITS funds can be found in Reference 41.

86.5 What We Have Learned [32]

Now, with the National ITS Program more than a decade old in the United States, it certainly is timely, appropriate, and necessary to ask: Have we succeeded in deploying ITS? Has that deployment had a positive effect on surface transportation? What have we learned from these ITS deployments that can guide us in the future?

A recent study by the Federal Highway Administration (FHWA) [32] has addressed these questions. While many possible definitions exist, success here was tied to effectiveness — that is, whether an ITS application addresses major societal goals such as enhanced safety and improved quality of life — and to deployment of each particular ITS technology or application. Implicit in this metric for success is the belief in the test of the marketplace and the ITS community's ability to select those technologies and applications it sees as cost-effective and beneficial.

How It Was Done

The ITS Joint Program Office (JPO) of the FHWA of the U.S. DOT funds the development of several databases that are used to judge various ITS technologies and applications. These databases include the following:

- Metropolitan ITS Deployment Tracking Database, maintained by the Oak Ridge National Laboratory
- Commercial Vehicle Information Systems Network Deployment Tracking Database, maintained by the John A. Volpe National Transportation Systems Center (Volpe Center)
- 1998 Survey of Transit Agencies, conducted by the Volpe Center
- ITS cost database, maintained by Mitretek Systems

Deployment levels for various technologies were defined as follows:

- Deployed in fewer than 10% of the possible sites = limited deployment
- Deployed in 10 to 30% of the possible sites = moderate deployment
- Deployed in more than 30% of the possible sites = widespread deployment

Deployment levels are based on the actual presence of particular technologies, not future plans to deploy, even if funding for the deployment has already been secured. However, simply identifying an ITS technology or application as unsuccessful (i.e., not adequately deployed) is not a sufficient base for understanding how to subsequently advance in that area. The study, therefore, included the reason for the lack of success, choosing among three fundamental causes for a technology or application not being deployed:

1. The technology simply did not function effectively in a real-world environment.
2. While the technology or application worked in a technical sense, it was too costly, meaning any one of the following:
 - A. It was simply too expensive to deploy compared with the potential benefits that accrued from its deployment.
 - B. The absolute costs of acquisition, operations, and maintenance were considered too large by the deploying organization.
 - C. The technology used was not suitable for a particular application.
3. Institutional barriers prevented the effective deployment of the technology or application.

Any of these reasons for lack of success could potentially be overcome in the future. Technologies can be enhanced; prices of various technologies can and do fall, often dramatically; and institutional barriers, while often tenacious, can be overcome with careful work over the long term. Further, a particular technology or application may not have had time to develop a “following” in the marketplace, given development and deployment cycles. Therefore, each technology was characterized as one of the following: successful, unsuccessful, holds promise, or jury is still out. To be sure, the deployment level does not necessarily relate directly to success. For example, a technology that is only moderately deployed could be considered successful because it serves as an appropriate technological solution, though only for a small segment of the market.

The areas included within the scope of this study are [32] freeway, incident, and emergency management, and electronic toll collection (ETC); arterial management; traveler information systems; Advanced Public Transportation Systems; Commercial Vehicle Operations (CVO); crosscutting technical issues; and crosscutting institutional issues.

Freeway, Incident, and Emergency Management, and Electronic Toll Collection

This area includes a number of different, albeit related, technologies. Various technologies, including transportation management centers, ramp metering, dynamic message signs, roadside infrastructure, and dynamic lane and speed control, form the basis of these applications. ETC is one of the fundamental and earliest-deployed ITS technologies. It is also the most common example of the electronic linkage between vehicle and infrastructure that characterizes ITS. Freeways (i.e., limited-access highways) represent a major and early ITS application area. Incident management on those facilities is of primary importance in reducing nonrecurrent congestion. Emergency management predates ITS as a concept but is enhanced by the addition of ITS technologies.

Although a number of systems have seen widespread deployment, much more can be accomplished. Institutional issues preventing truly integrated services are a major barrier. An important technical advancement would be to upgrade such systems to be predictive (in the sense of predicting when congestion will occur in the future as a function of current traffic patterns and expectations about the future) as opposed to the responsive systems currently in place. There is a need to institutionalize operation budgets for these kinds of systems as well as a need to attract high-quality technical staff for deployment and operations support.

Arterial Management

Arterials are high-capacity roadways controlled by traffic signals, with access via cross-streets and often abutting driveways. Arterial management predates ITS, with early deployments going back to the 1960s; it is a useful ITS application with current deployment. However, adaptive control strategies, which make real-time adjustments to traffic signals based on sensing conditions (e.g., queues), at arterials are not in widespread use. While some argue that such control strategies have potential for substantial benefits, only a handful are deployed nationally, of which four are federally funded field operational tests. The reasons for this deployment lag include cost issues and concerns that algorithms for adaptive traffic control simply do not perform well. In particular, when traffic volumes are heavy, the state-of-the-art algorithms appear to break down (although vendors claim otherwise). Also, system complexity drives the need for additional training.

Widespread deployment has not yet occurred for traveler information systems for arterials, even though studies suggest safety and delay reduction benefits. The hope is that with the addition of cellular phones, or cellular phone geolocation for traffic probes, and implementation of a national three-digit traveler information number (511), more deployment will occur. Integration of various traffic management technologies with arterial management is an important next step. Integration of arterial management with emergency vehicle management, transit management, and freeway management would represent important and useful advances.

Traveler Information Systems

Traveler information is one of the core concepts of ITS. Among the items valued by consumers are high-quality information, easy and timely accessibility to that information, a high-quality user interface, and low prices, preferably free. Consumer demand for traveler information is a function of the amount of congestion on the regional transportation network, the overall characteristics of that network, what is provided on the supply side in terms of information quality and user interface, characteristics of individual trips, and driver and transit user characteristics.

Examples abound of various kinds of traveler information systems, with extensive deployment of various kinds of systems. While people value high-quality traveler information in the conceptual sense, they are not necessarily willing to pay for it. After all, free information — although often of lower quality — is universal (e.g., radio helicopter reports). So, whether traveler information systems can be a viable stand-alone commercial enterprise is likewise unclear. More likely, transportation information will be offered as part of some other package of information services. The Internet is likely to be a major basis of traveler information delivery in the future.

The analysis of traveler information systems brings home the fact that ITS operates within the environment of people's expectations for information. In particular, timeliness and quality of information are on a continually increasing slope in many non-ITS applications, with people's expectations heightened by the Internet and related concepts. Traveler information providers, whether in the public or private sector, need to be conscious of operating in the context of these changed expectations. Further, the effective integration of traveler information with network management, or transportation management systems, of which freeway and arterial management are examples, is currently virtually nonexistent. Both network management and traveler information systems would benefit by more substantial integration, as would the ultimate customers — travelers and freight carriers — of these systems.

Advanced Public Transportation Systems

That transit has difficulty attracting market share is a well-established fact. Reasons include the following: land-use patterns incompatible with transit use; lack of high-quality service, with travel times too long and unreliable; lack of comfort; security concerns; and incompatibility with the way people currently travel (for example, transit is often not suited for trip chaining). The hypothesis is that ITS transit technologies — including automatic vehicle location, passenger information systems, traffic signal priority, and electronic fare payment — can help ameliorate these difficulties, improving transit productivity, quality of service, and real-time information for transit users.

Using ITS to upgrade transit clearly has potential. However, deployment has, for the most part, been modest, stymied by a number of constraints: lack of funding to purchase ITS equipment, difficulties in integrating ITS technologies into conventional transit operations, and lack of human resources needed to support and deploy such technologies. Optimistically, there will be a steady but slow increase in the use of ITS technologies for transit management as people with ITS expertise join transit agencies. However, training is needed, and inertia must be overcome in deploying these technologies in a chronically capital-poor industry. Integrating transit services with other ITS services is potentially a major intermodal benefit of ITS transit deployments; it is hoped that this integration, including highway and transit, multiprovider services and intermodal transfers, will be feasible in the near term. Still, the question remains: How can we use ITS to fundamentally change transit operations and services? The transit industry needs a boost, and it can be vital in providing transportation services, especially in urban areas, and in supporting environmentally related programs. Can ITS be the mechanism by which the industry reinvents itself? The jury is certainly still out on that question.

Commercial Vehicle Operations

This review is limited to the public sector side of CVO systems (i.e., it does not include fleet management) as states fulfill their obligation to ensure safety and enforce other regulations related to truck operations on their highways. These systems fall under the CVISN rubric and deal with roadway operations, including safety information exchange and electronic screening, as well as back-office applications such as electronic credentialing.

While CVISN is experiencing some deployment successes, much remains to be done. Participation by carriers is voluntary in most programs, and requiring use of transponders by truckers may be difficult. Certainly these facts make universal deployment challenging. Also important as a barrier to deployment is consistency among states, particularly contiguous ones. Recognizing trucking as a regional or even national business, the interface between the trucking industry and the various states needs to be consistent for widespread deployment to occur. While each state has its own requirements for such systems, driven by its operating environment, states must work toward providing interstate interoperability. Expanded public–public partnerships are needed among states and between the federal government and states.

Some public and private sector tensions occur in the CVISN program, as well. A good example is how truckers like the technologies that support weigh station bypass, whereby they are not required to stop at a weigh station if they have been previously checked. In such systems, the information is passed down the line from an adjoining station or even another state. At the same time, truckers are concerned about equity in tax collection and the privacy of their origin–destination data, because of competitive issues. Ironically, the same underlying CVISN system drives both applications. Public–private partnerships need to be developed in this application for public and private benefits to be effectively captured.

Crosscutting Technical and Programmatic Issues

Advanced technology is at the heart of ITS, so it is helpful to consider technical issues that affect ITS functions and applications. Technical issues include how one deals with rapidly changing technologies and how this aspect relates to the need for standards. Rapid obsolescence is a problem. All in all, technology issues are not a substantial barrier to ITS deployment. Most technologies perform; the

question is, are they priced within the budget of deploying organizations, and are those prices consistent with the benefits that can be achieved? Two core technologies are those used for surveillance and communication.

Surveillance technologies have experienced some successes in cellular phone use for incident reports and in video use for incident verification, but the jury is still out on cellular phone geolocation for traffic probes. The lack of traffic flow sensors in many areas and on some roadway types continues to inhibit the growth of traveler information and improved transportation management systems.

Communications technologies have experienced some success with the Internet for pretrip traveler information and credentials administration in CVO. Emerging technologies include wireless Internet and automated information exchange. The growth rate of these technologies is high. In particular, the number of Americans having access to the Internet is growing rapidly, portending increased use of ITS applications [48].

Crosscutting Institutional Issues

Institutional issues are the key barrier to ITS deployment. The ten most prominent issues are awareness and perception of ITS, long-range operations and management, regional deployment, human resources, partnering, ownership and use of resources, procurement, intellectual property, privacy, and liability. Awareness and public and political appreciation of ITS as a system that can help deal with real and meaningful issues (e.g., safety and quality of life) are central to deployment success. Building a regional perspective to deployment using public–public and public–private partnerships is important. Recognizing that one must plan for sustained funding for operations in the long term is critical. Dealing with procurement questions is an important institutional concern, and public sector agencies are not accustomed to procuring high-technology components where intellectual property is at issue.

Fundamentally, ITS deployment requires a cultural change in transportation deployment organizations that have traditionally focused on providing conventional infrastructure. No silver bullet exists for achieving this cultural change; rather, it is a continuing, ongoing, arduous process and one that must be undertaken if ITS is to be successfully deployed.

Conclusions

A useful typology for assessing the above seven areas is along the three major dimensions commonly used to characterize transportation issues: technology, systems, and institutions [35]. Technology includes infrastructure, vehicles, and hardware and software that provide transportation functionality. Systems are one step removed from the immediacy of technology and deal with how holistic sets of components perform. An example is transportation networks. Institutions refer to organizations and interorganizational relationships that provide the basis for developing and deploying transportation programs.

Technology

Four technologies are central to most ITS applications:

1. Sensing: typically the position and velocity of vehicles on the infrastructure
2. Communicating: from vehicle to vehicle, between vehicle and infrastructure, and between infrastructure and centralized transportation operations and management centers
3. Computing: processing of the large amounts of data collected and communicated during transportation operations
4. Algorithms: typically computerized methods for dynamically operating transportation systems

One overarching conclusion is that the quality of technology is not a major barrier to the deployment of ITS. Off-the-shelf technology exists, in most cases, to support ITS functionality. An area where important questions about technology quality still remain is algorithms. For example, questions have been raised about the efficacy of software to perform adaptive traffic signal control. Also, the quality of collected information may be a technical issue in some applications.

Issues do remain on the technology side. In some cases, technology may simply be considered too costly for deployment, operations, and maintenance, particularly by public agencies that see ITS costs as not commensurate with the benefits to be gained by their deployment. In other cases, the technology may be too complex to be operated by current agency staff. Also, in some cases, technology falters because it is not easy to use, either by operators or transportation customers. Nonintuitive kiosks and displays for operators that are less than enlightening are two examples of the need to focus more on user interface in providing ITS technologies.

Systems

The most important need at the ITS systems level is integration of ITS components. While exceptions can certainly be found, many ITS deployments are stand-alone applications (e.g., ETC). It is often cost-effective in the short run to deploy an individual application without worrying about all the interfaces and platforms required for an integrated system. In their zeal to make ITS operational, people often have opted for stand-alone applications — not necessarily an unreasonable approach for the first generation of ITS deployment. However, for ITS to take the next steps forward, it will be important, for reasons of both efficiency and effectiveness, to think in terms of system integration. For example, the integration of services for arterials, freeways, and public transit should be on the agenda for the next generation of ITS deployments. Further integration of services, such as incident management, emergency management, traveler information, and intermodal services, must be accomplished. While this integration certainly adds complexity, it is also expected to provide economies of scale in system deployment and improvements in overall system effectiveness, resulting in better service for freight and traveling customers.

Another aspect of system integration is interoperability — ensuring that ITS components can function together. Possibly the best example of this function is interoperability of hardware and software in vehicles and on the infrastructure (e.g., ETC devices). The electronic linkage of vehicles and infrastructure must be designed using system architecture principles and open standards to achieve interoperability. It is quite reasonable for the public to ask whether their transponders will work with ETC systems across the country or even regionally. Unfortunately, the answer most often is no. Additionally, while it is important to make this technology operate properly on a broad geographic scale, it should also work for public transportation and parking applications. Systems that need to work at a national scale, such as CVO, must provide interoperability among components. No doubt, institutional barriers to interoperability exist (e.g., different perspectives among political jurisdictions), and these barriers inhibit widespread deployment.

Another important example of needed integration is between Advanced Transportation Management Systems and Advanced Traveler Information Systems. The former provides for operations of networks, the latter for traveler information, pretrip and in-vehicle, to individual transportation customers. For the most part, these two technologies, while conceptually interlinked, have developed independently. Currently, there are limited evaluative data on the technical, institutional, and societal issues related to integrating ATMS and ATIS, whereby ATMS, which collect and process a variety of network status data and estimates of future demand patterns, provide travelers (via ATIS services) with dynamic route guidance. This integration, together with ATMS-derived effective operating strategies for the network — which account for customer response to ATIS-provided advice, can lead to better network performance and better individual routes.

Institutions

The integration of public and private sector perspectives on ITS, as well as the integration of various levels of public sector organizations, is central to advancing the ITS agenda. The major barriers to ITS deployment are institutional in nature. This conclusion should come as no surprise to observers of the ITS scene; the very definition of ITS speaks of applying “well-established technologies,” so technological breakthroughs are not needed for ITS deployment. But looking at transportation from an intermodal, systemic point of view requires a shift in institutional focus that is not easy to achieve. Dealing with intra- and interjurisdictional questions, budgetary frameworks, and regional-level perspectives on transportation systems; shifting institutional foci to operations rather than construction and maintenance; and training, retaining,

and compensating qualified staff are all institutional barriers to widespread deployment of ITS technologies. Thinking through how to overcome various institutional barriers to ITS is the single most important activity we can undertake to enhance ITS deployment and develop successful implementations.

Operations

Recent years have brought an increasing emphasis on transportation operations, as opposed to construction and maintenance of infrastructure, as a primary focus. ITS is at the heart of this initiative, dealing as it does with technology-enhanced operations of complex transportation systems. The ITS community has argued that this focus on operations through advanced technology is the cost-effective way to go, given the extraordinary social, political, and economic costs of conventional infrastructure, particularly in urban areas. Through ITS, it is argued, one can avoid the high up-front costs of conventional infrastructure by investing more modestly in electronic infrastructure, then focusing attention on effectively operating that infrastructure and the transportation network at large.

While ITS can provide less expensive solutions, they are not free. There are up-front infrastructure costs and additional spending on operating and maintaining hardware and software. Training staff to support operations requires resources. Spending for ITS is of a different nature than spending for conventional infrastructure, with less up front and more in the out years. Therefore, planning for operations requires a long-term perspective by transportation agencies and the political sector. For that reason, it is important to institutionalize operations within transportation agencies. Stable budgets need to be provided for operations and cannot be the subject of year-to-year fluctuation and negotiation, which is how maintenance has traditionally been, if system effectiveness and efficiency are to be maintained. Human resource needs must be considered as well.

To justify ITS capital costs as well as continuing costs, it is helpful to consider life cycle costing in the evaluation of such programs. The costs and benefits that accrue over the long term are the important metric for such projects. But organizations need to recognize that a lack of follow-through will cause those out-year benefits to disappear as nonmaintained ITS infrastructure deteriorates and algorithms for traffic management are not recalibrated.

Mainstreaming

The term *mainstreaming* is used in different ways in the ITS setting. Some argue that mainstreaming means integrating ITS components into conventional projects. A good example is the Central Artery/Ted Williams Tunnel project in Boston, which includes important ITS elements as well as conventional infrastructure. Another is the Woodrow Wilson Bridge on I-95, connecting Maryland and Virginia, currently undergoing a major redesign, which includes both conventional infrastructure and ITS technologies and applications. This approach has the advantage of serving as an opportunity for ITS deployment within construction or major reconstruction activities. Typically, the ITS component is a modest fraction of total project cost. Even so, ITS technologies and applications can sometimes come under close political scrutiny well beyond their financial impact on the project. For example, on the Woodrow Wilson Bridge, the decommitting of various ITS elements is being considered [49].

Another definition of ITS mainstreaming suggests that ITS projects not be protected by special funds sealed for ITS applications but that ITS should compete for funding with all other transportation projects. The advantage of this method is that ITS would compete for a much larger pool of money; the disadvantage is that ITS, in the current environment, might not compete particularly successfully for that larger pool. Those charged with spending public funds for transportation infrastructure have traditionally spent virtually all their money on conventional projects. Convincing these decision makers that funds are better spent on ITS applications may be difficult.

This issue is clearly linked to human resource development. Professionals cannot be expected to select ITS unless they are knowledgeable about it, so education of the professional cadre is an essential precondition for success of mainstreaming — by either definition. Of course, the National ITS Program must also be prepared to demonstrate that the benefits of ITS deployments are consistent with the costs incurred. Protected ITS funds — funds that can be spent only on ITS applications — may be a good

transition strategy as professional education continues and ITS benefits become clearer, but in the longer run, there are advantages to ITS being mainstreamed.

Human Resources

An important barrier to success in the deployment of new technologies and applications embodied in ITS is a lack of people to support such systems. The ITS environment requires skilled specialists representing new technologies. It also needs broad generalists with policy and management skills who can integrate advanced thinking about transportation services based on new technologies [35]. The ITS community has recognized these needs, and various organizations have established substantial programs for human resource development. FHWA's Professional Capacity Building program is a premier example but not the only one. Universities have also developed relevant programs that, along with graduate transportation programs undergoing substantial ITS-related changes around the country, can provide a steady stream of talented and newly skilled people for the industry. However, we must emphasize that institutional changes in transportation organizations are needed if these people are to be used effectively and retained, as people with high-technology skills can often demand much higher salaries than are provided by public sector transportation organizations. Cultural change, along with appropriate rewards for operations staff, for example, will be necessary in organizations where the culture strongly favors conventional infrastructure construction and maintenance.

The need for political champions for ITS has long been understood in the ITS community. Here, though, we emphasize the need at all levels of implementing organizations for people with the ability to effectively deploy ITS. The political realities may require public sector organizations to “contract in” staff to perform some of the high-technology functions inherent in ITS, as opposed to permanently hiring such individuals. Also, “contracting out” — having private sector organizations handle various ITS functions on behalf of the public sector — is another option. In the short run, these options may form useful strategies. In the long run, developing technical and policy skills directly in the public agency has important advantages for strategic ITS decision making.

The Positioning of ITS

Almost from its earliest days, ITS has unfortunately been subject to overexpectations and overselling. Advocates have often promoted the benefits of ITS technologies and applications and have minimized the difficulties in system integration during deployment. Often ITS has been seen by the public and politicians as a solution looking for a problem. Overtly pushing ITS can be counterproductive. Rather, ITS needs to be put to work in solving problems that the public and agencies feel truly exist.

Safety and quality of life are the two most critical areas that ITS can address. Characterizing ITS benefits along those dimensions when talking to the public or potential deploying agencies is a good strategy. The media can also help to get the story out about ITS [37].

Operator versus Customer Perspective

Information is at the heart of ITS. The provision of information to operators to help them optimize vehicle flows on complex systems is one component. The flow of information to customers (drivers, transit users, etc.) so they can make effective choices about mode, route choice, etc. is another component. There is a great deal of overlap in these two information sets, yet sharing information between operators and customers is often problematic. Operators are usually public sector organizations. From their perspective, the needs of individual travelers should be subordinate to the need to make the overall network perform effectively. On the other hand, private sector information providers often create and deliver more tailored information focusing on the needs of particular travelers rather than overall system optimization.

It is not surprising that the agendas of the public sector agencies operating the infrastructure and those of the information-provider private sector companies differ. Nonetheless, it seems clear that the ultimate customer — the traveler — would benefit from a more effective integration of these two perspectives. This issue is both a technical and an institutional one and is an important example of the need for service integration.

Regional Opportunities

From a technological and functional point of view, ITS provides, for the first time, an opportunity to manage transportation at the scale of the metropolitan-based region. Along with state or even multistate geographic areas, metropolitan-based regions — the basic geographic unit for economic competition and growth [34] and for environmental issues — can now be effectively managed from a transport point of view through ITS. While a few regions in Europe and the United States have made progress, ITS technologies generally have not been translated into a regionally scaled capability. The institutional barriers are, of course, immense, but the prize from a regional viability perspective is immense, as well. Thinking through the organizational changes that will allow subregional units some autonomy, but at the same time allow system management at the regional scale, is an ITS issue of the first order [33]. Indeed, this approach could lead to new paradigms for strategic planning on a regional scale, supported by the information and organizational infrastructure developed in the context of ITS.

The strategic vision for ITS is as the integrator of transportation, communications, and intermodalism on a regional scale [35,37]. Multistate regions with traffic coordination over very large geographic areas, as in the mountain states, is an important ITS application. Corridors such as I-95, monitored by the I-95 Corridor Coalition and stretching from Maine to Virginia, represent an ITS opportunity, as well.

Surface Transportation as a Market

Surface transportation needs to be thought of as a market with customers with ever-rising and individual expectations. Modern markets provide choices. People demand choices in level of service and often are willing to pay for superior service quality; surface transportation customers will increasingly demand this service differentiation, as well. While a market framework is not without controversy in publicly provided services, surface transportation operators can no longer think in terms of “one size fits all.” High-occupancy toll (HOT) lanes, where people driving a single-occupancy vehicle are permitted to use an HOV lane if they pay a toll, are an early example of this market concept in highway transportation. HOT lanes are enabled by ITS technologies. Other market opportunities building on ITS will doubtless emerge, as well.

Assessment summaries of technologies are in [Tables 86.1](#) through 86.9 in the Appendix.

86.6 Benefits of ITS

It is interesting to reflect on how technology has influenced transportation in the United States. The steam engine improved travel by boat and railroad, resulting in coast-to-coast systems. The internal combustion engine freed the vehicle from a fixed guideway or waterway and encouraged the construction of farm-to-market roads as well as enabled travel by air. ITS will move another step forward by providing traveler information and by operating traffic management and control systems. This quantum leap will have a major impact on today’s lifestyle [6].

Attempting to quantify the benefits of widely deployed ITS technologies at the birth of what was then IVHS was similar to what planners of the U.S. interstate highway system tried to do in the 1950s. It was impossible to anticipate all of the ways that applications of ITS technology may affect society, just as planners of the interstate highway system could not have anticipated all of its effects on American society. Recognizing the importance of the issue, however, Mobility 2000, an ad hoc coalition of industry, university, and federal, state, and local government participants, whose work led to the establishment of ITS America, addressed the potential benefits of applying ITS technology in the United States. Numerous benefits were predicted for urban and rural areas and for targeted groups, such as elderly and disadvantaged travelers. Positive benefits were also found in regard to the environment [2].

ITS represents a wide collection of applications, from advanced signal control systems to ramp meters to collision warning systems. In order to apply ITS technologies most effectively, it is important to know which technologies are most effectively addressing the issues of congestion and safety. Some technologies provide more cost-effective benefits than others, and as technology evolves, the choices to deployers change. Often, several technologies are combined in a single integrated system, providing synergistic

benefits that exceed the benefits of any single technology. It is important to know which technologies and technology combinations provide the greatest benefits, so that transportation investments can be applied most effectively to meet the growing transportation demands of our expanding economy [40].

Since 1994, the U.S. DOT's ITS Joint Program Office has been actively collecting information on the impacts that ITS and related projects have on the operation and management of the nation's surface transportation system. The evaluation of ITS is an ongoing process. Significant knowledge is available for many ITS services, but gaps in knowledge also exist [39]. In general, all ITS services have shown some positive benefit, and negative impacts are usually outweighed by other positive results. For example, higher speeds and improved traffic flow result in increases in nitrous oxides, while other measures that indicate increased emissions, such as fuel consumption, travel time, and delay, are reduced. Because of the nature of the data, it is often difficult to compare data from one ITS project to another. This is because of the differences in context or conditions between different ITS implementations. Thus, statistical analysis of the data is not done across data points. In several cases, ranges of reported impacts are presented and general trends can be discussed. These cases include traffic signal systems, automated enforcement, ramp metering, and incident management [39].

Most of the data collected to date are concentrated within metropolitan areas. The heaviest concentrations of such data are in arterial management systems, freeway management, incident management, transit management, and regional multimodal traveler information. Most of the available data on traffic signal control systems are from adaptive traffic control. For freeway management, most data are concentrated around benefits related to ramp metering. There are also recent studies on the benefits of ITS at highway–rail intersections.

There has been an increase in the implementation and evaluation of rural ITS. Several state and national parks are now examining and implementing improved tourism and travel information systems, and several rural areas are implementing public travel services. Many states are examining the benefits of incorporating ITS, specifically weather information, into the operation and maintenance of facilities and equipment. Many of the data reported for rural ITS are concentrated in the areas of crash prevention and security. A significant amount of information is available for road weather management activities, including winter weather-related maintenance, pavement condition monitoring, and dissemination of road weather information.

ITS for Commercial Vehicle Operations (ITS/CVO) continues to provide benefits to both carriers and state agencies. ITS/CVO program areas usually report benefits data from directly measurable effects. Therefore, it might be expected that these data are accurate and only a few data points would be necessary to convince carriers, states, and local authorities of the possible benefits of implementing these systems. To date, most of the data collected for ITS/CVO are for cost, travel time, and delay savings for carrier operations.

ITS program areas and user services associated with driver assistance and specific vehicle classes are still being developed and planned. As market penetrations increase and improved systems are developed, there will be ample opportunity to measure and report data based on actual measurements [39].

Taxonomy and Measures of Effectiveness

To track the progress toward meeting ITS program goals, the JPO has identified and established a set of measures of effectiveness. These measures are termed “A Few Good Measures” and are used as a standard in the reporting of much of the ITS benefits data currently available. Data collected are not limited to these measures; additional measures are also reported when available. The few good measures are:

- Safety: usually measured by impacts on crashes, injuries, fatalities
- Delay: usually measured in units of time
- Cost: measured in monetary amount
- Effective capacity: measured in throughput or traffic volumes
- Customer satisfaction: usually results from user surveys
- Energy and environment: usually measured in fuel consumption and emissions

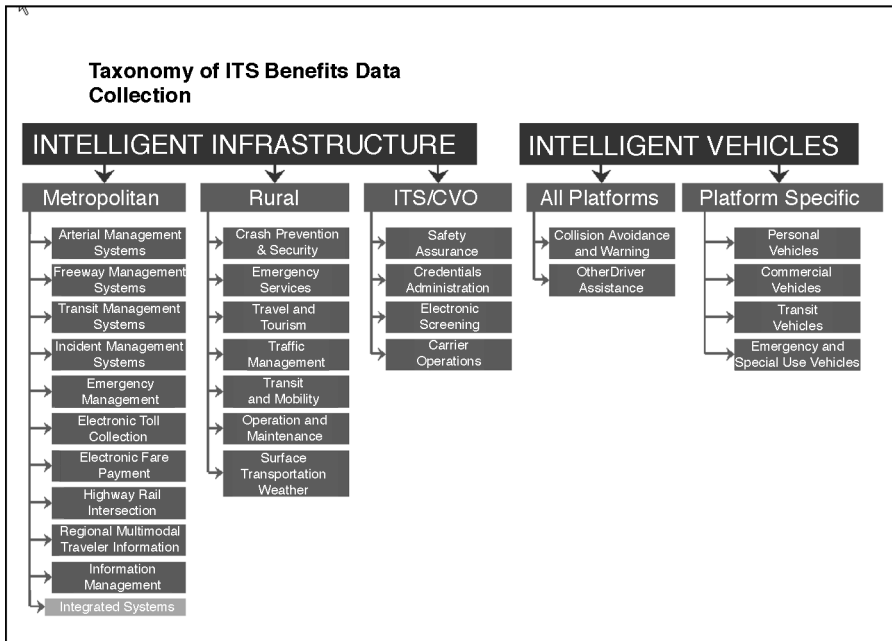

FIGURE 86.2 ITS benefits taxonomy. (Mitretek Systems, *Taxonomy for Classification of ITS Benefits*, Department of Transportation ITS JPO, Washington, D.C., June 2000.)

The benefits database desk reference (Figure 86.3) provides a brief summary of the metropolitan data available in the online database. The desk reference is updated regularly and is also available at the database web site. It is based on a taxonomy developed [42] for the classification of benefits (Figure 86.2).

A cost database is also available and can be found through the ITS web page of the U.S. DOT [44], with more details in Reference 45. The ITS unit cost database consists of cost estimates for a set of ITS elements. These cost estimates are categorized as capital, and operating and maintenance (O&M) costs (also known as nonrecurring and recurring costs, respectively). These costs are presented in a range to capture the lows and highs of the cost elements from the different data sources identified on the cost data sources page. The cost data are useful in developing project cost estimates during the planning process. However, the user is encouraged to find local and regional data sources and current vendor data to perform a more detailed cost estimate. The set of ITS elements is based primarily on the unit cost elements in the National ITS Architecture Cost Analysis and the ITS Deployment Analysis System (IDAS) equipment list. IDAS is software developed by the Federal Highway Administration [44] that can be used in planning for ITS deployment. IDAS can estimate relative costs and benefits for more than 60 types of ITS investments. Practitioners will find a number of useful features that enhance ITS planning.

One of the powerful aspects of ITS is the capability of components to share information and resources with other components. This integration of individual components allows the formation of a unified regional traffic control and management system. To better describe the flow of information between components, a number of integration links have been developed for the metropolitan ITS infrastructure. These links represent both inter- and intracomponent sharing of information. Each of the links has been assigned a number and an origin or destination path from one component to another. For example, metropolitan integration link number 29 is from transit management to incident management and represents the ability of transit agencies to notify incident management agencies of incident location, severity, and type. Figure 86.4 depicts the links in metropolitan integration, and definitions of the links can be found in Table 86.10 in the Appendix [43].

For a more complete understanding of these components, integration, and how they can be interpreted, refer to the following documents: “Tracking the Deployment of Integrated Metropolitan Intelligent Transportation Systems Infrastructure in the USA: FY 1997 Results,” Document 5883, September 1998;

| Metropolitan Benefits By Program Area | | |
|---------------------------------------|-----------------------|--|
| Program Area/Benefit Measure | | Summary |
| Arterial Management Systems | Safety Improvements | Automated enforcement of traffic signals has reduced red-light violations 20–75%. |
| | Delay Savings | Adaptive signal control has reduced traffic delay 14–44%. Transit signal priority has reduced bus journey times by 7%. |
| | Throughput | |
| | Customer Satisfaction | In Michigan, 72% of surveyed drivers felt “better off” after signal control improvements. |
| | Cost Savings | Transit signal priority on a Toronto Transit Line allowed same level-of-service with less rolling stock. |
| | Environmental | Improvements to traffic signal control have reduced fuel consumption 2–13%. |
| | Other | Between 1969 and 1976, traffic signal preemption systems in St. Paul, MN, reduced emergency vehicle accidents by 71%. |
| Freeway Management Systems | Safety Improvements | Ramp Metering has shown a 15–50% reduction in crashes. |
| | Delay Savings | In Minneapolis-St. Paul, MN, ramp metering has reduced freeway travel time 22%, for an annual savings of 25,121 vehicle-hours. |
| | Throughput | Ramp metering has increased throughput 13–16%. |
| | Customer Satisfaction | After the Twin Cities ramp meter shutdown test, 69% of travelers supported modified continued operations. |
| | Cost Savings | The GA Navigator (integrated system) supported incident delay reductions, for an annual savings of \$44.6 million. |
| | Environmental | |
| | Other | Ramp metering has shown an 8–60% increase in freeway speeds. |
| Transit Management Systems | Safety Improvements | In Denver, AVL systems with silent alarms have supported a 33% reduction in bus passenger assaults. |
| | Delay Savings | CAD/AVL has improved on-time bus performance 9–23%. |
| | Throughput | |
| | Customer Satisfaction | In Denver, installation of CAD/AVL decreased customer complaints by 26%. |
| | Cost Savings | In San Jose, AVL has reduced paratransit expense from \$4.88 to \$3.72 per passenger. |
| | Environmental | |
| Incident Management Systems | Other | More efficient bus utilization has resulted in a 4–9% reduction in fleet size. |
| | Safety Improvements | In San Antonio, integrated VMS and incident management systems decreased accidents by 2.8%. |
| | Delay Savings | Incident management in city and regional areas has saved 0.95–15.6 million vehicle-hours of delay per year. |
| | Throughput | |
| | Customer Satisfaction | Customers have been very satisfied with service patrols (hundreds of letters). |
| | Cost Savings | Cost savings have ranged from 1–45 million dollars per year, depending on coverage area size. |
| | Environmental | Models of the Maryland CHART system have shown fuel savings of 5.8 million gallons per year. |
| Emergency Management Systems | Other | The I-95 TMS system in PA has decreased highway incidents 40% and cut closure time 55%. |
| | Safety Improvements | In Palm Beach, GPS/AVL systems have reduced police response times by 20%. |
| | Delay Savings | |
| | Throughput | |
| | Customer Satisfaction | 95% of drivers equipped with PushMe Mayday system felt more secure. |
| | Cost Savings | |
| | Environmental | |
| Other | | |

and “Measuring ITS Deployment and Integration,” Document 4372, January 1999. Both documents are available on the FHWA electronic document library [44].

Figure 86.4 illustrates the numbered links that represent the flow of information between metropolitan ITS components. Much of the data collected regarding integration illustrates benefits to delay and travel time savings or cost savings. A few evaluation studies are currently planned or in progress that may

| Metropolitan Benefits By Program Area | | |
|--|------------------------|---|
| Program Area/Benefit Measure | Summary | |
| Electronic Toll Collection | Safety Improvements | Driver uncertainty about congestion contributed to a 48% increase in accidents at E-PASS toll stations in Florida.* |
| | Delay Savings | The New Jersey Turnpike Authority (NJTA) E-Zpass system has reduced vehicle delay by 85%. |
| | Throughput | Tappan Zee Bridge: Manual lane 400–450 vehicles/hour (vph), ETC lane 1000 vph. |
| | Customer Satisfaction | |
| | Cost Savings | ETC has reportedly reduced roadway maintenance and repair costs by 14% |
| | Environmental | NJTA models indicate E-Zpass saves 1.2 mil gallons of fuel per yr, 0.35 tons of VOC per day, and 0.056 tons NOx per day. |
| | Other | 20% of travelers on two bridges in Lee County, FL, adjusted their departure times as a result of value pricing at electronic tolls. |
| Electronic Fare Payment | Safety Improvements | |
| | Delay Savings | |
| | Throughput | |
| | Customer Satisfaction | Europe has enjoyed a 71–87% user acceptance of smart cards for transit/city coordinated services. |
| | Cost Savings | The Metro Card System saved New York approximately \$70 million per year. |
| | Environmental Other | |
| Highway Rail Intersections | Safety Improvements | In San Antonio, VMS with railroad crossing delay information decreased crashes by 8.7%. |
| | Delay Savings | |
| | Throughput | |
| | Customer Satisfaction | School bus drivers felt in-vehicle warning devices enhanced awareness of crossings. |
| | Cost Savings | |
| | Environmental Other | Automated horn warning systems have reduced adjacent noise impact areas by 97%. |
| Regional Multimodal Traveler Information | Safety Improvements | IDAS models show the ARTIMIS traveler information system has reduced fatalities 3.2% in Cincinnati and Northern Kentucky. |
| | Delay Savings | A model of SW Tokyo shows an 80% decrease in delay if 15% of vehicles shift their departure time by 20 min. |
| | Throughput | |
| | Customer Satisfaction | 38% of TravTek users found in-vehicle navigation systems useful when travelling in unfamiliar areas. |
| | Cost Savings | |
| | Environmental | EPA-model estimates of SmarTraveler impacts in Boston show 1.5% less NOx and 25% less VOC emissions. |
| | Other | Models of Seattle show freeway-ATIS is 2x more effective in reducing delay if integrated with arterial ATIS. |

FIGURE 86.3 Metropolitan benefits (Continued).

include results for several integration links. Few data have been reported for components that use information collected using arterial management (links 1 to 4). It is expected that the primary benefit for these integration links would be delay and travel time savings. The sharing of information between arterial management and freeway management (links 2 and 11), which can be used to change ramp-metering rates and traffic signal times, may yield significant advantages [43].

86.7 Five-Year Plan [38]

With the passage of the Transportation Equity Act for the 21st Century in 1998, Congress reaffirmed the role of the U.S. DOT in advancing the development and integrated deployment of ITS technologies. A five-year plan was developed presenting the U.S. DOT's goals, key activities, and milestones for the National ITS Program for FY 1999 through 2003.

| Metropolitan Benefits By Measure | | |
|----------------------------------|---|---|
| Benefit Measure/Program Area | | Summary |
| Safety Improvements | Arterial Management | Automated enforcement of traffic signal has reduced red-light violations 20–75%. |
| | Freeway Management | Ramp metering has shown a 15–50% reduction in crashes. |
| | Transit Management | In Denver, AVL systems with silent alarms have supported a 33% reduction in bus passenger assaults. |
| | Incident Management | In San Antonio, integrated VMS and incident management systems decreased accidents by 2.8%. |

information and communications infrastructure that would enable the nation to realize the vision set forth by Congress — to manage multiple transportation facilities as unified systems for greater efficiency, safety, customer service, and quality of life. TEA-21 continues the legacy of ISTEA by building on the success of research and development to date. Today, many ITS technologies are available, and

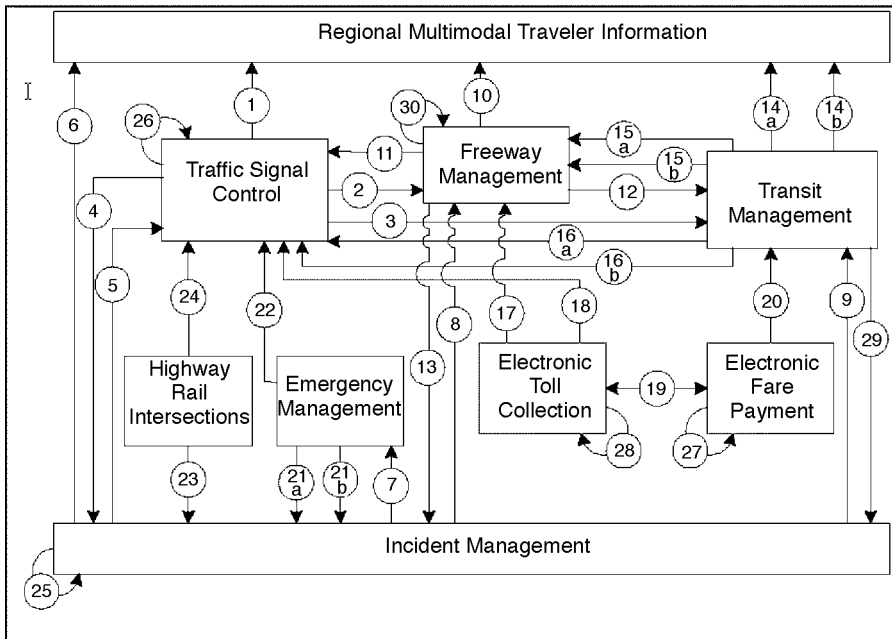

FIGURE 86.4 Metropolitan integration links. (From Mitretek Systems, ITS Benefits: Data Needs Update 2000, prepared in connection with ITS Benefits Data Needs Workshop, August 2000.)

the National ITS Program will shift its emphasis accordingly to the deployment of proven ITS technologies in an integrated fashion, while continuing to advance ITS capabilities through further research.

Intelligent Infrastructure and Intelligent Vehicles

The National ITS Program focuses on two main objectives: deployment of intelligent infrastructure and testing and evaluation of intelligent vehicle technologies. Intelligent infrastructure and intelligent vehicles provide the information and control needed to better manage surface transportation facilities (highways, roads, transit, and rail), to improve the safety of vehicles operating on those facilities, and to help users of all modes make better decisions about travel. Intelligent infrastructure is the necessary network of technologies — a communications and information backbone — that supports and unites key ITS services for metropolitan, rural, statewide, and commercial vehicle application. Intelligent vehicle technologies improve safety and enhance mobility of the vehicles that operate on our roadways. Such technologies apply to four classes of vehicles: light vehicles (passenger cars, vans, and light trucks), transit vehicles (buses), commercial vehicles (trucks and interstate buses), and specialty vehicles (emergency response, enforcement, and highway maintenance vehicles). ITS products and services must be seamlessly integrated and interoperable. Over time, intelligent vehicles will increasingly interact with intelligent infrastructure to yield even greater gains in mobility and traveler safety.

Intelligent infrastructure and intelligent vehicle objectives are addressed through four program areas: metropolitan ITS infrastructure, rural ITS infrastructure, commercial vehicle ITS infrastructure, and intelligent vehicles. Each program area targets a specific environment in which ITS capabilities are used. The metropolitan and rural ITS infrastructure program areas address network-based technologies deployed in those two settings. The commercial vehicle ITS infrastructure program area focuses on the integrated technologies needed specifically for safety and administrative regulation of interstate trucking. Finally, the intelligent vehicles program area targets in-vehicle safety systems for all users and geographic settings.

ITS Program Strategies

The National ITS Program utilizes eight program strategies that work cooperatively to advance the state of ITS across the country:

1. **Conducting research:** advances ITS infrastructure and vehicle capabilities by bringing technologies from visionary concepts to viable and attractive solutions to transportation problems. Continued research and development are necessary for increasing the real-time capabilities of ITS infrastructure components, improving intelligent vehicle capabilities, and developing successive generations of ITS technologies.
2. **Accelerating the development of standards:** allows communications, surveillance, monitoring, and computer processing systems to “speak” to each other, provides design guidance to manufacturers, and reassures purchasers that their systems will be compatible with other ITS elements.
3. **Building professional capacity:** ensures that transportation professionals across the country have the skills necessary to design, deploy, operate, and maintain ITS systems. ITS requires new technical skills, such as systems engineering, electronics, and communications, as well as institutional skills, which include coalition building.
4. **Creating funding incentives:** encourages more widespread integration of ITS in metropolitan, rural, and commercial vehicle settings. The overall trend in ITS funding has shifted from dedicated special funds to the use of traditional transportation funding mechanisms such as the Highway Trust Fund (including the Mass Transit Account). However, temporary funding incentives are still necessary to foster integration and national interoperability and to accelerate deployment.
5. **Providing guidance and technical assistance:** aids implementers seeking to deploy integrated ITS. The U.S. DOT provides specialized technical support through its federal field staff, through the publication of guidance documents on best practices for ITS deployment, and with the Peer-to-Peer Network, a resource composed of professionals from the private and public sectors who are on call to provide short-term, no-cost technical assistance to transportation colleagues across the country.
6. **Ensuring consistency with the National ITS Architecture and standards:** helps in planning for ITS integration, reducing development time and cost, and laying the groundwork for a seamless national ITS network. The U.S. DOT is working with stakeholders to develop federal policy on consistency and is actively training stakeholders on this issue.
7. **Evaluating the program:** essential for understanding the value and effectiveness of ITS activities and for measuring progress toward deployment goals. Tracking and evaluation are consistent with the spirit of the Government Performance and Results Act and allow for the continual refinement of the National ITS Program.
8. **Showcasing benefits:** communicates positive results realized through the use of ITS technologies to multiple decision makers. By understanding the benefits of ITS, decision makers can compare ITS to other transportation options when addressing local transportation issues. Showcasing benefits also encourages integration of ITS systems. For example, deployment sites demonstrate successful interjurisdictional working relationships and interagency coordination. By learning about the deployment sites, decision makers better understand the operation and management planning that is necessary to achieve integration in their areas.

Program Area Goals, Key Activities, Milestones

The eight ITS program strategies are used to meet specific goals in each of the four ITS program areas: metropolitan, rural, and commercial vehicle infrastructure, and intelligent vehicles.

Metropolitan ITS Infrastructure Program Area

The metropolitan ITS program has demonstrated proven technologies for metropolitan application. Model deployments in metropolitan settings have been successful and will continue to be showcases for

other areas. However, while individual systems are being purchased and installed around the country, sites are just beginning to integrate systems across jurisdictions and modes. Since integration has been limited, communities are not yet reaping the full benefits of ITS.

The metropolitan component of the National ITS Program is focused on meeting the goals for integrated deployment laid out by former Secretary of Transportation Federico Peña in 1996 and reiterated by former Secretary of Transportation Rodney Slater. Known as Operation TimeSaver, the U.S. DOT's objective is to facilitate integrated deployment of basic ITS services in 75 metropolitan areas by 2006. At present, 36 sites are considered to have some elements of integration, and additional sites show the clear beginnings of integrated systems.

Goal

By 2003, the metropolitan program aims to have 64 sites achieve the Operation TimeSaver goal for integrated deployment.

Key Activities and Milestones

The Operation TimeSaver goal will be met using all eight ITS program strategies as follows:

Conducting research: Traffic management and transit management research will be advanced under TEA-21. New models for traffic management, such as the ITS Deployment Analysis System, have been developed that more accurately represent the impact of ITS, allowing transportation planners and designers to compare ITS with other transportation options more effectively. This model was made available to the ITS planning community in 1999. A more sophisticated planning model — the Transportation Analysis and Simulation System (TRANSIMS) — is under development and will be available for initial use in 2002. In transit management, research will focus on the application of integrated transit systems through operational tests in areas such as fleet management, electronic fare payments, and traveler information. From 1999 to 2003, this research will be guided by the Federal Transit Administration's (FTA) 5-year research and technology plan.

Accelerating the development of standards: Development of standards, such as the National Transportation Communications for ITS Protocol (NTCIP) and the Transit Communications Interface Profiles (TCIP), will help facilitate integration in metropolitan areas. NTCIP will allow traffic management and operations personnel to better control, manage, and monitor virtually all the devices used on the roadway. TCIP will allow data to be shared among transit departments and other operating entities, such as emergency response services and regional traffic management centers. Because these standards are fundamental to metropolitan transportation operations, a training course on each standard is necessary. The course on NTCIP is already available, on a request basis, through the Institute of Traffic Engineers, and it will be available to stakeholders through 2003. A course on TCIP will be developed, with delivery expected to occur from 2001 to 2003.

Building professional capacity: Training courses will continue to be offered on all aspects of metropolitan ITS deployment. Courses will be updated as new information is made available.

Creating funding incentives: TEA-21 funding incentives are being offered to metropolitan public sector applicants to support technical integration and jurisdictional coordination of ITS infrastructure. Funding will be offered to both highway and transit projects, and the U.S. DOT will work with Congress and the funding recipients to ensure that both the spirit and intent of TEA-21 funding criteria are met. The U.S. DOT will allocate funding incentives annually based on programmatic goals and the criteria defined in TEA-21. Funding available for integration was set by TEA-21 at \$75 million in 1999, \$83 million in 2000, \$83 million in 2001, \$85 million in 2002, and \$85 million in 2003. A maximum of 90% of this funding is available to metropolitan areas.

Providing guidance and technical assistance: Special guidance and technical assistance are being offered to transportation officials through federal field staff expertise, guidance documents, and the Peer-to-Peer Network to assist in the planning, design, operation, and maintenance of met-

ropolitan ITS. In addition, federal field staff will work with their state and local partners to develop “ITS service plans” that outline local technical guidance needs and plans for delivery. Development of ITS service plans began with a focus on the top 78 metropolitan areas and has expanded over time to include statewide concerns that typically involve rural ITS applications. The U.S. DOT started with 62 service plans being implemented (49 from the top 78 metropolitan areas and 13 statewide plans) in FY 2000. U.S. DOT expects to expand over time and to include activities in other metropolitan areas beyond the top 78.

Ensuring consistency with the National ITS Architecture and standards: The National ITS Architecture and standards will be instrumental in catalyzing integrated ITS deployment across the country, enabling areas to meet local needs while reducing development costs and risks, facilitating future expansion capability, and fostering interoperability. Interim policy guidance on consistency with the National ITS Architecture and standards was issued in 1999. The interim guidance was implemented until release of the final policy; the final policy will be implemented through 2003 and beyond.

Evaluating the program: Program evaluations track levels of deployment and integration in the 75 metropolitan areas. Evaluations are being used to demonstrate ITS benefits and to measure progress toward the Operation TimeSaver goal. From 1999 through 2003, U.S. DOT will conduct annual tracking surveys, assemble the data received, and report findings. Using this information, the metropolitan program will be refined as appropriate.

Showcasing benefits: The four metropolitan model deployment sites funded under ISTEA — Phoenix, Arizona; Seattle, Washington; San Antonio, Texas; and the New York–New Jersey–Connecticut metropolitan area — will continue to showcase the benefits of metropolitan ITS technologies under TEA-21. These sites have brought together public and private sector partners to integrate existing infrastructure with new traveler information systems. In addition, results of deployment evaluations will be incorporated into publications to disseminate benefits information.

Through these eight strategies, the metropolitan ITS program will continue to pursue the deployment of integrated, intelligent transportation systems — including advanced traffic management, traveler information, and public transit systems — that will improve urban transportation management in the 75 largest urban areas. At the same time, there are 340 major metropolitan areas nationwide that could benefit from advanced technologies, and the U.S. DOT’s field staff is working actively with all interested communities.

Rural and Statewide ITS Infrastructure Program Area

Information technologies are currently being applied in rural settings to help improve the safety and mobility of rural travelers. However, rural and statewide ITS applications are not yet as well defined as metropolitan and commercial vehicle applications. Under TEA-21, the rural program will focus primarily on research and field operational testing to further develop rural infrastructure components. Through these tests, the U.S. DOT will identify solutions that reduce the public sector costs of providing, operating, and maintaining rural ITS infrastructure. Lessons learned from the metropolitan program will be leveraged to the maximum possible extent, as will rural program resources. For example, the U.S. DOT will cooperate with other organizations and other federal departments involved in the mobility of people (such as Health and Human Services) in order to develop innovative ITS-supported services such as mobility management. Systems such as multiagency mobility management, automatic collision notification, tourist information, and weather information will be the primary focus in the early years of the program.

Goal

By 2003 the rural ITS program aims to have demonstrated in ten locations a statewide information network that is multijurisdictional and multimodal within a state and able to share data across state lines.

Key Activities and Milestones

To reach this goal, the rural ITS program will focus primarily on conducting research through operational tests. The other seven program strategies will be used to a more limited extent.

Conducting research: Seven areas have been identified for further research: surface transportation weather and winter mobility, emergency services, statewide and regional traveler information infrastructure, rural crash prevention, rural transit mobility, rural traffic management, and highway operations and maintenance. While activities are expected in all seven areas, the U.S. DOT has worked with stakeholders to categorize and prioritize the list. Initial efforts will focus on multiagency mobility management services, weather information, emergency services, and regional traveler information. Operational tests are currently under way for all four services, and additional rounds of tests will be conducted through 2003.

Accelerating the development of standards: The U.S. DOT is just beginning to identify what standards may be necessary for rural-specific ITS applications. Standards are identified by assessing user needs, defining rural ITS infrastructure, and modifying the National ITS Architecture. The rural ITS program is actively seeking stakeholder participation in this process, and modifications to the National ITS Architecture are being made as rural ITS applications are defined. Once the National ITS Architecture is revised, ITS standards requirements can be identified. U.S. DOT defined unique rural user services in 1999 and proceeded to develop them.

Building professional capacity: Professional capacity building for rural practitioners involves modifying existing ITS courses to reflect the needs of rural ITS users and exploring distance-learning opportunities. Practitioners with rural expertise will help tailor existing courses to a rural audience. Initiatives are under way to overcome barriers of limited time and travel funding experienced most acutely by rural partners. U.S. DOT is exploring methods to deliver training through satellite broadcast, CD-ROM, and the Internet. As with other parts of the National ITS Program, the U.S. DOT has planned to transfer course delivery to the National Highway Institute and National Transit Institute in 2001.

Creating funding incentives: TEA-21 funding incentives are being offered to rural public sector applicants to support deployment of individual project components and the integration of existing ITS components. Funding will be offered to both highway and transit projects, and the U.S. DOT will work with Congress and the funding recipients to ensure that both the spirit and intent of TEA-21 funding criteria are met. U.S. DOT will allocate funding annually based on programmatic goals and TEA-21 criteria. A minimum of 10% of available funding will be used in rural areas.

Providing guidance and technical assistance: The U.S. DOT will provide guidance and technical assistance primarily by disseminating the results of rural field operational tests to stakeholders. Materials, such as lessons learned and simple solutions compendia, technical toolboxes, and catalogs of available systems, will be compiled and packaged for stakeholders in an Advanced Rural Transportation Systems toolbox. Assistance also will be available to rural stakeholders through federal field staff and the Peer-to-Peer Network.

Ensuring consistency with the National ITS Architecture and standards: Interim policy guidance on consistency with the National ITS Architecture and standards was issued in October 1998. The U.S. DOT expected to issue a final policy on consistency in FY 2001. This policy will be instrumental in catalyzing integrated ITS deployment across the country. In rural areas, stakeholders will be engaged in the policy development process to work through consistency issues at the statewide planning level. The interim guidance is being implemented until release of the final policy; the final policy will be implemented through 2003 and beyond.

Evaluating the program: Rural ITS infrastructure components must be defined before they can be tracked, so program evaluation activities are just beginning. Once the components are defined, quantifiable indicators will be identified as they have been for metropolitan applications.

Showcasing benefits: In these early stages of the rural ITS program, benefits of rural ITS applications are being showcased through field operational tests. These tests are not of the same scale as the metropolitan model deployments, but they still provide rural stakeholders the opportunity to see rural ITS technologies in operation and the benefits to rural America. Tests include automatic collision notification, traveler information, weather information technologies, and traveler information in a national park setting.

Commercial Vehicle ITS Infrastructure Program Area

The commercial vehicle ITS infrastructure program focuses on increasing safety for commercial drivers and vehicles while improving operating efficiencies for government agencies and motor carriers. At the center of the program is the deployment of Commercial Vehicle Information Systems and Networks, which link existing information systems to enable the electronic exchange of information. The initial implementation of CVISN, known as Level 1, addresses safety information exchange, credentials administration, and electronic screening; it is being prototyped in two states and piloted in eight states nationwide. The U.S. DOT expected CVISN Level 1 capabilities to be achieved in Maryland, Virginia, Washington, Kentucky, California, Colorado, Connecticut, Michigan, Minnesota, and Oregon by 2000 or 2001, depending on the availability of discretionary deployment incentive funding from Congress.

Goal

The U.S. DOT has set a goal of having 26 to 30 states deploy CVISN Level 1 capabilities by 2003. Achievement of this goal will depend on the extent to which funds authorized for CVISN in TEA-21 are appropriated for that use.

Key Activities and Milestones

All eight ITS program strategies are being used to meet the commercial vehicle program area goal as follows:

Conducting research: Research efforts will continue the development, testing, and implementation of technologies necessary to support commercial vehicle safety enforcement and compliance goals. Under TEA-21, FHWA and the Federal Motor Carrier Safety Administration (FMCSA) will undertake coordinated activities intended to reduce or eliminate transportation-related incidents and the resulting deaths, injuries, and property damage. These activities include demonstrating cost-effective technologies for achieving improvement in motor carrier enforcement, compliance, and safety while keeping up with the latest technological advances. The U.S. DOT will define CVISN Level 2 capabilities and expects to demonstrate prototype technologies in two or three states from 2000 through 2003.

Accelerating the development of standards: The U.S. DOT will continue to update and maintain the CVISN architecture to ensure consistency and interoperability, to include lessons learned from deployments, and to keep current with changing technology. In addition, two standards — electronic data interchange (EDI) and dedicated short-range communication (DSRC) — are essential to the demonstration of CVISN. EDI supports safety information and credential information exchange and has been approved. The U.S. DOT has completed a DSRC standard at 5.9 GHz, which is necessary for vehicle-to-roadside exchange of information. The U.S. DOT's emphasis has shifted to developing guidelines for compatibility and certification testing of the DSRC standard. Ultimately, independent testing organizations will be responsible for certification testing of DSRC.

Building professional capacity: Professional capacity building is critical to states, vendors, and FHWA and FMCSA project managers in order to implement CVISN. In addition to the current suite of commercial vehicle ITS awareness and deployment courses, training and technical assistance will be available to states in the areas of interoperability testing for conformance with the National ITS Architecture, systems integration issues and lessons learned, and commercial vehicle ITS project monitoring and maintenance.

Creating funding incentives: TEA-21 authorized \$184 million over 6 years to deploy CVISN in a majority of states. Funding was allocated based on programmatic goals and TEA-21 criteria as follows: \$27.2 million in 1999, \$30.2 million in 2000, \$32.2 million in 2001, \$33.5 million in 2002, and \$35.5 million in 2003. The funding will assist prototype and pilot states, as well as other interested states, in reaching CVISN Level 1 capabilities.

Providing guidance and technical assistance: The U.S. DOT has developed an integrated strategy to support states through the deployment of CVISN. From 1999 through 2003, U.S. DOT will continue to provide support to states through tool kits, guides, the Peer-to-Peer Network, and outreach.

Ensuring consistency with the National ITS Architecture and standards: The interim guidance issued in October 1998 and the final policy expected in 2001 apply equally to commercial vehicle ITS applications. At the heart of CVISN is the need for interoperability among federal, state, carrier, and other commercial vehicle systems and networks that allow the exchange of data. The development of a policy to ensure consistency with the National ITS Architecture and approved standards supports this interoperability. Federal field staff will implement the policy through 2003 and beyond.

Evaluating the program: Deployment tracking surveys will be conducted for all 50 states at 2-year intervals from 1999 to 2003. In addition, field operational tests will be completed and results will be incorporated into ITS costs and benefits databases.

Showcasing benefits: All eight pilot states serve as model deployments to showcase the benefits of CVISN. Benefits information were collected from the sites and incorporated into brochures and materials for distribution to stakeholders in 1999 and 2000. CVISN technologies were also showcased across the country in 1999 and 2000 with the commercial vehicle technology truck, a traveling classroom that contains commercial vehicle technologies and provides an interactive learning environment for stakeholders.

Intelligent Vehicle Initiative Program Area

Under ISTEA, U.S. DOT research in crash avoidance, in-vehicle information systems, and Automated Highway Systems pointed to new safety approaches and promising solutions that could significantly reduce motor vehicle crashes. Preliminary estimates by the National Highway Traffic Safety Administration showed that rear-end, lane change, and roadway departure crash avoidance systems have the potential, collectively, to reduce motor vehicle crashes by one sixth, or about 1.2 million crashes annually. Such systems may take the form of warning drivers, recommending control actions, and introducing temporary or partial automated control of the vehicle in hazardous situations. These integrated technologies can be linked to in-vehicle driver displays that adhere to well-founded human factors requirements. The U.S. DOT has harnessed these efforts into one program, the Intelligent Vehicle Initiative (IVI).

Goal

IVI is focused on working with industry to advance the commercial availability of intelligent vehicle technologies and to ensure the safety of these systems within the vehicles.

Key Activities and Milestones

This program is solely a research effort; therefore, only the conducting research program strategy applies.

Conducting research: Intelligent vehicle research aims to identify in-vehicle technologies to counter a series of problems that are major causes of vehicle crashes. To help speed the development of solutions, IVI has been organized into manageable tasks by dividing the spectrum of problems into eight problem areas and segmenting vehicle types into four vehicle platforms. Each problem area will be studied in the platform(s) where new technologies are most needed and can be readily adopted. Currently, the IVI program is moving forward through pilot research and testing projects within each platform. Projects range from defining safety needs for specialty vehicles to widespread initial trial deployment of automatic collision notification systems for light vehicles. In general, the light and commercial vehicle platforms are further along in the process because they benefited from prior research. However, the transit and specialty vehicle platforms will advance rapidly by adapting research conducted in the other platforms. In addition to the core in-vehicle technologies, the IVI program will also begin to explore possible vehicle infrastructure cooperative technologies as well as ways to help improve the ability of drivers to receive and process more information in the vehicle.

Eight IVI problem areas:

- Rear-end collision avoidance
- Lane change and merge collision avoidance
- Road departure collision avoidance

- Intersection collision avoidance
 - Vision enhancement
 - Vehicle stability
 - Safety-impacting services
 - Driver condition warning
- Four IVI platforms:
- Light vehicles
 - Commercial vehicles
 - Transit vehicles
 - Specialty vehicles

To accomplish programmatic objectives, IVI is undertaking public and private partnerships with the motor vehicle industry and infrastructure providers. For transit, key partnerships with fleet operators will also be necessary, as transit vehicle designs are influenced not only by the vehicle manufacturers but also by transit agencies. The U.S. DOT will use multiple platforms to allow the program to focus initial research on the classes of vehicles where new technology will be adopted most quickly. Other vehicle types can then be equipped with the proven technology. The U.S. DOT will also study linkages with intelligent infrastructure, multiple systems integration, generations of vehicles with increased capabilities, and human factors. Finally, peer review will be used to help keep the goals and objectives of the program on target. Under TEA-21, the intelligent vehicle program was to form a public or private partnership to mutually govern and conduct enabling research for intelligent vehicles, engage the Transportation Research Board for a multiyear peer review, and complete initial operational tests on all platforms by 2001.

Additional Areas Covered in the Plan

In addition to program area goals and activities, this report also covers the National ITS Architecture and ITS standards, emerging program activities, and an update of ITS user services.

The National ITS Architecture and ITS Standards

The full benefits of ITS cannot be realized unless systems are integrated, rather than deployed as individual components. At the urging of public and private sector stakeholders, the U.S. DOT is facilitating system integration and technical interoperability through the development of the National ITS Architecture and ITS standards. The National ITS Architecture is a framework that defines the functions performed by ITS components and the ways in which components can be integrated into a single system. It can be used to help agencies plan and design both projects and deployment approaches that meet near-term needs while keeping options open for eventual system expansion and integration. The U.S. DOT will ensure that the National ITS Architecture responds to changing needs of the National ITS Program and the ITS industry by keeping the architecture up-to-date and relevant as new ITS applications emerge.

Since the inception of the ITS Program under ISTEA, stakeholders have recognized that ITS standards are necessary to achieve technical interoperability. Without technical standards, state and local governments, as well as consumers, risk buying products that do not necessarily work together or consistently in different parts of the country. The U.S. DOT is facilitating the creation of technical standards to minimize public sector risk in procuring these products. The overall goal of the ITS standards program is to have a comprehensive set of ITS standards developed and routinely used as states and localities deploy integrated, intermodal systems.

Over the past several years, the U.S. DOT has funded standards development organizations in conjunction with industry volunteer support to accelerate the traditional standards development process. Under TEA-21, the U.S. DOT expects that all ITS standards identified in the baseline National ITS Architecture will be developed and that the ITS standards program will increasingly focus on implementation. A first step in this direction will include the testing of approved ITS standards under realistic transportation conditions. Additionally, the U.S. DOT worked with the ITS user community in FY 1999 to identify critical ITS standards. In a report to Congress, 17 standards were identified as critical for national interoperability

or as foundation standards for the development of other critical standards. Development of critical standards will be actively monitored, and provisional standards may be established.

Emerging Program Activities

As the National ITS Program evolves and transportation opportunities arise, it becomes apparent that new areas can benefit from ITS. Five such areas will be addressed under TEA-21: intermodal freight, ITS data archiving, rail transit, pedestrian and bicycle safety, and accessibility.

The goal of the emerging **intermodal freight** program is to facilitate goods movement around congested areas, across multiple modes, and with international trading partners to the north and south. The application of advanced information and communications technologies to the intermodal system offers opportunities to strengthen the links between the separate modal systems that currently operate as competitors. Under TEA-21, the intermodal freight program will conduct field operational tests to identify benefits and opportunities for ITS applications for border and corridor safety clearance applications and for intermodal freight applications that enhance operational efficiency. By 2001, the U.S. DOT expected to have enough information to develop an intermodal freight ITS to be added to the National ITS Architecture.

ITS data archiving addresses the collection, storage, and distribution of ITS data for transportation planning, administration, policy, operations, safety analyses, and research. The recently approved archived data user service, the 31st user service in the National ITS Architecture, addresses this new area and was integrated into the architecture in early FY 2000.

Rail transit is an important transit mode that historically has used advanced technologies in its operations. However, little attention has focused on how rail can benefit from system integration and ITS information. The U.S. DOT aims to address rail transit as a part of identifying integrated transit systems across agencies, modes, or regions.

Efforts toward **pedestrian and bicycle safety** focus on creating more pedestrian-friendly intersections through the use of adaptive crosswalk signals, inclusion of pedestrian and bicycle flows in traffic management models, and the promotion of in-vehicle technologies to detect and avert impending vehicle-pedestrian collisions.

Accessibility: Improvement can be made in this area, especially for rural Americans, with better information coordination and dispatching for ride sharing, paratransit, and other public transit efforts. Moreover, efforts will be aimed at improving mobility and safety for two user groups underserved by current pedestrian crossings: the elderly and the disabled. The U.S. DOT will support ITS solutions that meet the needs of these Americans.

Update of ITS User Services

The National ITS Program focuses on the development and deployment of a collection of interrelated user services. These are areas in which stakeholders have identified potential benefits from advanced technologies that improve surface transportation operations. The user services have guided the development of the National ITS Architecture and ITS standards, as well as research and development of ITS systems. In 1993, the ITS America National Program Plan introduced a set of ITS user services and subservices. When the 1995 National ITS Program Plan was published, 29 user services were identified. However, in keeping with the evolving nature of the National ITS Architecture, two new services have been identified: highway-rail intersection and the archived data user service.

ITS solutions for highway-rail intersections aim to avoid collisions between trains and vehicles at highway-rail grade crossings. Examples of intersection control technologies include advisories and alarms to train crews, roadside variable message signs, in-vehicle motorist advisories, warnings, automatic vehicle stopping, improved grade crossing gates and equipment, and automated collision notification.

Archived data services require ITS-related systems to have the capability to receive, collect, and archive ITS-generated operational data for historical purposes and for secondary users. ITS technologies generate massive amounts of operational data. These data offer great promise for application in areas such as transportation administration, policy, safety, planning, operations, safety analyses, and research. Intelli-

gent transportation systems have the potential to provide data needed for planning performance monitoring, program assessment, policy evaluation, and other transportation activities useful to many modes and for intermodal applications. Below are listed all 31 ITS user services, including the two new ones. The user services have been grouped together in seven areas: travel and traffic management, public transportation management, electronic payment, Commercial Vehicle Operations, emergency management, advanced vehicle safety systems, and information management.

ITS user services are defined not along lines of common technologies but rather by how they meet the safety, mobility, comfort, and other needs of transportation users and providers. They represent essential, but not exclusive, ITS products and services.

Travel and traffic management:

- Pretrip travel information
- En route driver information
- Route guidance
- Ride matching and reservation
- Traveler services information
- Traffic control
- Incident management
- Travel demand management
- Emissions testing and mitigation
- Highway–rail intersection*

Public transportation management:

- Public transportation management
- En route transit information
- Personalized public transit
- Public travel security

Electronic payment:

- Electronic payment services

Commercial Vehicle Operations:

- Commercial vehicle electronic clearance
- Automated roadside safety inspection
- Onboard safety monitoring
- Commercial vehicle administrative processes
- Hazardous material incident response
- Commercial fleet management

Emergency management:

- Emergency notification and personal security
- Emergency vehicle management

Advanced vehicle safety systems:

- Longitudinal collision avoidance
- Lateral collision avoidance
- Intersection collision avoidance
- Vision enhancement for crash avoidance
- Safety readiness
- Pre-crash restraint deployment
- Automated vehicle operation

Information management:

- Archived data user service*

*User service added since the first edition of the National ITS Program Plan in 1995.

86.8 “The National Intelligent Transportation Systems Program Plan: A Ten-Year Vision” [46]

The Goals

“The National Intelligent Transportation Systems Program Plan: A Ten-Year Vision” sets forth the next-generation research agenda for ITS. It identifies benefits areas and associated goals against which change and progress can be measured. These goals provide the guideposts for fully realizing the opportunities that ITS technology can provide in enhancing the operation of the nation’s transportation systems, in improving the quality of life for all citizens, and in increasing user satisfaction, whether for business or personal travel. The goals include:

Safety: reduce annual transportation-related fatalities by 15% overall by 2011, saving 5000 to 7000 lives per year

Security: have a transportation system that is well protected against attacks and responds effectively to natural and manmade threats and disasters, enabling the continued movement of people and goods, even in times of crisis

Efficiency and economy: save at least \$20 billion per year by enhancing throughput and capacity with better information, better system management, and the containment of congestion by providing for the efficient end-to-end movement of people and goods, including quick, seamless intermodal transitions

Mobility and access: have universally available information that supports seamless, end-to-end travel choices for all users of the transportation system

Energy and environment: save a minimum of 1 billion gallons of gasoline each year and reduce emissions at least in proportion to this fuel saving

This plan develops a series of programmatic and enabling themes to describe the opportunities, benefits, and challenges of the transportation system of the future and activities required to realize this system.

Programmatic Theme 1

A new, bold transportation vision is needed to set the directions and mold the institutions for the next 50 years. This new, bold vision is based on information management and availability, on connectivity, and on system management and optimization — in short, the creation of an Integrated Network of Transportation Information.

Programmatic Theme 2

Transportation-related safety is clearly more than safe driving. However, in recent years, motor vehicle crashes have resulted in more than 40,000 fatalities and more than 3 million injuries each year. Driver error remains the leading cause of crashes, cited in more than 80% of police crash reports. In-vehicle systems, infrastructure improvements, and cooperative vehicle infrastructure systems can help drivers avoid hazardous mistakes by minimizing distraction, helping in degraded driving conditions, and providing warnings or control in imminent crash situations.

Programmatic Theme 3

Getting emergency response teams as quickly as possible to the scene of a crash or other injury-producing incident is critical to saving lives and returning roadways to normal, unimpeded operation. ITS technologies, coupled with computer-aided dispatch, wireless communications, records management systems, private call centers, and websites, can be used to achieve these objectives.

Programmatic Theme 4

Advanced transportation management involves using advanced technology to intelligently and adaptively manage the flow of goods and people through the physical infrastructure.

Enabling themes set the stage and lay the groundwork for the application of technology to surface transportation.

Enabling Theme 1

A culture of transportation systems management and operations will be created over the next 10 years to focus increasingly on safety, security, customer service, and systems performance. The demands of both the external and internal environments are generating changes in the culture of both service providers and users.

Enabling Theme 2

ITS and the information management and communications capabilities that it brings will support a new level of cooperative operations among multiple agencies, across boundaries and travel modes. An increase in the level of investment in ITS by the public sector will improve the cost–benefit balance of the transportation network as a whole.

Enabling Theme 3

Traditional business–government partnerships need to be redefined to enhance private sector opportunities in the commercial marketplace. Government needs to help accelerate deployment by adopting and encouraging the adoption by others of appropriate ITS products and services.

Enabling Theme 4

While the new information opportunities that ITS creates are clearly valuable — in many cases essential, the sheer volume of information also creates potential problems, e.g., overload, distraction, and confusion. ITS designers must consider what the vehicle operator is capable of doing while operating a vehicle safely. User-centered design is a fundamental concept within human factors engineering and is a proven method of promoting effective, successful, and safe design.

The Stakeholders

More than a dozen major stakeholders are identified and called on to contribute to the realization of this plan. Most of these stakeholders fall into one of three macrolevel groups: the public sector, the private sector, and universities.

86.9 Case Study: Incident Management

Although congestion is recognized as a problem for commuters and motor carriers alike, information on the scope and cost of congestion is limited. A 1984 staff study by the FHWA found that freeway congestion in the nation's 37 largest metropolitan areas was responsible for 2 billion vehicle hours of delay at a cost of \$16 billion [10,11]. By 2005, those figures could rise to as high as 8 billion vehicle hours and \$88 billion annually. Most of the cost of congestion is borne by large cities. A dozen large urban areas account for more than 80% of freeway congestion cost. New York, Los Angeles, San Francisco, and Houston have the highest congestion costs, about \$2 billion each in current dollars; Detroit, Chicago, Boston, Dallas, and Seattle, about \$1 billion each; and Atlanta, Washington, D.C., and Minneapolis, about \$500 million each. The patterns of past growth and the trends for the immediate future all point toward the conclusion that congestion will continue to be a significant metropolitan and national issue. Without attention, congestion will sap the productivity and competitiveness of our economy, contribute to air pollution, and degrade the quality of life in our metropolitan areas [10].

The term *recurring problem* is used to describe congestion when it routinely occurs at certain locations and during specific time periods. The term *nonrecurring problem* is used to describe congestion when it is due to random events such as accidents or, more generally, incidents [18].

Recurring Congestion

The most common cause of recurring congestion is excessive demand, the basic overloading of a facility that results in traffic stream turbulence. For instance, under ideal conditions, the capacity of a freeway is approximately 2000 to 2200 passenger cars per lane per hour. When the travel demand exceeds this number, an operational bottleneck will develop. An example is congestion associated with nonmetered freeway ramp access. If the combined volume of a freeway entrance ramp and the main freeway lanes creates a demand that exceeds the capacity of a section of freeway downstream from the ramp entrance, congestion will develop on the main lanes of the freeway, which will result in queuing upstream of the bottleneck. The time and location of this type of congestion can be predicted [18].

Another cause of recurring congestion is the reduced capacity created by a geometric deficiency, such as a lane drop, difficult weaving section, or narrow cross section. The capacity of these isolated sections, called geometric bottlenecks, is lower than that of adjacent sections along the highway. When the demand upstream of the bottleneck exceeds the capacity of the bottleneck, congestion develops and queuing occurs on the upstream lanes. As above, the resulting congestion can also be predicted [18].

Nonrecurring Congestion: Incidents

Delays and hazards caused by random events constitute another serious highway congestion problem. Referred to as temporary hazards or incidents, they can vary substantially in character. Included in this category is any unusual event that causes congestion and delay [18]. According to FHWA estimates, incidents account for 60% of the vehicle hours lost to congestion. Of the incidents that are recorded by police and highway departments, the vast majority, 80%, are vehicle disablements — cars and trucks that have run out of gas, have a flat tire, or have been abandoned by their drivers. Of these, 80% wind up on the shoulder of the highway for an average of 15 to 30 minutes. During off-peak periods when traffic volumes are low, these disabled vehicles have little or no impact on traffic flow. However, when traffic volumes are high, the presence of a stalled car or a driver changing a flat tire in the breakdown lane can slow traffic in the adjacent traffic lane, causing 100 to 200 vehicle hours of delay to other motorists [10].

An incident that blocks one lane of three on a freeway reduces capacity in that sense of travel by 50% and even has a substantial impact on the opposing sense of travel because of rubbernecking [12]. If traffic flow approaching the incident is high (near capacity), the resulting backup can grow at a rate of about 8.5 miles per hour — that is, after 1 hour, the backup will be 8.5 miles long [12,13]. Traffic also backs up on ramps and adjacent surface streets, affecting traffic that does not even intend to use the freeway. Observations in Los Angeles indicate that in off-peak travel periods, each minute of incident duration results in 4 or 5 minutes of additional delay. In peak periods, the ratio is much greater [12,14].

Accidents account for only 10% of reported incidents. Most are the result of minor collisions, such as sideswipes and slow-speed rear-end collisions [10]. Forty percent of accidents block one or two lanes of traffic. These often involve injuries or spills. Each such incident typically lasts 45 to 90 minutes, causing 1200 to 2500 vehicle hours of delay [10,15]. It is estimated that major accidents make up 5 to 15% of all accidents and cause 2500 to 5000 vehicle hours of delay per incident [10,16]. Very few of these major incidents, typically those involving hazardous materials, last 10 to 12 hours and cause 30,000 to 40,000 vehicle hours of delay. These incidents are rare, but their impacts can be catastrophic and trigger gridlock [10]. To be sure, these statistics are location specific and may differ across areas in the United States.

Incident Management

Incident congestion can be minimized by detecting and clearing incidents as quickly as possible and diverting traffic before vehicles are caught up in the incident queue. Most major incidents are detected within 5 to 15 minutes; however, minor incidents may go unreported for 30 minutes or more [10]. Traffic information for incident detection is typically collected from loop detectors and includes occupancy and volume averaged at 20- to 60-second intervals, usually across all lanes. Detector spacing along the freeway

is a half-mile on the average. Certain systems in the United States and Canada (e.g., California I-880 and Ontario's Queen Elizabeth Way) also use paired detectors to collect speed data [20].

During an incident the queue continues to build until the incident is cleared and traffic flow is restored. The vehicle hours of delay that accrue to motorists are represented in the exhibit by the area that lies between the normal flow rate and the lower incident flow rates. If the normal flow of traffic into the incident site is reduced by diverting traffic to alternate routes, the vehicle hours of delay are minimized (shaded area). If normal traffic flow is not diverted, additional vehicle hours of delay (hatched area) are accrued [10]. The time saved by an incident management program depends on how well the stages of an incident are managed.

Effective incident detection requires consideration of all major false alarm sources. In particular, traffic flow presents a number of inhomogeneities, hard to distinguish from those driven by incidents. Events producing traffic disturbances include bottlenecks, traffic pulses, compression waves, random traffic fluctuations, and incidents. Sensor failure, also treated as an event, is related only to the measurement component of detection systems. The major characteristics of each event are described below [20].

Incidents

Incidents are unexpected events that block part of the roadway and reduce capacity. Incidents create two traffic regimes, congested flow upstream (high occupancies) and uncongested downstream (low occupancies). Two shock waves are generated and propagate upstream and downstream, each accompanying its respective regime. The congested-region boundary propagates upstream at approximately 16 kilometers per hour (10 miles per hour), where the value depends on incident characteristics, freeway geometry, and traffic level. Downstream of the incident, the cleared region boundary propagates downstream at a speed that can reach 80 kilometers per hour (50 miles per hour) [50].

The evolution and propagation of each incident is governed by several factors, the most important of which are incident type, number of lanes closed, traffic conditions prior to incident, and incident location relative to entrance and exit ramps, lane drops or additions, sharp turns, grade, and sensor stations. Other, less important factors that are harder to model include pavement condition, traffic composition, and driver characteristics.

Incident patterns vary depending on the nature of the incident and prevailing traffic conditions [50]. The most distinctive pattern occurs when the reduced capacity from incident blockage falls below oncoming traffic volume so that a queue develops upstream. This pattern, which is clearest when traffic is flowing freely prior to the incident, is typical when one or more moving lanes are blocked following severe accidents. The second pattern type occurs when the prevailing traffic condition is freely moving but the impact of the incident is not severe. This may result, e.g., from lane blockage that still yields reduced capacity higher than the volume of incoming traffic. This situation may lead to missed detection, especially if the incident is not located near a detector. The third type characterizes incidents that do not create considerable flow discontinuity, as when a car stalls on the shoulder. These incidents usually do not create observable traffic shock waves and have limited or no noticeable impact on traffic operations. The fourth type of incident occurs in heavy traffic when a freeway segment is already congested. The incident generally leads to clearance downstream, but a distinguishable traffic pattern develops only after several minutes, except in a very severe blockage. This type of incident is often observed in secondary accidents at the congested region upstream of an incident in progress.

Bottlenecks

Bottlenecks are formed where the freeway cross section changes, e.g., in lane drops or additions. While incidents have only a temporary effect on occupancies, bottlenecks generally result in longer-lasting spatial density or occupancy discrepancies.

Traffic Pulses

Traffic pulses are created by platoons of cars moving downstream. Such disturbances may be caused by a large entrance ramp volume; for instance, a sporting event letting out. The observed pattern is an

increase in occupancy in the upstream station followed by a similar increase in the downstream station. When ramp metering is present, traffic pulses are rarely observed.

Compression Waves

Compression waves occur in heavy, congested traffic, usually following a small disturbance, and are associated with severe slow-down, speed-up vehicle speed cycles. Waves are typically manifested by a sudden, large increase in occupancy that propagates through the traffic stream in a direction counter to the traffic flow. Compression waves result in significantly high station occupancies of the same magnitude as that in incident patterns.

Random Fluctuations

Random fluctuations are often observed in the traffic stream as short-duration peaks of traffic occupancy. These fluctuations, although usually not high in magnitude, may form an incident pattern or obscure real incident patterns.

Detection System Failures

Detection system failures may be observed in several forms, but a particular form often results in a specific pattern. This pattern is observed with isolated high-magnitude impulses in the 30-second volume and occupancy measurements, appearing simultaneously in several stations. These values are considered outliers or impulsive data noise [20].

Formulation of Incident Detection Problem

Incident detection can be viewed as part of a statistical decision framework in which traffic observations are used to select the true hypothesis from a pair, i.e., incident or no incident. Such a decision is associated with a level of risk and cost. The cost of a missed detection is expressed in terms of increased delays, and the cost of a false alarm is expressed in terms of incident management resources dispatched to the incident location. The objective of incident detection is to minimize the overall cost.

To formulate the incident detection problem in a simple incident versus no-incident environment, we observe the detector output that has a random character and seek to determine which of two possible causes, incident or normal traffic, produced it. The possible causes are assigned to a hypothesis, i.e., incident H_1 versus no-incident (normal traffic) H_0 . Traffic information is collected in real time and processed through a detection test, in which a decision is made based on specific criteria. Traffic information, such as occupancy, represents the observation space. We can assume that the observation space corresponds to a set of N observations denoted by the observation vector \mathbf{r} . Following a suitable decision rule, the total observation space Z is divided into two subspaces, Z_1 and Z_0 . If observation \mathbf{r} falls within Z_1 , the decision is d_1 ; otherwise the decision is d_0 .

To discuss suitable decision rules, we first observe that each time the detection test is performed four alternatives exist, depending on the true hypothesis H_i and the actual decision d_j , $i = 0$ or 1 :

1. H_0 true; choose H_0 (correct “no incident” decision)
2. H_0 true; choose H_1 (false alarm)
3. H_1 true; choose H_1 (correct “incident” decision)
4. H_1 true; choose H_0 (missed incident)

The first and third alternatives correspond to correct choices; the second and fourth correspond to errors.

The Bayes’ minimum error decision rule is based on the assumption that the two hypotheses are governed by probability assignments, known as a priori probabilities P_0 and P_1 . These probabilities represent the observer’s information about the sources (incident or no incident) before the experiment (testing) is conducted. Further, costs C_{00} , C_{10} , C_{11} , and C_{01} are assigned to the four alternatives. The first subscript indicates the chosen hypothesis and the second the true hypothesis. The costs associated with

a wrong decision, C_{10} , C_{01} , are dominant. Each time the detection test is performed, the minimum error rule considers the risk (cost) and attempts to minimize the average risk. The risk function is written,

$$R = C_{00}P_0P(d_0/H_0) + C_{01}P_1P(d_0/H_1) + C_{10}P_0P(d_1/H_0) + C_{11}P_1P(d_1/H_1) \quad (86.1)$$

that is,

$$R = \sum \sum C_{ij} P_j P(d_i/H_j) \quad i, j = 0, 1$$

where the conditional probabilities $P(d_i/H_j)$ result from integrating $p(\mathbf{r}/H_j)$, the conditional probability to observe the vector \mathbf{r} over Z_j , the observation subspace in which the decision is d_i . In particular, the probability of detection is

$$P(d_1/H_1) = P_D = \int_{z_1} p(\mathbf{r}/H_1) d\mathbf{r}$$

and the probability of false alarm is

$$P(d_1/H_0) = P_F = \int_{z_1} p(\mathbf{r}/H_0) d\mathbf{r}$$

Minimizing the average risk yields the *likelihood ratio* test:

$$\Lambda(\mathbf{r}) = \frac{p(\mathbf{r}/H_1)}{p(\mathbf{r}/H_0)} \underset{H_0}{\overset{H_1}{>}} \frac{(c_{10} - c_{00}) P_0}{(c_{01} - c_{11}) P_1}$$

where the second part in the inequality represents the test threshold, and the conditional and a priori probabilities can be estimated through time observations of incident and incident-free data. However, obtaining an optimal threshold requires realistic assignment of costs to each alternative. This is further impeded by the fact that incidents (or false alarms) are not alike in frequency, impact, and consequences. Therefore, an optimal threshold cannot practically be established. Previous attempts to use the Bayes' decision rule employed a simplified risk function to overcome the cost assignment issue and reduce the calibration effort. For instance, Levin and Krause [51] obtained a suboptimal threshold by maximizing the expression

$$R = P(d_0/H_0) + P(d_1/H_1)$$

using the relative spatial occupancy difference between adjacent stations as the observation parameter.

An alternative procedure to Bayes' rule, applicable when assigning realistic costs or a priori probabilities is not feasible, is the Neyman–Pearson (NP) criterion. The NP criterion views the solution of the optimization of the risk function in Equation (86.1) as a constrained maximization problem. This is necessitated by the fact that minimizing P_F and maximizing P_D are conflicting objectives. Therefore, one must be fixed while the other is optimized:

Constrain $P_F \leq \alpha$ and design a test to maximize P_D under this constraint.

Similarly to the minimum error criterion, the NP test results in a likelihood ratio test:

$$\Lambda(\mathbf{r}) \geq \lambda$$

where the threshold λ is a function of P_F only. Decreasing λ is equivalent to increasing Z_1 , the region where the decision is d_1 (incident). Thus, both P_F and P_D increase as λ decreases. The Neyman–Pearson lemma [52] implies that the maximum P_D occurs at $P_F = \alpha$.

The lemma holds since P_D is a nondecreasing function of P_F . In practical terms, an NP procedure implies that after an incident test has been designed, it is applied to a data set initially employing a high (restrictive) threshold, which results in low P_F . The threshold is incrementally reduced until P_F increases to the upper tolerable limit α . The corresponding P_D represents the detection success of the test at false alarm α . An NP procedure seems more applicable to incident detection than a minimum error procedure for two reasons. First, the only requirement is the constraint on P_F , which can easily be assessed by traffic engineers to a tolerable limit. Second, an NP procedure does not require separate threshold calibration since no optimal threshold, in the Bayesian sense, is sought. Instead, thresholds result from the desirable P_F .

The decision process is facilitated by the likelihood ratio $\Lambda(\mathbf{r})$. In signal detection practice, $\Lambda(\mathbf{r})$ is replaced by a *sufficient statistic* $l(\mathbf{r})$, which is simpler than the $\Lambda(\mathbf{r})$ function of the data. The values of the sufficient statistic are then compared to appropriate thresholds to decide which hypothesis is true. In incident detection applications, however, the tests of an algorithm are designed empirically so that they only approximately can be considered as sufficient statistics.

Need for All Incident Management Stages to Perform

Classical incident management strategies at the incident management components of detection, verification, response, and traffic management are aimed at minimizing the negative effects of nonrecurrent congestion that are due to incidents. The basic idea is that fast clearance of the incident scene can help to alleviate the incident-related congestion. Early and reliable detection and verification of the incident, together with integrated motorway and nonmotorway traffic management strategies, are important contributions that improve the efficiency of the incident response, i.e., the actions taken once an incident has occurred. However, it would still be better if the incident had been avoided in the first place. A first requirement, then, is that one can recognize conditions in which an incident is more likely to occur. The component of incident probability estimation should be developed and added to the incident management suite for this purpose.

Automatic incident detection (AID) involves two major elements: a traffic detection system that provides the traffic information necessary for detection and an incident detection algorithm that interprets the information and ascertains the presence or absence of a capacity-reducing incident.

Most AID algorithms have been developed based on loop detector data. Detection has typically been based on models that determine the expected traffic state under normal traffic conditions and during incidents. Comparative (or pattern recognition) algorithms establish predetermined incident patterns in traffic measurements and attempt to identify these patterns by comparing detector output against pre-selected thresholds. One of these involves separating the flow-occupancy diagram into areas corresponding to different states of traffic conditions (e.g., congested and not congested) and detecting incidents after observing short-term changes of the traffic state. These algorithms operate on a detector output of 30- to 60-second occupancy and volume data.

Time series and statistical algorithms employ simple statistical indicators or time series models to describe normal traffic conditions and detect incidents when measurements deviate significantly from the model output. A third class includes algorithms that involve macroscopic traffic flow modeling to describe the evolution of traffic variables; the diversity of incident patterns requires development of a large number of pattern-specific models, and this has limited the potential of these algorithms for practical applications. Other methods include detection of stationary or slow-moving vehicles, filtering to reduce

the undesired effects of traffic disturbances, application of fuzzy sets, transform analysis, and neural networks to take advantage of learning processes.

Recent work addressed the vehicle reidentification problem, lexicographic optimization, and derivation of section-related measures of traffic system performance using current inductive loops that provide vehicle waveforms. Another promising recent work performs real-time detection and characterization of motorway incidents using a three-step process, i.e., symptom identification of anomalous changes in traffic characteristics, signal processing for stochastic estimation of incident-related lane traffic characteristics, and pattern recognition.

In Europe, algorithms tested with data from loops are of the comparative type (e.g., HERMES I; German I, II, and IV; and Dutch MCSS), time series type (GERDIEN), or the type employing filtering (HERMES II). They use typical aggregate data (speed, volume, and occupancy) and aim to detect congestion and slow-moving or stopped vehicles. Other AID techniques extract traffic data from radar, such as the Millimetric Radar System (MMW) and German III. Using machine vision, AID systems serve as loop detector emulators (CCATS VIP and IRB), qualitative traffic state detectors (IMPACTS), or vehicle tracking detectors (TRISTAR and CCIDS).

Despite substantial research, algorithm implementation has been hampered by limited performance reliability, substantial implementation needs, and strong data requirements. Several problems require the attention of developers:

False alarm rate (FAR): The high number of false alarms has discouraged traffic engineers from integrating these algorithms in automated traffic operations. Algorithm alarms typically trigger the operator's attention; the operator verifies the validity of the alarm using closed-circuit TV cameras and decides on the appropriate incident response. In most cases, incident response is initiated only after an incident has been reported by the police or motorists.

Calibration: The need for algorithm calibration has not been extensively assessed, and lack of adequate calibration often leads to significantly deteriorated algorithm performance. Calibration by optimization of a set of different algorithms on the same field data set is the most reliable way for comparative evaluation across algorithms.

Evaluation: The major method adopted for comparatively evaluating the performance of AID algorithms is that of the operating characteristic curves. Performance tests have shown the following [53]:

United States

Time series algorithms performed worse than comparative ones.

DELOS, an algorithm based on filtering, produced 50% fewer false alarms than comparative algorithms, e.g., California type.

The time series algorithm by Persaud et al. produced a good detection rate but too many false alarms to be practical.

France

Comparative algorithms produced at least 30% fewer false alarms than single-variable time series algorithms (Standard Normal Deviate, Double Exponential, and ARIMA) at all detection levels.

DELOS performed better than the time series algorithm developed by Persaud et al.

IN-RESPONSE Project in Europe

DELOS and Algorithm 8 were evaluated against machine vision methods, and the results showed each to have its strengths under given conditions.

Canada

The time series algorithm by Persaud et al. produced fewer false alarms than the California algorithm and was adopted as its replacement.

Transferability: Some understanding of algorithm transferability potential has been achieved, mainly in the IN-RESPONSE, HERMES, MARGOT-LLAMD, and EUROCOR projects and in a comparative evaluation in Minnesota and California (analysis of 213 incidents over 1660 hours, 24 hours a day) [54].

FIGURE 86.5 Performance envelope. (Used with permission from J. Barcelo and L. Montero.)

Traffic management objectives: While most U.S. efforts seek to remove the incident and achieve smooth traffic flow, work in Europe focuses on warning drivers of congestion even if no incident has occurred and on assisting stopped vehicles. Work in rural areas has focused on achieving AID with sparse instrumentation. The latter two objectives can often best be addressed by AID systems that are based on machine vision. Such systems have achieved performance equivalent to that of loop detectors. However, the additional advantage of the new systems is that they can detect incidents that do not influence traffic substantially or that cannot be detected by loop-based systems but are still a risk to the motorist.

Addressing the need for determining improved performance of incident detection methods under varying conditions, a recent project, PRIME, tested incident detection algorithms that have not been extensively tested in Europe, and more advanced sensing hardware. The project addressed all incident management components, i.e., estimation of incident probability, incident detection, incident verification, and integrated incident response strategies. Recent results from the project indicate that the **incident detection** component has satisfied the specifications in terms of detection rate and false alarm rate. For instance, application of the modified Persaud algorithm in Barcelona resulted in the performance envelope shown in Figure 86.5 [55].

The real-time **estimation of incident probability** is sparsely documented.

From IN-RESPONSE [56], it was concluded that the incident probability estimation model was a promising way of linking real-time 1-minute traffic and weather data to static data on road geometry for estimating incident probability. The technique could not be properly evaluated because of the shortage of incident data and the inaccuracy of the time stamps.

The same lack of incident data was reported in Reference 57. The authors presented several empirical methods for analyzing incident data. A key issue raised was whether an accident was responsible for the measured variability in traffic conditions or whether these conditions were caused by the accident.

The problem of data availability was not reported in Reference 58, which used a model similar to that in IN-RESPONSE (binary logit) to establish relationships between incident likelihood and explanatory variables such as weather and traffic conditions.

A method of overcoming this shortage of incident data is to simulate incident situations [59]. The cellular automaton-based microscopic simulation model TRANSIMS was used to estimate the probability of accidents. The model used a relationship between the probability of an incident and a safety criterion (braking power).

PRIME developed EIP hierarchical logit, logit, and fuzzy models with online data and simulation. The performance was good in terms of estimation rate but had several false alarms; see the performance envelope shown in Figure 86.6 with data from Barcelona.

FIGURE 86.6 Performance envelope. (Used with permission from J. Barcelo and L. Montero.)

Incident verification (IV) aims to accumulate evidence and information about possible detected incidents and use this additional information to drop false alarms, merge repeated alarms, and provide complete incident reports in case of real incidents.

Most countries with an operational traffic management system are using one or more incident verification methods, primarily CCTV and patrol vehicles. Realizing the potential of using cellular telephones as an incident management tool, many highway agencies have formed partnerships with cellular telephone carriers to implement programs that encourage drivers to report randomly occurring motorway incidents.

However, information obtained from cellular phones varies in the detail and quality, and the incident may be reported after considerable time has elapsed. Therefore, the feasibility of motorway surveillance systems utilizing cellular phones needs to be carefully evaluated. A survey of 42 traffic management centers in the United States found that 75% use cellular detection. However, in most states, such as Texas, video cameras are deployed for verification. Weaknesses of cellular phones include a very low rate of detecting small incidents, the highest rate of false alarms, and limited information on the incident severity. Also, cellular phone messages need further verification and cannot tell when the incident is cleared. Incidents reported by cellular phones show greater incident duration by 14 minutes on the average than similar incidents reported by the CHP/MSP. This extra delay is due to the incident verification process by dispatching an officer.

FIGURE 86.7 Effect of parameters on performance. (Used with permission from B. Dendrou.)

Cellular phone false alarms fall into two categories: (1) reporting incorrect or incomplete information regarding the location of the incident and its severity and (2) erroneous calls, including fake or prank calls. On the other hand, wireless phone users can report incidents that traditional methods cannot capture, such as debris, flooding, or wandering animals.

Incident management requirements for incident verification within advanced transport telematics (ATT) systems cannot rely solely on cellular phones. Cellular phone reports may contribute significantly to the incident detection in combination with other sources and may be used in the verification of incidents, including those detected by other methods. This would require proper fusion of cellular phone data with information from other sources and use of appropriate technologies, such as video surveillance.

When all sites use the same automated and reliable procedure, consistent information about the incidents will be collected. Information that could be retrieved to verify an incident in this way can include one or more incident attributes, e.g.:

- Location (road number, travel direction, kilometer point, and lane)
- Type and severity (injuries, fire, trapped injuries, or hazardous goods)
- Identity of source
- Type of assistance needed (mechanical, police, or emergency)
- Certainty

Results with data from Athens, Greece indicate the effect of parameters on performance, i.e., the effect of the number of calls required, mobile phone penetration, traffic volume, etc.; see [Figure 86.7](#) [55].

Additional performance improvements in PRIME were attained with the development of specialized hardware and software, such as panoramic camera and accompanying algorithms that transform the original image acquired by a panoramic camera ([Figure 86.8a](#)) to a bird's-eye view that can be further processed ([Figure 86.8b](#)) and, through a homography-based transformation, transform the original image of a machine vision camera ([Figure 86.8c](#)) to top-down view ([Figure 86.8d](#)) for easier calculations and error reduction [55].

Appendix

TABLE 86.1 Incident Management Assessment Summary

| Technology | Deployment Level | Limiting Factors | Comments |
|---|----------------------------------|------------------------------------|-------------------|
| Service patrols | Widespread deployment | Cost, staffing | Successful |
| Common communication frequencies | Limited deployment ^a | Cost, institutional issues | Successful |
| Automated incident detection algorithms | Medium deployment ^a | Technical performance | Mixed |
| Cellular communication for incident detection | Widespread deployment | Availability, institutional issues | Jury is still out |
| Motorist call boxes | Limited deployment ^a | Being replaced by cell phone use | Successful |
| CCTV (ground, airborne, high magnification) | Widespread deployment | Cost | Successful |
| Cellular geolocation (old generation) | Operational testing ^a | Accuracy | Unsuccessful |
| Cellular geolocation (emerging generation) | Operational testing ^a | Availability, institutional issues | Jury is still out |
| Regional incident management programs | Limited deployment ^a | Institutional issues | Holds promise |

^a Quantitative deployment tracking data not available. Deployment level determined by expert judgment.

Source: Federal Highway Administration, What Have We Learned about Intelligent Transportation Systems? U.S. Department of Transportation, Washington, D.C., 2000.

TABLE 86.2 Freeway Management Assessment Summary

| Technology/System | Deployment Level | Limiting Factors | Comments |
|--|------------------------------------|---|---|
| Transportation management centers (may incorporate multiple technologies) ^a | Widespread deployment ^b | Implementation cost, staffing | Successful |
| Portable transportation management centers (may incorporate multiple technologies) | Limited deployment ^b | Implementation cost, staffing | Successful |
| Road closure and restriction systems (may incorporate multiple technologies) | Limited deployment ^b | Institutional issues | Successful |
| Vehicle detection systems (may incorporate multiple technologies) | Widespread deployment | Cost, maintenance | Mixed — depends on technology |
| Vehicles as probes (may incorporate multiple technologies) | Limited deployment | Cost, integration | Jury is still out |
| Ramp metering (includes multiple technologies) | Medium deployment | Politics, user appearance | Successful |
| Dynamic message signs (includes multiple technologies) | Widespread deployment | Cost, changing technology | Mixed — due to operations quality |
| Highway advisory radio (includes multiple technologies) | Medium deployment | Staffing | Mixed — due to operations quality |
| Dynamic lane control | Medium deployment | Not in MUTCD for main lanes ^c | Successful — especially on bridges and in tunnels |
| Dynamic speed control/variable speed limit | Technical testing ^b | Not in MUTCD; may require local legislation to be enforceable | Holds promise |
| Downhill speed warning and rollover warning systems | Limited deployment ^b | Cost | Successful |

^a A transportation management center may control several of the systems listed in the table and will possibly utilize additional technologies, such as video display systems, local area networks, flow monitoring algorithms, geographic information systems, graphic user interfaces, and database management systems.

^b Quantitative deployment tracking data not available. Deployment level determined by expert judgment.

^c Main lanes are freeway lanes that are not tunnels or bridges.

TABLE 86.3 Emergency Management Assessment Summary

| Technology | Deployment Level | Limiting Factors | Comments |
|---|------------------------------------|---|-------------------|
| GPS/differential GPS on emergency management fleets | Widespread deployment | Cost | Successful |
| Mayday systems | Widespread deployment ^a | Cost, vehicle choice | Successful |
| Mayday processing centers/customer service centers | Widespread deployment ^a | Cost | Successful |
| Public safety answering points | Widespread deployment ^a | Cost, staffing | Successful |
| CDPD communication | Limited deployment ^a | Availability | Jury is still out |
| Onboard display | Widespread deployment | Cost, user acceptance | Successful |
| Preemption infrared signal system | Widespread deployment | Institutional issues, lack of standards | Successful |
| Computer-aided dispatch | Widespread deployment | Cost, support staffing | Successful |
| Automatic vehicle location | Widespread deployment | Cost | Successful |
| Networked systems among agencies | Limited deployment ^a | Institutional issues, integration cost | Holds promise |

^a Quantitative deployment tracking data not available. Deployment level determined by expert judgment.

Source: Federal Highway Administration, What Have We Learned about Intelligent Transportation Systems? U.S. Department of Transportation, Washington, D.C., 2000.

TABLE 86.4 Electronic Toll Collection Assessment Summary

| Technology | Deployment Level | Limiting Factors | Comments |
|-------------------------------------|---------------------------------|---|-------------------|
| Dedicated short-range communication | Widespread deployment | Need for standard | Successful |
| Smart cards | Limited deployment | Commercial and user acceptance; need for standard | Successful |
| Transponders | Widespread deployment | Privacy | Successful |
| Antennas | Widespread deployment | Technical performance | Successful |
| License plate recognition | Limited deployment ^a | Technical performance | Jury is still out |

^a Quantitative deployment tracking data not available. Deployment level determined by expert judgment.

Source: Federal Highway Administration, What Have We Learned about Intelligent Transportation Systems? U.S. Department of Transportation, Washington, D.C., 2000.

TABLE 86.5 Arterial Management Assessment Summary

| Technology | Deployment Level | Limiting Factors | Comments |
|---|---|---|--|
| Adaptive control strategies | Limited deployment | Cost, technology, perceived lack of benefits | Jury is still out — has shown benefits in some cases; cost still a prohibitive factor; some doubt among practitioners on its effectiveness |
| Arterial information for ATIS | Moderate deployment | Limited deployment of appropriate surveillance; difficulty in accurately describing arterial congestion | Holds promise — new surveillance technology likely to increase the quality and quantity of arterial information |
| Automated red-light-running enforcement | Moderate deployment ^a | Controversial; some concerns about privacy, legality | Successful — but must be deployed with sensitivity and education |
| Automated speed enforcement on arterial streets | Limited deployment ^a | Controversial; some concerns about privacy, legality | Jury is still out — public acceptance lacking; very controversial |
| Integration of time-of-day and fixed-time signal control across jurisdictions | Widespread deployment | Institutional issues still exist in many areas | Successful — encouraged by spread of closed-loop signal systems and improved communications |
| Integration of real-time or adaptive control strategies across jurisdictions (including special events) | Limited deployment | Limited deployment of adaptive control strategies; numerous institutional barriers | Holds promise — technology is becoming more available; institutional barriers falling |
| Integration with freeway (integrated management) | Limited deployment | Institutional issues exist; lack of standards between systems preventing integration | Holds promise — benefits have been realized from integrated freeway arterial corridors |
| Integration with emergency (signal preemption) | Widespread deployment | None | Successful |
| Integration with transit (signal priority) | See Chapter 5, “What Have We Learned about Advanced Public Transportation Systems?” | See Chapter 5, “What Have We Learned about Advanced Public Transportation Systems?” | See Chapter 5, “What Have We Learned about Advanced Public Transportation Systems?” |

^a Quantitative deployment tracking data not available. Deployment level determined by expert judgment.

Source: Federal Highway Administration, What Have We Learned about Intelligent Transportation Systems? U.S. Department of Transportation, Washington, D.C., 2000.

TABLE 86.6 ATIS Assessment Summary

| ATIS Service | Deployment Level | Limiting Factors | Comments |
|---|---|---|---|
| Real-time traffic information on the Internet | Widespread deployment | While deployment is widespread, customer satisfaction with the services seems related to local traffic conditions and website information quality | Mixed — the characteristics of the websites vary, depending on the availability and quality of the user interface and underlying traffic data |
| Real-time transit status information on the Internet | Limited deployment | Transit authorities have limited funds for ATIS investments and little data that establish a relationship between ridership and ATIS | Holds promise — where the service is available, reports suggest that there is high customer satisfaction with the service |
| Static transit system information on the Internet | Widespread deployment | N/A | Successful |
| Real-time traffic information on cable television | Limited deployment | Limited by information quality and production costs, although one service provider has developed a way to automate production | Successful — as evaluated in a highly congested metropolitan area where consumers value the easy, low-tech access to traffic information |
| Real-time transit status information at terminals and major bus stops | Limited deployment | Cost | Successful — where evaluated in greater Seattle |
| Dynamic message signs | Widespread deployment | Positive driver response is a function of sign placement, content, and accuracy | Successful — drivers really appreciate accurate en route information |
| In-vehicle navigation systems (no traffic information) | Limited deployment ^a | Purchase cost | Holds promise — as prices fall, more drivers will purchase the systems |
| In-vehicle dynamic route guidance (navigation with real-time traffic information) | No commercial deployment; the San Antonio MMDI installed prototype systems in public agency vehicles ^a | Irregular coverage and data quality, combined with conflicting industry geocode standards, have kept this product from the market | Holds promise — manufacturers are poised to provide this service once issues are resolved |
| Fee-based traffic and transit information services on palm-type computers | Unknown deployment | Service providers make this service available through their websites; actual subscription levels are unknown | Jury is still out — requires larger numbers of subscribers becoming acclimated to mobile information services |

Note: N/A = not applicable.

^a Quantitative deployment tracking data not available. Deployment level determined by expert judgment.

Source: Federal Highway Administration, What Have We Learned about Intelligent Transportation Systems? U.S. Department of Transportation, Washington, D.C., 2000.

TABLE 86.7 APTS Assessment Summary

| Technology | Deployment Level | Limiting Factors | Comments |
|---|---------------------------------------|--|---|
| Automatic vehicle location | Moderate deployment | Cost, fleet size, service type, staff technological competence | Successful — use continues to grow; new systems principally use GPS technology, but usually augmented by dead reckoning |
| Operations software | Widespread deployment | N/A | Successful |
| Fully automated dispatching for demand response | Research and development ^a | Still in research and development stage | Jury is still out |
| Mobile data terminals | Moderate deployment ^a | Most frequently deployed with automatic vehicle location systems | Successful — reduces radio frequency requirements |
| Silent alarm/covert microphone | Moderate deployment ^a | Most frequently deployed with automatic vehicle location systems | Successful — improves security of transit operations |
| Surveillance cameras | Limited deployment ^a | Cost | Holds promise — enhances onboard security; deters vandalism |
| Automated passenger counters | Limited deployment | Cost | Holds promise — provides better data for operations, scheduling, planning, and recruiting at lower cost |
| Pretrip passenger information | Widespread deployment | N/A | Successful — improves customer satisfaction |
| En route and in-vehicle passenger information | Limited deployment | Cost, lack of evidence of ridership increases | Jury is still out |
| Vehicle diagnostics | Limited deployment | Cost, lack of data on benefits | Jury is still out |
| Traffic signal priority | Limited deployment | Institutional issues, concerns about impacts on traffic flows | Holds promise — reduces transit trip times; may reduce required fleet size |
| Electronic fare payment | Limited deployment | Cost | Holds promise — increases customer convenience |

Note: N/A = not applicable.

^a Quantitative deployment tracking data not available. Deployment level determined by expert judgment.

Source: Federal Highway Administration, What Have We Learned about Intelligent Transportation Systems? U.S. Department of Transportation, Washington, D.C., 2000.

TABLE 86.8 CVISN Assessment Summary

| Technology | Deployment Level | Limiting Factors | Comments |
|---|--|--|--|
| Safety Information Exchange | | | |
| Laptop computers with Aspen or equivalent | Widespread deployment | N/A | Successful |
| Wireless connections to SAFER at roadside | Moderate deployment | Technical challenges with communications among systems | Holds promise — for identifying frequent violators of safety laws |
| CVIEW or equivalent | Limited deployment | Connections to legacy state system | Jury is still out — being tested in three or four states |
| Electronic Screening | | | |
| One or more sites equipped with DSRC | Widespread deployment (number of states); limited deployment (number of carriers) | Interoperability | Holds promise — deployment trend is positive |
| Electronic Credentialing | | | |
| End-to-end IRP and IFTA processing | Limited deployment | Challenges and costs of connecting legacy systems | Holds promise — potential for significant cost savings to states and carriers |
| Connection to IRP and IFTA clearinghouses | Limited deployment | Institutional issues | Jury is still out — cost savings can be realized only with widespread deployment |

TABLE 86.9 Crosscutting Technical Issues Assessment Summary

| Technology | Deployment Level | Limiting Factors | Comments |
|---|--|---|---|
| Sensor and Surveillance Technologies | | | |
| Cell phones for incident reporting | Widespread deployment ^{a,b} | N/A | Successful |
| Cell phones for emergency notification | Limited deployment ^{a,b} | Relatively new; mostly sold in new vehicles; takes long time to reach 30% of vehicle fleet | Successful — number of equipped vehicles growing rapidly |
| GPS for position, determination, automatic vehicle location | Moderate deployment in fleets (transit, trucking, emergency vehicles) ^c | N/A | Successful — use continuing to grow ^c |
| Video surveillance | Widespread deployment | N/A | Successful |
| DSRC (toll tags) for travel time data | Limited deployment | Mostly used only in areas with electronic toll collection; requires power and communications to readers | Successful — holds promise |
| Direct link between Mayday systems and public safety answering points | Limited deployment ^b | Still in research and test phase; significant institutional policy and technical issues | Jury is still out — no known deployments |
| Cellular geolocation for traffic probes | Limited deployment | New technologies just beginning field trials | Jury is still out — older technology unsuccessful |
| Communications Technologies | | | |
| Loop detectors | Widespread deployment | N/A | Successful |
| Alternatives to loop detectors | Widespread deployment | Initial cost, familiarity | Holds promise — video widespread; others limited; many cities use only for a few locations |
| Real-time, in-vehicle traffic information | Limited deployment ^{a,b} | Cost, commercial viability | Jury is still out |
| LIDAR for measuring automotive emissions | Limited deployment ^b | Minnesota test was unsuccessful; technology didn't work well enough | Unsuccessful — no known deployment |
| Internet for traveler information | Widespread deployment | N/A | Successful — free services Jury is still out — on commercial viability |
| High-speed Internet | Limited deployment ^b | Slow rollout; availability limited | Holds promise |
| Fully automated Internet-based exchange | Limited deployment ^b | New technology | Holds promise |
| DSRC | Widespread deployment | N/A | Successful — current use mostly limited to electronic toll collection |
| DSRC at 5.9 GHz | Limited deployment ^b | Frequency just recently approved for use; standards in development | Jury is still out — no known deployment in the U.S., but used in other countries at 5.8 GHz |
| Fiber optics for wire line communications | Widespread deployment | N/A | Successful |
| Digital subscriber line | Limited deployment | New technology; first applied to ITS in 1999 | Holds promise — several deployments; many more locations considering |
| 220-MHz radio channels for ITS | Limited deployment | ITS is too small a market to support unique communications systems | Unsuccessful — only known use during Atlanta test during the 1996 Olympic Games |

TABLE 86.9 Crosscutting Technical Issues Assessment Summary (*Continued*)

| Technology | Deployment Level | Limiting Factors | Comments |
|--|-----------------------------------|---|---|
| High-speed FM subcarrier for ITS | Limited deployment ^{a,b} | Low demand to date for in-vehicle real-time data | Jury is still out — multiple conflicting “standards” and proprietary approaches; competition from other wireless technologies |
| CDPD for traveler information | Limited deployment ^{a,b} | Lack of real-time information to send; limited use of CDPD by consumers | Unsuccessful — CDPD will soon be overtaken by other wireless data technologies |
| Wireless Internet | Limited deployment ^{a,b} | New technology | Jury is still out — on ITS uses; general use predicted to grow rapidly |
| Local area wireless | Limited deployment | New technology | Jury is still out |
| Low-power FM | Limited deployment ^b | Just legalized by FCC; first licenses not yet granted | Jury is still out — brand new; no deployments yet |
| High-speed fixed wireless | Limited deployment ^b | New technology | Jury is still out |
| Analysis Tools | | | |
| Models incorporating operations into transportation planning | Limited deployment ^b | Emerging technology; cost and institutional issues may become factors for some approaches | Jury is still out — IDAS available; PRUEVIIN methodology demonstrated; TRANSIMS in development |

Note: N/A = not applicable; FCC = Federal Communications Commission.

^a Quantitative deployment tracking data are not available. Deployment level was determined by expert judgment.

^b For in-vehicle consumer systems, deployment levels are based on the percent of users or vehicle fleet, not number of cities available. For example, real-time in-vehicle traffic is available in more than two dozen cities, but the percentage of drivers subscribing to it is small.

^c For AVL using GPS in transit, the moderate-level assessment is based on the percent of transit agencies using the technology according to a 1998 survey of 525 transit agencies conducted by the John A. Volpe National Transportation Systems Center. This measure was used for consistency with the transit section of this report. If the 78 major metropolitan areas are used as a measure, then the deployment level is “widespread,” as 24 of 78 cities use GPS-based AVL.

TABLE 86.10 Definitions of the Metropolitan Integration Links

Definitions of the metropolitan integration links represent both inter- and intracomponent sharing of information. Each of the links has been assigned a number and an origin or destination path from one component to another. The definitions used are from the most recent version of the draft report titled “Tracking the Deployment of the Integrated Metropolitan Intelligent Transportation Systems Infrastructure in the USA: FY 1999 Results,” prepared by the Oak Ridge National Laboratory and Science Applications International Corporation for the U.S. Department of Transportation’s ITS Joint Program Office, dated March 2000.

- Link 1: Arterial management to regional multimodal traveler information: Arterial travel time, speed, and condition information is displayed by regional multimodal traveler information media.
- Link 2: Arterial management to freeway management: Freeway management center monitors arterial travel times, speeds, and conditions using data provided from arterial management to adjust ramp meter timing, lane control, or HAR in response to changes in real-time conditions on a parallel arterial.
- Link 3: Arterial management to transit management: Transit management adjusts transit routes and schedules in response to arterial travel time, speed, and condition information collected as part of arterial management.
- Link 4: Arterial management to incident management: Incident management monitors real-time arterial travel times, speeds, and conditions using data provided from arterial management to detect arterial incidents and manage incident response activities.
- Link 5: Incident management to arterial management: Arterial management monitors incident severity, location, and type information collected by incident management to adjust traffic signal timing or provide information to travelers in response to incident management activities.
- Link 6: Incident management to regional multimodal traveler information: Incident location, severity, and type information is displayed by regional multimodal traveler information media.
- Link 7: Incident management to emergency management: Incident severity, location, and type data collected as part of incident management are used to notify emergency management for incident response.
- Link 8: Incident management to freeway management: Incident severity, location, and type data collected by incident management are monitored by freeway management for the purpose of adjusting ramp meter timing, lane control, or HAR messages in response to freeway or arterial incidents.
- Link 9: Incident management to transit management: Transit management adjusts transit routes and schedules in response to incident severity, location, and type data collected as part of incident management.
- Link 10: Freeway management to regional multimodal traveler information: Freeway travel time, speed, and condition information is displayed by regional multimodal traveler information.
- Link 11: Freeway management to arterial management: Freeway travel time, speed, and condition data collected by freeway management are used by arterial management to adjust arterial traffic signal timing or arterial VMS messages in response to changing freeway conditions.
- Link 12: Freeway management to transit management: Transit management adjusts transit routes and schedules in response to freeway travel time, speed, and condition information collected as part of freeway management.
- Link 13: Freeway management to incident management: Incident management monitors freeway travel time, speed, and condition data collected by freeway management to detect incidents or manage incident response.
- Link 14a: Transit management to regional multimodal traveler information: Transit routes, schedules, and fare information is displayed on regional multimodal traveler information media.
- Link 14b: Transit management to regional multimodal traveler information: Transit schedule adherence information is displayed on regional multimodal traveler information media.
- Link 15a: Transit management to freeway management: Freeway ramp meters are adjusted in response to receipt of transit vehicle priority signal.
- Link 15b: Transit management to freeway management: Transit vehicles equipped as probes are monitored by freeway management to determine freeway travel speeds or travel times.
- Link 16a: Transit management to arterial management: Traffic signals are adjusted in response to receipt of transit vehicle priority signal.
- Link 16b: Transit management to arterial management: Transit vehicles equipped as probes are monitored by arterial management to determine arterial speeds or travel times.
- Link 17: Electronic toll collection to freeway management: Vehicles equipped with electronic toll collection tags are used as probes and monitored by freeway management to determine freeway travel speeds or travel times.
- Link 18: Electronic toll collection to arterial management: Vehicles equipped with electronic toll collection tags are used as probes and monitored by arterial management to determine arterial travel speeds or travel times.
- Link 19: Electronic toll collection to electronic fare payment: Transit operators accept electronic toll collection–issued tags to pay for transit fares.
- Link 20: Electronic fare payment to transit management: Ridership details collected as part of electronic fare payment are used in transit service planning by transit management.
- Link 21a: Emergency management to incident management: Incident management is notified of incident location, severity, and type by emergency management to identify incidents on freeways or arterials.

TABLE 86.10 Definitions of the Metropolitan Integration Links (*Continued*)

- Link 21b: Emergency management to incident management: Incident management is notified of incident clearance activities by emergency management to manage incident response on freeways or arterials.
- Link 22: Emergency management to arterial management: Emergency management vehicles are equipped with traffic signal priority capability.
- Link 23: Highway–rail intersection to incident management: Incident management is notified of crossing blockages by highway–rail intersection to manage incident response.
- Link 24: Highway–rail intersection to arterial management: Highway–rail intersection and arterial management are interconnected for the purpose of adjusting traffic signal timing in response to train crossing.
- Link 25: Incident management intracomponent: Agencies participating in formal working agreements or incident management plans coordinate incident detection, verification, and response.
- Link 26: Arterial management intracomponent: Agencies operating traffic signals along common corridors share information and possible control of traffic signals to maintain progression on arterial routes.
- Link 27: Electronic fare payment intracomponent: Operators of different public transit services share common electronic fare payment media.
- Link 28: Electronic toll collection intracomponent: Electronic toll collection agencies share a common toll tag for the purpose of facilitating “seamless” toll transactions.
- Link 29: Transit management to incident management: Transit agencies notify incident management agencies of incident locations, severity, and type.
- Link 30: Freeway management intracomponent: Agencies operating freeways within the same region share freeway travel time, speed, and condition data.

Ocean engineering is a relatively new branch of engineering. The need for this new specialty was recognized in the 1960s. Several universities, including Texas A&M, MIT, Florida Atlantic, the U.S. Coast Guard Academy, and the U.S. Naval Academy, have established undergraduate degree programs in ocean engineering. Several universities have also developed programs at the graduate level specializing in ocean engineering.

Ocean and coastal engineering covers many topics, generally divided between shallow water (coastal engineering) and deep water (ocean engineering), shown in [Figure 87.1](#) and [Figure 87.2](#).

87.1 Wave Phenomena

Wave phenomena are of great importance in coastal and ocean engineering. Waves determine the composition and geometry of beaches. Since waves interact with human-made shore structures or offshore structures, safe design of these structures depends to a large extent on the selected wave characteristics. The structural stability criteria are often stated in terms of extreme environmental conditions (wave heights, periods, water levels, astronomical tides, storm surges, tsunamis, and winds). Waves in the ocean constantly change and are irregular in shape, particularly when under the influence of wind; such waves are called *seas*. When waves are no longer under the influence of wind and are out of the generating area, they are referred to as *swells*. Many wave theories have been developed, including the Airy, cnoidal, solitary, stream function, Stokian, and so forth. [Figure 87.3](#) describes the regions of validity for various wave theories. Cnoidal and stream function theories apply principally to shallow

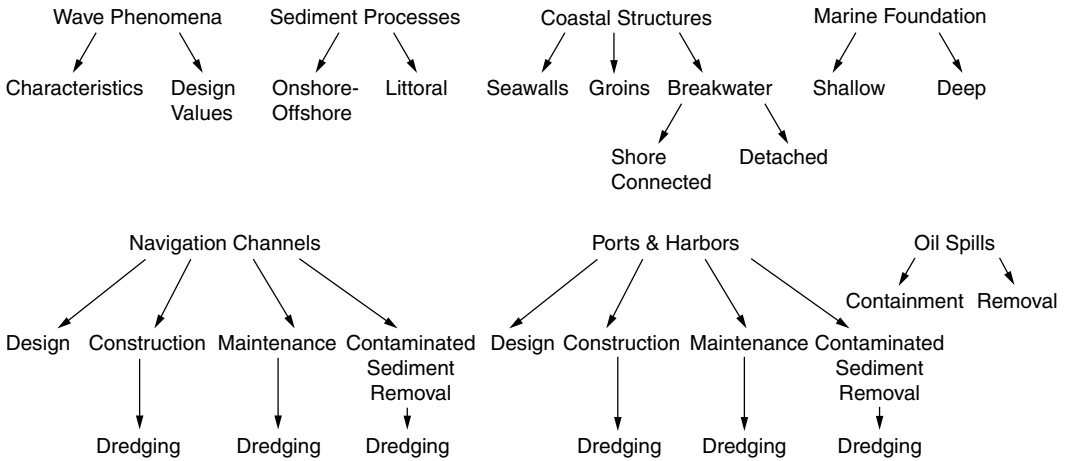

FIGURE 87.1 Coastal engineering (shallow water).

FIGURE 87.2 Ocean engineering (deep water).

and transitional water, whereas Airy and Stokian theories apply to transitional and deep water (Airy applies to low amplitude waves).

Airy (Low Amplitude)

Wavelength is given by the following equations.

Shallow water
$$L = T\sqrt{gh} = CT \tag{87.1}$$

Transitional water
$$L = \frac{gT^2}{2\pi} \tanh\left(\frac{2\pi h}{L}\right) \tag{87.2}$$

Deep water
$$L_o = \frac{gT^2}{2\pi} = C_o T \tag{87.3}$$

where T = wave period; g = acceleration due to gravity; h = water depth; and C = wave celerity. Subscript o denotes deep water conditions.

Cnoidal (Shallow Water, Long Waves)

The theory originally developed by Boussinesq [1877] has been studied and presented in more usable form by several researchers. Wavelength is given by

FIGURE 87.3 Regions of validity for various wave theories (Source: Le Méhauté, B. 1969. *An Introduction to Hydrodynamics and Water Waves*, Report No. ERL 118-POL3-1&2. U.S. Department of Commerce, Environmental Science Services Administration, Washington, DC.)

$$L = \sqrt{\frac{16d^3}{3H}} kK(k) \tag{87.4}$$

and wave period by

$$T \sqrt{\frac{g}{h}} = \sqrt{\frac{16y_t}{3H}} \frac{h}{y_t} \left[\frac{kK(k)}{1 + \frac{H}{y_t k^2} \left(\frac{1}{2} - \frac{E(k)}{K(k)} \right)} \right] \tag{87.5}$$

where y_t = distance from the bottom to the wave trough; k = modulus of the elliptic integrals; $K(k)$ = complete elliptic integral of the first kind; and $E(k)$ = complete elliptic integral of the second kind.

Cnoidal waves are periodic and of permanent form; thus $L = CT$.

Stream Function

Stream function was developed by Dean [1977] and is of analytical form with the wavelength L , coefficients $X(n)$, and the value of stream function on the free surface ψ_η determined numerically. The expression for the stream function, ψ , for a wave system rendered stationary by a reference frame moving with the speed of the wave, C , is

$$\psi = \left(\frac{L}{T} - U \right) z + \sum_{n=1}^{NN} X(n) \sinh \left[\frac{2\pi n}{L} (h+z) \right] \cos \left(\frac{2\pi n x}{L} \right) \quad (87.6)$$

with the coordinate z referenced to the mean water level; U is a uniform current.

Stream function (Table 87.1) provides values of wavelength $L' = L/L_0$, $\eta'_c = \eta_c/H$ (water surface elevation above mean water), $\eta'_t = \eta_t/H$ (wave surface elevation below mean water), u'_c (horizontal dimensionless velocity at the crest), w'_m (maximum dimensionless vertical velocity), $(F'_D)_m$ (maximum dimensionless drag force), and $(F'_I)_m$ (maximum dimensionless inertia force).

Stokian (Third Order)

Wavelength is given by

$$L = \frac{gT^2}{2\pi} \tanh \left(\frac{2\pi h}{L} \right) \left\{ 1 + \left(\frac{\pi H}{L} \right)^2 \left[\frac{5 + 2 \cosh(4\pi h/L) + 2 \cosh^2(4\pi h/L)}{8 \sinh^4(2\pi d/L)} \right] \right\} \quad (87.7)$$

87.2 Sediment Processes

Along the coasts the ocean meets land. Waves, currents, tsunamis, and storms have been shaping the beaches for many thousands of years. Beaches form the first defense against the waves and are constantly moving on, off, and along the shore (littoral drift). Figure 87.4 provides a definition for terms describing a typical beach profile. The shoreline behavior is very complex and difficult to understand; it cannot be expressed by equations because many of the processes are site specific. Researchers have, however, developed equations that should be summarized. There are two basic sediment movements:

1. On- and offshore
2. Parallel to the shore and at an angle to the shore.

87.3 Beach Profile

Information on beach profiles is essential in designing structural modifications (such as seawalls, revetments, and breakwaters, both connected and detached, pipeline crossings, and beach replenishment. Bruun [1954] indicated that many beach profiles (Figure 87.5) can be represented by

$$h(x) = Ax^{2/3}$$

where h is the water depth at a distance x offshore, and A is a dimensional scale parameter.

Dean [1977] showed that H_b/wT is an important parameter distinguishing **barred** profiles from nonbarred profiles (where H_b is breaking wave height, w is fall velocity of sediment in water, and T is wave period). This parameter is consistent with the following beach profiles in nature:

TABLE 87.1 Selected Summary of Tabulated Dimensionless Stream Function Quantities

| Case | h/L_0 | H/L_0 | L' | η'_c | η'_t | u'_c | w'_m | $\theta(w'_m)^*$ | $(F'_D)_m$ | $(F'_I)_m$ | $\theta(F'_I)_m$ | P'_{Dc} (Bottom) |

Milder slope profiles { High waves
Short periods
Small sediment diameter

Steeper profiles { Low waves
Long periods
Large sediment diameter

When $\frac{H_b}{wT} > 0.85$, one can expect **bar** formation. (87.8a)

When $\frac{H_b}{wT} < 0.85$, a monotonic profile can be expected. (87.8b)

Later, on the basis of large laboratory data, Kriebel et al. [1986] found the value of 2.3 rather than 0.85 in Equation (87.8a) and Equation (87.8b).

87.4 Longshore Sediment Transport

The longshore transport (Q) is the volumetric rate of sand movement parallel to the shoreline. Much longshore transport occurs in the surf zone and is caused by the approach of waves at an angle to the shoreline.

FIGURE 87.4 Visual definition of terms describing a typical beach profile. (Source: Department of the Army. 1987. *Shore Protection Manual*, vols. I and II. Department of the Army, Corps of Engineers, Coastal Engineering Research Center, Waterways Experiment Station, Vicksburg, MS.)

FIGURE 87.5 Beach profile scale factor, A , versus sediment diameter, D , in relationship $h = Ax^{2/3}$. (Source: Dean, R. G. 1991. Beach profiles. In *Handbook of Coastal and Ocean Engineering, Volume 2*, ed. J. B. Herbich. Gulf, Houston. Copyright 1990 by Gulf Publishing Company, Houston. Used with permission. All rights reserved.)

Longshore transport rate (Q , given in unit volume per second) is assumed to depend upon the longshore component of wave energy flux, P_l (Department of the Army, 1984):

$$Q = \frac{K}{(\rho_s - \rho)g\alpha} P_l \quad (87.9)$$

where K = dimensionless empirical coefficient (based on field measurements) = 0.39; ρ_s = density of sand; ρ = density of water; g = acceleration due to gravity; and α = ratio of the volume of solids to total volume, accounting for sand porosity = 0.6.

General Energy Flux Equation

The energy flux per unit length of wave crest or, equivalently, the rate at which wave energy is transmitted across a plane of unit width perpendicular to the direction of wave advance, is

$$P = EC_g \quad (87.10)$$

where E is wave energy density and C_g is wave group speed. The wave energy density is calculated by

$$E = \frac{\rho g H^2}{8} \quad (87.11)$$

where ρ is mass density of water, g is acceleration of gravity, and H is wave height.

If the wave crests make an angle α with the shoreline, the energy flux in the direction of wave advance per unit length of beach is

$$P \cos \alpha = \frac{\rho g H^2}{8} C_g \cos \alpha \quad (87.12)$$

The longshore component of wave energy flux is

$$P_l = P \cos \alpha \sin \alpha = \frac{\rho g H^2}{8} C_g \cos \alpha \sin \alpha \quad (87.13)$$

FIGURE 87.6 Threshold of sand movement by waves with Shields, Sleath, and Tsuchiya empirical curves, as well as the theoretical curve. (Source: Tsuchiya, Y. 1991. Threshold of sand movement. In *Handbook of Coastal and Ocean Engineering, Volume 2*, ed. J. B. Herbich. Gulf, Houston. Copyright 1990 by Gulf Publishing Company, Houston. Used with permission. All rights reserved.)

or

$$P_l = \frac{\rho g}{16} H^2 C_g \sin 2\alpha \quad (87.14)$$

Threshold of Sand Movement by Waves

The threshold of sand movement by wave action has been investigated by a number of researchers [e.g., Tsuchiya, 1991]. Figure 87.6 shows the modified Shields diagram, where $\tau_{*c} = 1/\epsilon \psi_l(D_{v*})$, and $\psi_l(D_{v*})$ is a function of sediment-fluid number only, plotted as a function of D_{v*} .

The empirical formula shown by dashed lines is as follows:

$$\begin{aligned} \tau_{*c} &= 0.20 && \text{for } D_{v*} \leq 1 \\ &= 0.20 D_{v*}^{-2/3} && \text{for } 1 \leq D_{v*} \leq 20 \\ &= 0.010 D_{v*}^{1/5} && \text{for } 20 \leq D_{v*} \leq 125 \\ &= 0.050 && \text{for } 125 \leq D_{v*} \end{aligned} \quad (87.15)$$

87.5 Coastal Structures

Wave forces act on coastal and offshore structures; the forces may be classified as due to non-breaking, breaking, and broken waves. Fixed coastal structures include:

1. Wall-type structures such as **seawalls**, bulkheads, revetments, and certain types of breakwaters
2. Pile-supported structures such as piers and offshore platforms
3. Rubble structures such as breakwaters, **groins**, and revetments

Seawalls

Forces due to nonbreaking waves may be calculated using Sainflou or Miche–Rundgren formulas. Employing the Miche–Rundgren formula, the pressure distribution is

FIGURE 87.7 Pressure distributions for nonbreaking waves. (Source: Department of the Army, 1987. *Shore Protection Manual*, vols. I and II. Department of the Army, Corps of Engineers, Coastal Engineering Research Center, Waterways Experiment Station, Vicksburg, MS.)

$$p_1 = \left(\frac{1 + \chi}{2} \right) \frac{\gamma H_i}{\cosh(2\pi h / L)} \quad (87.16)$$

where χ = wave reflection coefficient; γ = unit weight of water; H_i = incident wave height; h = water depth; and L = wavelength.

Figure 87.7 shows the pressure distribution at a vertical wall at the crest and trough of a clapotis.

Forces due to breaking waves may be estimated by Minikin and Goda methods. The Minikin method described by the Department of the Army [1984] estimates the maximum pressure (assumed to act on the SWL) to be:

$$p_m = 101\gamma \frac{H_b}{L_D} \frac{d_s}{D} (D + d_s) \quad (87.17)$$

where p_m is the maximum dynamic pressure, H_b is the breaker height, d_s is the depth at the toe of the wall, D is the depth one wavelength in front of the wall, and L_D is the wavelength in water depth D . The distribution of dynamic pressure is shown in Figure 87.8. The pressure decreases parabolically from p_m at the WL to zero at a distance of $H_b/2$ above and below the SWL. The force represented by the area under the dynamic pressure distribution is

$$R_m = \frac{p_m H_b}{3} \quad (87.18)$$

Goda's method [1985] assumes a trapezoidal pressure distribution (Figure 87.9). The pressure extends to a point measured from SWL at a distance given by η^* :

$$\eta^* = 0.75(1 + \cos \beta) H_{\max} \quad (87.19)$$

in which β denotes the angle between the direction of wave approach and a line normal to the breakwater. The wave pressure at the wall is given by

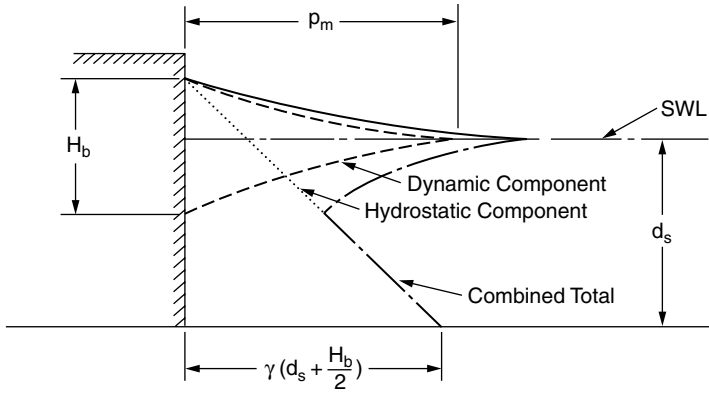

FIGURE 87.8 Minikin wave pressure diagram. (Source: Department of the Army, 1987. *Shore Protection Manual*, vols. I and II. Department of the Army, Corps of Engineers, Coastal Engineering Research Center, Waterways Experiment Station, Vicksburg, MS.)

FIGURE 87.9 Distribution of wave pressure on an upright section of a vertical breakwater. (Source: Goda, Y. 1990. Random wave interaction with structures. In *Handbook of Coastal and Ocean Engineering, Volume 1*, ed. J. B. Herbich. Gulf, Houston. Copyright 1990 by Gulf Publishing Company, Houston. Used with permission. All rights reserved.)

$$p_1 = \frac{1}{2}(1 + \cos\beta)(\alpha_1 + \alpha_2 \cos^2\beta)\gamma H_{\max} \quad (87.20)$$

$$p_2 = \frac{p_1}{\cosh(2\pi h/L)} \quad (87.21)$$

$$p_3 = \alpha_3 p_1 \quad (87.22)$$

in which

$$\alpha_1 = 0.6 + 0.5 \left[\frac{4\pi h/L}{\sinh(4\pi h/L)} \right]^2 \quad (87.23)$$

$$\alpha_2 = \min \left[\frac{h_b - d}{3h_b} \left(\frac{H_{\max}}{d} \right)^2, \frac{2d}{H_{\max}} \right] \quad (87.24)$$

FIGURE 87.10 Rubble-mound section for wave exposure on both sides with moderate overtopping conditions. (Source: Department of the Army, 1987. *Shore Protection Manual*, vols. I and II. Department of the Army, Corps of Engineers, Coastal Engineering Research Center, Waterways Experiment Station, Vicksburg, MS.)

$$\alpha_3 = 1 - \frac{h'}{h} \left[1 - \frac{1}{\cosh(2\pi h / L)} \right] \quad (87.25)$$

Breakwaters

Rubble-mound breakwaters are the oldest form of breakwaters, dating back to Roman times. The rubble mound is protected by larger rocks or artificial concrete units. This protective layer is usually referred to as **armor** or cover layer.

$$W = \frac{\gamma_r H^3}{K_D (S_r - 1)^3 \cot \theta} \quad (87.26)$$

where W = weight in newtons or pounds of an individual armor unit in the primary cover layer; γ_r = unit weight (saturated surface dry) of armor unit in N/m^3 or lb/ft^3 ; S_r = specific gravity of armor unit, relative to the water at the structure ($S_r = w_r / w_w$); w_w = unit weight of water: freshwater = 9800 N/m^3 (62.4 lb/ft^3); seawater = $10,047 \text{ N/m}^3$ (64.0 lb/ft^3); θ = angle of structure slope measured from horizontal in degrees; and K_D = stability coefficient that varies primarily with the shape of the armor units, roughness of the armor unit surface, sharpness of edges, and degree of interlocking obtained in placement.

Figure 87.10 presents the recommended three-layer section of a rubble-mound breakwater. Note that underlayer units are given in terms of W , the weight of armor units.

Automated coastal engineering system (ACES) describes the computer programs available for the design of breakwaters using Hudson and related equations.

Van der Meer [1987] developed stability formulas for plunging (breaking) waves and for surging (nonbreaking) waves. For plunging waves,

$$H_s / \Delta D_{n50} * \sqrt{\xi_z} = 6.2 P^{0.18} (S / \sqrt{N^{0.2}}) \quad (87.27)$$

For surging waves,

$$H_s / \Delta D_{n50} = 1.0 P^{-0.13} (S / \sqrt{N^{0.2}}) \sqrt{\cot \alpha} \xi_z^P \quad (87.28)$$

where

H_s = **significant wave height** at the toe of the structure

FIGURE 87.11 Influence of slope angle. (Source: Van der Meer, J. W. 1990. Rubble mounds — Recent modifications. In *Handbook of Coastal and Ocean Engineering, Volume 1*, ed. J. B. Herbich. Gulf, Houston, TX. Copyright 1990 by Gulf Publishing Company, Houston, TX. Used with permission. All rights reserved.)

$$\xi_z = \text{surf similarity parameter, } \xi_z = \frac{\tan \alpha}{\sqrt{2\pi H_s / g T_z^2}}$$

T_z = zero up-crossing wave period

α = slope angle

Δ = relative mass density of the stone, $\Delta = \rho_a / (\rho - 1)$

ρ_a = mass density of the stone

ρ = mass density of water

D_{n50} = nominal diameter of the stone, $D_{n50} = (W_{50} / \rho_a)^{1/3}$

W_{50} = 50% value (median) of the mass distribution curve

P = permeability coefficient of the structure

S = damage level, $S = A / D_{n50}^2$

A = erosion area in a cross-section

N = number of waves (storm duration)

Influence of breakwater slope angle is depicted in Figure 87.11.

87.6 Navigational Channels

The development of very large commercial craft (VLCC) and ultralarge commercial craft (ULCC) forced many government planners and port managers to evaluate existing channels. Navigational channels allow large vessels to reach harbors. Of paramount design consideration is the safety of vessels in a channel, particularly when passing [Herbich, 1992].

Vessel behavior in channels is a function of bottom suction, bank suction, interference of passing ships, waves, winds, and currents. Most major maritime countries have criteria regarding the depth and width of channels. The international commission ICORELS (sponsored by the Permanent International Association of Navigation Congresses — PIANC) recommends that general criteria for gross underkeel clearances can be given for drawing up preliminary plans:

TABLE 87.2 General Criteria for Channel Widths

| Location | Minimum Channel Width in Percent of Beam | | | |
|------------------------------------|--|---------|---------|------------------------------|
| | Vessel Controllability | | | Channels with Yawing Forces |
| | Very Good | Good | Poor | |
| Maneuvering lane, straight channel | 160 | 180 | 200 | Judgment ^a |
| Bend, 26° turn | 325 | 370 | 415 | Judgment ^a |
| Bend, 40° turn | 385 | 440 | 490 | Judgment ^a |
| Ship clearance | 80 | 80 | 80 | 100 but not less than 100 ft |
| Bank clearance | 60 | 60 plus | 60 plus | 150 |

^a Judgment will have to be based on local conditions at each project.

Source: U.S. Army Corps of Engineers. 1983. *Engineering Manual: Hydraulic Design of Deep Draft Navigation Projects*, EM 1110-2-1613. U.S. Army Corps of Engineers, Washington, DC.

- *Open sea area.* When exposed to strong and long stern or quarter swells where speed may be high, the gross underkeel clearance should be about 20% of the maximum draft of the large ships to be received.
- *Waiting area.* When exposed to strong or long swells, the gross underkeel clearance should be about 15% of the draft.
- *Channel.* For sections exposed to long swells, the gross underkeel clearance should be about 15% of the draft.

The *Engineering Manual* [U.S. Army Corps of Engineers, 1983] provides guidance for the layout and design of deep-draft navigation channels. Table 87.2 provides the general criteria for channel widths.

87.7 Marine Foundations

Design of marine foundations is an integral part of any design of marine structures. The design criteria require a thorough understanding of marine geology; geotechnical properties of sediments at a given location; and wind, wave, currents, tides, and surges during maximum storm conditions. In the arctic areas information on fast ice and pack ice is required for the design of offshore structures (on artificial islands) and offshore pipelines.

A number of soil engineering parameters are required, as shown in [Table 87.3](#). Many of the properties may be obtained employing standard geotechnical methods. Geotechnical surveys and mapping of seabed characteristics have reached a high degree of sophistication. High-resolution geophysical surveys determine water depth, seafloor imagery, and vertical profiles. Bottom-mapping systems include multibeam bathymetry, sea beam, side-scan sonars, and subbottom profilers (including shallow, medium, and deep penetration types).

The geotechnical investigation is designed to include sediment stratigraphy; sediment types; and sediment properties, including density, strength, and deformational characteristics. Deployment systems employed for sampling *in situ* include self-contained units, drilling rigs, and submersibles. ([Figure 87.12](#) shows the deployment systems.)

There are many *in situ* testing devices; these include the vane shear test, cone penetrometer test, pressure meter, shear vane velocity tools, temperature probes, natural gamma logger, and so forth [Young, 1991].

87.8 Oil Spills

The best method of controlling oil pollution is to prevent oil spills in the first place. This may include such techniques as rapid removal of oil from stricken tankers, continuous monitoring of oil wells, killing wild wells at sea, and containing oil spills under the water surface. Spilled oil, being lighter than water, floats on the water surface and spreads laterally. As oil is spilled, several regimes are generally assumed:

TABLE 87.3 Soil Engineering Parameters Normally Required for Categories of Geotechnical Engineering Applications

| Application | Soil Classification | Grain Size | Atterberg Limits | Strength Properties | | | | Common Properties | | | Subbottom Depth of Survey |
|--------------------------|---------------------|------------|------------------|---------------------|------------------|---------|-----------------|-------------------|-------|-------|---|
| | | | | Clay | | Sand | | Clay | | Sand | |
| | | | | S_u, S_t | \bar{c}, ϕ' | ϕ' | ϕ or S_u | C_v, k | C_c | C_c | |
| Shallow foundation | Yes | Yes | Yes | Yes | Yes | Yes | Yes | Yes | Yes | Yes | 1.5 to 2 × foundation width |
| Deadweight anchors | Yes | No | No | Yes | Yes | Yes | No | No | No | No | 1.5 to 2 × anchor width |
| Deep pile foundations | Yes | Yes | Yes | Yes | Yes | Yes | No | Yes | Yes | No | 1 to 1.5 × pile group width, below individual pile tips |
| Pile anchors | Yes | Yes | Yes | Yes | Yes | Yes | No | No | No | No | To depth of pile anchor |
| Direct-embedment anchors | Yes | Yes | No | Yes | Yes | Yes | Yes | Yes | No | No | To expected penetration of anchor, maximum 33 to 50 ft clay; 13 to 33 ft sand |
| Drag anchors | Yes | Yes | No | Yes | No | No | No | No | No | No | 33 to 50 ft clay; 10 to 16½ ft sand for large anchors |
| Penetration | Yes | Yes | No | Yes | No | Yes | Yes | No | No | No | 33 to 50 ft clay; 13 to 33 ft sand |
| Breakout | Yes | Yes | Yes | Yes | Yes | Yes | Yes | No | No | No | 1 × object width plus embedment depth |
| Scour | Yes | Yes | No | Yes | No | No | No | No | No | No | 3.3 to 16½ ft; related to object size and water motion |
| Slope stability | Yes | Yes | Yes | Yes | Yes | Yes | No | No | No | No | 33 to 100 ft; more on rare occasions |

Note: S_u = undrained shear strength; S_t = sensitivity; \bar{c} = drained cohesion intercept; ϕ' = drained friction angle; ϕ = undrained friction angle for sands rapidly sheared; C_v = coefficient of consolidation; k = permeability; C_c = compression index.

FIGURE 87.12 Deployment systems used for sampling, in situ, and experimental testings. (Source: Marine Board, National Research Council. 1989. *Our Seabed Frontier — Challenges and Choices*, National Academy Press, Washington, DC.)

gravity-inertial, gravity-viscous, and surface tension. In the early stage, generally less than 1 h, the gravity-inertial regime, or inertial spread, dominates and is described by

$$R = k_4 (\Delta g L t^2)^{1/4} \tag{87.29}$$

where R = radius of the oil slick; k_4 = nondimensional coefficient experimentally determined to be 1.14; Δ = the ratio of the absolute difference between the densities of sea water and the oil to that of seawater; g = force of gravity; L = original volume of oil spilled; and t = time.

When the oil film thickness becomes equal to the viscous layer in the water, a transition occurs from the gravity-inertial regime to the gravity-viscous regime. This viscous spreading is described by

$$\text{Radius of oil stock} = R = k_5 \left(\frac{\Delta g L^2 t^{3/2}}{\nu^{1/2}} \right)^{1/6} \tag{87.30}$$

where k_5 is the nondimensional coefficient determined to be about 1.45, ν is the kinematic viscosity of water, Δ is the ratio of the difference between density of seawater and oil, L is the original volume of spilled oil, and t is the time.

The last phase, the surface tension regime, occurs when the oil film thickness drops below a critical level, which is a function of the net surface tension, the mass densities of the oil and the water, and the force of gravity. The surface tension spread is described by

$$R = k_6 \left(\frac{\sigma^2 t^3}{\rho^2 \nu} \right)^{1/4} \quad (87.31)$$

where $k_6 = 2.30$, experimentally determined; σ = surface tension; and ρ = density of water.

For large spills, on the order of 10,000 tons, inertial and viscous spreading will dominate for about the first week, with the surface tension spread controlling thereafter.

Although the exact mechanisms that cause the termination of spreading are unknown, the terminal areas of several oil slicks have been observed and used to determine an analytical relationship for the maximum area of a given oil spill based on the properties of the oil. This is described by

$$A_T = K_a \left(\frac{\sigma^2 V^6}{\rho^2 \nu D^3 s^6} \right)^{1/8} \quad (87.32)$$

where K_a = undetermined constant or order unit; V = volume of oil that can be dissolved in this layer; D = diffusivity; and s = solubility of the significant oil fractions in the water.

In addition, the area covered by the oil slick is not allowed to exceed A_T ; therefore, spreading is terminated at the time

$$t = \left(\frac{V\rho}{s\sigma} \right)^{1/2} \left(\frac{\nu}{D} \right)^{1/4} \left(\frac{K_a}{\pi k_6^2} \right)^{2/3} \quad (87.33)$$

Oil may be set up by wind and current against a barrier; any containment device must take the setup estimates into account. There are a number of containment devices (barriers) that prevent oil from spreading. Most mechanical-type oil containment barriers fail in wave heights greater than 2 ft, when the wave steepness ratio is greater than 0.08, and in currents normal to the barrier greater than about 0.7 knots.

Oil may also be removed from the water surface by skimming devices. Most mechanical skimming devices have only been able to work in waves less than 2 to 3 ft in height, in moderate currents.

87.9 Offshore Structures

Many types of offshore structures have been developed since 1947, when the first steel structure was installed in 18 feet of water. Since that time over 4100 template-platforms have been constructed on the U.S. continental shelf in water depths less than 600 feet (Figure 87.13).

Deep-water marine structures include gravity platforms, fixed platforms, guyed tower, tension-leg platform, and a buoyant compliant tower (Figure 87.14).

Wave forces on certain types of offshore platforms are computed by the Morrison equation, which is written as the sum of two individual forces, inertia and drag. The equation may be written as

$$f(t) = C_M \rho \frac{\pi}{4} D^2 \dot{u}(t) + \frac{1}{2} C_D \rho D |u(t)| u(t) \quad (87.34)$$

The force, f , as a function of time, t , is written as a function of the horizontal water particle velocity, $u(t)$, and the horizontal water particle acceleration, $\dot{u}(t)$, at the axis of the cylinder, and is dependent on

FIGURE 87.13 Template-type pile foundation structure. (Source: Young, A. G. 1991. Marine foundation studies. In *Handbook of Coastal and Ocean Engineering, Volume 2*, ed. J. B. Herbich. Gulf, Houston. Copyright 1990 by Gulf Publishing Company, Houston. Used with permission. All rights reserved.)

FIGURE 87.14 Range of water depths for various types of deep-water marine structures. (Source: Marine Board, National Research Council. 1989. *Our Seabed Frontier — Challenges and Choices*, National Academy Press, Washington, DC.)

the water density, ρ . The quantities C_M and C_D are defined as the inertia (or mass) coefficient and the drag coefficient, respectively.

The design and dynamic analysis of offshore platforms, which include jacket structures, topside structures, pile foundations, and dynamic analysis, may be found in Hsu [1991]; discussion of wave forces is given in Chakrabarti [1991].

Defining Terms

Armor unit — A relatively large quarry stone or concrete shape that is selected to fit specified geometric characteristics and density. It is usually of nearly uniform size and usually large enough to require individual placement. In normal cases it is used as primary wave protection and is placed in thicknesses of at least two units.

Artificial nourishment — The process of replenishing a beach with material (usually sand) obtained from another location.

Attenuation — (1) A lessening of the amplitude of a wave with distance from the origin. (2) The decrease of water-particle motion with increasing depth. Particle motion resulting from surface oscillatory waves attenuates rapidly with depth and practically disappears at a depth equal to a surface wavelength.

Bar — A submerged or emerged embankment of sand, gravel, or other unconsolidated material built on the sea floor in shallow water by waves and currents.

Diffraction — The phenomenon by which energy is transmitted laterally along a wave crest. When a part of a train of waves is interrupted by a barrier, such as a breakwater, the effect of diffraction is manifested by propagation of waves into the sheltered region within the barrier's geometric shadow.

Dunes — (1) Ridges or mounds of loose, wind-blown material, usually sand. (2) Bed forms smaller than bars but larger than ripples that are out of phase with any water-surface gravity waves associated with them.

Ebb current — The tidal current away from shore or down a tidal stream, usually associated with the decrease in height of the tide.

Fetch — The area in which seas are generated by a wind having a fairly constant direction and speed. Sometimes used synonymously with *fetch length* or *generating area*.

Flood current — The tidal current toward shore or up a tidal stream, usually associated with an increase in the height of the tide.

Groin — A shore protection structure built (usually perpendicular to the shoreline) to trap littoral drift or retard erosion of the shore.

Harbor oscillation (harbor surging) — The nontidal vertical water movement in a harbor or bay. The vertical motions are usually low, but when oscillations are excited by a tsunami or storm surge, they may be quite large. Variable winds, air oscillations, or surf beat also may cause oscillations. See **seiche**.

Hurricane — An intense tropical cyclone in which winds tend to spiral inward toward a core of low pressure, with maximum surface wind velocities that equal or exceed 33.5 meters per second (75 mph or 65 knots) for several minutes or longer at some points. *Tropical storm* is the term applied if maximum winds are less than 33.5 meters per second.

Mean high water (MHW) — The average height of the high waters over a 19-year period. For shorter periods of observations, corrections are applied to eliminate known variations and reduce the results to the equivalent of a mean 19-year value.

Probable maximum water level — A hypothetical water level (exclusive of wave run-up from normal wind-generated waves) that might result from the most severe combination of hydrometeorological, geoseismic, and other geophysical factors and that is considered reasonably possible in the region involved, with each of these factors considered as affecting the locality in a maximum manner. This level represents the physical response of a body of water to maximum applied

phenomena such as hurricanes, moving squall lines, other cyclonic meteorological events, tsunamis, and astronomical tide, combined with maximum probable ambient hydrological conditions such as wave setup, rainfall, runoff, and river flow. It is a water level with virtually no risk of being exceeded.

Refraction — (1) The process by which the direction of a wave moving in shallow water at an angle to the contours is changed. The part of the wave advancing in shallower water moves more slowly than that part still advancing in deeper water, causing the wave crest to bend toward alignment with the underwater contours. (2) The bending of wave crests by currents.

Scour — Removal of underwater material by waves and currents, especially at the base or toe of a shore structure.

Seawall — A structure separating land and water areas, primarily designed to prevent erosion and other damage due to wave action.

Seiche — (1) A standing wave oscillation of an enclosed water body that continues, pendulum fashion, after the cessation of the originating force, which may have been either seismic or atmospheric. (2) An oscillation of a fluid body in response to a disturbing force having the same frequency as the natural frequency of the fluid system. Tides are now considered to be seiches induced primarily by the periodic forces caused by the sun and moon.

Significant wave — A statistical term relating to the one-third highest waves of a given wave group and defined by the average of their heights and periods. The composition of the higher waves depends upon the extent to which the lower wave are considered.

Wave spectrum — In ocean wave studies, a graph, table, or mathematical equation showing the distribution of wave energy as a function of wave frequency. The spectrum may be based on observations or theoretical considerations. Several forms of graphical display are widely used.

88.3 Water Treatment Processes

Coagulation • Mechanisms of Destabilization • Solution
Chemistry • Flocculator Design • Sedimentation • Filtration

The goal of drinking water treatment is to provide a water supply that is both safe and pleasing to consume. To meet this goal, conventional water treatment plants utilize the physicochemical processes of coagulation, sedimentation, filtration, and disinfection. The following sections will review the important aspects of water quality, drinking water regulations, and the main processes in conventional water treatment.

88.1 Water Quality

Microbial Contamination

Microorganisms present in water supplies can cause immediate and serious health problems. Infections by bacteria, viruses, and protozoa usually cause gastrointestinal distress; however, some, such as the bacterium *Vibrio cholerae*, can result in death. The protozoa *Giardia lamblia* and *Cryptosporidium* form chlorine-resistant cysts, and just a few cysts can cause disease. Beyond these, a vast number of pathogenic organisms exist, and water suppliers cannot feasibly monitor for all of them. Therefore, they monitor for **indicator organisms** instead. The total coliform group of bacteria is the most common indicator. Unfortunately, some pathogens (e.g., viruses and protozoa) are more resistant to conventional water treatment processes than are total coliforms.

Chemical Contamination

Inorganic Contaminants

Toxic metals and other inorganic compounds contaminate water supplies from both human-made and natural sources. Nitrates, common in groundwaters, cause methemoglobinemia or “blue-baby syndrome” in infants. Fluoride, added by many water suppliers in small doses to prevent tooth decay, causes a

weakening of the bones called *skeletal fluorosis* at concentrations above 4 mg/L. Radon, a naturally occurring radionuclide, may cause lung cancer from long-term exposures in the air after being released from water.

Organic Contaminants

Most organic contaminants are either volatile organic chemicals (VOCs) or synthetic organic chemicals (SOCs). Dissolved VOCs transfer to the gas phase when exposed to the atmosphere. They are typically found in groundwaters that have been contaminated by leaks from industrial storage facilities. Examples include trichloroethylene (TCE) and tetrachloroethylene (PCE), both probable carcinogens. SOCs are more soluble in water and include pesticides and pollutants from leaking underground gasoline storage tanks, such as benzene and toluene. The health effects of SOCs range from central nervous system damage to cancer.

Aesthetic Aspects of Water Quality

Color and Turbidity

Inorganic metals such as iron and organic compounds such as natural organic matter (NOM) cause color. In addition to being aesthetically undesirable, color in the form of NOM is a precursor to the formation of **disinfection by-products (DBPs)**, which may cause cancer. Turbidity is the cloudiness of a water and is determined by measuring the amount of light scattered by suspended particles in water. The unit of turbidity is the nephelometric turbidity unit (NTU). Although not a direct threat to health, turbidity decreases the efficiency of disinfection, and particles that cause turbidity can transport harmful chemicals through a treatment plant.

Taste and Odor

Zinc, copper, iron, and manganese can be detected by taste at concentrations of 1 mg/L. Hydrogen sulfide, a common contaminant in groundwaters, is detectable at concentrations of 100 ng/L. Many tastes and odors in surface waters result from biological activity of filamentous bacteria and blue-green algae. These organisms produce geosmin and methylisoborneol (MIB), which cause an earthy or musty smell. Both are detected at concentrations of 10 ng/L [Tate and Arnold, 1990].

Alkalinity

Alkalinity is a measure of the buffering capacity of a water. Alkalinity determines the magnitude of pH changes during coagulation and affects the solubility of calcium carbonate in the distribution system. In natural waters the carbonate system dominates alkalinity. In such systems, bicarbonate (HCO_3^-), carbonate (CO_3^{2-}), and hydroxide (OH^-) ions are the major species of alkalinity.

Temperature and pH

Temperature and pH affect coagulation, disinfection, and corrosion control. Equilibrium constants and reaction rates vary with temperature. The hydrogen ion concentration, measured as pH, is an important chemical species in these processes. Furthermore, the density and viscosity of water vary with temperature; thus, it is an important variable in the design of mixing, flocculation, sedimentation, and filtration process units.

88.2 Drinking Water Regulations

In the U.S., the Environmental Protection Agency (EPA) sets standards to regulate drinking water quality. Typically, the EPA establishes a maximum contaminant level goal (MCLG) and a maximum contaminant level (MCL) for each contaminant. An MCLG is the level at which no adverse health effect occurs. An MCL is set as close to the MCLG as is economically and technically feasible. A primary MCL is a legally enforceable standard based on a potential health risk. A secondary MCL is a nonenforceable standard based on a potential adverse aesthetic effect. [Table 88.1](#) lists some MCLs of important drinking water contaminants.

TABLE 88.1 Some Drinking Water Standards

| Contaminant | MCL ^a | Sources |
|----------------------------------|----------------------|---|
| Arsenic | 0.05 | Geological, pesticide residues; industrial waste and smelter operations |
| Asbestos | 7 mfl ^b | Natural mineral deposits; also in asbestos/cement pipe |
| Benzene | 0.005 | Fuel (leaking tanks); solvent commonly used in manufacture of industrial chemicals, pharmaceuticals, pesticides, paints, and plastics |
| Cadmium | 0.005 | Natural mineral deposits; metal finishing; corrosion product plumbing |
| Chromium | 0.1 | Natural mineral deposits; metal finishing; textile, tanning, and leather industries |
| Mercury | 0.002 | Industrial/chemical manufacturing; fungicide; natural mineral deposits |
| Nitrate (as N) | 10 | Fertilizers, feedlots, sewage; naturally in soil, mineral deposits |
| Polychlorinated biphenyls (PCBs) | 0.0005 | Electric transformers, plasticizers; banned in 1979 |
| Radium 226/228 | 5 pCi/L ^c | Radioactive waste; geological/natural |
| Tetrachloroethylene (PCE) | 0.005 | Dry cleaning; industrial solvent |
| Toluene | 1 | Chemical manufacturing; gasoline additive; industrial solvent |
| Trichloroethylene (TCE) | 0.005 | Waste from disposals of dry cleaning materials and manufacturing of pesticides, paints, waxes, and varnishes; paint stripper; metal degreaser |

^a Maximum contaminant level, in milligrams per liter unless otherwise noted.

^b Million fibers per liter, with fiber length greater than 10 μm .

^c Picocurie (pCi) is the quantity of radioactive material producing 2.22 nuclear transformations per minute.

Source: U.S. Environmental Protection Agency, 1991. *Fact Sheet: National Primary Drinking Water Standards*.

In 1974, the U.S. Congress enacted the Safe Drinking Water Act (SDWA), which was the first law to cover all public drinking water utilities in the U.S. In 1986, Congress amended the SDWA, and, as a result, in 1989 the EPA promulgated the Surface Water Treatment Rule (SWTR). The SWTR established standards for all water treatment plants that use surface water as a source. Subsequently, the EPA also modified the standards for total coliforms, lead, and copper.

Total Coliform Rule

The total coliform rule set the MCLG for total coliforms at zero. The MCL is currently based on a presence–absence test. Utilities must monitor the distribution system for total coliforms taking a specified number of samples based on the population served by the utility. No more than 5.0% of the samples taken per month should be positive for total coliforms. Small systems taking fewer than 40 samples per month can have no more than one positive sample.

Surface Water Treatment Rule

Turbidity

Filtered water turbidity must never exceed 5 NTU and should meet the MCL in 95% of the samples taken either continuously or every 4 h. The MCL is either 0.5 or 1.0 NTU depending on the type of filter used. For conventional and direct filtration the MCL is 0.5 NTU.

Disinfectant Residual

The disinfectant concentration or residual entering the distribution system cannot be less than 0.2 mg/L for more than 4 h. A disinfectant residual must be detectable in 95% of the samples taken monthly at consumers' taps for 2 consecutive months.

Treatment Techniques

Instead of setting an MCL for the pathogens *Giardia lamblia* and viruses, the U.S. EPA specified a treatment technique, that is, disinfection and possibly filtration. To ensure the required disinfection, utilities must determine *CT* values, where *C* is the concentration of disinfectant and *T* is the contact time

between disinfectant and water. The *CT* value required for *Giardia lamblia* corresponds to 99.9% (3 log) removal or inactivation, and for viruses it corresponds to 99.99% (4 log) removal or inactivation. Filtration must be practiced unless the utility demonstrates that adequate treatment occurs without it and that the water source is free from significant contamination. Conventional filtration plants receive a *CT* credit of 2.5 log removal for *Giardia lamblia* and 2.0 log removal of viruses.

Lead and Copper Rule

The EPA also specified a treatment technique for lead and copper. However, in this case, the treatment technique need not be implemented unless an action level is exceeded. Action levels of 0.015 mg/L for lead and 1.3 mg/L for copper are set at the consumer's tap. If these action levels are exceeded during an extensive sampling program, the utility must perform a corrosion control study to determine the best technique to minimize the corrosivity of the water entering the distribution system.

Future Regulations

At present, no regulation exists regarding the protozoa *Cryptosporidium*, in part because of a lack of technical information about the organism. The EPA is in the process of collecting this information. Regulations are also expected in the near future for DBPs. The EPA is expected to lower the MCLs for total trihalomethanes (THMs) from 0.10 to 0.08 mg/L and to set MCLs for total haloacetic acids at 0.04 mg/L. In addition, removals of total organic carbon, a precursor to DBP formation, are to be specified under an Enhanced Surface Water Treatment Rule.

88.3 Water Treatment Processes

Figure 88.1 shows the treatment processes in a conventional surface water treatment plant. After being withdrawn from a source (lake or river), raw water is a suspension of small, stable colloidal particles whose motions are governed by molecular diffusion. In coagulation these particles are destabilized by the addition of a coagulant during rapid mixing. Flocculation promotes the collisions of these unstable particles to produce larger particles called *flocs*. In sedimentation, these flocs settle under the force of gravity. The particles that do not settle are removed during filtration. A disinfectant such as chlorine is then added, and, after a certain amount of contact time, the treated water is distributed to consumers. Direct filtration plants omit the sedimentation and occasionally the flocculation processes. These plants are suitable for raw waters with low to moderate turbidities and low color. The following sections describe

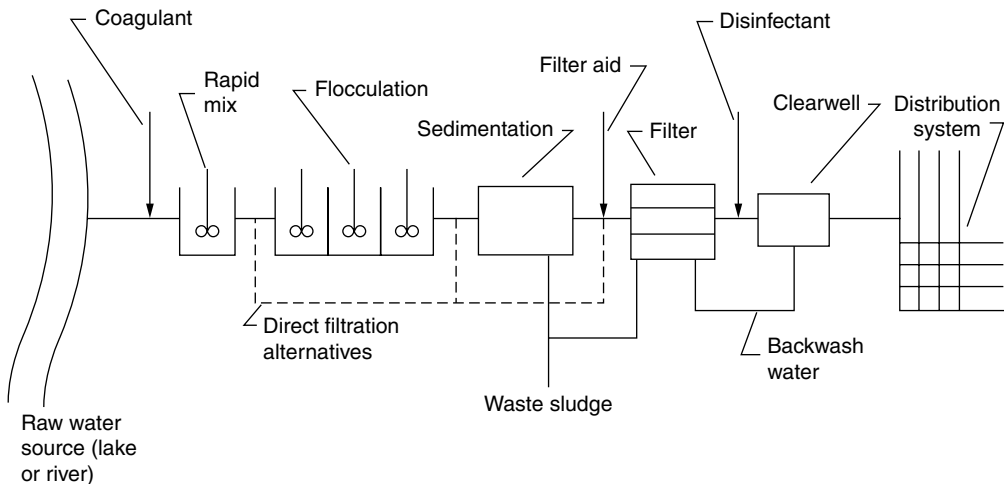

FIGURE 88.1 Schematic of a conventional water treatment plant.

the underlying theory and design of each of the major processes: coagulation, sedimentation, filtration, and disinfection.

Coagulation

In coagulation, small particles combine into larger particles. Coagulation consists of three separate and sequential processes: coagulant formation, particle destabilization, and interparticle collisions. The first two steps occur during rapid mixing, whereas the third occurs during flocculation. In natural waters, particles (from 10 nm to 100 μm in size) are stable, because they have a negative surface charge.

Mechanisms of Destabilization

The possible mechanisms of particle destabilization are double layer compression, polymer bridging, **charge neutralization**, and **sweep coagulation**. In water treatment the last two mechanisms predominate; however, when organic polymers are used as coagulants, polymer bridging can occur. In charge neutralization the positively charged coagulant, either the hydrolysis species of a metal salt (alum or ferric chloride) or polyelectrolytes, adsorbs onto the surface of the negatively charged particles. As a result, the particles have no net surface charge and are effectively destabilized. In sweep coagulation a metal salt is added in concentrations sufficiently high to cause the precipitation of a metal hydroxide (e.g., aluminum hydroxide). The particles are enmeshed in the precipitate, and it “sweeps” the particles out of the water as it forms and settles.

Solution Chemistry

With metal salt coagulants, the mechanism of coagulation is determined by the coagulant dose and the pH of the equilibrated solution. The most common coagulant is alum [$Al_2(SO_4)_3 \cdot 14.3 H_2O$]. The alum coagulation diagram, shown in Figure 88.2, indicates the regions where each mechanism dominates. A

FIGURE 88.2 The alum coagulation diagram that defines the mechanism of coagulation based on pH and alum dose. (Source: Amirtharajah, A. and Mills, K. M. 1982. Rapid mix design for mechanisms of alum coagulation. *J. AWWA*. 74(4):210–216.)

similar diagram exists for ferric chloride [Amirtharajah and O'Melia, 1990]. Important considerations in using the alum coagulation diagram are that the boundaries of the restabilization zone vary with the surface area of the raw water particles and that significant concentrations of NOM rather than turbidity can control the alum dose required for effective treatment.

Rapid Mix Design

At a fundamental level the rapid-mixing unit provides encounters between molecules and particles in the source water and the coagulant species. These encounters are controlled by the hydrodynamic parameters and geometry of the mixer, molecular properties of the source water, and the kinetics of the coagulation reactions. Research indicates that coagulation by sweep coagulation is insensitive to mixing intensity. Although its applicability is questionable on theoretical grounds, the **G-value** is widely used to represent mixing intensity in both rapid mix and flocculation units. The *G*-value is computed as

$$G = \sqrt{\frac{P}{\mu V}} = \sqrt{\frac{\epsilon}{\nu}} \quad (88.1)$$

where *G* is the velocity gradient (sec^{-1}), *P* is the *net* power input to the water (W), μ is the dynamic viscosity of water ($\text{N} \cdot \text{sec}/\text{m}^2$), *V* is the mixing volume (m^3), ϵ is the rate of energy dissipation per mass of fluid (W/kg), and ν is the kinematic viscosity (m^2/sec). Mixing time, *t*, is an important design parameter, and it can vary from less than 1 sec in some in-line mixers to over a minute in back-mix reactors. In general, short times (<1 sec) are desired for the charge neutralization mechanism and longer times (10 to 30 sec) for sweep coagulation.

Flocculator Design

In flocculation, physical processes transform smaller particles into larger aggregates or flocs. Interparticle collisions cause the formation of flocs, and increased mixing with increased velocity gradients accelerates this process. However, if the mixing intensity is too vigorous, turbulent shear forces will cause flocs to break up. Studies of the kinetics of flocculation [Argaman and Kaufman, 1970] indicate that a minimum time exists below which no flocculation occurs regardless of mixing intensity and that using tanks in series significantly reduces the overall time required for the same degree of flocculation. [Figure 88.3](#) illustrates these two conclusions. In current designs, *G*-values are tapered from one tank to the next with the highest *G*-value in the first tank and decreasing in each successive compartment. *G*-values are between 60 and 10 sec^{-1} , and total detention times are close to 20 min.

Sedimentation

During sedimentation, gravity removes the flocs produced during the preceding flocculation process. These flocs continue to aggregate as they settle, and, as a result, experimental techniques are required to describe their settling behavior. Rectangular sedimentation basins are the most common in water treatment practice. Designs are based on the overflow rate, which is the flow rate divided by the surface area. The overflow rate indicates the settling velocity of the discrete (nonflocculant) particles that are removed with 100% efficiency. Typical overflow rates are 1.25 to 2.5 m/h. Plate and tube settlers are often added to the last two thirds of a basin to increase the overflow rate by a factor of three.

Filtration

In the U.S., the most common filters are dual-media filters, in which water flows by gravity through a porous bed of two layers of granular media. The top layer is anthracite coal, and the bottom layer is sand. Filters are operated until one of two criteria is exceeded — the effluent turbidity standard or the allowable

FIGURE 88.3 A graph illustrating the benefit of tanks in series for flocculation. (Source: Argaman, Y. and Kaufman, W. J. 1970. Turbulence and flocculation. *ASCE J. Sanitary Engineering Div.* 96(SA2):223–241.)

head loss through the filter. The filters are cleaned by backwashing to remove the particles that have been collected on the filter media.

The removal of particles in a dual-media filter occurs within the pores of the filter and is mediated by transport mechanisms that carry small particles across fluid streamlines to distances close to the filter grains (also called *collectors*). When particles are very close to the collectors, short-range surface forces cause the collector to capture the particle. The dominant transport mechanisms in water filtration are diffusion and sedimentation. Diffusion is transport resulting from random Brownian motion by bombardment of the particle by molecules of water. Diffusion is increasingly important for particles less than $1\ \mu\text{m}$ in size. Sedimentation is due to the force of gravity and the associated settling velocity of the particle, which causes it to cross streamlines and reach the collector. This mechanism becomes increasingly important for particles greater than $1\ \mu\text{m}$ in size (for a size range of 5 to $25\ \mu\text{m}$). The combination of these two mechanisms results in a minimum net transport efficiency for a size of approximately $1\ \mu\text{m}$. It is interesting to extrapolate this result to two important microbial contaminants. Cysts of *Giardia lamblia*, with dimensions of 10 to $15\ \mu\text{m}$, are probably removed by the sedimentation mechanism, whereas *Cryptosporidium*, with a dimension close to 3 to $5\ \mu\text{m}$, is probably close to the minimum net transport efficiency. Unfortunately, a theory of filtration that is sufficiently general and predictive does not yet exist. Therefore, designers must rely on empirical evidence from pilot-scale tests for guidance.

Chemical Pretreatment

Evidence clearly shows that chemical pretreatment for particle destabilization is the most important variable affecting filtration efficiency. Plant-scale studies have shown that filtration rates between 5 and 15 m/h can treat water equally well given adequate chemical pretreatment.

Initial Degradation and Filter Ripening

Just after backwashing, filters typically have poor effluent quality, and the quality improves during the course of the run. The improvement with time is called *filter ripening*. Studies have shown that greater than 90% of the particles passing through a well-operated filter do so during the initial stages of filtration. If the duration of filter ripening is short, then the initial filter effluent can be wasted until the effluent turbidity reaches a desired level. Particles removed during a filter run function as collectors themselves, resulting in filter ripening.

Rate Changes

Any rate changes during filtration cause a significant deterioration of the effluent quality. The degradation in quality can be quantitatively correlated directly with the magnitude of the rate change and inversely with the duration of the rate change. This fact forms the basis for the superiority of variable declining-rate filters over the traditional constant-rate filters. In variable declining-rate filters the rate through the filter is controlled by the hydraulics of the filter; therefore, clean filters have a higher rate than dirty ones. However, in constant-rate filters, the rate is controlled by a mechanically actuated valve in the effluent piping. Each time the valve opens, the rate through the filter changes slightly, possibly causing a poorer effluent quality. With well-destabilized suspensions, the difference in effluent quality from these systems is minimal [Amirtharajah, 1988].

Polymers

Polyelectrolytes can assist in improving effluent quality when added in small amounts as a filter aid (0.1 to 1.0 mg/L) just prior to filtration. Polymers cause the attachment forces to be stronger, and, therefore, backwashing is more difficult. Polymers are important in direct-filtration plants where sedimentation and possibly flocculation are not included. However, polymers are not a substitute for adequate pretreatment.

Backwashing

In the U.S., filters have traditionally been backwashed by fluidizing the filter media for a specific period of time. However, very few particle contacts occur between fluidized particles. Hence, particulate fluidization with water alone is an intrinsically weak process. Air scour with subfluidization water wash causes abrasions between particles throughout the depth of the bed. Surface wash causes collisions at the top of the bed. Both processes are effective auxiliaries for cleaning. When polymers are used, air scour or surface wash is necessary.

Disinfection

A variety of disinfectants are available in water treatment, including chlorine, chloramines, chlorine dioxide, and ozone. In the U.S., however, chlorine is the most common disinfectant. Chlorine gas is added to water to form hypochlorous acid (HOCl). At pHs between 6 and 9, HOCl dissociates to form the hypochlorite ion (OCl^-) and hydrogen ion (H^+). HOCl has the greatest disinfection power. The extent of disinfection in a water treatment plant is determined by computing *CT* values as mentioned in Section 88.2. The *CT* value required varies with chlorine concentration, pH, and temperature.

Although increasing the *CT* value may provide a large factor of safety against microbial contamination, disinfection causes the formation of disinfection byproducts (DBPs), which are suspected carcinogens. DBPs result from reactions between disinfectants and NOM, which is ubiquitous in natural waters. The most common DBPs from chlorine are the THMs: chloroform, bromodichloromethane, dibromochloromethane, and bromoform. Other technologies such as membranes and adsorption will be used in the future, together with the traditional water treatment processes, to reduce the threat from both microorganisms and DBPs.

Defining Terms

Alkalinity — The ability of a water to resist changes in pH. Includes the following species: carbonate, bicarbonate, and hydroxide.

Charge neutralization — A mechanism of coagulation in which positively charged coagulants adsorb to the surface of negatively charged colloids. The resulting colloids, with no net surface charge, are effectively destabilized.

Disinfection byproducts (DBPs) — Byproducts that result from the reactions of disinfectants such as chlorine with the natural organic matter that is present in all natural waters. DBPs such as trihalomethanes are suspected carcinogens.

G-value — A measure of mixing intensity in turbulent mixing vessels. Used in the design of both rapid mix and flocculation units.

Indicator organisms — Easily detectable organisms that act as a surrogate for waterborne pathogens. Although not pathogenic themselves, indicators are present in the same environs as pathogens but in larger concentrations.

Sweep coagulation — A mechanism of coagulation in which particles are enmeshed in a precipitate of metal hydroxide, such as aluminum hydroxide.

- 89.1 [Control of Particulate Matter](#)
Electrostatic Precipitators • Fabric Filtration • Wet Scrubbing
- 89.2 [Control of Gaseous Pollutants](#)
Absorption Processes • Adsorption • Incineration Processes

Air pollution is defined as contamination of the atmosphere with solid particles, liquid mists, or gaseous compounds in concentrations that can harm people, plants, or animals, or reduce environmental quality. Particulate matter (PM) constitutes a major class of air pollution. Ambient (outdoor) air quality standards exist for particulate matter less than 10 μm (PM-10), and many industries have emission limits on total PM. Particles have various shapes, different chemical and physical properties, and a wide range of sizes — from less than 0.01 to over 100 μm in **aerodynamic diameter**. The major gaseous pollutants that are emitted into the air include sulfur oxides, nitrogen oxides, carbon monoxide, and volatile organic compounds (such as petroleum fuels and organic chemicals). Major sources of air pollution include combustion processes (especially fossil fuel power plants), motor vehicles, and the materials processing and petrochemical industries.

89.1 Control of Particulate Matter

Control of PM involves separation and removal of the PM from a flowing stream of air. A control device is chosen based on the size and properties (density, corrosivity, reactivity) of the particles, the chemical and physical characteristics of the gas (flow rate, temperature, pressure, humidity, chemical composition), and the collection efficiency, E , desired. The calculation of E is based on the fraction of mass removed:

$$E = (M_i - M_e)/M_i \quad (89.1)$$

where E is the collection efficiency (fraction), M is the mass flow rate of the pollutant (g/sec), and i and e are subscripts indicating the input or exit stream. The efficiency of most devices is a strong function of particle size, decreasing rapidly as particle size decreases.

A key operating parameter of most control devices is the pressure drop (ΔP). In general, to increase efficiency of a device, more energy must be expended, which often shows up as ΔP through the system. But moving the air through that ΔP can account for a major portion of the operating cost. The fan power required is given by

$$W = Q\Delta P/\eta \quad (89.2)$$

where W is the power (kW), Q is the volumetric flow rate (m^3/sec), ΔP is the pressure drop (kPa), and η = fan/motor efficiency.

TABLE 89.1 Ranges of Values for Key ESP Parameters

| Parameter | Range of Values |
|--|---|
| Drift velocity w_e | 1.0 to 10 m/min |
| Channel width D | 15 to 40 cm |
| Specific collection area (plate area/gas flow) | 0.25 to 2.1 m ² /(m ³ /min) |
| Gas velocity u | 1.2 to 2.5 m/sec (70 to 150 m/min) |
| Aspect ratio R (duct length/height) | 0.5 to 1.5 (not less than 1.0 for $\eta > 99\%$) |
| Corona power ratio P_c/Q (corona power/gas flow) | 1.75 to 17.5 W/(m ³ /min) |
| Corona current ratio I_c/A (corona current/plate area) | 50 to 750 μ A/m ² |
| Power density versus resistivity | |
| Ash Resistivity, ohm-cm | Power Density, W/m ² |
| 10^4 to 10^7 | 43 |
| 10^7 to 10^8 | 32 |
| 10^9 to 10^{10} | 27 |
| 10^{11} | 22 |
| 10^{12} | 16 |
| 10^{13} | 10.8 |
| Plate area per electrical set A_s | 460 to 7400 m ² |
| Number of electrical sections N_s | |
| a. In the direction of gas flow | 2 to 8 |
| b. Total | 1 to 10 bus sections/(1000 m ³ min) |

Cyclones are moderate-efficiency mechanical separators that depend on centrifugal force to separate PM from the air stream. These precleaners are typically much less expensive than the more efficient devices discussed herein: electrostatic precipitators, fabric filters, and wet scrubbers [Cooper and Alley, 1994].

Electrostatic Precipitators

An electrostatic precipitator (ESP) applies electrical force to separate PM from the gas stream. A high voltage drop is established between the electrodes (many sets of large plates in parallel, with vertical wires in between). The particles being carried by the gas flowing between the electrodes acquire a charge, and then are attracted to an oppositely charged plate, while the cleaned gas flows through the device. The plates are cleaned by rapping periodically, and the dust is collected in hoppers in the bottom of the device.

The classic Deutsch equation (first published in 1922) is used for preliminary design and performance evaluation:

$$E = 1 - \exp(-wA/Q) \quad (89.3)$$

where w is the drift velocity, A is the collection area, and Q is the gas volumetric flow rate, all in a consistent set of units.

In design, this equation is used to estimate the total plate area needed, and thus the size and cost of the ESP. The drift velocity, w , is a key parameter, and is a function of many variables (including the particle's diameter and resistivity, the electrical field strength, and the gas viscosity). Ranges of values of some operating and design parameters are given in Table 89.1.

The resistivity of the dust is a measure of its resistance to electrical conduction. Resistivity is very important to the design and operation of an ESP because

1. For different dusts, it can range over many orders of magnitude.

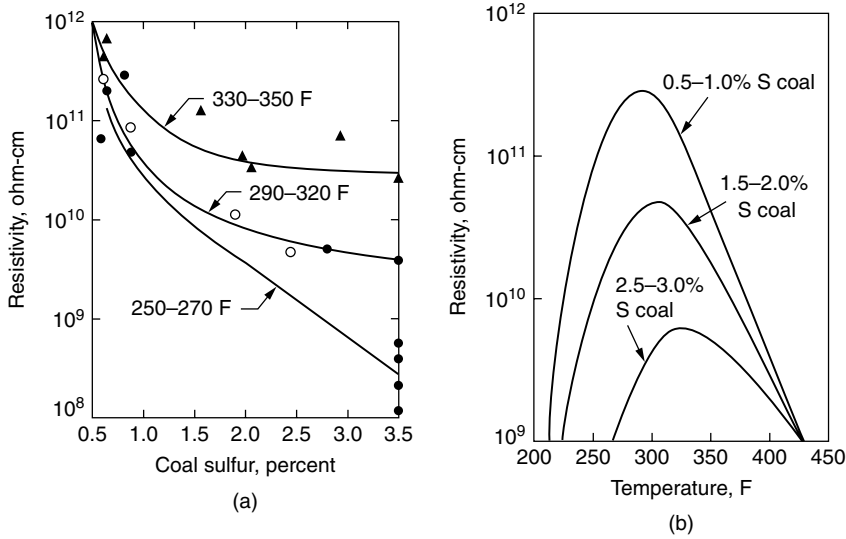

FIGURE 89.1 Variations of resistivity of coal fly ash. (Source: Cooper, C. D. and Alley, F. C. 1994. *Air Pollution Control — A Design Approach*, 2nd ed. Waveland Press, Prospect Heights, IL. With permission.)

- For a given ESP, an increase in dust resistivity can decrease the drift velocity markedly, reducing the collection efficiency.

Resistivity is also quite dependent on operating conditions. For example, for coal fly ash, the resistivity is a strong function of temperature and sulfur content of the coal (see Figure 89.1).

ESPs can be designed for efficiencies above 99% on many types of dry dusts or wet fumes, and can handle large volumes of air with very low ΔP (less than 1 in. H_2O). However, they tend to have high capital costs and take up a lot of space. The capital cost is a quantitative function of the plate area [Vatavuk, 1990].

Fabric Filtration

A fabric filter (or baghouse) operates on the age-old principle of filtering air through a cloth to remove dust. The air passes through the cloth, leaving the dust behind and providing a clean air stream. The dust builds up as a loosely packed mat on the cloth until removed by shaking or blowing; the dust is then collected in hoppers. There are three main types of baghouses (classified by cleaning method): shaker, reverse-air, and pulse-jet. The first two types have parallel compartments; each compartment is taken off-line, cleaned, and returned to service sequentially while the filtering continues in the other compartments. The pulse-jet baghouse has only one compartment, and the bags are cleaned in sequence by blasts of high-pressure air while filtration occurs.

The efficiency of a fabric filter system is extremely high and is almost independent of particle size because of the mat of dust that builds up on the cloth. However, as the thickness of the dust mat increases, so does the pressure drop. The baghouse ΔP can be related to key operating variables through the filter drag model:

$$\Delta P/V = K_1 + K_2 W \quad (89.4)$$

where V is the filtering velocity (m/min), W is the fabric area dust density (g/m^2), and K_1 and K_2 are empirical constants. V is defined simply as the volumetric gas flow rate divided by the on-line fabric area. The filtering velocity is a key design parameter: some values are shown in Table 89.2.

Baghouses often achieve efficiencies above 99.9% on many types of dry dusts, are fairly flexible to operating changes, and can handle large volumes of air with reasonable pressure drops (6 to 12 in. H_2O).

TABLE 89.2 Recommended Filtering Velocities in Baghouses

| Type of Dust | Filtering Velocity, m ³ /m ² or m/min | |
|---|---|------------|
| | Shaker or Reverse-Air | Pulse-Jet |
| Carbon, graphite, sugar, paint pigments | 0.6 to 0.7 | 1.6 to 2.4 |
| Glass, gypsum, limestone, quartz | 0.8 to 0.9 | 3.0 to 3.5 |
| Leather, tobacco, grains | 1.0 to 1.1 | 3.8 to 4.2 |

However, they cannot handle highly humid gases, they have high capital costs, and they take up a lot of space. The capital cost is related quantitatively to the fabric area [Vatavuk, 1990].

Wet Scrubbing

A wet scrubber employs the principle of impaction and interception of the particles by droplets of water. The larger, heavier droplets are then easily separated from the gas. Later, the particles are separated from the water stream, and the water treated prior to reuse or discharge. Spray chambers and venturi scrubbers are shown in [Figure 89.2](#).

During design, the collection efficiency of scrubbers can be related to a number of gas and liquid parameters through specific equations [Cooper and Alley, 1994]. Some of the most important variables include the liquid-to-gas ratio, the particle diameter, and, in a venturi, the gas velocity (which is directly related to pressure drop). In high-efficiency venturis, ΔP can exceed 60 in. H₂O. Extrapolating the performance of existing scrubbers can be done successfully using the contacting power approach. Contacting power is the energy expended per unit volume of gas treated and is related to collection efficiency through the following equation:

$$E = 1 - \exp[-a(P_T)^b] \quad (89.5)$$

where P_T is the contacting power, kW/1000 m³/h, and a and b are empirical constants.

Scrubbers have been used on a wide variety of dry or wet PM with efficiencies as high as 99%, while removing some soluble gases as well. Successful use of wet scrubbers also requires (1) good humidification of the gases prior to entering the scrubber and (2) good separation of the water mist before exhausting the scrubbed gases. The disadvantages include potential for corrosion and the production of a liquid effluent that must be further treated. Capital costs of scrubbers have been related to the gas scrubbing capacity [Peters and Timmerhaus, 1991].

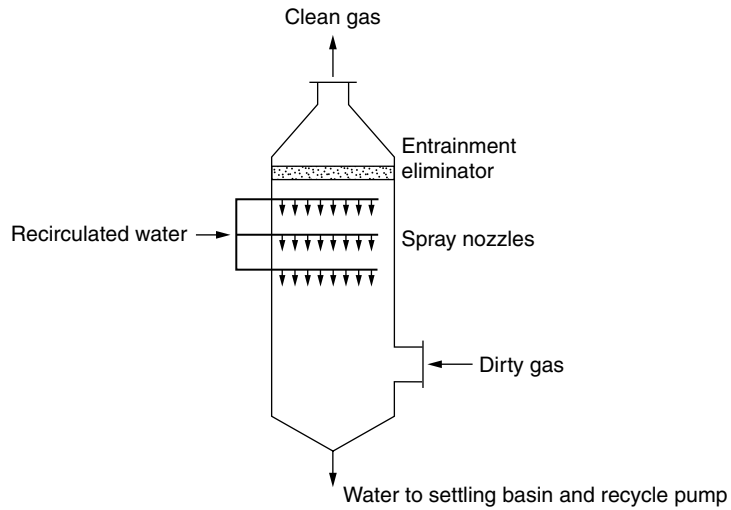

89.2 Control of Gaseous Pollutants

The most widely used processes for gaseous pollution control are absorption, adsorption, and incineration. The selection of the most practical process for a specific control application is based primarily on the chemical and physical properties of the pollutant to be removed. Some of the properties include vapor pressure, chemical reactivity, toxicity, solubility, flammability, and corrosiveness.

The following sections describe the design basics for each process and some typical applications. This section will refer to gases and vapors where gases are defined as substances far removed from the liquid state and vapors are substances existing near condensation conditions.

Absorption Processes

Absorption refers to the transfer of a material from a gas or vapor mixture to a contacting liquid, which in most cases is either water or an aqueous alkaline or acidic solution. The contacting process is typically carried out in a cylindrical tower partially filled with an inert packing to provide a large wetted surface to contact the incoming gas stream. The process is shown schematically in [Figure 89.3](#), where V and L designate the flow rates in mol/h of the vapor and liquid streams. The concentrations of the liquid streams

(a) Vertical spray chamber (countercurrent flow)

(b) Horizontal spray chamber (cross-flow)

FIGURE 89.2 Common types of wet scrubbers. (a), (b) Spray chambers. (Source: Cooper, C. D. and Alley, F. C. 1994. *Air Pollution Control — A Design Approach*, 2nd ed. Waveland Press, Prospect Heights, IL. With permission.) (c) venturi scrubber with cyclone separator.

in mol fraction are designated by x and the vapor phase concentrations are designated by y . The height of the packed section is shown as Z , and subscripts indicate the location of the variable, t referring to the top of the tower and b the bottom. The height of the packed bed is a function of the rate of transfer of material (which we will refer to as the solute) from the gas phase to the liquid phase. The transfer rate is dependent on the concentration driving force across the gas-liquid interface, which is approximated by $(y - y^*)$, where y^* is the mol fraction of the solute in the gas phase that would be in equilibrium with the solute concentration in the bulk liquid phase. The following relationship referred to as the operating line for the tower is developed from an overall material balance around the tower by substituting the solute-free liquid and gas flow rates, L' and V' .

$$\frac{y}{1-y} = \frac{L'_m}{V'_m} \left(\frac{x}{1-x} \right) + \left[\frac{y_b}{1-y_b} - \frac{L'_m}{V'_m} \left(\frac{x_b}{1-x_b} \right) \right] \quad (89.6)$$

where $L'_m = L(1-x)$ and $V'_m = V(1-y)$. The operating line provides a relationship between the solute concentrations in the bulk liquid and gas phases. The overall driving force in the packed bed is shown graphically in Figure 89.4, where the operating line is the upper curve and the lower line is the equilibrium line for the solute at the operating temperature and pressure of the tower (y^* vs. x). These two lines will be linear only at low solute concentrations (lean gas mixtures), which fortunately is the case in many air pollution control applications.

The basic design equation for the height of the packed bed is

FIGURE 89.4 Operating the equilibrium lines. (Source: Cooper, C. D. and Alley, F. C. 1994. *Air Pollution Control — A Design Approach*, 2nd ed. Waveland Press, Prospect Heights, IL. With permission.)

$$\left(\frac{K_y a}{G_{my}} \right) Z_t = \int_{y_t}^{y_b} \frac{dy}{(1-y)(y-y^*)} \quad (89.7)$$

The reciprocal of the term in parentheses, the overall mass transfer rate divided by the molar gas phase flux, is referred to as H_y , the height of a transfer unit based on the overall gas phase driving force. The value of the integral may then be thought of as the number of transfer units, N_{ty} . Hence, Equation (89.7) may also be written as

$$Z_t = (N_{ty})(H_y) \quad (89.8)$$

For the case of linear operating and equilibrium lines, the integral can be replaced with

$$\int_{y_t}^{y_b} \frac{dy}{(1-y)(y-y^*)} = \frac{y_b - y_t}{\Delta y_{LM}} \quad (89.9)$$

where

$$\Delta y_{LM} = (y - y^*)_{LM} = \frac{(y_b - y_b^*) - (y_t - y_t^*)}{\ln \left[\frac{(y_b - y_b^*)}{(y_t - y_t^*)} \right]}$$

The value of H_T may be calculated from empirical relations that are presented in many texts or from experimental plots provided by manufacturers of tower packings. Typically, H_T values range from 1.0 to 3.0 ft. The diameter of an absorption tower must be such that the gas and liquid velocities will provide good phase contact but at the same time will not result in a gas pressure drop sufficient to cause liquid hold-up or flooding. Flooding—gas velocity correlations are also provided by suppliers of tower packing and are discussed in detail by McCabe et al. [1985] and Cooper and Alley [1994].

Tower costs are estimated based on the total weight of the tower shell plus 10 to 20% additional for manholes and fittings. To this is added the packing cost. Costing procedures for towers and auxiliaries are presented in detail by Peters and Timmerhaus [1991]. Major operating costs include blower power, spent absorbent liquid disposal, and (in the case of acid gas treatment) chemical costs.

In many applications gas absorbers are utilized to recover valuable chemicals from exhaust streams, which reduces the load on subsequent pollution control equipment. Examples of this application include recovery of light hydrocarbon ends from wellhead gas and recovery of HCl gas in hydrochloric acid production. Strictly air pollution control applications include removal of oxides of sulfur and nitrogen, chlorine, and ammonia.

Adsorption

The removal of low-concentration gases and vapors from an exhaust stream by the adherence of these materials to the surface of a porous solid adsorbent is referred to as adsorption. Adsorbents used in air pollution applications include activated carbon, alumina, bauxite, and silica gel. Activated carbon (most frequently used) is prepared by partially oxidizing lignite, bituminous coal, and petroleum coke. A typical fixed-bed system employing carbon as the adsorbent is shown schematically in Figure 89.5.

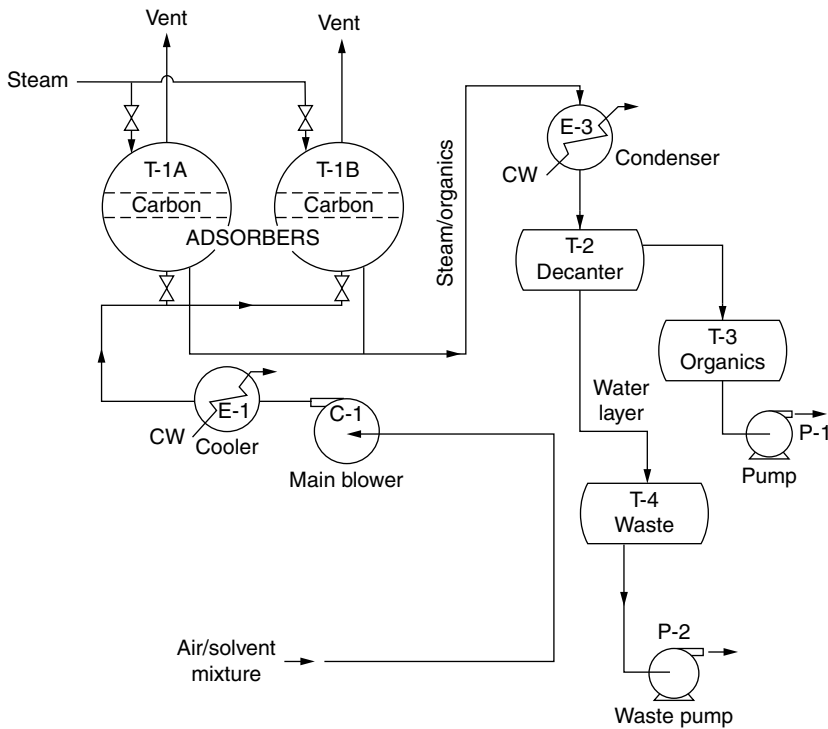

FIGURE 89.5 Flow sheet for a fixed-bed system. (Source: Cooper, C. D. and Alley, F. C. 1994. *Air Pollution Control — A Design Approach*, 2nd ed. Waveland Press, Prospect Heights, IL. With permission.)

FIGURE 89.6 The adsorption wave and breakthrough curve. (Source: Cooper, C. D. and Alley, F. C. 1994. *Air Pollution Control — A Design Approach*, 2nd ed. Waveland Press, Prospect Heights, IL. With permission.)

This system incorporates two horizontal cylindrical vessels, each containing a bed of granular activated carbon supported on a heavy screen. An air-solvent or air-pollutant mixture from a plant source flows through a cooler and then into one carbon bed while the other bed is being regenerated. A monitor-controller located in the vent stack detects a preset maximum concentration (breakthrough) and switches the incoming exhaust stream to the other bed, which has completed a regeneration cycle. The bed undergoing regeneration is contacted with saturated steam, which drives off the adsorbed material and carries it to a condenser, where it is condensed along with the steam. If the adsorbed material is insoluble in water, the condensed mixture goes to a decanter and is separated for final disposal.

When a material is adsorbed it may be weakly bonded to the solid (physical adsorption) or it may react chemically with the solid (chemisorption). Physical adsorption permits economical regeneration of the adsorbent and is practical in air pollution control applications such as solvent recovery and the removal of low-concentration odorous and toxic materials. The design of fixed-bed physical adsorption systems is described below.

The actual adsorption onto a carbon bed occurs in a concentration zone called the adsorption zone, as shown in Figure 89.6. The zone is bounded by saturated carbon upstream and clean carbon downstream. Unlike the steady state conditions in an absorption tower, adsorption is an unsteady state process in which the mass transfer driving force goes to zero as the carbon bed becomes saturated with respect to the partial pressure of the adsorbate (material adsorbed) in the gas stream.

The quantity of adsorbent in each bed is based on the saturation capacity for the adsorbate at the operating conditions of the adsorber. The operating adsorbent capacity is normally supplied by the manufacturer of the adsorbent or estimated by using 30% of the saturation capacity, as shown on the capacity curve (isotherm) illustrated in Figure 89.7.

For a two-bed system each bed must contain sufficient adsorbent to adsorb all solvent or pollutant in the incoming gas stream while the other bed is being regenerated, usually a period of 0.5 to 1.0 h. The cross-sectional area of each bed is determined by assuming that the superficial velocity of the gas in the

FIGURE 89.7 Adsorption isotherms for activated carbon. (Source: Cooper, C. D. and Alley, F. C. 1994. *Air Pollution Control — A Design Approach*, 2nd ed. Waveland Press, Prospect Heights, IL. With permission.)

bed is in the range of 70 to 100 ft/sec. The system blower power is based on the pressure drop through the bed, fittings, and condenser. In most applications, the expended bed is regenerated by passing low pressure-saturated steam through it at a rate of 0.3 to 0.5 pounds of steam per pound of carbon. The size of the condenser is based on 70 to 80% of this heat load. Cooper and Alley [1994] present examples of typical fixed-bed adsorber design.

Vatavuk [1990] reported that the purchased equipment cost (PEC) of packaged adsorber systems containing up to 14,000 pounds of carbon can be estimated by

$$PEC = 129(M_C)^{0.848} \quad (89.10)$$

where PEC = purchase cost, 1988 dollars and M_C = mass of carbon, pounds.

Typical grades of carbon utilized in adsorbers cost from 2 to 3 dollars per pound and have a normal service life of 5 to 7 years. The major utility costs are for steam, blower power, and cooling water. Average blower horsepower requirement is 6 to 8 hp/1000 SCFM of gas throughput.

Carbon adsorption has been shown to be applicable for the control of many types of gaseous pollutants, including volatile organic compounds (VOC), chlorinated solvents, and odorous materials.

Incineration Processes

Incineration of polluted exhaust streams offers an effective but costly means of controlling a wide variety of contaminants, including VOCs, which constitute a major fraction of the total annual emissions in the U.S. and play an important role in the **photochemical smog** process. A pollution control incinerator, also referred to as an afterburner or thermal oxidizer, is shown schematically in [Figure 89.8](#). The incoming polluted air is injected into the flame mixing chamber, heated, and held in the reaction chamber until the desired pollutant destruction efficiency is obtained.

The process design of an incinerator requires specification of an operating temperature and a residence time in the reaction chamber. Typical operating condition ranges to provide the required “three Ts” of combustion are temperature (1000 to 1500°F), residence time (0.3 to 0.5 sec), and turbulence (mixing velocity 20 to 40 ft/sec). Burner fuel requirements are estimated from a steady state enthalpy balance, as shown in Equation (89.11):

FIGURE 89.8 Schematic diagram of a vapor incinerator. (Source: Cooper, C. D. and Alley, F. C. 1994. *Air Pollution Control — A Design Approach*, 2nd ed. Waveland Press, Prospect Heights, IL. With permission.)

$$0 = \dot{M}_{PA}h_{PA} + \dot{M}_Gh_G + \dot{M}_{BA}h_{BA} - \dot{M}_Eh_E + \dot{M}_G(-\Delta H_c)_G + \sum \dot{M}_{VOC_i}(-\Delta H_c)_{VOC_i}X_i - q_L \quad (89.11)$$

where \dot{M} = mass flow rate, kg/min or lbm/min; h = specific enthalpy, kJ/kg or Btu/lbm; $-\Delta H_c$ = net heat of combustion (lower heating value), kJ/kg or Btu/lbm; X_i = fractional conversion of VOC_{*i*}; and q_L = rate of heat loss from the incinerator, kJ/min or Btu/min.

In most designs, the heat generated by combustion of the pollutant is ignored, but at concentrations in the 1000 ppm range, this heat may be roughly 10% of the burner heat requirement. Insurance regulations limit the combustible pollutant concentration entering the incinerator to 25% of the **lower explosion limit** (LEL).

To reduce the required operating temperature in the reaction chamber, the combustion mixture may be passed over a catalyst bed, which greatly increases the pollutant oxidation rate. Typically, the catalyst is either palladium or platinum, although Cr, Mn, Co, and Ni are used. The catalyst is deposited on an alumina support or wire screen, which is placed just downstream of the burner mix chamber. The total amount of catalyst surface area required is in the range of 0.2 to 0.5 ft² per SCFM of waste gas. Typical operating temperature for catalytic incinerators is in the range of 600 to 900°F.

Combustion kinetics are extremely complicated and often incinerator design is based on empirical data or the results of pilot scale tests. The application of simplified kinetic reaction models to incinerator design is described by Cooper and Alley [1994].

The choice between a thermal or catalytic incinerator is in most cases a trade-off between capital and operating cost. The installed cost of a catalytic unit will normally be 40 to 70% higher than that of a thermal unit, but the catalytic unit will require 30 to 50% less fuel for the same waste gas throughput. Offsetting this saving, however, is the service life of the catalyst, which is usually 4 to 6 years. Fuel costs for both units may be lowered by incorporating heat recovery equipment in the overall design. The cost of a packaged thermal unit handling up to 30,000 SCFM with facilities for 50% heat recovery may be estimated with the following equation [Vatavuk, 1990]:

$$P = \$4920Q^{0.389} \quad (89.12)$$

where P = manufacturer's f.o.b. price, 1988 dollars and Q = waste gas flow rate, SCFM.

The cost of catalytic units (not including the catalyst) equipped for 50% heat recovery may be found from [Vatavuk, 1990]

$$P = \exp(11.7 + 0.0354Q) \quad (89.13)$$

where P = manufacturer's f.o.b. price, 1988 dollars and Q = waste gas flow rate, thousands of SCFM.

Catalyst costs in 1988 were \$3000 per cubic foot for precious metals and \$600 per cubic foot for common metals.

Both catalytic and thermal incinerators find widespread use in the chemical process industries, in coating and film printing operations, and in food processing. Recent VOC emission regulations should promote increased sales of these units.

Defining Terms

Aerodynamic diameter — The diameter of a unit density sphere ($\rho_p = \rho_w = 1000 \text{ kg/m}^3$) that has the same settling velocity as the particle in question.

Contacting power — The quantity of energy dissipated per unit volume of gas treated.

Lower explosion limit — The lowest concentration of a flammable gas, vapor, or solid in air that will provide flame propagation throughout the mixture.

Photochemical smog — An air pollution condition resulting from a series of photochemical reactions involving various volatile organic compounds and oxides of nitrogen in the lower atmosphere.

Figure 90.1 shows a basic schematic of a wastewater treatment process providing primary and secondary treatment using the **Activated Sludge Process**. This is the model, the prototype, of the system in common use today. In secondary treatment (which provides BOD removal beyond what is achievable by simple sedimentation), there are actually three commonly used approaches: **trickling filter**, **activated sludge**, and **oxidation ponds**. Our focus, for illustrative and instructive purposes, is mainly on the activated sludge process. The purpose of Figure 90.1 is to allow the reader to follow the treatment process step-by-step as it is presented (as it is actually configured in the real world) and to assist understanding of how all the various unit processes sequentially follow and tie into each other.

90.1 Wastewater Sources, Classification, and Characteristics

Wastewater treatment is designed to use (to mimic) the natural purification processes (the self-purification processes of streams and rivers) to the maximum level possible. It completes the process in a controlled environment rather than over many miles of stream or river. We can say that a wastewater treatment plant is a stream (the self-purification process) in a box (the treatment plant). The treatment plant is also designed to remove other contaminants, which are not normally subjected to natural processes, as well as treating the solids, which are generated throughout the treatment unit steps. A typical wastewater treatment plant is designed to achieve many different purposes:

- Protect public health
 - Protect public water supplies
 - Protect aquatic life
-

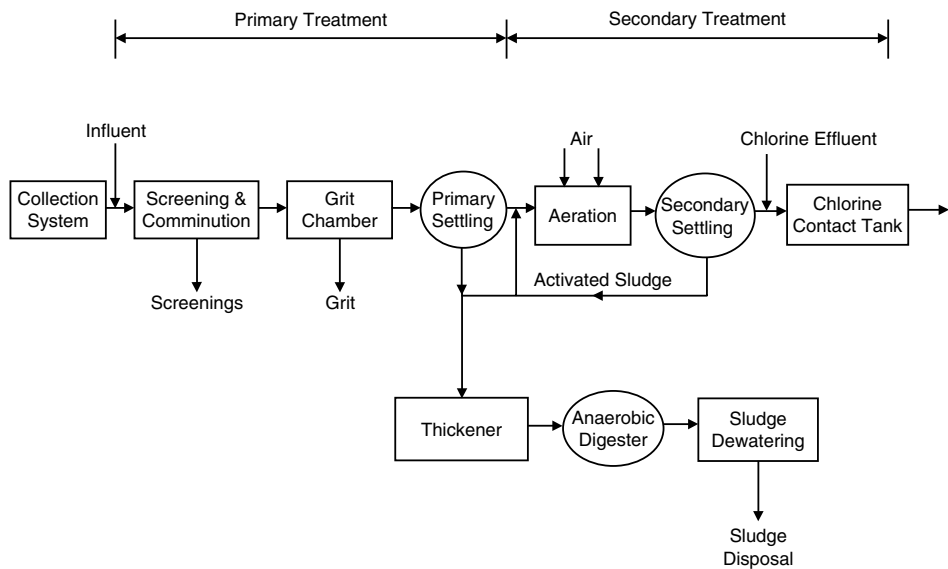

FIGURE 90.1 Schematic of an example wastewater treatment process providing primary and secondary treatment using activated sludge process.

- Preserve the best uses of the waters
- Protect adjacent lands

Wastewater Sources

The principal **sources** of domestic wastewater in a community are the residential areas and commercial districts. Other important sources include institutional and recreational facilities and stormwater (runoff) and groundwater (infiltration). Each source produces wastewater with specific characteristics.

Wastewater is generated by five major sources:

1. *Human and animal wastes* — contain the solid and liquid discharges of humans and animals and are considered by many to be the most dangerous from a human health viewpoint. The primary health hazard is present because of the millions of bacteria, viruses, and other microorganisms (some of which may be pathogenic) present in the wastestream.
2. *Household wastes* — are wastes, other than human and animal wastes, discharged from the home. Household wastes usually contain paper, household cleaners, detergents, trash, garbage, and other substances the homeowner discharges into the sewer system.
3. *Industrial wastes* — includes industry-specific materials that can be discharged from industrial processes into the collection system. Typically contains chemicals, dyes, acids, alkalis, grit, detergents, and highly toxic materials.
4. *Stormwater runoff* — Many collection systems are designed to carry both the wastes of the community and stormwater runoff. In this type of system when a storm event occurs, the wastestream can contain large amounts of sand, gravel, and other grit as well as excessive amounts of water.
5. *Groundwater infiltration* — Groundwater will enter older collection systems through cracks or improperly sealed pipe joints. Not only can this add large amounts of water to wastewater flows but also additional grit.

Wastewater Classification

Wastewater can be classified according to the sources of flow: domestic, sanitary, industrial, combined, and stormwater.

1. *Domestic (sewage) wastewater* — mainly contains human and animal wastes, household wastes, small amounts of groundwater infiltration, and small amounts of industrial wastes.
2. *Sanitary wastewater* — consists of domestic wastes and significant amounts of industrial wastes. In many cases, the industrial wastes can be treated without special precautions. However, in some cases the industrial wastes will require special precautions or a pretreatment program to ensure the wastes do not cause compliance problems for the wastewater treatment plant.
3. *Industrial wastewater* — industrial wastes only. Often an industry will determine that it is safer and more economical to treat its waste independent of domestic waste.
4. *Combined wastewater* — is the combination of sanitary wastewater and stormwater runoff. All the wastewater and stormwater of the community is transported through one system to the treatment plant.
5. *Stormwater* — a separate collection system (no sanitary waste) that carries stormwater runoff including street debris, road salt, and grit.

Wastewater Characteristics

Wastewater is characterized in terms of its physical, chemical, and biological agents. The **physical characteristics** of wastewater are based on color, odor, temperature, and flow.

The **chemical characteristics** include organic matter, the measurement of organic matter, inorganic matter, and gases. For the sake of simplicity, we specifically describe chemical characteristics in terms of alkalinity, biochemical oxygen demand (BOD), chemical oxygen demand (COD), dissolved gases, nitrogen compounds, pH, phosphorus, solids (organic, inorganic, suspended, and dissolved solids), and water.

When it enters the treatment plant, wastewater can be characterized in **biological terms** because influent typically contains millions of microorganisms, including algae, bacteria, protozoa, and viruses. The majority of these organisms are nonpathogenic; however, several pathogenic organisms may also be present (these may include the organisms responsible for typhoid, tetanus, hepatitis, dysentery, gastroenteritis, and other diseases).

90.2 Wastewater Terminology and Definitions

Wastewater treatment, like many other technical fields, has its own unique terms with their own meaning. Even though some of these terms are unique to wastewater treatment, many are also common to other professions. Wastewater treatment is a combination of engineering, biology, mathematics, hydrology, chemistry, physics, and other disciplines; many of the terms used in these disciplines are also used in wastewater treatment. However, terms such as *sludge and biosolids*; *unit processes*; *systems*; and *primary, secondary treatment* frequently appear in the literature, and their usage is not always consistent.

Activated sludge is the unit process where solids are formed when microorganisms are used to treat wastewater. **Biosolids**, according to *Merriam-Webster's Collegiate Dictionary, Tenth Edition* (1998): biosolid *n* (1977) — “solid organic matter recovered from a sewage treatment process and used especially as fertilizer — usually used in plural.” At present, the term biosolids is used in many places (and even in describing activated “biosolids”) to replace the standard term sludge. The author (along with others in the field) views the term sludge as an ugly four-letter word that is inappropriate to use in describing biosolids. Biosolids is a product that can be reused; it has some value. Because biosolids has some value, it should not be classified as a “waste” product, and when beneficial reuse of biosolids is practiced, it is not.

As mentioned, wastewater treatment is a series of steps. Each of the steps can be accomplished using one of more treatment processes or types of equipment. The major categories of treatment steps are a series of **unit processes** (conversion processes). The entire process is made of individual unit processes tied together — from influent end to effluent end — in trainlike fashion. Note that the term unit process should not be confused with the term **unit operations**, which have been used to describe contaminant removal by physical forces (screening, sedimentation, and filtration).

The term **reactor** refers to a vessel or containment structure. These vessels are more commonly referred to as unit process structures such as clarifiers, contact basins, aeration basins, digesters, and others.

Preliminary treatment removes materials that could damage plant equipment or would occupy treatment capacity without being treated. **Primary treatment** removes settleable and floatable solids (may not be present in all treatment plants). **Secondary treatment** removes BOD₅ (Biological Oxygen Demand) and dissolved and colloidal suspended organic matter by biological action; organics are converted to stable solids, carbon dioxide, and more organisms. **Advanced waste treatment** (sometimes referred to as tertiary treatment when the objective is nutrient removal only) uses physical, chemical and biological processes to remove additional BOD₅, solids, and nutrients.

90.3 Wastewater Treatment

Wastewater collection systems collect and convey wastewater to the treatment plant. The complexity of the system depends on the size of the community and the type of system selected. Methods of collection and conveyance of wastewater include gravity systems, force main systems, vacuum systems, and combinations of all three types of systems.

The initial stage in the wastewater treatment process (following collection and influent pumping) is **preliminary treatment**. Raw influent entering the treatment plant may contain many kinds of materials (trash). The purpose of preliminary treatment is to protect plant equipment by removing these materials which could cause clogs, jams, or excessive wear to plant machinery. In addition, the removal of various materials at the beginning of the treatment process saves valuable space downstream within the treatment plant. Preliminary treatment may include many different processes, each designed to remove a specific type of material, which is a potential problem for the treatment process. Processes include wastewater collections — influent pumping, screening, shredding, grit removal, flow measurement, preaeration, chemical addition, and flow equalization; the major processes are shown in [Figure 90.1](#).

The purpose of **primary treatment** (primary sedimentation or primary clarification) is to remove settleable organic and floatable solids. Normally, each primary clarification unit can be expected to remove 90 to 95% settleable solids, 40 to 60% total suspended solids, and 25 to 35% BOD₅.

Sedimentation may be used throughout the plant to remove settleable and floatable solids. It is used in primary treatment, secondary treatment, and advanced wastewater treatment processes.

Upon completion of screening, degritting, and settling in sedimentation basins, large debris, grit, and many settleable materials have been removed from the wastestream. What is left is referred to as **primary effluent**. Usually cloudy and frequently gray in color, primary effluent still contains large amounts of dissolved food and other chemicals (nutrients).

The main purpose of **secondary treatment** is to provide biochemical oxygen demand (BOD) removal beyond what is achievable by primary treatment. Essentially, secondary treatment refers to those treatment processes that use biological processes to convert dissolved, suspended, and colloidal organic wastes to more stable solids that can either be removed by settling or discharged to the environment without causing harm. There are three commonly used approaches, all of which take advantage of the ability of microorganisms to convert organic wastes (via biological treatment), into stabilized, low-energy compounds. Two of these approaches, the *trickling filter* [and/or its variation, the *rotating biological contactor (RBC)*] and the *activated sludge* process, sequentially follow normal primary treatment. The third, *ponds* (oxidation ponds or lagoons), however, can provide equivalent results without preliminary treatment.

Most secondary treatment processes decompose solids aerobically, producing carbon dioxide, stable solids, and more organisms. Since solids are produced, all of the biological processes must include some form of solids removal (settling tank, filter, etc.).

Secondary treatment processes can be separated into two large categories: fixed film systems and suspended growth systems.

Fixed film systems are processes, which use a biological growth (biomass or slime), which is attached to some form of media. Wastewater passes over or around the media and the slime. When the wastewater and slime are in contact, the organisms remove and oxidize the organic solids. The media may be stone,

redwood, synthetic materials or any other substance that is durable (capable of withstanding weather conditions for many years), provides a large area for slime growth while providing open space for ventilation, and is not toxic to the organisms in the biomass. Fixed film devices include trickling filters and rotating biological contactors (RBCs).

Trickling filters have been used to treat wastewater since the 1890s. It was found that if settled wastewater was passed over rock surfaces, slime grew on the rocks and the water became cleaner (i.e., a fixed film biological treatment method designed to remove BOD₅ and suspended). Today we still use this principle but, in many installations, instead of rocks we use plastic media. In most wastewater treatment systems, the *trickling filter* follows primary treatment and includes a secondary settling tank or clarifier. Trickling filters are widely used for the treatment of domestic and industrial wastes.

The **Rotating Biological Contactor (RBC)** is a biological treatment system and is a variation of the trickling filter. Still relying on microorganisms that grow on the surface of a medium, the RBC also is a **fixed film** biological treatment device. An RBC consists of a series of closely spaced (mounted side by side), circular, plastic (synthetic) disks, that are typically about 3.5 m in diameter and attached to a rotating horizontal shaft. Approximately 40% of each disk is submersed in a tank containing the wastewater to be treated. As the RBC rotates, the attached biomass film (slime) that grows on the surface of the disk moves into and out of the wastewater. While submerged in the wastewater, the microorganisms (slime) absorb organics; while they are rotated out of the wastewater, they are supplied with needed oxygen for aerobic decomposition. As the slime reenters the wastewater, excess solids and waste products are stripped off the media as **sloughings**. These sloughings are transported with the wastewater flow to a settling tank for removal.

Suspended growth systems are processes that use a biological growth, which is mixed with the wastewater. Typical suspended growth systems consist of various modifications of the **activated sludge process**.

As shown in [Figure 90.1](#), the **activated sludge process** follows primary settling. The basic components of an activated sludge sewage treatment system include an aeration tank and a secondary settling basin, or clarifier. Primary effluent is mixed with settled solids recycled from the secondary clarifier and is then introduced into the aeration tank. Compressed air is injected continuously into the mixture through porous diffusers located at the bottom of the tank, usually along one side.

In operation, wastewater is fed continuously into an aerated tank, where the microorganisms metabolize and biologically flocculate the organics. Microorganisms (activated sludge) are settled from the aerated *mixed liquor* under quiescent conditions in the final clarifier and are returned to the aeration tank. Left uncontrolled, the number of organisms would eventually become too great; therefore, some must periodically be removed (wasted). A portion of the concentrated solids from the bottom of the settling tank must be removed from the process (waste activated sludge or WAS). Clear supernatant from the final settling tank is the plant effluent.

Like potable water, wastewater effluent is **disinfected** to protect public health in general. In wastewater treatment, this is particularly important when the secondary effluent is discharged into a body of water used for swimming and/or for a downstream water supply.

Wastewater treatment can be accomplished using **ponds**. Ponds are relatively easy to build and to manage, they accommodate large fluctuations in flow, and they can also provide treatment that approaches conventional systems (producing a highly purified effluent) at much lower cost. The actual degree of treatment provided depends on the type and number of ponds used. Ponds can be used as the sole type of treatment or they can be used in conjunction with other forms of wastewater treatment; that is, other treatment processes followed by a pond or a pond followed by other treatment processes.

90.4 Advanced Wastewater Treatment

Biological nitrification is the first basic step of *biological nitrification–denitrification*. In nitrification, the secondary effluent is introduced into another aeration tank, trickling filter, or biodisc. Because most of the carbonaceous BOD has already been removed, the microorganisms that drive this advanced step are

the nitrifying bacteria *Nitrosomonas* and *Nitrobacter*. In nitrification, the ammonia nitrogen is converted to nitrate nitrogen, producing a *nitrified effluent*. At this point, the nitrogen has not actually been removed, only converted to a form that is not toxic to aquatic life and that does not cause an additional oxygen demand.

The nitrification process can be limited (performance affected) by alkalinity (requires 7.3 parts alkalinity to 1.0 part ammonia nitrogen); pH; dissolved oxygen availability; toxicity (ammonia or other toxic materials); and process mean cell residence time (sludge retention time). As a general rule, biological nitrification is more effective and achieves higher levels of removal during the warmer times of the year.

Biological denitrification removes nitrogen from wastewater. When bacteria come in contact with a nitrified element in the absence of oxygen, they reduce the nitrates to nitrogen gas, which escapes the wastewater. The denitrification process can be accomplished in either an anoxic activated sludge system (suspended growth) or in a column system (fixed growth). The denitrification process can remove up to 85% or more of nitrogen. After effective biological treatment, little oxygen-demanding material is left in the wastewater when it reaches the denitrification process.

The denitrification reaction will only occur if an oxygen demand source exists when no dissolved oxygen is present in the wastewater. An oxygen demand source is usually added to reduce the nitrates quickly. The most common demand source added is soluble BOD or methanol. Approximately 3 mg/l of methanol is added for every 1 mg/l of nitrate–nitrogen. Suspended growth denitrification reactors are mixed mechanically but only enough to keep the biomass from settling without adding unwanted oxygen.

Submerged filters of different types of media may also be used to provide denitrification. A fine media downflow filter is sometimes used to provide both denitrification and effluent filtration. A fluidized sand bed where wastewater flows upward through a media of sand or activated carbon at a rate to fluidize the bed may also be used. Denitrification bacteria grow on the media.

Land application is application of secondary effluent onto a land surface. This procedure can provide an effective alternative to the expensive and complicated advanced treatment methods. A high-quality polished effluent (i.e., with low effluent levels of TSS, BOD, phosphorus, and nitrogen compounds as well as refractory organics) can be obtained by the natural processes that occur as the effluent flows over the vegetated ground surface and percolates through the soil.

Limitations are involved with land application of wastewater effluent. For example, the process needs large land areas. Soil type and climate are also critical factors in controlling the design and feasibility of a land treatment process.

Recent experience has shown that **biological nutrient removal (BNR)** systems are reliable and effective in removing nitrogen and phosphorus. The process is based upon the principle that, under specific conditions, microorganisms will remove more phosphorus and nitrogen than is required for biological activity. Several patented processes are available for this purpose. Performance depends on the biological activity and the process employed.

90.5 Solids (Sludge/Biosolids)

The wastewater treatment unit processes described to this point remove solids and BOD from the wastewater before the liquid effluent is discharged to its receiving waters. What remains to be disposed of is a mixture of solids and wastes, called *process residuals* — more commonly referred to as *sludge* or *biosolids*.

The most costly and complex aspect of wastewater treatment can be the collection, processing, and disposal of sludge. This is the case because the quantity of sludge produced may be as high as 2% of the original volume of wastewater, depending somewhat on the treatment process being used.

Because sludge can be as much as 97% water content, and because the cost of disposal will be related to the volume of sludge being processed, one of the primary purposes or goals (along with **stabilizing** it so it is no longer objectionable or environmentally damaging) of sludge treatment is to separate as much of the water from the solids as possible. Sludge treatment methods may be designed to accomplish both of these purposes.

TABLE 90.1 Typical Water Content of Sludges

| Water Treatment Process | % Moisture of Sludge Generated | lb Water/lb Sludge Solids |
|-------------------------|--------------------------------|---------------------------|
| Primary sedimentation | 95 | 19.0 |
| Trickling filter | | |
| Humus — low rate | 93 | 13.3 |
| Humus — high rate | 97 | 32.3 |
| Activated sludge | 99 | 99.0 |

Source: USEPA's *Operational Manual: Sludge Handling and Conditioning*, EPA-430/9-78-002, 1978.

When we speak of **sludge** or **biosolids**, we are speaking of the same substance or material; each is defined as the suspended solids removed from wastewater during sedimentation, then concentrated for further treatment and disposal or reuse. The difference between the terms **sludge** and **biosolids** is determined by their ultimate end use.

Sludge forms initially as a 3 to 7% suspension of solids, and with each person typically generating about 4 gallons of sludge per week, the total quantity generated each day, week, month, and year is significant. Because of the volume and nature of the material, sludge management is a major factor in the design and operation of all water pollution control plants.

The composition and characteristics of sewage sludge vary widely and can change considerably with time. Notwithstanding these facts, the basic components of wastewater sludge remain the same. The only variations occur in quantity of the various components as the type of sludge and the process from which it originated changes.

The main component of all sludges is *water*. Prior to treatment, most sludge contains 95 to 99+% water (see Table 90.1). This high water content makes sludge handling and processing extremely costly in terms of both money and time. Sludge handling may represent up to 40% of the capital cost and 50% of the operation cost of a treatment plant. As a result, the importance of optimum design for handling and disposal of sludge cannot be overemphasized. The water content of the sludge is present in a number of different forms. Some forms can be removed by several sludge treatment processes, thus allowing the same flexibility in choosing the optimum sludge treatment and disposal method.

Sludge treatment processes can be classified into a number of major categories: thickening, digestion (or stabilization), de-watering, incineration, and land application. Each of these categories is further subdivided according to the specific processes that are used to accomplish sludge treatment.

The solids content of primary, activated, trickling-filter, or even mixed sludge (i.e., primary plus activated sludge) varies considerably, depending on the characteristics of the sludge. Note that the sludge removal and pumping facilities and the method of operation also affect the solids content. **Sludge thickening** (or *concentration*) is a unit process used to increase the solids content of the sludge by removing a portion of the liquid fraction. By increasing the solids content, more economical treatment of the sludge can be effected. Sludge thickening processes include gravity thickeners, flotation thickeners, and solids concentrators.

Equipment used for **aerobic digestion** consists of an aeration tank (digester), which is similar in design to the aeration tank used for the activated sludge process. Either diffused or mechanical aeration equipment is necessary to maintain the aerobic conditions in the tank. Solids and supernatant removal equipment is also required.

In operation, process residuals (sludge/biosolids) are added to the digester and aerated to maintain a dissolved oxygen (D.O.) concentration of 1.0 mg/L. Aeration also ensures that the tank contents are well mixed. Generally, aeration continues for approximately 20 days retention time. Periodically, aeration is stopped and the solids are allowed to settle. Sludge and the clear liquid supernatant are withdrawn as needed to provide more room in the digester. When no additional volume is available, mixing is stopped for 12 to 24 h before solids are withdrawn for disposal. Process control testing should include alkalinity, pH, % solids, and % volatile solids for influent sludge, supernatant, digested sludge, and digester contents.

Anaerobic digestion is the traditional method of sludge stabilization. It involves using bacteria that thrive in the absence of oxygen and is slower than aerobic digestion, but has the advantage that only a small percentage of the wastes is converted into new bacterial cells. Instead, most of the organics are converted into carbon dioxide and methane gas.

The purpose of composting sludge is to stabilize the organic matter, reduce volume, and to eliminate pathogenic organisms. In a **composting operation**, dewatered solids are usually mixed with a bulking agent (i.e., hardwood chips) and stored until biological stabilization occurs. The composting mixture is ventilated during storage to provide sufficient oxygen for oxidation and to prevent odors. After the solids are stabilized, they are separated from the bulking agent. The composted solids are then stored for curing and applied to farmlands or used for other beneficial uses.

In the **lime stabilization** process, residuals are mixed with lime to achieve a pH of 12.0. This pH is maintained for at least 2 h. The treated solids can then be dewatered for disposal or directly land applied.

Thermal treatment (or wet air oxidation) subjects sludge to high temperature and pressure in a closed reactor vessel. The high temperature and pressure rupture the cell walls of any microorganisms present in the solids and cause chemical oxidation of the organic matter. This process substantially improves dewatering and reduces the volume of material for disposal. It also produces a very high-strength waste, which must be returned to the wastewater treatment system for further treatment.

Chlorine oxidation also occurs in a closed vessel. In this process chlorine (100 to 1000 mg/L) is mixed with a recycled solids flow. The recycled flow and process residual flow are mixed in the reactor. The solids and water are separated after leaving the reactor vessel. The water is returned to the wastewater treatment system, and the treated solids are dewatered for disposal. The main advantage of chlorine oxidation is that it can be operated intermittently. The main disadvantage is production of extremely low pH and high chlorine content in the supernatant.

Digested sludge removed from a digester is still mostly liquid. **Sludge dewatering** is used to reduce volume by removing the water to permit easy handling and economical reuse or disposal. Dewatering processes include sand drying beds, vacuum filters, centrifuges, filter presses (belt and plate), and incineration.

Drying beds have been used successfully for years to dewater sludge. Composed of a sand bed (consisting of a gravel base, underdrains and 8 to 12 inches of filter-grade sand), drying beds include an inlet pipe, splash pad containment walls, and a system to return filtrate (water) for treatment. In some cases, the sand beds are covered to provide drying solids protection from the elements.

Rotary vacuum filters have also been used for many years to dewater sludge. The vacuum filter includes filter media (belt, cloth, or metal coils), media support (drum), vacuum system, chemical feed equipment, and conveyor belt(s) to transport the dewatered solids.

Pressure filtration differs from vacuum filtration in that the liquid is forced through the filter media by a positive pressure instead of a vacuum. Several types of presses are available, but the most commonly used types are plate and frame presses and belt presses.

Centrifuges of various types have been used in dewatering operations for at least 30 years and appear to be gaining in popularity.

The purpose of **land application of biosolids** is to dispose of the treated biosolids in an environmentally sound manner by recycling nutrients and soil conditioners. In order to be land applied, wastewater biosolids must comply with state and federal biosolids management/disposal regulations. Biosolids must not contain materials that are dangerous to human health (i.e., toxicity, pathogenic organisms, etc.) or dangerous to the environment (i.e., toxicity, pesticides, heavy metals, etc.). Treated biosolids are land applied by either direct injection or application and plowing in (incorporation).

90.6 Future of Wastewater Treatment

Earth was originally allotted a finite amount of water — we have no more or no less than that original allotment today. Thus, it logically follows that, in order to sustain life, as we know it, we must do

everything we can to preserve and protect our water supply. Moreover, we also must purify and reuse the water we presently waste (i.e., wastewater).

The Paradigm Shift

Historically, the purpose of wastewater treatment has been to protect the health and well being of our communities. The purpose of wastewater treatment processes has not changed. However, primarily because of new regulations that include (1) protecting against protozoan and virus contamination; (2) implementation of the multiple barrier approach to microbial control; and (3) regulations for trihalomethanes (THMs) and disinfection byproducts (DBPs), the paradigm has shifted.

A **paradigm shift** is defined as a major change in the way things are thought about, especially scientifically. Once a problem can no longer be solved in the existing paradigm, new laws and theories emerge and form a new paradigm, overthrowing the old if it is accepted. Simply, a paradigm shift represents “a profound change in the thoughts, perceptions, and values that form a particular vision of reality” [Capra, 1982]. For our purposes, we use the term paradigm shift to mean a change in the way things are understood and done.

Multiple-Barrier Concept

Drinking water standards are regulations that the U.S. Environmental Protection Agency (USEPA) sets to control the level of contaminants in the nation’s drinking water. These standards are part of the Safe Drinking Water Act’s “**multiple barrier approach**” to drinking water protection. Note that the multiple barrier approach can be applied to protecting potable water as well as to wastewater treatment. First, we will examine how this concept applies to our potable water supply (see [Figure 90.2](#)).

The multiple barrier approach includes the following elements.

1. **Assessing and protecting drinking water sources** — means doing everything possible to prevent microbes and other contaminants from entering water supplies. Minimizing human and animal activity around our watersheds is one part of this barrier.
2. **Optimizing treatment processes** — provides a second barrier. This usually means filtering and disinfecting the water. It also means making sure that the people who are responsible for our water are properly trained/certified and knowledgeable of the public health issues involved.
3. **Ensuring the integrity of distribution systems** — this consists of maintaining the quality of water as it moves through the system on its way to the customer’s tap.
4. **Effecting correct cross-connection control procedures** — this is a critical fourth element in the barrier approach. It is critical because the greatest potential hazard in water distribution systems is associated with cross-connections to nonpotable waters. There are many connections between potable and nonpotable systems — every drain in a hospital constitutes such a connection — but cross-connections are those through which backflow can occur [Angele, 1974].
5. **Continuous monitoring and testing of the water before it reaches the tap** — is a critical element in the barrier approach. It should include having specific procedures to follow should potable water ever fail to meet quality standards.

With the involvement of USEPA, local governments, drinking water utilities, and citizens, these multiple barriers ensure that the tap water in the United States and territories is safe to drink. Simply, in the

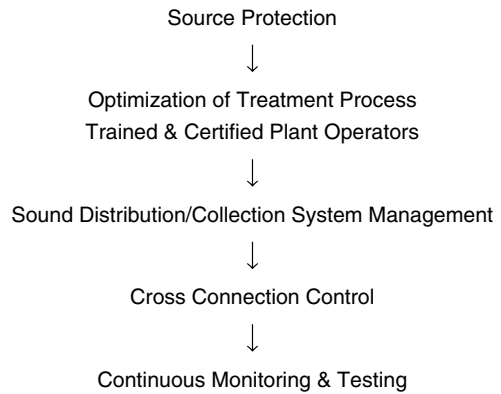

FIGURE 90.2 Multiple barrier approach.

multiple-barrier concept, we employ a holistic approach to water management that begins at the source and continues with treatment, through disinfection and distribution.

Multiple-Barrier Approach: Wastewater Operations

Not shown in [Figure 90.1](#) is the fate of the used water; that is, what happens to the wastewater produced? Wastewater is treated via the multiple-barrier treatment train, which consists of the combination of pollution prevention, pretreatment programs, and unit processes used in the treatment plant. The primary mission of the wastewater treatment plant (and the operator) is to treat the wastestream to a level of purity acceptable to return it to the environment or for immediate reuse (i.e., reuse in such applications as irrigation of golf courses, etc.).

Water/wastewater operators maintain a continuous urban water cycle, a “hidden function,” on a daily basis. B.D. Jones sums up this point as follows [Jones, 1980]:

Delivering services is the primary function of municipal government. It occupies the vast bulk of the time and effort of most city employees, is the source of most contacts that citizens have with local governments, occasionally becomes the subject of heated controversy, and is often surrounded by myth and misinformation. Yet, service delivery remains the “hidden function” of local government.

Wastewater service professionals treat the urban wastestream to remove pollutants before discharging the effluent into the environment. Water and wastewater treatment services are the urban circulatory system [Cox, 1939; AJP, 1930]. In addition, like the human circulatory system, the urban circulatory system is less than effective if flow is not maintained as per design.

Maintaining flow is what wastewater treatment is all about. Seems easy enough, water has been flowing literally for eons — no problem there. However, this is not to say that wastewater operations are not without problems and/or challenges. The dawn of the twenty-first century brought with it, for many of us, aspirations of good things ahead in the constant struggle to provide quality food and water for humanity. However, the only way in which we can hope to accomplish this is to stay on the cutting edge of technology and to face all challenges head on. Some of these “challenges” are addressed in the following section.

Management Problems Facing Wastewater Operations

Problems come and go, shifting from century to century, decade to decade, year to year, and also from site to site. They range from the problems caused by natural forces (storms, earthquakes, fires, floods, and droughts) to those caused by social forces, currently including terrorism.

In general, five areas are of concern to many wastewater managers:

1. Complying with regulations, and coping with new and changing regulations
2. Maintaining infrastructure
3. Privatization and/or reengineering
4. Benchmarking
5. Upgrading security

1. Compliance with New, Changing, and Existing Regulations¹

Adapting the workforce to the challenges of meeting changing regulations and standards for wastewater treatment is a major concern. In regards to wastewater collection and treatment, the National Pollution Discharge Elimination System program (NPDES) issues permits that control wastewater treatment plant discharges. “Meeting permit” is always a concern for wastewater treatment managers because the effluent discharged into water bodies affects those downstream of the release point. Individual point source dischargers must use the best available technology (BAT) to control the levels of pollution in the effluent

¹This section adapted from Drinan, J.E., *Water & Wastewater Treatment: A Guide for the Nonengineering Professional*. Lancaster, PA: Technomic Publishing Company, Lancaster, PA, 2001. pp. 2–3.

they discharge into streams. As systems age and best available technology changes, meeting permit with existing equipment and unit processes becomes increasingly more difficult.

2. Maintaining Infrastructure

During the 1950s and 1960s, the U.S. government encouraged the prevention of pollution by providing funds for the construction of municipal wastewater treatment plants, water-pollution research, and technical training and assistance. New processes were developed to treat sewage, analyze wastewater, and evaluate the effects of pollution on the environment. In spite of these efforts, however, expanding population with its corresponding industrial and economic growth caused the pollution and corresponding implications to increase.

In response to the need to make a coordinated effort to protect the environment, the National Environmental Policy Act (NEPA) was signed into law on January 1, 1970. In December of that year, the USEPA was created to bring under one agency all of the pollution-control programs related to air, water, and solid wastes. In 1972, the Water Pollution Control Act Amendments expanded the role of the federal government in water pollution control and significantly increased federal funding for construction of wastewater treatment plants.

Many of the wastewater treatment plants in operation today are the result of federal grants made over the years. For example, because of the 1977 Clean Water Act Amendment to the Federal Water Pollution Control Act of 1972 and the 1987 Clean Water Act reauthorization bill, funding for wastewater treatment plants was provided.

Some large sanitation districts, with their multiple plant operations, and even a larger number of single plant operations in smaller communities still in operation today are a result of these early environmental laws and federal grants.

Many of these locally or federally funded treatment plants are aging and becoming less efficient. Complicating the problems associated with natural aging and associated wear on equipment is the increasing pressure on older systems to meet demands of increased population and urban growth. Facilities built in the 1960s and 1970s are now 30 to 40 years old, and not only are they showing signs of wear and tear, they simply were not designed to handle the level of growth (increase in flow) that has occurred in many municipalities.

Regulations often necessitate a need to upgrade. By matching funds or providing federal money to cover some of the costs, municipalities can take advantage of a window of opportunity to improve their facilities at a lower direct cost to the community. Federal dollars, of course, do not come without strings attached; they are to be spent on specific projects in specific areas. On the other hand, many times new regulatory requirements are put in place without the financial assistance needed to implement them. When this occurs, either the local community ignores the new requirements (i.e., until caught and forced to comply) or faces the situation and implements local tax hikes to pay the cost of compliance.

An example of how a change in regulations can force the issue is demonstrated by the demands made by the Occupational Safety and Health Administration (OSHA) and USEPA in their Process Safety Management (PSM)/Risk Management Planning (RMP) regulations. These regulations put the use of elemental chlorine (and other listed hazardous materials) under scrutiny. Moreover, because of these regulations, plant managers throughout the country are forced to choose which side of a double-edged sword cuts their way the most. One edge calls for full compliance with the regulations (analogous to stuffing the regulation through the eye of a needle). The other edge calls for substitution, that is, replacing toxic elemental chlorine with a nonlisted hazardous chemical (e.g., hypochlorite) or a physical (ultraviolet irradiation, UV) disinfectant — either way, a very costly undertaking.

3. Privatization and/or Re-engineering¹

As mentioned, wastewater treatment operations are undergoing a paradigm shift. We explained that this paradigm shift focuses on the holistic approach to treating water. The shift is, however, more inclusive.

¹Adapted from Johnson, R. and Moore, A., Policy Brief 17 Opening the Floodgates: Why Water Privatization will Continue. Reason Public Institute. January 2002, pp. 1-3, [www.rppi.org/pbrief 17]. Accessed May 14, 2002.

It also includes “thinking outside the box.” That is, in order to remain efficient and therefore competitive in the real world of operations, wastewater facilities have either bought into the new paradigm shift or have been forcibly “shifted” to doing other things (often these “other” things have little to do with wastewater operations).

Experience has shown that few words conjure up more fear among municipal plant managers (and other employees) than “privatization” or “reengineering.” **Privatization** means allowing private enterprise to compete with government in providing public services, such as water and wastewater operations. **Existing management**, on the other hand, can accomplish reengineering internally, or it can be used (and usually is) during the privatization process. Reengineering is the systematic transformation of an existing system into a new form to realize quality improvements in operation, system capability, functionality, performance, or evolvability at a lower cost, better schedule, or lower risk to the customer.

Many on-site managers consider privatization and/or reengineering schemes threatening. In the worst case scenario, a private contractor could bid the existing staff out of their jobs. What might happen in the best case? Privatization and/or re-engineering are often a very real threat that forces on-site managers into workforce cuts, improving efficiency and cutting costs. At the same time, on-site managers must still ensure that the community receives safe drinking water and that the facility meets standards and permits, with fewer workers — without causing injury or accident to workers, and/or damage to the facility and/or the environment.

Local officials may take a hard look at privatization and/or re-engineering for a number of reasons:

- **Decaying infrastructures.** As mentioned, many wastewater operations include infrastructure that dates back to the early 1900s. The most recent systems were built with federal funds during the 1970s, and even these now need upgrading or replacing.
- **Mandates.** The federal government has reduced its contributions to local wastewater systems over the past 30 years, while at the same time imposing stricter water quality and effluent standards under the Clean Water Act and Safe Drinking Water Act. Moreover, as previously mentioned, new unfunded mandated safety regulations, such as OSHA’s Process Safety Management and USEPA’s Risk Management Planning, are expensive to implement using local sources of revenues or state revolving loan funds.
- **Hidden function.** Earlier we stated that much of the work of wastewater treatment is a “hidden function.” Because of this lack of visibility, it is often difficult for local officials to commit to making the necessary investments in local wastewater systems. Simply, local politicians lack the political will; wastewater pipes and/or interceptors are not visible and not perceived as immediately critical for adequate funding to fund operations. Thus, it is easier for elected officials to ignore utility needs in favor of expenditures of more visible services, such as police and fire. Additionally, raising sewage rates to cover operations and maintenance is not always effected because it is an unpopular move for elected officials, meaning that sewer rates often do not adequately cover the actual cost of providing services in many municipalities.

In many locations throughout the United States, expenditures for wastewater services are the largest facing local governments today. (Note: This is certainly the case for those municipalities struggling to implement the latest stormwater requirements). Thus, this area presents a great opportunity for cost savings. Through privatization, private wastewater companies can take advantage of advanced technology, more flexible management practices, and streamlined procurement and construction practices to lower costs and make the critical improvements more quickly.

4. Benchmarking

Primarily out of self-preservation (to retain their lucrative positions), many utility directors work against the trend to privatize water, wastewater, and other public operations. Usually the real work to prevent privatization is delegated to the individual managers in charge of each specific operation. Moreover, working against privatization by these “local” managers is also in their own self-interest and in the interest of their workers, whose jobs may be at stake.

Start → Plan → Research → Observe → Analyze → Adapt

FIGURE 90.3 Benchmarking process.

The question is, of course, how does one go about preventing his or her wastewater operation from being privatized? The answer is rather straightforward and clear: Efficiency must be improved at reduced cost. In the real world, this is easier said than done — but is not impossible. For example, for those facilities under Total Quality Management (TQM), the process can be much easier. The advantage TQM offers the plant manager is the variety of tools to help plan, develop, and implement wastewater efficiency measures. These tools include self-assessments, statistical process control, International Organization for Standards (ISO) 9000 and 14,000, process analysis, quality circle, and benchmarking (see Figure 90.3).

Benchmarking is a process for rigorously measuring your performance vs. “best-in-class” operations, and using the analysis to meet and exceed the best in class.

What benchmarking is:

1. Benchmarking vs. best practices gives wastewater managers a way to evaluate their operations overall.
 - A. How effective
 - B. How cost effective
2. Benchmarking shows plant managers both how well their operations stack up and how well those operations are implemented.
3. Benchmarking is an objective-setting process.
4. Benchmarking is a new way of doing business.
5. Benchmarking forces an external view to ensure correctness of objective setting.
6. Benchmarking forces internal alignment to achieve plant goals.
7. Benchmarking promotes teamwork by directing attention to those practices necessary to remain competitive.

Potential results of benchmarking:

1. Benchmarking may indicate direction of required change rather than specific metrics.
2. Costs must be reduced.
3. Customer satisfaction must be increased.
4. Return on assets must be increased.
5. Maintenance must be improved.
6. Operational practices must be improved.
7. Best practices are translated into operational units of measure.

Targets:

1. Consideration of available resources converts benchmark findings to targets.
2. A target represents what can realistically be accomplished in given time frame.
3. Can show progress toward benchmark practices and metrics.
4. Quantification of precise targets should be based on achieving benchmark.

When forming a benchmarking team, the goal should be to provide a benchmark that evaluates and compares privatized and reengineered wastewater treatment operations to the operation in order to be more efficient and remain competitive and make continual improvements. It is important to point out that benchmarking is more than simply setting a performance reference or comparison; it is a way to facilitate learning for continual improvement. The key to the learning process is looking outside one's own plant to other plants that have discovered better ways of achieving improved performance.

As shown in [Figure 90.3](#), the benchmarking process consists of five steps.

Step 1: Planning. Managers must select a process (or processes) to be benchmarked. A benchmarking team should be formed. The process of benchmarking must be thoroughly understood and

documented. The performance measure for the process should be established (i.e., cost, time, and quality).

Step 2: **Research.** Information on the “best-in-class” performer must be determined through research. The information can be derived from the industry’s network, industry experts, industry and trade associations, publications, public information, and other award-winning operations.

Step 3: **Observation.** The observation step is a study of the benchmarking subject’s performance level, processes, and practices that have achieved those levels, and other enabling factors.

Step 4: **Analysis.** In this phase, comparisons in performance levels among facilities are determined. The root causes for the performance gaps are studied. To make accurate and appropriate comparisons, the comparison data must be sorted, controlled for quality, and normalized.

Step 5: **Adaptation.** This phase is putting what is learned throughout the benchmarking process into action. The findings of the benchmarking study must be communicated to gain acceptance, functional goals must be established, and a plan must be developed. Progress should be monitored and, as required, corrections in the process made.

The bottom line on privatization — Privatization is becoming of greater concern. Governance boards see privatization as a potential way to shift liability and responsibility from the municipality’s shoulders, with the attractive bonus of cutting costs. Wastewater facilities face constant pressure to work more efficiently, more cost effectively, with fewer workers, to produce a higher quality product; that is, all functions must be value added. Privatization is increasing, and many municipalities are seriously considering outsourcing parts or all of their operations to contractors.

5. Upgrading Security

You may say Homeland Security is a Y2K problem that doesn’t end January 1 of any given year.

— Governor Tom Ridge [Henry, 2002]

One consequence of the events of September 11 is USEPA’s directive to establish a Water Protection Task Force to ensure that activities to protect and secure water supply/wastewater treatment infrastructure are comprehensive and carried out expeditiously. Another consequence is a heightened concern among citizens in the United States over the security of their critical water/wastewater infrastructure. The nation’s water/wastewater infrastructure, consisting of several thousand publicly owned water/wastewater treatment plants, more than 100,000 pumping stations, hundreds of thousands of miles of water distribution and sanitary sewers, and another 200,000 miles of storm sewers, is one of America’s most valuable resources, with treatment and distribution/collection systems valued at more than \$2.5 trillion. Wastewater treatment operations taken alone include the sanitary and storm sewers forming an extensive network that runs near or beneath key buildings and roads and is contiguous to many communication and transportation networks. Significant damage to the nation’s wastewater facilities or collection systems would result in loss of life; catastrophic environmental damage to rivers, lakes, and wetlands; contamination of drinking water supplies; long-term public health impacts, destruction of fish and shellfish production; and disruption of commerce, the economy, and our normal way of life.

Governor Tom Ridge points out the security role for the public professional (including water/wastewater professionals):

Americans should find comfort in knowing that millions of their fellow citizens are working every day to ensure our security at every level — federal, state, county, municipal. These are dedicated professionals who are good at what they do. I’ve seen it up close, as Governor of Pennsylvania.... But there may be gaps in the system. The job of the Office of Homeland Security will be to identify those gaps and work to close them [Henry, 2002].

It is to shore up the “gaps in the system” that has driven many water/wastewater facilities to increase security. Moreover, USEPA in its *Water Protection Task Force Alert #IV: What Wastewater Utilities Can do*

Now to Guard Against Terrorist and Security Threats (October 24, 2001) made several recommendations to increase security and reduce threats from terrorism. These recommendations include:

1. Guarding against unplanned physical intrusion
 - Lock all doors and set alarms at your office, pumping stations, treatment plants, and vaults, and make it a rule that doors are locked and alarms are set.
 - Limit access to facilities and control access to pumping stations and chemical and fuel storage areas, giving close scrutiny to visitors and contractors.
 - Post guards at treatment plants, and post “Employees Only” signs in restricted areas.
 - Control access to storm sewers.
 - Secure hatches, metering vaults, manholes, and other access points to the sanitary collection system.
 - Increase lighting in parking lots, treatment bays, and other areas with limited staffing.
 - Control access to computer networks and control systems, and change the passwords frequently.
 - Do not leave keys in equipment or vehicles at any time.
2. Making security a priority for employees
 - Conduct background security checks on employees at hiring and periodically thereafter.
 - Develop a security program with written plans and train employees frequently.
 - Ensure all employees are aware of communications protocols with relevant law enforcement, public health, environmental protection, and emergency response organizations.
 - Ensure that employees are fully aware of the importance of vigilance and the seriousness of breaches in security, and make note of unaccompanied strangers on the site and immediately notify designated security officers or local law enforcement agencies.
 - Consider varying the timing of operational procedures if possible so if someone is watching the pattern changes.
 - Upon the dismissal of an employee, change passcodes and make sure keys and access cards are returned.
 - Provide customer service staff with training and checklists of how to handle a threat if it is called in.
3. Coordinating actions for effective emergency response
 - Review existing emergency response plans, and ensure they are current and relevant.
 - Make sure employees have necessary training in emergency operating procedures.
 - Develop clear protocols and chains-of-command for reporting and responding to threats along with relevant emergency, law enforcement, environmental and public health officials, as well as consumers and the media. Practice the emergency protocols regularly.
 - Ensure key utility personnel (both on and off duty) have access to crucial telephone numbers and contact information at all times. Keep the call list up to date.
 - Develop close relationships with local law enforcement agencies, and make sure they know where critical assets are located. Request they add your facilities to their routine rounds.
 - Work with local industries to ensure that their pretreatment facilities are secure.
 - Report to county or state health officials any illness among the employees that might be associated with wastewater contamination.
 - Report criminal threats, suspicious behavior, or attacks on wastewater utilities immediately to law enforcement officials and the relevant field office of the Federal Bureau of Investigation.
4. Investing in security and infrastructure improvements
 - Assess the vulnerability of collection/distribution system, major pumping stations, water/wastewater treatment plants, chemical and fuel storage areas, outfall pipes, and other key infrastructure elements.
 - Assess the vulnerability of the storm water collection system. Determine where large pipes run near or beneath government buildings, banks, commercial districts, or industrial facilities or are contiguous with major communication and transportation networks.

- Move as quickly as possible with the most obvious and cost-effective physical improvements, such as perimeter fences, security lighting, tamper-proofing manhole covers and valve boxes, etc.
- Improve computer system and remote operational security.
- Use local citizen watches.
- Seek financing for more expensive and comprehensive system improvements.

The bottom line on security — Again, when it comes to the security of our nation and even of water/wastewater treatment facilities, few have summed it up better than Governor Ridge.

Now, obviously, the further removed we get from September 11, I think the natural tendency is to let down our guard. Unfortunately, we cannot do that. The government will continue to do everything we can to find and stop those who seek to harm us. And I believe we owe it to the American people to remind them that they must be vigilant, as well [Henry, 2002].

Technical Management vs. Professional Management

Wastewater treatment management is directed toward providing treatment of incoming raw influent (no matter what the quantity), at the right time, to meet regulatory requirements, and at the right price to meet various requirements.

The techniques of management are manifold both in water resource management and wastewater treatment operations. In water treatment operations, for example, management techniques may include “storage to detain surplus water available at one time of the year for use later, transportation facilities to move water from one place to another, manipulation of the pricing structure for water to reduce demand, use of changes in legal systems to make better use of the supplies available, introduction of techniques to make more water available through watershed management, cloud seeding, desalination of saline or brackish water, or area-wide educational programs to teach conservation or reuse of water” [Mather, 1984]. Many of the management techniques employed in water treatment operations are also employed in wastewater treatment. In addition, wastewater treatment operations employ management techniques that may include upgrading present systems for nutrient removal, reuse of process residuals in an earth-friendly manner, and area-wide educational programs to teach proper domestic and industrial waste disposal practices.

The manager of a wastewater treatment plant, in regards to expertise, must be a well-rounded, highly skilled individual. No one questions the need for incorporation of these highly trained practitioners in the profession — well-versed in the disciplines of sanitary engineering, biology, chemistry, hydrology, environmental science, safety principles, accounting, auditing, technical aspects, and operations. Based on personal experience, however, engineers, biologists, chemists, scientists, and others with no formal management training are often hindered (limited) in their ability to solve the complex management problems currently facing both industries.

There are those who will view this opinion with some disdain. However, in the current environment where privatization, the need to upgrade security, and other pressing concerns are present, skilled “management professionals” are needed to manage and mitigate these problems.

Ross E. McKinney
Environmental Consultant

Solid wastes are primarily a problem for urban and industrial areas. Although solid wastes have been a problem for urban centers since the beginning of time, it was the rapid growth of the industrial society that generated the current problems. As the standard of living increased, the consumption of goods produced solid wastes that created environmental pollution when they were discarded without proper treatment. Recently, the industrialized countries have begun to examine solid wastes and to develop methods for reducing their production as well as processing them for return to the environment without creating pollution. Although progress has been made, more is required.

91.1 Regulations

The primary solid waste regulations are at the local government level. One of the primary functions of local government is to protect the health of its citizens. Solid waste collection and processing are primarily a public health problem that can only be managed at the local level. Most communities have developed ordinances to handle solid waste storage, collection, and processing.

Local government derives its authority from state government. Since solid wastes are public health problems, many states have placed their solid waste regulations under state departments of health. In recent years, a number of states have moved control of solid wastes to departments of environmental pollution control or departments of natural resources. The authority for all solid waste regulations resides in each state legislature, with the development of detailed regulations assigned to the appropriate state agency.

In 1965, the federal government became involved in solid waste legislation when Congress passed the first federal solid waste legislation as an addendum to the 1965 Federal Air Pollution legislation. The primary purpose of this federal legislation was to reduce the number of open burning dumps that were creating air pollution and to determine the status of state solid waste programs. The Resource Recovery Act was passed by Congress in 1970 to assist in the development of new systems of processing solid wastes and recovering materials for reuse. This was followed by the Resource Conservation and Recovery Act of 1976 (RCRA). The most important components of this legislation were Subtitle C, which dealt with hazardous solid wastes, and Subtitle D, which dealt with sanitary landfills. Problems with buried hazardous wastes resulted in Congress's passing the Comprehensive Environmental Response, Compensation and Liability Act of 1980 (CERCLA), also known as the Superfund Act. RCRA was amended by Congress

in 1980 and in 1984. The 1984 amendments were designated the Hazardous and Solid Waste Amendments. In 1986 the Superfund Amendments and Reauthorization Act (SARA) passed Congress. Congress has had recent difficulty passing new legislation, but it has allowed existing legislation to continue, permitting the federal Environmental Protection Agency (EPA) to develop regulations covering the areas of concern. As a net result, it is essential to keep informed on the continuous stream of regulations published in the *Federal Register*.

Overall, federal regulations provide national policies in solid wastes, whereas the state regulations are designed to implement the federal regulations. However, it must be recognized that ultimate control of solid waste operations is at the local level. It is at the local level that federal and state policies and regulations are converted to action. For the most part, regulations are being developed in response to public perception of environmental problems, and the two are not always in a logical sequence.

91.2 Characteristics

One of the more interesting aspects of solid waste management is the simple fact that very little real data exist on current municipal solid waste characteristics. It is too difficult to collect detailed data on solid waste characteristics for even the largest cities. A few detailed studies have been made when the economic considerations for specific solid waste-processing systems were high enough to justify determination of solid waste characteristics. Most engineers use the data generated by the U.S. EPA [EPA, 2002] as the basis for municipal solid waste characteristics. The EPA data represent approximate characteristics based on a material flow methodology developed at Midwest Research Institute in 1969. The EPA composition data are a reasonable estimate on a national basis. It should be recognized that solid waste characteristics vary with the section of the country, the seasons of the year, and economic conditions.

The EPA Office of Solid Waste recognized that solid wastes are composed of many different materials, making composition analyses difficult if a common set of criteria are not used. As a result, a broad classification of nine categories was used. Although several subcategories have been added for specific projects, the nine categories have gained widespread acceptance. Table 91.1 gives the percentage of total solid wastes for the nine categories as estimated by the EPA for the year 2000 [EPA, 2002]. It is estimated that 75% of municipal solid waste is combustible and 25% is noncombustible. The combustibility characteristics of solid wastes are important when solid wastes are to be processed by incineration, whereas the general solid waste characteristics are used for evaluating solid waste recycling and solid waste reduction projects. It should be noted that the EPA solid waste characteristics are based on an “as collected” basis, which includes about 20% moisture. Variations in moisture content are important when evaluating solid waste characteristics for incineration. Care should be taken before using general solid waste characteristics in solid waste treatment facilities design.

TABLE 91.1 Characteristics of Solid Wastes Generated in 2000

| Type of Waste | Percentage of Total Solid Waste |
|-------------------------------|---------------------------------|
| Paper and paperboard | 37.4 |
| Glass | 5.5 |
| Metals | 7.8 |
| Plastics | 10.7 |
| Rubber, leather, and textiles | 6.7 |
| Wood | 5.5 |
| Food wastes | 11.2 |
| Yard wastes | 12.0 |
| Other wastes | 3.2 |

91.3 Generation

Data on solid waste generation are a little better than data on solid waste characteristics, since more communities have gathered data on the weight of solid wastes handled than on solid waste analyses. However, it should be recognized that weight data may not be much better than characterization data. Accurate weight data require checking the scales at regular intervals to ensure accuracy. It is also important to weigh trucks both before and after unloading to determine the real weight of the solid wastes. Use of a truck tare weight to minimize the number of weight measurements will often result in high weight values. The key to proper evaluation of generation data is regular collection and weighing of solid wastes from the same areas of the community.

Generation data are generally reported in pounds per person per day. With a uniform generation rate, it is easy to determine the total solid waste production for various sizes of communities. The EPA data on solid waste generation [EPA, 2002] indicated a change from 2.7 lb/person/day in 1960 to 4.5 lb/person/day in 2000. It has been found that solid waste generation is primarily a function of economic conditions. Municipal solid waste generation decreases during poor economic periods and increases with good economic growth. Concern over the generation of solid wastes has resulted in changes in the packaging of materials. Smaller packages and lighter packaging materials have contributed to the decrease in the weight of packaging wastes. Increased advertising has generated more pages of newspapers and magazines that quickly become outdated. Careful evaluation of social conditions indicates that there is a limit to how much solid waste a person can actually generate on a daily basis. A study for the Institute for Local Self-Reliance [Platt et al., 1990] found that residential solid waste generation for 15 cities ranged from 1.9 to 5.5 lb/person/day with a median of 3.3 lb/person/day. Unfortunately, the economics of some solid waste projects depend upon a reasonable estimation of the solid waste generation rate. The ease of collecting solid waste generation data should allow engineers to obtain sufficient data on municipal solid waste generation for project design.

91.4 Collection

Solid wastes must be collected where they are generated. This means that a system must be developed to go to every building in the community at some time frequency. Currently, residential solid wastes can be conveniently collected once weekly. A few communities employ twice-weekly collection. Commercial buildings may require more frequent collection, depending on the rate of generation and the size of the storage containers. Restaurants often require daily solid waste collection.

Every solid waste generator must have a suitable storage container to hold solid wastes between collections. Residences tend to use individual containers, each having a maximum capacity of 30 gallons, to minimize the weight in any single container. Recently, large plastic containers with wheels have been used in more communities. The householder is able to wheel the solid wastes from the garage to the curb for pickup without difficulty. Special mechanisms on the collection trucks allow the solid waste collector to transfer the solid wastes from the wheeled container to the collection truck with a minimum of effort. Apartment buildings, office buildings, and commercial establishments produce larger quantities of solid wastes than residences and require larger solid waste containers. Storage containers range in size from 1 to 10 yd³. Small storage containers can be dumped into rear-loading collection trucks or side-loading trucks, whereas large storage containers require front-loading collection trucks.

Solid wastes weigh between 200 and 250 lb/yd³ in loose containers. Collection trucks use hydraulic compaction to maximize the quantity of solid wastes that can be collected before dumping. Although it is possible to compact solid wastes to 600 to 700 lb/yd³, most collection trucks average 500 lb/yd³ after compaction. Rear-loading compaction trucks range in size from 9 to 32 yd³, with 20 yd³ trucks being the most commonly used for residential collection. Side-loading compaction trucks range from a small, 6 yd³, to a large, 35 yd³. Front-loading compaction trucks range from 22 to 42 yd³, with 30 and 35 yd³ trucks being most widely used for commercial routes. Roll-off units are used by industrial and special commercial accounts having large quantities of stable solid wastes. Roll-off units range in size from 10

to 30 yd³ and may be attached to stationary compaction units to increase the capacity of the roll-off unit. When the roll-off unit is full, the collection truck pulls the roll-off unit onto the truck frame for transport to the processing site. The collection trucks all have special unloading mechanisms to remove the compacted solid wastes at the desired processing site.

Collection crew size depends upon the specific collection pattern of each community. One-person crews are used for some side-loading residential collections, roll-off collections, and some front-loading commercial collections. Two-person crews are used in which one person is the driver and the other person is the collector. The two-person crews are quite common in areas where collection can only be made on one side of the street at a time. Three-person crews are most common in residential collection from both sides of the street. Four-person crews have been used in large communities. The size of collection crews and collection trucks depends on the size of the collection routes and the time allotted for collection activities. Time–motion studies are very important for evaluating crew collection efficiency, whereas good operation and maintenance records are important for evaluating the drivers and determining equipment replacement.

91.5 Transfer and Transport

Transport from the collection route to the solid waste processing site is an important parameter affecting the cost of operations. It is part of the rest time for collectors. If the transport distance is too long, valuable collection time can be lost. As a result, transfer stations have been constructed in large cities to permit smaller collection trucks to unload and return to collection routes. The solid wastes in the transfer station are placed into larger transfer trucks, 50 to 70 yd³ capacity, for transport to the final processing site. The large transfer trucks normally have only a single driver, reducing labor costs. Transfer stations are economical only in very large cities and require special design for efficient traffic flow. Small transfer stations where individuals bring their solid wastes in their own automobiles or trucks have been used in rural areas.

Recently, large cities have examined transporting solid wastes by rail for final processing. Rail transport is very expensive and has been used only in crowded areas where several communities are contiguous and no processing site can be found in any of the communities. Barge transport has also been used to move large quantities of solid wastes more economically. Transport of solid wastes from one area to other distant areas has created social and political problems that have limited long-distance transport of unprocessed solid wastes.

91.6 Processing and Resource Recovery (Recycling)

Solid waste processing has moved from incineration and open dumps to burial in sanitary landfills to partial recycling. Incineration has been the primary processing system for solid wastes in large cities over the past 100 years. The British pioneered incineration with energy recovery at the end of the last century, but it has been in only the last two decades that many energy recovery incineration systems have been constructed in the U.S. Poor designs and poor operations limited the use of energy recovery incineration even though it was quite successful in Europe. Incineration has application only in the very crowded areas of the country where heat energy can be easily used by adjacent industrial operations. It is important to understand that incineration simply converts combustible solid wastes to gaseous wastes that must be discharged to the atmosphere for final disposal and the noncombustible solid wastes to ash that must be returned to the land. Because of the potential for air pollution, the EPA has required extensive air pollution control equipment for solid waste incinerators, increasing the capital and operating costs. The U.S. Supreme Court has indicated that municipal solid waste ash must pass the hazardous waste criteria or be treated as hazardous waste. The high cost of incineration has limited its use to highly populated areas that produce large quantities of solid wastes on a continuous basis. Even in these areas, social and political pressures have limited the use of incineration for processing solid wastes. New York City has used

incineration of municipal solid wastes as extensively as any large city in the United States but has begun phasing out all of its incinerators without replacing them. New York City is planning to use modern waste-to-energy incinerators outside of the city limits.

Sanitary landfills are the engineered burial of solid wastes. Fundamentally, sanitary landfills are sound processing systems for municipal solid wastes. The two most common forms of sanitary landfills are trench landfills and area landfills. Both methods employ heavy equipment to compact the solid wastes to at least 1000 lb/yd³. Unfortunately, inadequate designs and improper operations have combined to create a poor public image for sanitary landfills. The major problems with sanitary landfills have been (1) the failure to apply adequate soil cover on the compacted solid waste at the end of each day, allowing wind to blow the solid wastes over the landfill surface and odors to escape, and (2) allowing water to enter the landfill, creating leachate and methane gas. Leachate passing through the sanitary landfill has contaminated groundwater as well as surface waters in some locations. Methane gas formation has produced fires in a few landfills, creating concern in the media over the safety of sanitary landfills. The simplicity of sanitary landfills has made them the most popular form of solid waste processing with local government. The failure of local government to operate sanitary landfills properly has led the EPA to develop more complex regulations under Subtitle D of RCRA. Leachate and gas collection systems — as well as water barriers and sampling systems to prove that leachate and gas are not leaving the landfill and creating environmental pollution — will be required in the future. The cost of sanitary landfill processing of solid wastes will increase significantly as the EPA develops more stringent operational requirements. The number of operational sanitary landfills in the United States has decreased from 7924 in 1988 to 1967 in 2000.

Reuse and recycling have long been important parts of the solid waste processing system. Most countries with limited economic bases do not have serious solid waste problems. These countries use and reuse all their resources as a necessity. As countries grow economically, their production of solid wastes increases. In 1970, the United States demonstrated that municipal solid waste recycling was technically feasible. Unfortunately, recycling of solid wastes was not as cost effective as using raw materials and did not gain much acceptance. Environmental groups brought pressure on various industrial groups to begin recycling. The aluminum can industry developed the best recycling system and survived the challenge from environmentalists. The plastic industry recognized the dangers that adverse media exposure posed and began to develop methods for plastic recycling. Glass was easily recycled, but was too heavy to ship very far and was made from an abundant material widely available in nature. Office paper was the easiest paper product to recycle. Corrugated cardboard was also recyclable. Newspapers were abundant but had to be used at a lower product level or de-inked for fiber recovery. The problem with lower product formation was that ultimately the material had to be processed back into the environment. De-inking was expensive and produced water pollution with concentrated solids that had to be processed before being returned to the environment.

The EPA established a Municipal Solid Waste Task Force in 1988 to develop a national agenda for solid wastes [EPA, 1989]. With the help of various environmental organizations they published *The Solid Waste Dilemma: An Agenda for Action*. They called for a national goal of a reduction of 25% in solid wastes by source reduction/recycling by 1992. It was recognized that 17% of the solid wastes was composed of yard wastes that could be removed and composted for reuse. This fact meant that only 8% more solid waste reduction was necessary in the form of metal cans, glass bottles, and newspapers. A number of state legislatures quickly accepted the 25% reduction goal and eliminated the discharge of yard wastes to sanitary landfills. Local communities had to eliminate collection of yard wastes or establish separate collections and composting programs. A few states legislated mandatory recycling. Unfortunately, mandating recycling created a sudden increase in recyclables that overwhelmed the markets, driving the prices down and increasing the costs. This meant that the excess solid wastes were buried in sanitary landfills rather than being recycled. It was quickly learned that even the commodity of solid waste was governed by supply and demand economics. The basic problem was excessive social and political pressures for an instant solution to problems that required time and patience to resolve. During the past decade most communities have established composting projects to remove yard wastes from the municipal solid waste

stream. Some communities have established special collections for paper, glass, aluminum and steel cans, and specific plastics. The EPA [2002] estimated that 30.1% of the municipal solid wastes produced in 2000 were “recovered and recycled or composted.” Part of the problem is measuring the solid waste reduction. The EPA developed methodology to assist everyone in using the same parameters to measure solid waste production and reduction. The total solid waste stream is the sum of the solid wastes sent to the disposal site and the solid wastes recycled. The fraction of the solid wastes recycled is simply the solid waste recycled divided by the total solid wastes produced. Since the recycled wastes are often processed by private handlers, care must be taken to verify that the recycled solid waste data are correct.

91.7 Final Disposal

There is no doubt that solid waste reduction, reuse, and recycling are the best methods for processing solid wastes. The major issue is the same today as it was in 1970 — economics. Society has not learned how to reduce the production of solid wastes while maintaining an economically viable operation. Solving the problem of solid waste involves determining what materials should not be produced and how to efficiently employ people in meaningful endeavors. Reuse and recycling are more attractive since work is required to reprocess the waste materials into useful products. It should be recognized that all materials come from the earth and most materials are still available in solid wastes. Recycling is the ultimate solid waste process, with wastes being converted back to raw materials for manufacture to new products to benefit all people. The strength of democratic societies lies in their ability to adapt to current conditions with a minimum of wasted effort. Until complete recycling systems are developed that can economically process solid wastes, storage will continue to be the final disposal of solid wastes. Storage may take many forms, including burial below the ground surface or above the ground surface, as in a sanitary landfill. When society needs the buried materials, sanitary landfills will become mines for future generations. Few people recognize that the future of current societies depends on their ability to process solid wastes back into the environment without creating serious pollution problems. The treatment of polluted air and polluted water also results in the production of solid wastes that must be returned to the environment. Survival does not depend on the heads of state or various legislative bodies, but on the action of a few individuals at the local level. Those dedicated individuals who collect and process all the solid wastes that society produces provide the environment that makes life worth living and allow the rest of society to do the things it finds most enjoyable. The future is bright because the solid waste profession has met all the challenges to date.

Defining Terms

Area landfill — A landfill constructed by placing the solid waste against a natural hill, compacting the solid waste to 1000 lb/yd³, and covering with the minimum of 2 ft soil for final cover. The next cell is constructed by placing the solid waste against the previous cell and raising the land surface to the top of the landfill.

Ash — Residual inorganic material remaining after incineration.

Incineration — Controlled burning of mixed solid wastes at a temperature of 1800°F for a sufficient time to oxidize 99% of the organic matter in the solid waste.

Solid wastes — All solid materials that have no significant economic value to the owner and are discarded as wastes.

Trench landfill — A landfill constructed by digging a trench 10 to 15 ft deep and 20 to 30 ft wide, filling it with solid waste, compacting the solid waste to 1000 lb/yd³, and covering with a minimum of 2 ft soil for final cover.

Waste recycling — The reuse of solid waste materials after separation and reprocessing to new products.

Waste reduction — The reduction in the production of solid wastes, primarily by reducing the production and consumption of goods by society.

Waste reuse — The direct reuse (without major processing) of solid wastes by members of society.

Hazardous waste management is a broad and evolving field. Applicable state and federal regulations comprising over 60,000 pages are continually being updated. Many of these regulations overlap and are subject to differences in interpretation that often lead to court rulings. Regulations, economic pressures, and public perception are forcing companies to rapidly change the way they manufacture products in order to minimize hazardous waste generation.

Over 200 million tons of solid hazardous waste are generated annually in the U.S. Huge quantities of hazardous waste deposited in landfills, ponds, fields, and other locations require removal or *in situ* treatment. Common hazardous wastes include solvents, acids, bases, heavy metals, pesticides, plating, and heat-treating wastes. Six major effects of improper hazardous waste management are groundwater contamination, contamination of surface runoff, air pollution, fire and explosion, and adverse health effects via direct contact or via the food chain.

This chapter provides a general overview of federal regulations governing hazardous waste management, as well as a brief review of the types of hazardous waste, waste minimization, and treatment and

disposal technologies. Four types of hazardous waste will be discussed here: chemical waste, radioactive waste, infectious waste, and mixed waste.

92.1 Regulatory Overview

Federal, state, and local governments regulate hazardous waste management. Federal regulatory agencies sometimes delegate authority to the state agencies provided that the state programs are at least as strict. Only federal regulations are discussed here. With a few exceptions, the Environmental Protection Agency (EPA) governs most federal hazardous waste management activities. The Department of Transportation (DOT) governs the transportation of all hazardous wastes except for high level nuclear waste.

The Nuclear Regulatory Commission (NRC) governs nuclear wastes from the private sector and coregulates mixed wastes with the Department of Energy (DOE). Other agencies, such as the Occupational Safety and Health Administration (OSHA) and the Bureau of Land Reclamation, have responsibilities within the hazardous waste management process. Important legislation is summarized in the following sections.

RCRA

Congress passed the Resource Conservation and Recovery Act (RCRA) in 1976 as an amendment to the Solid Waste Act of 1965. RCRA is composed of 10 parts covering all aspects of hazardous waste management with the exception of nuclear waste. It governs generation, storage, transportation, treatment, recycling, and disposal. The generator of hazardous waste is responsible for the waste through each of these steps and beyond. EPA was authorized by RCRA to establish and implement regulations governing hazardous waste management. This program involved:

1. Defining hazardous waste
2. Tracking the transportation of the waste
3. Establishing construction and operation standards for treatment, storage, and disposal facilities (TSDFs)
4. Establishing guidelines for state hazardous waste management programs

The Medical Waste Tracking Act (MWTa) of 1988 expanded RCRA to include regulating the disposal and treatment of medical waste.

CERCLA

The Comprehensive Environmental Response, Compensation and Liability Act (CERCLA) was passed in 1980 to address the cleanup of toxic waste sites. CERCLA provides for liability, compensation, cleanup, and emergency response to existing and closed hazardous waste sites. The heart of CERCLA is the Superfund, which started in 1980 as a \$1.6 billion fund. The Superfund Amendments and Reauthorization Act (SARA) of 1986 revised and broadened CERCLA, creating a \$8.5 billion fund to be collected through special taxes. Congress asserted that regardless of who was responsible for causing the contamination, the sites needed remediation in order to protect human health and the environment.

EPA involvement begins with the identification of a potential hazardous waste site. The EPA has developed the Emergency and Remedial Response Information System (CERCLIS) to document all of the sites in the U.S. that may be candidates for remedial action. As of 1993 the list was approaching 30,000 sites. In order to be eligible for cleanup under CERCLA, a site must first be placed on the National Priorities List (NPL). The NPL identifies the hazardous waste sites of immediate concern and ranks them according to their relative risk to public health and the environment. As of August 1990, 1187 sites were on the NPL list identified as "Superfund sites." The EPA addresses the cleanup of each site on a case-by-case basis. Part of EPA's process involves the identification of the potentially responsible parties (PRPs) for:

1. State or federal remedial action
2. Recovery of necessary response cost incurred
3. Damages to natural resources

The PRPs may include past owners or operators, generators of the hazardous substances that are at the site, or the transporters who brought the waste to the site. EPA tries to get the PRPs to initiate cleanup or to pay for the remediation, but if the PRPs cannot, the EPA uses money from the Superfund for the cleanup and tries to recover the monies later. No amount of care can guarantee a person handling hazardous substances protection from liability. The liability cannot be transferred to another party.

Under CERCLA, the EPA can respond to incidents involving hazardous substances in three ways:

1. Immediate removal and emergency response to prevent significant harm (completed within 6 months)
2. Planned removal, which is an expedited response to a situation that is not necessarily an emergency
3. Remedial response, which requires additional time and money intended to achieve a site solution that is a permanent remedy

TSCA

The Toxic Substance Control Act (TSCA) was passed in 1976 to prevent environmentally unsound chemicals such as DDT and PCBs from being released to the environment. TSCA gives the EPA 90 days to investigate the potential deleterious effects of new chemicals on the environment before allowing them to be manufactured. If a chemical poses a significant threat, the EPA may impose special restrictions, from warning labels to an outright ban. The EPA can also require testing of existing chemicals if there is insufficient information to form a risk assessment.

HSWA

Congress passed the Hazardous and Solid Waste Amendments (HSWA) in 1984. These amendments significantly broadened the scope and effectiveness of RCRA. A major theme of the HSWA is the protection of groundwater through the following measures:

- Hazardous waste landfill design requirements
- Requirements for small-quantity generators
- Requirements for underground storage tanks
- Requirements for landfilling of municipal wastes
- Restrictions on future land disposal
- Treatment requirements for waste deposited in landfills

Provisions of the HSWA ban the land disposal of specified types of hazardous wastes unless the wastes are first treated to levels that are protective of human health and the environment. The regulations specifically prohibit the disposal of bulk (noncontainerized) liquid wastes in landfills and surface impoundments. It prohibits disposal of containerized liquids unless no alternative is available. The amendments set out a series of deadlines for ending land disposal of various groups of hazardous wastes.

There are three exceptions to the land ban:

1. The waste meets EPA and state treatment standards.
2. A petitioner demonstrates to the EPA and/or state that the waste in question will not migrate from the disposal unit for as long as the wastes remain hazardous.
3. EPA has issued a variance extending the deadline.

In addition, the Occupational Health and Safety Act of 1970, the Hazardous Materials Transportation Act (HMTA) of 1975, portions of the 1970 Clean Air Act and as amended in 1990, the Clean Water Act (1972), and the Safe Drinking Water Act (1974) also regulate certain aspects of hazardous waste management.

Code of Federal Regulations

Once Congress passes legislation, federal agencies prepare and codify regulations that are published annually in the Code of Federal Regulations (CFR). The CFR has 50 titles. Title 10 contains the Atomic Energy Act and related NRC and DOE regulations, Title 29 the OSHA regulations, Title 40 the EPA regulations, and Title 49 the DOT regulations. The federal government publishes the daily amendments and potential changes to the annual CFR and court interpretations in the *Federal Register (FR)*. Several private companies sell computerized versions of the CFR as well as state regulations, including recent updates and legal interpretations. Users can access these databases via modem, floppy disks, or CD-ROM format. The computer databases allow for smaller storage space requirements, provide quicker access to specific regulations, and provide various advanced searching methods.

92.2 Definition of Hazardous Waste

Hazardous waste has been defined by RCRA as a “solid waste, or combination of solid wastes, which because of its quantity, concentration, or physical, chemical, or infectious characteristics may (1) cause, or significantly contribute to, an increase in mortality or an increase in serious irreversible or incapacitating reversible illness or, (2) pose a substantial present or potential hazard to human health or the environment when improperly treated, stored, transported or disposed of or otherwise managed” [EPA, 1990]. Other regulations may define hazardous waste differently, but RCRA sets the standard. The term *solid waste* includes solids and certain liquids or gases.

As shown in [Figure 92.1](#), the RCRA definition has a number of conditions and exceptions that are a result of overlap with other regulations and vestiges of earlier definitions of hazardous waste. Most of these exempted wastes are either regulated by other federal legislation or are regulated on the state and/or local level. The RCRA definition of solid waste does not include radioactive waste because this waste is governed by the Atomic Energy Act. The flowchart illustrates the general philosophy behind defining and classifying hazardous waste. We advise the reader to consult the CFR prior to classifying a waste. As shown on the chart, RCRA classifies a waste as hazardous if the CFR lists it as a hazardous waste or if it has hazardous characteristics.

Listed Wastes

EPA has defined and listed certain wastes as hazardous. A mixture of a listed hazardous waste and a nonhazardous solid waste is a hazardous waste. The “mixture rule” implies that any concentration of listed waste in a material makes it a hazardous waste. In recent years the EPA has allowed a more flexible interpretation that classifies certain wastes based on characteristic hazardous components and concentration. Furthermore, one may be able to de-list a listed waste by following procedures in 40 CFR 260. RCRA regulates unrinsed containers, inner linings, and any residue or soil contamination from hazardous waste as hazardous waste.

Nonlisted Wastes

If the waste is neither listed nor specifically exempted, the generator must make a judgment based on the hazardous characteristics of the waste. In some cases the generator can apply process knowledge of the waste or past experience to classify the waste as hazardous; otherwise, the waste must be tested at an approved laboratory. If the waste has any of the following four characteristics, it is hazardous:

1. Reactivity (coded D003)
 - Normally unstable
 - Ignites on contact with water
 - Releases toxic gases in contact with water

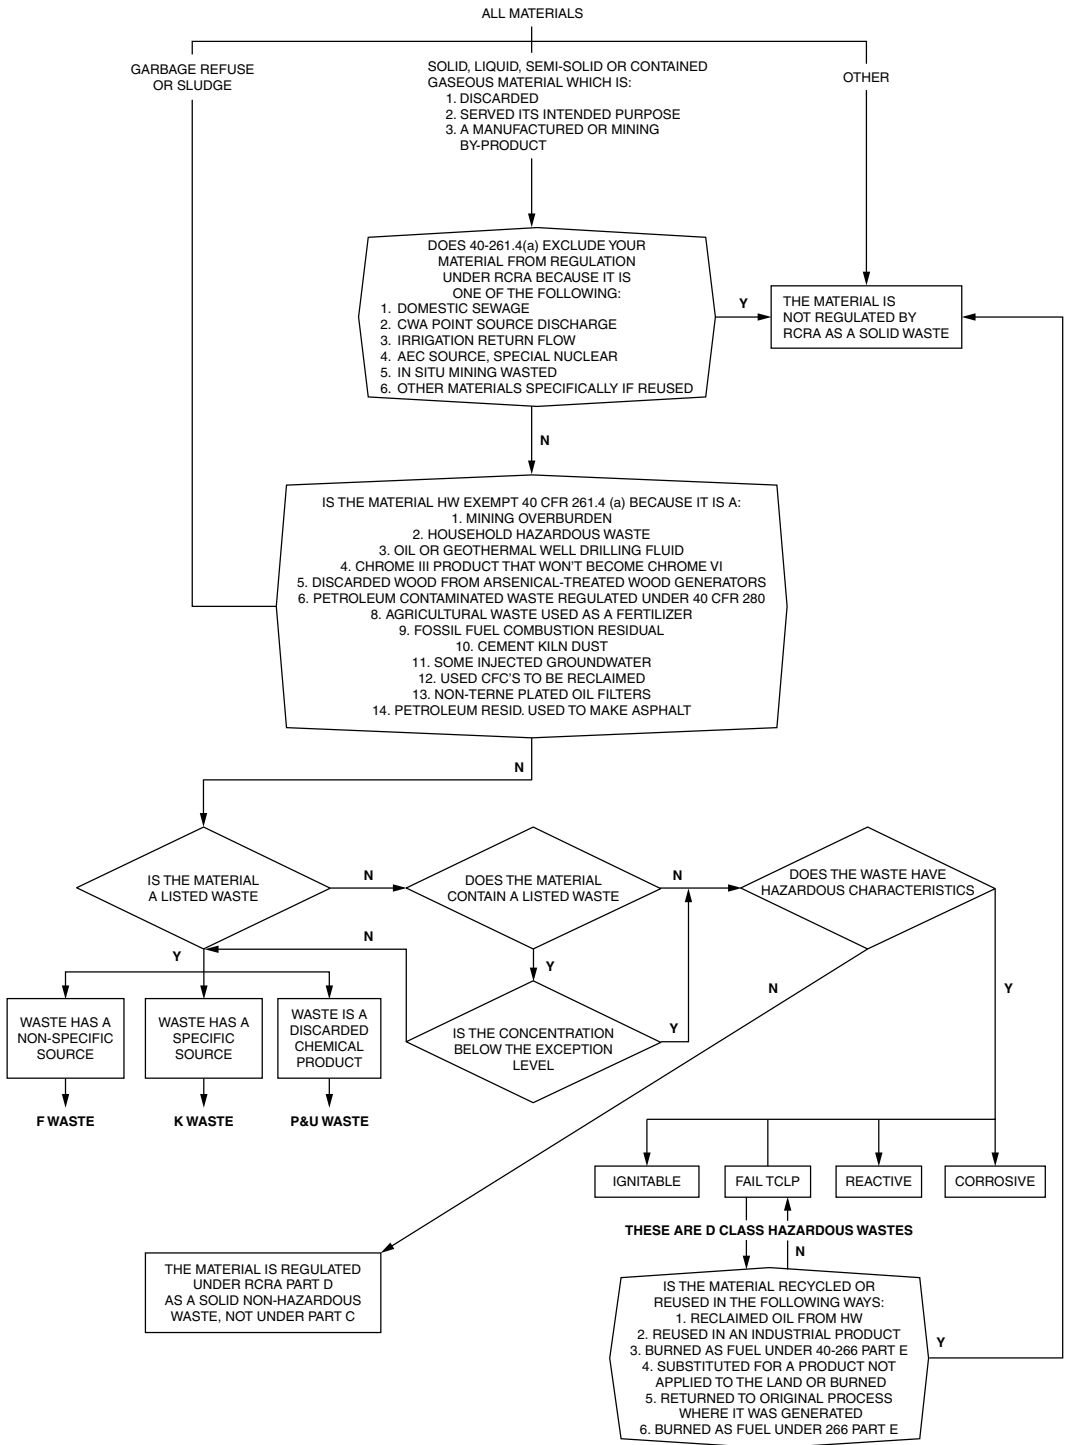

FIGURE 92.1 Definitions of hazardous wastes.

2. Corrosivity (coded D002)
 - Aqueous pH < 2 or > 12.5
 - Corrodes SAE steel at greater than 0.25 in./year
3. Ignitability (coded D003)
 - Flash point < 60°C
 - Solid ignitable compressed gas oxidizer
 - Listed as a Class A or Class B explosive
4. Toxicity (coded D###); capable of killing, injuring, or otherwise impairing a living organism on contact

The Toxic Characteristics Leaching Procedure (TCLP) is a laboratory method for estimating the leaching potential of a landfilled material. The evaluation of toxicity is based on the concentration of the specific chemical in the leachate. These chemicals and their maximum allowable concentrations are specified by [Table 1](#), 40 CFR 261.

Risk Assessment

Risk assessment is a quantitative means of evaluating the potential detrimental effects that an activity will have primarily on human health. Risk is a probability usually determined by obtaining a unit risk factor from toxicological data and using effective exposure data considering all pathways. Typically, the allowable target for a hazardous waste activity is a risk of $1 \cdot 10^{-6}$ chance of a person getting cancer during a lifetime of exposure due to the activity. Risk analysis has many applications, for example:

1. Determining allowable concentrations in the TCLP analysis and in concentrations of allowable listed wastes in solid wastes
2. Determining cleanup levels of hazardous waste sites under remediation
3. Determining the best treatment strategies for remediating hazardous waste sites
4. Permitting new hazardous waste activities such as a new TSDF
5. Being factored into the life cycle analysis process in new product design

92.3 Management of Hazardous Wastes

Nearly every manufacturing or service operation generates hazardous waste. This waste can be managed on-site or be transported to a permitted treatment, storage, and/or disposal facility (TSDF). Using the manifest system, the EPA follows the trail of hazardous waste from its initial generation through final deposit or treatment.

Hazardous Waste Generators

Generators are required to comply with RCRA, OSHA, and state and local regulations. If there is any release or potential release of toxic materials to the environment, generators will also have to comply with regulations in (1) the Clean Water Act, (2) the Clean Air Act, and (3) SARA Title III, as well as a wide variety of other industry-specific regulations and controls.

The EPA has defined three classes of hazardous waste generators: (1) conditionally exempt generators, (2) small-quantity generators (SQGs), and (3) large-quantity generators (LQGs). Several states have stricter definitions and tighter requirements for generators, especially concerning accident preparedness and contingency plans.

Conditionally exempt generators (40 CFR 261) account for the largest number of generators and produce the least quantity of hazardous waste — less than 100 kg/month of hazardous waste or less than 1 kg/month of acutely hazardous waste — or store less than 1000 kg of waste on site. Although RCRA exempts them from most of the extensive permitting requirements, it still requires them to (1) identify

their hazardous waste, and (2) treat hazardous waste on-site or transport it to a permitted TSDF or recycling facility.

SQGs generate less than 1000 kg/month or less than 1 kg/month of acutely hazardous waste or store less than 6000 kg of waste on site. RCRA allows SQGs to store wastes up to 180 days or 270 days if the nearest TSDF is more than 200 miles away. SQGs must obtain a 12-digit EPA identification number, follow proper waste transportation and storage requirements, and perform proper record keeping and reporting, including tracking of manifests.

LQGs are those that generate more than 1000 kg/month, or 1 kg/month of acutely toxic waste, or store more than 6000 kg of waste on site. RCRA requires these generators to comply with all requirements in 40 CFR 262–265 and related regulations outside RCRA. LQGs do not require a transfer storage and disposal facility (TSDF) permit if they (1) store only their wastes on-site (do not accept wastes from outside the facility), (2) store all wastes in a designated area, (3) store the wastes in proper containers properly marked as hazardous waste, and (4) comply with the requirements for owners or operators in subparts C (preparedness and prevention) and D (Contingency Plan and Emergency Procedures) in 40 CFR 265.

Storage of Hazardous Waste

Proper storage of hazardous waste provides for appropriate separation of wastes, separation of noncompatibles, easy access to the waste, reasonable protection from vandalism, and appropriate secondary containment. These practices result in the reduction of the incidence and severity of accidents, simplified compliance, reduced/eliminated fines, and more economical uses of space and management time. Hazardous wastes are stored in a variety of approved containers including drums, overpack containers, tanks, and impoundments.

Underground Storage Tanks

There are approximately 1.5 to 2 million underground storage tanks (USTs) in the U.S. USTs are regulated by the EPA through a mixture of statutory and regulatory provisions or by the states to which the authority has been delegated. In many instances, inconsistent federal, state, and local laws have resulted in conflicts regarding the designation of “responsible parties.” RCRA Subtitle I regulates tanks that contain a regulated Superfund substance or a liquid petroleum product with at least 10% of its volume underground (including piping connected to the tank). The statute requires tank owners to notify the state that they possess such tanks and directs the EPA to establish detection, prevention, release-detection requirements, and performance standards. Subtitle I does not cover approximately two-thirds of tanks, because either (1) other regulations cover these tanks, or (2) they do not pose a threat to human health and the environment. These tanks include

- Tanks holding 110 gallons or less
- Farm and residential tanks holding 1100 gallons or less of motor fuel used for noncommercial purposes
- Tanks storing heating oil burned on the premises where it is stored
- Tanks on or above the floor of underground areas such as basements or tunnels
- Septic tanks and systems for collecting stormwater and wastewater
- Flow through process tanks
- Emergency spill and overflow tanks
- Surface impoundments and pits
- Tanks storing hazardous waste (RCRA Subtitle C)

Approximately 200,000 USTs are leaking or have leaked at one time. The four major causes of releases are corrosion, faulty installation, piping failure, and overfilling. The majority of older tanks are bare steel and, therefore, galvanic corrosion is the most common fault. Federal regulations issued September 13, 1988 require that new UST systems be properly installed according to industry codes, equipped with spill

and overflow prevention devices, protected from corrosion, and equipped with leak detection devices. Tanks no longer in use must be decommissioned either by removal or by filling with an inert material.

Transportation of Hazardous Waste

The DOT regulates all aspects of the transportation, packaging, labeling, marking, and placarding of hazardous waste under the Hazardous Materials Tracing Act of 1975 (HMTA), 49 CFR 172–179. The HMTA was reauthorized in 1993 and governs all hazardous material shipments.

The DOT has five divisions that govern the transportation of hazardous waste/materials:

1. Coast Guard
2. Federal Aviation Administration
3. Federal Highway Administration
4. Federal Railroad Administration
5. Research and Special Programs Administration

Under RCRA, the EPA is directed to establish certain standards for transporters of hazardous materials and to coordinate transportation regulatory activities with the DOT. The transportation of hazardous waste may also be regulated on the local level. State and local governments may require shippers and carriers to provide information about the types of materials they handle, origins and destinations of shipments, routes followed, miles covered in a given year, proof of insurance coverage, vehicle inspection dates, and drivers employed. Some states require hazardous waste registration, special training and certification, prenotifications of shipments, and periodic summaries of activities. Local authorities may also restrict the routes that hazardous waste transporters take.

Generator Requirements

The generator is required to ship wastes in the proper containers and accurately mark and label them (40 CFR 262). In addition, the generator is responsible for providing the transporter with the proper placards per 49 CFR 172 F. The placards alert the first responders to a spill of hazardous materials. The placards are DOT approved and include the hazard symbol, ID number, and UN hazard class number. The placards are placed on the ends and sides of motor vehicles, rail cars, and freight containers. Each container must be labeled with a hazardous waste label, which includes the generator's name and address, the proper shipping name, DOT hazard class, EPA hazard class, and waste type. Other appropriate labels are required, such as "flammable" or "corrosive." Containers should be labeled so that the contents of a package can be identified if it is separated from its shipping papers.

Waste Manifests

The uniform hazardous waste manifest provides the mechanism for "cradle-to-grave" tracking of hazardous wastes. All hazardous waste shipments, except those from conditionally exempt SQGs, must be accompanied by this form. States with EPA authorization can print their own version, and they may have additional requirements. Part 262 D sets forth generator reporting and record-keeping requirements; hazardous waste import and export requirements are covered in subparts E and F, respectively. When shipping interstate, the shipper should use the receiving state's manifest. A copy of the manifest is kept by the generator, the transporter, and the owner of the receiving facility, and one copy is sent to the state. A second copy is returned to the generator upon arrival at the TSDF within 45 days of shipment. The manifest must be kept for 3 years or longer. SQGs are not required to submit copies of their manifests to the state, but LQGs are. The generator must keep a log of the manifest numbers used.

The manifest requires information about the generator, waste type, DOT shipping description (49 CFR 173.2), waste quantity alternate acceptance facility, spill cleanup precautions, TSDF authorization numbers, billing information, listing of hazardous materials and non-RCRA-regulated wastes, location of generator, hazardous waste numbers, physical state of waste, hazard code(s), and intended treatment or disposal method in code. It also requires the generator and transporter to certify that the wastes are in proper condition for transportation.

92.4 Hazardous Waste Treatment

Treatment means any method, technique, or process, designed to change the physical, chemical, or biological character or composition of any hazardous waste so as to neutralize such waste, or so as to recover energy or material resources from the waste, or so as to render such waste non-hazardous, or less hazardous; safer to transport, store, or dispose of; or amenable for recovery, amenable for storage, or reduced in volume. (40 CFR 260)

A facility that performs the above is required to obtain a RCRA Part B permit or operate under interim status until a permit is obtained. There are certain exceptions to these requirements, as specified in 40 CFR 265.

Treatment Options

Table 92.1 summarizes many of the hazardous waste treatment technologies available today. Many of these technologies have been adapted from other manufacturing fields, such as chemical, mining, plating, water and wastewater treatment, and concrete manufacture.

The four basic classifications of treatment technologies used here are physical, biological, chemical, and thermal. Physical treatments such as air stripping, sedimentation, and adsorption separate the hazardous constituent from the waste, resulting in a reduced volume of hazardous waste. Other physical treatments such as compaction and shredding reduce the size of the waste but not the total mass. Biological treatments such as bioreactors and composting result in the biological degradation of the hazardous constituents in a waste stream. Chemical treatments such as fixation, sterilization, and chemical oxidation destroy or reduce the toxicity or mobility of the contaminant by breaking and/or making chemical bonds in the hazardous constituents of the waste. Thermal treatments such as incineration, microwave treatment, and vitrification destroy the contaminants or reduce their mobility through intense heat.

The cost information provided in Table 92.1 is intended to serve as a general guideline only. The costs are from published project costs, vendor estimates, and EPA compiled reports, and have been estimated in terms of 1994 dollars. The cost of any hazardous waste treatment method is highly dependent on the specific contaminant, concentration, quantity of waste to be treated, treatment goals, regulatory fees, and restrictions, as well as a myriad of other performance goals.

Selecting a Suitable Waste Treatment Facility

The generator is ultimately responsible for the waste if the transporter or TSDf fails to handle the waste properly. It is therefore very important to exert adequate effort in investigating a TSDf. The following are some items to check out prior to shipping wastes anywhere.

Facilities need a RCRA Part B permit or interim status permit. One should obtain copies of all permits: state, local, and air and water emissions and check to see that the application or permits cover the appropriate waste types and processes. In addition, check for

- Notices of violations and court actions
- Plant security, alarms, and emergency response
- Safety practices and written procedures
- Spill containment and groundwater monitoring
- Laboratory certification
- Personnel qualifications and experience
- Housekeeping and waste-handling practices
- Financial stability — ability to pay for closure and postclosure monitoring, insurance; ability to compensate injured parties and indemnify clients against loss

TSDfs are usually very specific in the type of waste that they can accept. Generators may rely on the services of a waste broker to arrange for treatment or disposal. The broker may also arrange vendor

TABLE 92.1 Summary of Hazardous Waste Treatment Technologies

| Technology | Contaminant | Type | Requirements | Products | Cost ^a |
|--|--|--------------------|---|---|-----------------------|
| Adsorption | Organic contaminants | G, WW, GW, OW | Adsorbents such as activated carbon added to water and filter out, a cost highly dependent on concentration | Treated stream/aste carbon; carbon can absorb up to 55 organics | Carbon is \$2 to 3/lb |
| Aerobic bioreactor | Readily degradable toxic organics | GW, OW | Tank with air injection and biological population | Inerts, biomass, and reduced BOD waters | 200/ton |
| Air stripping | Petroleum, hydrocarbons, chlorinated solvents | W | Vacuum air stream | Gaseous or condensed contaminants and water | Variable |
| Anaerobic bioreactors | More recalcitrant and higher-concentration organics | W, WW | Anaerobic tank and biological population and possibly methane injection | Inerts, biomass, acids, and reduced-BOD water | 200/ton |
| Biological land treatment, composting, heaping | Petroleum and wood-treating wastes | S, SOL, SL | Open land and mixing equipment | Lesser-contaminated materials | 50/ton |
| Chelating | Heavy metals and radionuclides | S | Tank or <i>in situ</i> and chelating agents | Treated soil and liquid wastes | N/A |
| Chemical oxidation | Wide range of compounds include chlorinated HCs, cyanides, mercaptans, and phenols | SS, L, LW | Chemical oxidants include ozone, chlorine, hydrogen peroxide, and UV radiation | Inerts and intermediate products of oxidation | 200/ton |
| Compaction, grinding, shredding, baling, section, acid digestion | Biological and/or radioactive hazard | SOL | Appropriate equipment | Reduced volume of original waste but not reduced hazard or mass | On-site |
| Encapsulation or microencapsulation | Toxic leachable compounds and radioisotopes | L, OW, S, SED | Organophilic polymers and binders | Encapsulated landfillable or incinerable waste | 100 to 200/ton |
| Evaporation/distillation | Wide variety of aqueous or solvent-based contaminants including radionuclides | L, WW | Evaporation ponds or distillation equipment | Still bottoms, purified liquid | 10 to 100/ton |
| Gas/vapor sterilization | Biological hazard | SOL | Formaldehyde or ethylene oxide in vessel, ground solids | Disinfected wastes: May still have hazardous components | On-site |
| Incineration: thermal oxidizers of many types | Wide variety of organics, infectious waste, and nuclear wastes | G, S, SL, SED, SOL | Controlled high-temperature burner, fuel, air and emissions control | Inerts, ash, trace air pollutants | 500 to 1000/ton |
| Ion exchange | Some metals, cyanide, and other cations/anions including radioisotopes | W, WW | Appropriate resins | Treated water, contaminated resin | 20/ton |
| Irradiation | Biological hazard | SOL | Ultraviolet radiation, dry environment | Disinfected waste: May still have hazardous components | On-site |
| Magnetic separation | Metals, radionuclides, and nitrates | WW, GAS | Magnetic core, selective absorbers, organic polymers | Treated water to PPM level | N/A, high capital |
| Membrane processes: electrodialysis reverse osmosis, and ultrafiltration | Extreme toxics not removed by other processes; works on solutes | W | Specialized membranes and high-pressure pumps or direct electric current | Contaminated brine water and clean water | 20/ton |
| Microwave treatment | Biological hazard | SOL | Microwave radiation and moisture used to heat waste, shredded | Disinfected waste: May still have hazardous components | On-site |

| | | | | | |
|---|--|-------------|---|--|--------------------------|
| Neutralization | Contaminants with pH <2 or >12.5 | L, WW, S | Mixing equipment and lime, soda ash, or free acids | Large volume or neutral material | 100 to 200/ton |
| Physical treatments including screening, filtering, centrifugation | Pretreatment to remove large nonhazardous compounds including radionuclides | L, WW, S | Tanks, loading and unloading equipment | Clean or treated water requiring further treatment and contaminated sludge | 50/ton |
| Physical treatments including precipitation flocculation/coagulation, gas floatation, and clarification | Dissolved and suspended solids and some solutes usually inorganic; may include radionuclides | GW, WW | Settling tanks and flocculants such as alum; polymers and sludge removal equipment may require air supply | Clean or treated water requiring further treatment and concentrated contaminated sludge | 150/ton |
| Pyrolysis/molten salt baths | Wide variety of toxic organics | L | Controlled nonoxidizing burner | Cracked and thermally broken down organics suitable for fuel, further treatment, or disposal | N/A |
| Slurry bioreactors | Heavy and recalcitrant organics | S, SL | Tanks or lagoons, mixers and surfactants | Biomass, inerts, intermediates, and wet treated soil | 200/ton |
| Soil vapor extraction | Petroleum, hydrocarbons, chlorinated solvents | S | Vapor extraction equipment | Gaseous contaminants and clean soil | 50 to 100/ton |
| Solidification | Heavy metals, some organics and leachable liquids, and radioisotopes | S, SL, L | Binders, asphalts, hydraulic cements, ureaformaldehyde | Better structural materials, nonleaching suitable for landfilling or leaving in place | 30 to 80/ton |
| Stabilization/fixation | Heavy metals, acid sludges, some organics | S, SOL | Pozzolanic reagents and lime silicates | Nonleaching landfillable materials or remediated sites | 30 to 80 |
| Steam sterilization/autoclaving | Small-size solid biological hazard | SOL | High-temperature steam and oven | Disinfected waste: May still have hazardous components | On-site |
| Steam stripping | Volatile and semi-volatile compounds | W | High-pressure steam and vacuum extraction | High-concentration stream and clear water | Variable |
| Stream stripping, <i>ex situ</i> and <i>in situ</i> | Volatile organics | S | High-pressure stream and vacuum extraction | Hot water with contaminants | 32AZ80 200/cubic yard |
| Supercritical fluid extraction | Extractable organics | S, SL, W | High-pressure and -temperature fluids | Recovered organics and oxidized organics | 160/ton |
| Thermal desorption | Petroleum, hydrocarbons, chlorinated solvents | S, SL | Thermal desorption ovens, natural gas or electric heaters, air pollution controls | Gaseous contaminants and sterilized soil | 50 to 100/ton |
| Thermal inactivation | Biological hazard | SOL, L | High-temperature oven or vessel | Disinfected wastes: May still have hazardous components | On-site |
| Vitrification | Nonspecific, asbestos, and radioactive waste | S, SED, SOL | High-temperature and/or high-electric current air emissions control | Glassified wastes suitable for disposal or leave in place | N/A |

Note: G = gaseous waste; GW = contaminated groundwater; HC = hydrocarbons; L = liquid wastes; OW = oily water; S = contaminated soil; SED = sediments; SL = process sludges; SOL = waste solids; W = contaminated water; WW = industrial waste water.

^a In 1994 U.S. dollars

contracts, make arrangements for waste acceptance, and hire a transporter. The generator is ultimately responsible for the decisions the broker makes, and it is imperative that these selections be reviewed by a responsible member of the company.

Waste Disposal

The land disposal of hazardous waste is a highly discouraged practice in the U.S. However, it is inevitable that some wastes be disposed of because not enough treatment capacity or complete treatment technologies are available for all the wastes generated. [Table 92.2](#) summarizes the various disposal technologies currently available.

Remediation

Cleaning up hazardous waste sites involves the implementation of the CERCLA regulations. The cleanup process involves investigation, feasibility studies, risk assessment, record of decision, design of remediation systems, construction and implementation, and long-term monitoring. This topic is covered in more detail in another chapter.

92.5 Infectious Waste Management

Infectious wastes are biological wastes potentially contaminated with disease-producing organisms. They can pose a hazard to personnel who handle their disposal as well as to the general public. The EPA regulates medical waste management under RCRA Subtitle J, promulgated in the Medical Waste Tracking Act (MWTa) of 1988. RCRA defines regulated medical waste as “any solid waste generated in the diagnosis, treatment, or immunization of human beings or animals, in research pertaining thereto, or in production or testing of biologicals” (40 CFR 259). The MWTa directs the EPA to establish a demonstration program for managing and tracking medical waste. Much of the regulation is controlled by state and local government and varies widely from state to state. The EPA has seven recommended infectious waste categories:

1. Isolation wastes (wastes from patients with communicable diseases)
2. Cultures and stocks of infectious agents and associated biologicals
3. Human blood and blood products
4. Pathological wastes
5. Contaminated sharps
6. Contaminated animal carcasses, body parts, and bedding
7. Unused sharps

Storage of infectious wastes should consider the integrity of the packaging, storage temperature, the duration of storage, and the location and design of the storage area. In selecting the appropriate packaging, the waste type and handling and treatment methods should be taken into consideration. Protection from sharps is another important factor. The biohazard symbol must be prominent.

The EPA now requires that medical waste be sterilized prior to disposal to kill all pathogens in the wastes. Not all states enforce this yet for landfills. Incineration and steam sterilization are the most frequently used treatments; however, other processes are effective. There are approximately 6700 on-site incinerators at hospitals throughout the country, and approximately 60% of waste is treated on-site. If no longer hazardous after treatment, the material may be disposed of at a sanitary landfill or in the sewer if locally approved.

Biological indicators, which consist of a resistant strain of bacteria, test the effectiveness of treatment technologies. The indicators are placed in the waste prior to treatment, and their destruction indicates the success of the treatment. [Table 92.2](#) includes several infectious waste treatment options.

TABLE 92.2 Summary of Hazardous Waste Disposal Options

| Disposal | Description | Waste Type | Advantages | Limitations |
|---|--|---|---|---|
| Above-grade vaults | Engineered large steel and concrete structure above natural grade | LLW, segregated | Easy access to waste | Vulnerable to intrusion and erosion |
| Augured holes | Shallow drilled holes above water table | Class C low level | Tested by DOE, good worker protection | Difficult to remove wastes, small capacity |
| Below-grade vaults | Engineered structure below grade designed to be compatible with soil | LLW, segregated | Less vulnerable to intrusion and erosion | Waste less accessible |
| Carlsbad, NM, waste isolation pilot plant | DOE project designed to hold 6,000,000 cubic feet in salt formation | Transuranic defense wastes | Remote, already in pilot-plant stage | Controversial |
| Deep space | Canisters placed in indefinite orbit or into sun | HLW | Studied by NASA and DOE | |
| Deep well injection | Acid waste pumped to great depths into fractured rock | HLW and transuranic below critical level | Waste far removed from environment | Waste nonrecoverable |
| Earth-mounded concrete bunkers | Combined above- and below-grade disposal of structurally strong waste containers | LLW, HLW | Lower cost | Vulnerable to intrusion and erosion |
| Hanford mixed waste trenched | 427,000 cubic feet trenches for storage of mixed wastes from cleanup of Hanford site | Mixed wastes | First and only mixed waste disposal | |
| Ice sheet | Canisters dropped through ice meltdown | Self-heating HLW | Remote locations, heat removal | Conceptual only, potential ice movement |
| Improved shallow land disposal | Waste placed in deeper trenches with impermeable cap | LLW | Required since 1982, not allowed in some states | More costly and complex than older technology |
| Injection wells classes I, IV, V | Injection into porous rock formations not communicating with class I groundwater | HW, petroleum wastes, sewage, LLW | Widely practiced, secure | Potential drinking water contamination, subject to land ban |
| Landfill | Waste placed in subsurface cells with liners, cover, leachate, and groundwater collection monitoring and venting | Hazardous and medical wastes pretreated or not banned | Simply proven | Heavily taxed and discouraged, ultimate liability, land ban |
| Mined cavities | Hollowed-out regions in mineral deposits | LLW | No intruder accessibility | Hard to access |
| Modular concrete containers | Use of an overpack or "mini vault" to encase drums | LLW | Waste can be easily removed | |
| Ocean disposal | Concrete encased in drums at ocean bottom | LLW | Cheap, arguably low risk | Now banned, some drums have leaked |

TABLE 92.2Summary of Hazardous Waste Disposal Options (*Continued*)

| Disposal | Description | Waste Type | Advantages | Limitations |
|-------------------------|--|---|--|--|
| Ocean plate disposal | Canisters of waste between continental shelf and moving plates through holes drilled | HLW and transuranic | Geologic stability | Conceptual, not good for some isotopes |
| Salt mines | Liquid wastes placed into hollowed mines | Nonspecific | Cheaper, inaccessible | Nonrecoverable |
| Shale grout injection | High-pressure water cracks shale and then waste in cement, slurry is pumped into formation | HLW, trans | Waste relatively immobile, far away from surface | Waste nonrecoverable |
| Shallow land disposal | Waste placed in unlimited earthen trenches up to 30 feet deep | LLW | Cheap and easy | Now banned |
| Surface impoundment | Placement of wastes into impoundments open to atmosphere | Liquid hazardous waste, uranium mine tailings | Reduces volume, low technology | Essentially short-term storage, historically problematic |
| Yucca Mountain facility | Underground repository for waste in canisters will open approximately 2010 | Nuclear spent fuel, defense wastes | Retrievable waste, very remote, highly regulated | Very expensive, capacity limited to 70,000 tons |

Note: HLW = high-level radioactive waste; HW = hazardous waste; LLW = low-level radioactive waste. Class A waste = LLW not requiring stabilization, short half-life; Class B waste = LLW requiring stabilization but will decay within 100 years; Class C waste = LLW requiring stabilization and shielding during handling, longer half-life.

92.6 Radioactive Waste Management

Sources

Radioactive wastes come from a wide variety of sources, including nuclear power plants, government reactors, private industry, defense, and medical activities. Nuclear power waste sources include mine tailings, enrichment, fuel fabrication, reactor operation, spent nuclear fuel, and decommissioning of reactors. Industrial sources include production processes, research and manufacturing of radiopharmaceutical compounds, smoke detectors, and watch dials. Defense wastes include waste from manufacture of nuclear weapons and operation of nuclear-powered vessels. The volume of defense waste generated is 10 times that of commercial waste. Medical sources include wastes from medical diagnosis, treatment, and research.

There are three classifications of nuclear waste: high level (HLW), transuranic, and low level (LLW). HLWs contain materials that were exposed to high-level nuclear reactions or contain spent fuel from nuclear reactions. High-level wastes currently exist at federal government facilities such as the Hanford Reservation Center in Washington, the Idaho National Engineering Laboratory, the former Western New York Nuclear Service Center in West Valley, New York, and Savannah River. Transuranic wastes are compounds having more protons than uranium, for example, plutonium. These wastes are primarily produced by the reprocessing of spent fuels and by processing weapons-grade material. LLW can be produced from any action involving radioactive material. The largest source is from mine tailings of uranium and thorium mines. Other sources mainly consist of contaminated clothing, equipment, structural material, cleanup materials, and a large amount of potentially contaminated material — such as packing and paper — and activated material.

Government Involvement

The Atomic Energy Act (AEA) of 1954 was the first legislation to include controlling radioactive waste management. As of 1986, 18 federal laws governed radioactive waste management programs. These laws are enforced by the DOE, NRC, EPA, DOT, the Department of the Interior, various smaller agencies, and state-mandated programs. Congress determined LLW to be a state issue. The Nuclear Waste Policy Act of 1982 established a framework for developing and maintaining a system for HLW management and disposal in the U.S. As part of this act the U.S. Treasury established a nuclear waste fund to receive payments for disposal fees. The DOE, through the Office of Civilian Radioactive Waste Management (OCRWM), develops geological repositories in compliance with 10 CFR 60.

The NRC reviews nuclear safety, siting, construction, and operation of repositories for the commercial sector. It also inspects the activities of the OCRWM. The NRC is responsible for regulating the receipt, possession, and the use and transfer of radioactive materials to protect public health and safety and the common defense and security of the U.S.

CFR Title 10 contains the NRC regulations. Part 20 provides the basic standards for protection from radiation. Other technical requirements are spelled out in 29 CFR 1926; OSHA “Safety and Health Requirements for Construction”; the ASME code for pressure and piping; the American Concrete Institute “Code Requirements for Nuclear Safety Related Concrete Structures” (ACI 349–80); and relevant parts of the Uniform Building Code, the Uniform Mechanical Code, and the National Electric Code.

The EPA is responsible for developing environmental standards to protect the health and safety of the public and the environment from potential hazards in the management and disposal of nuclear wastes.

Health Concerns with Radiation Exposure

Radiation exposure may cause severe acute health effects and chronic carcinogenic, teratogenic, or mutagenic effects. The principle of *as low as reasonably achievable* (ALARA) is the basis for the management of nuclear waste originally established in the Atomic Energy Act of 1954. The hazardous nature of a waste stream is measured by a number of factors:

1. Activity level expressed as nanocuries/gram (nCi/g) of waste
2. The type of radioactive emission: alpha, beta, gamma
3. The half-life of the waste isotopes
4. The relative physical stability of the waste
5. The mobility, leachability, or in some cases volatility of the waste

Activity is measured in units of curies. One curie (Ci) is equivalent to the disintegration rate of one gram of radium or $3.7 \cdot 10^{10}$ disintegrations/sec. A rad is the dose of ionizing radiation that produces energy absorption of 100 erg/g in any medium. The *relative biological effectiveness* (RBE) is used as a measure of the specific biological damage caused by different types of radiation. It is used to calculate the rem (roentgen-equivalent, man) dose unit, which is determined by multiplying the absorbed dose in rad by the RBE.

The EPA sets standards for exposure to radioactive materials in the environment: “the combined annual dose equivalent to any member of the public in the general environment resulting from: (1) Discharges of radioactive material and direct and indirect radiation from such management and storage and (2) all operations covered by part 190 [the uranium fuel cycle] shall not exceed 25 millirems to the whole body, 75 millirems to the thyroid, and 25 millirems to any other critical organ” (40 CFR 191). Waste management facilities must meet these criteria with “reasonable expectation” for 1000 years and provide a “reasonable expectation” that releases will be limited for 10,000 years (40 CFR 191.16).

Disposal/Storage

Nuclear wastes cannot be detoxified or the hazards reduced like those of other waste through traditional treatment methods. The relative hazards of nuclear waste decrease over time such that proper storage of wastes over time can render the wastes nonhazardous. In many cases the disposal of nuclear waste is a storage problem. The treatment that is performed on the wastes usually involves either concentrating the wastes to reduce volume or stabilizing the physical form of the wastes to reduce the mobility and simplify handling of the waste. Special precautions must be taken to avoid exceeding the “criticality” of the fissile material waste that could cause a runaway nuclear reaction.

Table 92.1 and Table 92.2 summarize applicable treatment and disposal technologies for radioactive wastes. HLW and transuranic waste present a health risk.

Disposal facilities for HLW and transuranic wastes must be on federally owned land and are regulated solely by the Atomic Energy Act regulations in 10 CFR 60. The design concept for the disposal of HLW and transuranic wastes is to place the appropriate canisters in a deep geologic depository. The DOE has collected \$10 billion since 1988 in taxes to cover the cost of building storage facilities. Construction is scheduled to begin in the year 2010; however, the DOE has not yet cited an interim storage permit. This design concept includes a temporary storage facility known as a *monitored retrievable storage* (MRS). As listed in Table 92.2, numerous other technologies have been suggested; however, there is no current plan of further development of these alternative technologies.

Management of LLW

The states have responsibility to provide for the safe management of LLW generated within their borders. States may license the LLW facility themselves or the NRC licenses them. In addition to radiological protection, the states must regulate other aspects of the management of the facilities. Certain requirements for LLW facilities are provided in 10 CFR 61.

As of June 1994, only two sites were open for LLW disposal: Barnwell County, South Carolina, and Hanford, Washington. These two sites, however, accept waste from a limited number of locations. Other disposal sites have submitted license applications, but the federal government under environmental pressure has been slow to approve them. The lack of permanent disposal facilities for LLW has caused the thousands of generators throughout the country to store the wastes at their own sites and may cause those generators without adequate storage capacity to shut down.

States have the right to regulate radioactive wastes that are exempt from NRC enforcement. The NRC exempts wastes that:

1. Cause < 10 millirem exposure/year/person
2. Cause < 1 millirem of exposure to a large group/year
3. Guarantee that no person receives > 100 millirem/year from all activities at the licensed facility

Transportation

The DOT primarily governs transportation of radioactive materials as specified in 49 CFR 173–178. These regulations specify performance criteria for packaging, package activity limits, driver-training requirements, and routing restrictions. The NRC regulates the receipt, possession, use, and transfer of byproducts and sources of special nuclear materials.

The NRC also sets standards for the design and performance of packages used to transport high-level radioactive materials and conducts inspection of its licenses. Other NRC regulations require the advance notification to the states of certain shipments and provide for physical security measures.

92.7 Mixed Wastes

Mixed waste (MW) is both hazardous and radioactive. Since mixed waste is considered hazardous under RCRA and radioactive under the Atomic Energy Act, both the NRC and the EPA work to address the management of the wastes. It is generated by pharmaceutical and biomedical research laboratories, universities and research laboratories, nuclear reactors, commercial facilities, analytical laboratories, DOE/DOD facilities, new TSDFs, and old disposal sites.

DOE estimates that it generated 22,000 cubic meters of mixed wastes in 1990 and has an inventory of 107,000 cubic meters of MW from past operations. It also estimates that they will generate 600,000 cubic meters remediating their sites. In contrast, commercial mixed waste is generated at a rate of 140,000 cubic feet per year; however, 70% of commercial mixed waste is incinerated and some materials are pretreated, thereby further reducing the volume.

The generation and characterization of mixed wastes will likely increase as cleanup of CERCLA sites proceeds. Although land disposal restrictions require treatment of mixed wastes, there is very little treatment or disposal capacity for mixed wastes in the U.S. A new mixed waste facility is scheduled to be opened in Hanford, Washington (see [Table 92.2](#)); however, it is only designed for mixed waste from on-site remediation activities. Consequently, most mixed waste is stored either on-site or at designated facilities. Storing of mixed wastes can be problematic because RCRA may not allow storing of hazardous waste under a facilities permit. Therefore, the EPA enacted a policy to relax enforcement of storage regulations of certain mixed waste generators. Most generators are not equipped to store mixed wastes, which can pose a health and safety problem for workers.

92.8 Corrective Action

Corrective action refers to the investigation and remediation of releases of hazardous constituents from facilities that have or are seeking hazardous waste facility permits or are operating under interim status. RCRA Section 3004(u) requires that any permits issued after 8 November 1984 require corrective action for all releases of hazardous waste or hazardous constituents from any solid waste management unit at the facility. Corrective action beyond the facility boundary must be performed where necessary to protect human health and the environment, as part of ongoing permit conditions.

Under RCRA, the term *release* is broader than as defined under CERCLA. The RCRA classification includes releases that are exempt under CERCLA and covered by the Clean Air Act and NPDES permits. The EPA broadly defines the term *release* to include a release of any amount to soil, surface water, groundwater, or air of any hazardous waste or hazardous material listed in Appendix VIII of 40 CFR 261.

Once there has been a release, the corrective action process begins in five steps:

1. An RCRA facility assessment is made, which is a desktop review of all information available, a site inspection, and optional sampling.
2. A corrective action order is given as specified in permit conditions.
3. An RCRA facility investigation is performed to characterize the extent of contamination resulting from the spill, including risk assessment and contaminant movement modeling. This investigation includes feasibility studies of treatment technologies.
4. Interim measures are taken to address releases of immediate concern.
5. A corrective measure study sets forth the proposed remediation alternatives. This study is required if the contamination found exceeds an “action level.”

Cleanup levels required under corrective action are discussed in 40 CFR 254. These levels are subject to interpretation based on health risk assessments.

92.9 Waste Minimization

Waste minimization entails modifying a process in order to reduce the volume or the toxicity of the waste generated prior to any treatment, storage, or disposal. It includes source reduction and environmentally sound recycling; equipment and process changes; product reformulation; raw material substitution; and improvements in inventory control and housekeeping, maintenance, and training.

Waste generators can achieve significant savings by reducing raw material consumption, waste disposal, or treatment fees and by taking advantage of tax credits given for waste minimization efforts. Federal law explicitly states that waste reduction is the preferred antipollution method. The 1984 amendments to RCRA promulgated a new federal policy that, wherever feasible, the generation of hazardous waste is to be reduced or eliminated as expeditiously as possible. The EPA ranks management options as follows:

1. Waste reduction
2. Waste separation and concentration
3. Waste exchange and recycling off-site
4. Energy/material recovery
5. Incineration/treatment
6. Secure land disposal

The EPA published guidance on hazardous waste minimization in the 1993 publication *Hazardous Waste Minimization: Interim Final Guidance for Generators* (EPA/530-F-93-009). In this document, the EPA lists six basic elements that generators should incorporate into their waste minimization plan:

1. Top management support
2. Characterization of waste generation/management costs
3. Periodic waste minimization assessments
4. Cost allocation
5. Encouragement of technology transfer
6. Program implementation and evaluation

Life Cycle Design

Environmental groups have criticized waste minimization in the past for being too narrowly focused and sometimes resulting in process modifications that only shift pollutants from one medium to another. The solution to this problem is *life cycle design* (LCD). LCD is a method of product and process design that incorporates the minimization of waste production throughout every step of design and every step of the life of the product. This “cradle-to-grave” design method considers raw material extraction, product manufacturing, use, and final residual disposal. LCD establishes a more coherent means of integrating

environmental requirements with more traditional concerns in product development, such as performance, cost, and cultural and legal requirements.

Life cycle analysis (LCA) is one of the more promising systematic approaches for identifying and evaluating opportunities to improve the environmental performance of industrial activity. It is a useful tool for evaluating the environmental consequences of a product. LCA can be used in conjunction with LCD or be employed separately. By focusing on source reduction as well as reuse, recovery, and treatment, LCA gives a more accurate portrayal of the environmental impacts and true costs of a project. The EPA has put together a life cycle design manual as a guide for conducting and interpreting life cycle inventories.

92.10 Right-to-Know Laws

SARA Title III and the OSHA Hazard Communication Standard of 1985 established a regulatory program that requires disclosure of information to workers and the general public about the potential dangers of hazardous chemicals. These standards also require development of emergency response plans for chemical emergencies. Congress enacted these laws in response to the more than 2000 deaths caused by the release of a toxic chemical in Bhopal, India in 1984. The Clean Air Act amendments of 1990 placed additional responsibilities on the EPA and OSHA to enact legislation requiring further sharing of risk information and process hazard analysis. States and municipalities have passed additional right-to-know laws in response to specific companies' failures to disclose information about their process chemicals. Title III also requires the reporting of annual releases (42 USC 9061) and that facilities that release extremely hazardous chemicals over threshold amounts must immediately notify the community emergency coordinator and the state commission. The EPA now requires monitoring for 320 chemicals. A proposed new rule could double the requirements to 633 monitored chemicals.

The majority of state right-to-know laws address both community and employee access to information about workplace hazards. The requirements of right-to-know laws most relevant to hazardous material planning and emergency response include (1) providing public access to information on hazardous materials present, (2) conducting inventories or surveys, (3) establishing record-keeping and exposure-reporting systems, and (4) complying with container-labeling regulations for workplaces.

OSHA now requires chemical manufacturers and importers to prepare *material safety data sheets* (MSDSs) for all hazardous materials produced or used. The MSDSs must be available to a state agency, local fire chief, and the public as part of their community right-to-know programs.

The format of the MSDS form, also known as OSHA Form 20, is up to the provider. It must contain at least nine elements, as follows:

1. Manufacturer's name, address, and telephone number; chemical name, synonyms, and formula
2. Hazardous ingredients, approximate concentration, and threshold limit value (TLV)
3. Physical data of product
4. Fire and explosion hazard data for product
5. Health hazard data
6. Reactivity data
7. Spill or leak procedures
8. Special protective information
9. Special precautions

92.11 Computer Usage in Hazardous Waste Management

The use of computers has become increasingly important in hazardous waste management. Computers provide updates to current regulations, prepare reports and manifests, perform complex modeling, perform risk assessments and LCAs, serve as design tools, track waste disposal, manage inventory, and provide various other convenience services. Approximately 1500 software programs are available for

pollution management activities. Several periodicals and trade magazines review the available software and provide annual summaries of the packages offered.

Regulatory agencies will often produce their own software, which industry uses to do reporting. These software and databases are either on-line or available by computer disk. These systems include databases, training and procedure review packages, pollution-modeling programs, and emission calculation programs. One purpose for the software is to standardize calculations. Several regulatory agencies accept quarterly reports and release report information on computer disk. Computers provide direct access to environmental databases and provide on-line reports to the EPA and other regulatory bodies. Databases are available either on floppy disks, CD-ROM, or through modem access. These databases provide chemical and toxicological data, current environmental regulations and interpretations, and abstracts of published research articles.

Defining Terms

Code of Federal Regulations (CFR) — Contains detailed information on federal regulations including those dealing with the generation, treatment, reuse, storage, and disposal of hazardous waste.

Hazardous wastes — Wastes that may cause or contribute to mortality or may pose a threat to human health. More detailed definitions are given in regulations such as RCRA.

Mixed wastes — Wastes that contain both hazardous waste and radioactive waste.

Resource Conservation and Recovery Act (RCRA) — Initially passed by Congress in 1976, the original act and its amendments cover aspects of hazardous waste management.

Risk assessment — Involves determining potential health effects due to a specific chemical and potential human exposure. This leads to an estimation of the risk of developing an effect such as cancer due to a lifelong exposure.

93.1 Regulations

Federal and analogous state programs that address soil remediation include the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA, or Superfund) and the Resource Conservation and Recovery Act (RCRA). CERCLA, enacted in 1980, was the first comprehensive federal law addressing releases of hazardous substances into the environment. The primary goal of CERCLA was to establish a mechanism to respond to releases of hazardous substances at abandoned or uncontrolled hazardous waste sites that posed a threat to human health and the environment. The Superfund Amendments and Reauthorization Act of 1986 (SARA), Section 121, Cleanup Standards, stipulates that the U.S. Environmental Protection Agency (U.S. EPA) is required to select remedial actions involving treatment that “permanently and significantly reduce the volume, toxicity, or mobility of hazardous substances, pollutants, and contaminants.” Remedial actions must also meet all applicable or relevant and appropriate requirements (ARARs). Applicable requirements refer to standards, requirements, criteria, or limitations that specifically address a hazardous substance or waste-contaminated soil. Relevant and appropriate requirements refer to those cleanup standards that address problems or situations sufficiently similar to those encountered at the site so that their use is suitable. Under CERCLA, a revision of the National Contingency Plan (NCP) in 1985 addressed the need for rapid characterization of site risk and evaluation of remedial actions using a remedial investigation and feasibility study prior to selection of an action. For contaminated soil, the RI/FS process involves characterization of the extent of soil contamination at a site, determination of goals for cleanup, and evaluation of alternatives for reaching those goals. The

remedial design (RD) occurs after the selection of the remedial action(s). Federal regulatory agencies require the potentially responsible parties (PRPs) to evaluate and remediate contaminated soil, as the Superfund Law provided for both a response and an enforcement mechanism with financial resources originating from the PRPs or from the Superfund trust fund created by a tax on oil and chemical companies [Sims, 1990; Sellers, 1999; Shah, 2000].

The Resource Conservation and Recovery Act (RCRA) of 1976 addresses the treatment, storage, and disposal (TSD) of hazardous wastes. The Hazardous and Solid Waste Amendments (HSWA) were enacted in 1984 and included the land disposal restrictions (LDRs), or land ban. LDRs prohibit placement of hazardous waste on or in the soil for treatment without prior treatment [Sellers, 1999]. RCRA Corrective Action (RCRA-CA) represents the U.S. EPA's program to address the investigation and remediation of contamination at or from hazardous waste treatment, storage, or disposal facility. RCRA-CA involves the conduct of an RCRA facility assessment (RFA), and investigation (RFI), followed by a corrective measures study (CMS) that is followed by corrective measures implementation (CMI). A focus on results, rather than process, was the message of the May 1, 1996 Advance Notice of Proposed Rulemaking (ANPR) for the RCRA Corrective Action program. The results-based approach promulgated includes inviting innovative technical approaches for soil and site characterization and treatment. The U.S. EPA believes that there are approximately 6400 facilities subject to RCRA-CA [U.S. EPA, 2000].

A third program addressing contaminated soil, among other media, was initiated by the U.S. EPA in 1995 and is titled the Brownfield Economic Redevelopment Plan [Sellers, 1999; Shah, 2000]. Brownfields are parcels of land that have some contamination and are not developed because of perceived or real environmental contamination. The Brownfield Plan was developed to address concerns with regard to the multiple agency regulations, liability issues, and economic disincentives [Shah, 2000]. Reuse and revitalization of previously contaminated land for economic development is a high priority for the U.S. EPA. Both CERCLA and RCRA-CA sites can become involved in the Brownfields initiative, where appropriate [U.S. EPA, 2000]. As part of this initiative, 27,000 sites have been removed from the Superfund list and the U.S. EPA will not pursue Superfund action at these sites [Shah, 2000].

Therefore contaminated soil characterization and remediation may be a part of the CERCLA, RCRA-CA, and/or Brownfield regulatory processes, and the following technologies are applicable to all three regulatory programs. The following sections identify and describe current soil remediation technologies and processes for different classes of chemical contaminants and for different site conditions. Cost information is also included where available.

93.2 Mechanical/Chemical Treatments

Mechanical and chemical soil treatments rely on energy-intensive processes to physically remove, contain, or destroy soil contaminants. They include soil vapor extraction (SVE), solidification/stabilization, incineration, thermal desorption, chemical oxidation/reduction, containment, soil flushing, soil washing, and chemical extraction. In general, they are more costly than biological treatments, but usually have the advantage of shorter treatment times. Unless otherwise noted, the following technology descriptions are based on excerpts from the Federal Remediation Technologies Roundtable (FRTR) Remediation Technologies Screening Matrix, 4th edition [FRTR, 2002]

93.3 Soil Vapor Extraction

Soil vapor extraction (SVE) is an *in situ* unsaturated (vadose) zone soil remediation technology in which a vacuum is applied to the soil to induce the controlled flow of air and remove volatile and some semivolatile contaminants from the soil. The gas leaving the soil may be treated to recover or destroy the contaminants, depending on local and state air discharge regulations. Vertical extraction vents are typically used at depths of 1.5 meters (5 feet) or greater and have been successfully applied as deep as 91 meters (300 feet). Horizontal extraction vents (installed in trenches or horizontal borings) can be used as warranted by contaminant zone geometry, drill rig access, or other site-specific factors. Geomembrane

covers are often placed over the soil surface to prevent short-circuiting and to increase the radius of influence of the wells.

SVE is applicable to sites that have high soil permeability and are contaminated with volatile organic compounds (VOCs). The vapor pressure of the contaminants should be greater than about 0.5 torr for effective performance. SVE is not appropriate for semivolatile compounds such as PCBs and many pesticides. Drier soils are easier to clean than soils with high moisture content, but the process has been applied to partially saturated soils. The duration of operation and maintenance for *in situ* SVE is typically medium to long term.

93.4 Solidification/Stabilization

Solidification/stabilization (S/S) reduces the mobility of hazardous substances and contaminants in the environment through both physical and chemical means. Unlike other remedial technologies, S/S seeks to trap or immobilize contaminants within their “host” medium (i.e., the soil, sand, and/or building materials that contain them) instead of removing them through chemical or physical treatment. Leachability testing is typically performed to measure the immobilization of contaminants. S/S techniques can be used alone or combined with other treatment and disposal methods to yield a product or material suitable for land disposal or, in other cases, that can be applied to beneficial use.

Solidification/stabilization techniques include auger/caisson systems and injector head systems that apply S/S agents to soils to trap or immobilize contaminants. Implementation of this technology is highly dependent on the physical properties of soil. Another S/S technology is vitrification that can be applied either *in situ* or *ex situ*. Vitrification uses an electric current to melt soil or other earthen materials at extremely high temperatures (1600 to 2000°C or 2900 to 3650°F) and thereby immobilize most inorganics and destroy organic pollutants by pyrolysis. Radionuclides and heavy metals are retained within the molten soil. The timeframe for *in situ* S/S is short to medium term, while the *in situ* vitrification (ISV) process is typically short term.

93.5 Incineration

Incineration involves the use of high temperatures, 870 to 1200°C (1600 to 2200°F), to volatilize and combust (in the presence of oxygen) halogenated and other refractory organics in hazardous wastes. Often, auxiliary fuels are employed to initiate and sustain combustion. The destruction and removal efficiency (DRE) for properly operated incinerators exceeds the 99.99% requirement for hazardous waste and can be operated to meet the 99.9999% requirement for PCBs and dioxins. Off gases and combustion residuals generally require treatment.

Types of incinerators include circulating bed combustors (CBC), fluidized beds, infrared combustion, and rotary kilns. Incineration, primarily off-site, has been selected or used as the remedial action at more than 150 Superfund sites. Incineration is subject to a series of technology-specific regulations, including the following federal requirements: CAA (air emissions), TSCA (PCB treatment and disposal), RCRA (hazardous waste generation, treatment, storage, and disposal), NPDES (discharge to surface waters), and NCA (noise). The duration of incineration technology ranges from short to long term.

93.6 Thermal Desorption

Thermal desorption is a physical separation process and is not designed to destroy organics. Excavated wastes are heated to volatilize water and organic contaminants. A carrier gas or vacuum system transports volatilized water and organics to the gas treatment system. The bed temperatures and residence times designed into these systems will volatilize selected contaminants but will typically not oxidize them. Contaminated soils are excavated and then transported to a thermal desorption facility or processed on-site in a mobile thermal desorption unit.

Two common thermal desorption designs are the rotary dryer and thermal screw. Rotary dryers are horizontal cylinders that can be indirect or direct fired. The dryer is normally inclined and rotated. For the thermal screw units, screw conveyors or hollow augers are used to transport the medium through an enclosed trough. All thermal desorption systems require treatment of the off-gas to remove particulates and contaminants.

Based on the operating temperature of the desorber, thermal desorption processes can be categorized into two groups: high temperature thermal desorption (HTTD, 320 to 560°C [600 to 1000°F]) and low temperature thermal desorption (LTTD, 90 to 320°C [200 to 600°F]). HTTD is frequently used in combination with incineration, solidification/stabilization, or dechlorination, depending upon site-specific conditions. The technology has proven it can produce a final contaminant concentration level below 5 mg/kg for the target contaminants identified. LTTD is a full-scale technology that has been proven successful for remediating petroleum hydrocarbon contamination in all types of soil. Contaminant destruction efficiencies in the afterburners of these units are greater than 95%. The same equipment could probably meet stricter requirements with minor modifications, if necessary. Decontaminated soil retains its physical properties. Unless heated to the higher end of the LTTD temperature range, organic components in the soil are not damaged, which enables treated soil to retain the ability to support future biological activity.

93.7 Chemical Oxidation/Reduction

Oxidation chemically converts hazardous contaminants to nonhazardous or less toxic compounds that are more stable, less mobile, and/or inert. The chemical oxidants most commonly employed to date include peroxide, ozone, and permanganate (traditional oxidants including hypochlorites, chlorine, and chlorine dioxide may also be utilized). Oxidants have been able to cause the rapid and complete chemical destruction of many toxic organic chemicals; other organics are amenable to partial degradation as an aid to subsequent bioremediation. In general, the oxidants have been capable of achieving high treatment efficiencies (e.g., >90%) for unsaturated aliphatic (e.g., trichloroethylene [TCE]) and aromatic compounds (e.g., benzene), with very fast reaction rates (90% destruction in minutes). Matching the oxidant and *in situ* delivery system to the contaminants of concern and the site conditions is the key to successful implementation and achieving performance goals.

Oxidation using liquid hydrogen peroxide (H_2O_2) in the presence of native or supplemental ferrous iron (Fe^{+2}) produces Fenton's Reagent, which yields free hydroxyl radicals. These strong, nonspecific oxidants can rapidly degrade a variety of organic compounds. Fenton's Reagent oxidation is most effective under very acidic pH (e.g., pH 2 to 4) and becomes ineffective under moderate to strongly alkaline conditions. The reactions are extremely rapid and follow second-order kinetics.

Ozone gas can oxidize contaminants directly or through the formation of hydroxyl radicals. Like peroxide, ozone reactions are most effective in systems with acidic pH. The oxidation reaction proceeds with extremely fast, pseudo-first-order kinetics. Due to ozone's high reactivity and instability, O_3 is produced on-site, and it requires closely spaced delivery points (e.g., air sparging wells). *In situ* decomposition of the ozone can lead to beneficial oxygenation and biostimulation.

The reaction stoichiometry of permanganate (typically provided as liquid or solid $KMnO_4$, but also available in Na, Ca, or Mg salts) in natural systems is complex. Due to its multiple valence states and mineral forms, Mn can participate in numerous reactions. The reactions proceed at a somewhat slower rate than the previous two reactions, according to second-order kinetics. Depending on pH, the reaction can include destruction by direct electron transfer or free radical advanced oxidation — permanganate reactions are effective over a pH range of 3.5 to 12.

93.8 Landfilling and Containment

Excavation and off-site disposal is a well proven and readily implementable technology. Prior to 1984, excavation and off-site disposal was the most common method for cleaning up hazardous waste sites.

CERCLA includes a statutory preference for treatment of contaminants, and excavation and off-site disposal is now less acceptable than in the past. The disposal of hazardous wastes is governed by RCRA (40 CFR Parts 261-265), and the U.S. Department of Transportation (DOT) regulates the transport of hazardous materials (49 CFR Parts 172-179, 49 CFR Part 1387, and DOT-E 8876). Some pretreatment of the contaminated media usually is required in order to meet land disposal restrictions.

On-site containment involves installation of impermeable barriers around the contaminated region. Examples of barriers are trenches backfilled with a bentonite slurry (slurry walls) or lined with a synthetic geomembrane. The top of the contaminated site is usually capped with a clay layer. In some cases, the contaminated soil must be excavated and the empty hole lined with a barrier material before the contaminated soil is backfilled into the hole.

93.9 Soil Flushing

In situ soil flushing is the extraction of contaminants from the soil with water or other suitable aqueous solutions. Soil flushing is accomplished by passing the extraction fluid through in-place soils using an injection or infiltration process. Extraction fluids must be recovered from the underlying aquifer and, when possible, they are recycled. Types of extraction fluids include solvents (e.g., ethanol) and surfactants. Solvent addition is known as cosolvent flushing. Soil flushing can be applied to soils to dissolve either the source of contamination or the contaminant plume emanating from it. The flushing mixture is normally injected upgradient of the contaminated area, and the dissolved contaminants are extracted downgradient and treated above ground. Treatment of the extractant may be required to separate or destroy the contaminants prior to reinjection or release to a publicly owned treatment works. Also, residual flushing additives in the soil may be a concern and should be evaluated on a site-specific basis. The duration of soil flushing process is generally short to medium term.

93.10 Soil Washing

Soil washing is similar to soil flushing but takes place in a controlled reactor after the contaminated soil has been excavated and often involves particle size separation. This *ex situ* soil separation process, mostly based on mineral processing techniques, is widely used in Northern Europe and America for the treatment of contaminated soil. The process removes contaminants from soils by dissolving or suspending them in the wash solution (which can be sustained by chemical manipulation of pH for a period of time) or by concentrating them into a smaller volume of soil through particle size separation, gravity separation, and attrition scrubbing (similar to those techniques used in sand and gravel operations).

The concept of reducing soil contamination through the use of particle size separation is based on the finding that most organic and inorganic contaminants tend to bind, either chemically or physically, to clay, silt, and organic soil particles. The silt and clay, in turn, are attached to sand and gravel particles by physical processes, primarily compaction and adhesion. Washing processes that separate the fine (small) clay and silt particles from the coarser sand and gravel soil particles effectively separate and concentrate the contaminants into a smaller volume of soil that can be further treated or disposed of. Complex mixtures of contaminants in the soil (such as a mixture of metals, nonvolatile organics, and SVOCs) and heterogeneous contaminant compositions throughout the soil mixture make it difficult to formulate a single suitable washing solution. For these cases, sequential washing, using different wash formulations and/or different soil to wash fluid ratios, may be required. The duration of soil washing is typically short to medium term.

93.11 Chemical Extraction

Chemical extraction does not destroy wastes but is a means of separating hazardous contaminants from soils, sludges, and sediments, thereby reducing the volume of the hazardous waste that must be treated.

The technology uses an extracting chemical and differs from soil washing, which generally uses water or water with wash-improving additives. Two basic types of chemical extraction are acid extraction (for heavy metals) and solvent extraction (for organic contaminants). Physical separation steps are often used before chemical extraction to grade the soil into coarse and fine fractions, with the assumption that the fines contain most of the contamination. Physical separation can also enhance the kinetics of extraction by separating out particulate heavy metals, if these are present in the soil. The duration of operations and maintenance for chemical extraction is medium term.

93.12 Biological Treatments

As the ability of indigenous microorganisms to degrade many contaminants has been explored, biological treatments as engineering solutions at contaminated sites have become more prevalent. Many of these technologies rely on minimal site manipulation and in many cases may be less expensive than more intensive treatment processes. Most biological processes are considered to be long-term technologies, and extended analytical and administrative costs must be assessed.

93.13 Monitored Natural Attenuation

Natural subsurface processes such as dilution, volatilization, biodegradation, adsorption, and chemical reactions with subsurface materials are allowed to reduce contaminant concentrations to acceptable levels. Biological processes are often the primary mechanisms involved with organic contaminants. The term “monitored natural attenuation” (MNA) has been adopted to indicate that a remedial action is taking place at the site and that the solution is not merely perceived as a “no action” decision.

Consideration of the MNA option usually requires modeling and evaluation of contaminant degradation rates and pathways and predicting contaminant concentration in treated soils and at down gradient receptor points, especially when aqueous contaminant plumes are still expanding/migrating. The primary objective of site modeling is to demonstrate that natural degradation processes will reduce contaminant concentrations below regulatory standards or risk-based levels before potential exposure pathways are completed. In addition, long-term monitoring must be conducted throughout the process to confirm that degradation is proceeding at rates consistent with meeting cleanup objectives.

Compared with other remediation technologies, natural attenuation has the following advantages:

- Less generation or transfer of remediation wastes
- Less intrusive as few surface structures are required
- May be applied to all or part of a given site, depending on site conditions and cleanup objectives
- May be used in conjunction with, or as a follow-up to, other (active) remedial measures
- Overall cost likely lower than with active remediation

93.14 Bioremediation

Enhanced bioremediation is a process in which microorganisms (e.g., fungi, bacteria, and other microbes) degrade (metabolize) organic contaminants found in soil and/or groundwater, converting them to innocuous end products. Most often, these microorganisms are indigenous to the contaminated soils, but inoculation of acclimated microorganisms is also practiced. Nutrients, oxygen, or other amendments may be used to enhance bioremediation and contaminant desorption from subsurface materials.

The bioremediation of contaminated soils often involves the delivery of oxygen through tillage (land-farming) or venting (bioventing, see Section 93.15 below) to provide aerobic microorganisms an electron acceptor for the oxidation of organic contaminants. Excavated soils can also be placed into “biopiles” with oxygen distribution systems or composted with amendments that provide improved soil structure or act as substrates for fungal growth. Anaerobic degradation processes can also be encouraged through

the addition of easily degradable carbon sources that cause subsurface oxygen depletion and force alternate electron acceptors (e.g., nitrate and sulfate) to be utilized.

Although soil microorganisms with the ability to degrade many petroleum hydrocarbons have been shown to be ubiquitous, each site must be evaluated on an individual basis. Contaminant toxicity or extremely low contaminant concentrations (or bioavailability) may slow the bioremediation process. As with other technologies, laboratory- or field-scale feasibility studies are recommended to determine applicability. Enhanced bioremediation may be classified as a medium- to long-term technology.

93.15 Bioventing

Bioventing is a well-studied *in situ* method of bioremediation that stimulates the natural biodegradation of any aerobically degradable compounds in soil by providing oxygen to existing soil microorganisms. In contrast to soil vapor extraction, bioventing uses low air flow rates to provide only enough oxygen to sustain microbial activity. Oxygen is most commonly supplied through direct air injection into residual contamination in soil. In addition to degradation of adsorbed fuel residuals, volatile compounds are biodegraded as vapors move slowly through biologically active soil.

The U.S. Air Force (USAF) has produced a technical memorandum that summarizes the results of bioventing treatability studies of fuels conducted at 145 USAF sites [AFCEE, 1996]. The memorandum discusses overall study results and presents cost and performance data and lessons learned. Regulatory acceptance of this technology has been obtained in 30 states and in all 10 EPA regions, and the use of this technology in the private sector is growing rapidly following USAF leadership. Bioventing is a medium- to long-term technology. Cleanup ranges from a few months to several years.

93.16 Phytoremediation

Phytoremediation is a process that uses plants to remove, transfer, stabilize, and destroy contaminants in soil and sediment. The mechanisms of phytoremediation include enhanced rhizosphere biodegradation, phytoextraction (also called phyt-accumulation), phytodegradation, and phytostabilization. Enhanced rhizosphere biodegradation takes place in the soil immediately surrounding plant roots. Natural substances released by plant roots supply nutrients to microorganisms, which enhances their biological activities. Plant roots also loosen the soil and then die, leaving paths for transport of water and aeration. This process tends to pull water to the surface zone and dry the lower saturated zones. Phytoaccumulation is the uptake of contaminants by plant roots and the translocation/accumulation (phytoextraction) of contaminants into plant shoots and leaves.

Phytodegradation is the metabolism of contaminants within plant tissues. Plants produce enzymes, such as dehalogenase and oxygenase, that help catalyze degradation. Phytostabilization is the phenomenon of production of chemical compounds by plants to immobilize contaminants at the interface of roots and soil.

The most commonly used flora in phytoremediation projects are poplar trees, primarily because the trees are fast-growing and can survive in a broad range of climates. In addition, poplar trees can draw large amounts of water (relative to other plant species) as it passes through soil or directly from an aquifer. This may draw greater amounts of dissolved pollutants from contaminated media and reduce the amount of water that may pass through soil or an aquifer, thereby reducing the amount of contaminant flushed through or out of the soil or aquifer.

Phytoremediation may be applicable for the remediation of metals, pesticides, solvents, explosives, crude oil, PAHs, and landfill leachates. Some plant species have the ability to store metals in their roots. They can be transplanted to sites to filter metals from wastewater. As the roots become saturated with metal contaminants, they can be harvested. Hyper-accumulator plants may be able to remove and store significant amounts of metallic contaminants. Phytoremediation is considered a long-term treatment technology.

Defining Terms

Ex situ — A process conducted on excavated soil.

In situ — A process conducted in place, without excavation of soil.

PCBs — Polychlorinated biphenyls, dielectric compounds previously used in high-voltage electrical equipment such as transformers and capacitors.

Remedial action — Specific steps taken to decontaminate a site.

Surfactants — Surface active chemicals, typically found in soaps, that assist solubilization of nonpolar organic materials in water.

SVOCs — Semivolatile organic compounds, which slightly volatilize at room temperature.

VOCs — Volatile organic compounds, which readily volatilize at room temperature.

TABLE 93.1 Acronyms Used in Soil Remediation

| | |
|--------|--|
| ARAR | Applicable or relevant and appropriate requirements |
| CERCLA | Comprehensive Environmental Response Compensation and Liability Act |
| CMI | Corrective Measures Implementation (RCRA-CA) |
| CMS | Corrective Measures Study (RCRA-CA) |
| HRS | Hazardous ranking system (EPA's system for ranking the priority of cleanup sites) |
| LDR | Land Disposal Restrictions (HSWA 1984) |
| MCL | Maximum contaminant level, enforceable standards under the Safe Drinking Water Act |
| NCP | National Contingency Plan |
| NPL | National Priority List, a list of sites eligible for federal cleanup |
| PRPs | Potentially responsible parties, who may be held liable for cleanup costs pursuant to CERCLA |
| RA | Remedial action |
| RCRA | Resource Conservation and Recovery Act |
| RD | Remedial design |
| RFA | Remedial Facility Assessment (RCRA-CA) |

- 94.3 Routing and Flood Wave Propagation
- 94.4 Hydraulic Impact Determination and Mitigation
- 94.5 Sediment and Pollutant Control
Effects of Urban Runoff • Urban Runoff Transport

The application of the principles of hydrology and hydraulics in urban storm water management systems from a design and flood control standpoint is addressed within this chapter. The basic design approaches employed to develop such storm water systems are presented, including the incorporation of urban hydrology, floodplain hydraulics, and the design of urban storm drainage facilities such as inlets, storm sewers, and open channels. Also included within this discussion are the elements of flood control and mitigation, as well as sediment and pollutant control amenities to these urban systems.

Particular storm water design and management methods are presented, which include conventional and advanced analysis procedures using industry-standard computer models as well as next-generation technologies. The focus of this chapter is on bringing the theories of urban hydrology and hydraulics into real applications as are utilized to analyze and solve complex urban watershed problems.

94.1 Storm Water Design and Management Overview

Storm water management systems are commonly considered to be those manmade features such as storm sewers and open channels designed and constructed for the purposes of facilitating storm water runoff occurring from particular storm events. In actuality, the overall system is inherently complex as other features are also included that affect the performance of the system, such as streets, inlets, inlet leads, and special features such as detention basins and pollutant control amenities. In aggregate, these features form the basis of a complex urban storm water management system, as is commonly implemented today.

The basic analysis and design process is generally the same when first approaching a particular storm water project. These basic steps involve:

1. Define the drainage areas serving the project area.
 2. Determine the hydrologic response and runoff from these drainage areas given a particular design or actual storm event.
 3. Design the storm water conveyance conduits.
-

4. Analyze the effects of increased storm water quantity and decreased quality if any.
5. Mitigate any project negative effects.

While the above steps are indeed a simplification to the detailed process, this basic overview process is fundamental.

In almost all cases, developed urban communities already have some form of design guidelines or criteria. These may be established by the local community agency such as the city, or in many cases, these local guidelines are deferred to other agency criteria such as those established by various State departments of transportation or even various federal agencies. The point is that when approaching an urban storm water analysis or design project, one should remember that usually, some established guideline or procedure already exists. As urban environments become more complex in terms of development, thus restricting the construction of certain storm water features, project analyses and designs become inherently more complicated. This in turn requires even more complex approaches to solve commonly encountered urban storm water and flood control needs.

As a final overview note, urban flooding is as historic as the concept of urbanization itself. No matter what manmade features are designed and constructed, flooding cannot be eliminated with absolute certainty, as there will always be a potential storm event occurring over a project area that is of greater intensity than what was planned for. As engineers, we can only move, store, and treat storm water — we cannot control the quantity handed to us.

94.2 Design Procedures

A typical urban storm water system consists of streets constructed with curbs, gutters, inlets, and roadside ditches; underground storm sewers; and open outfall channels such as streams, bayous, and rivers receiving runoff from these features. When designing a system, the first basic step is the determination of the contributing drainage areas to the system such that the runoff from these areas may be determined. This entails the development of a drainage area map based upon the topography of the project area. Figure 94.1 illustrates a typical urban setting upon which a drainage area map has been developed to define the contributing drainage areas to storm sewer system junctions.

FIGURE 94.1 Typical urban drainage area map.

TABLE 94.1 Design Events and Frequencies

| Design Event Frequency | Percent Probability of Occurrence in any Given Year |
|------------------------|---|
| 2 | 50 |
| 5 | 20 |
| 10 | 10 |
| 25 | 4 |
| 50 | 2 |
| 100 | 1 |
| 500 | 0.2 |

More explicit drainage area maps are often prepared delineating the individual drainage areas based upon inlet placement, but as is commonly simplified, the drainage area map illustrated is intended for the design of the storm sewer system. Inlet design and placement is critical and is discussed later in this chapter.

The development of a proper drainage area map is a fundamental building block of any urban storm water system. Existing topographic maps and other map sources illustrating relative topographic contours may be used to develop the map. More advanced methods may be used such as aerial photography, which is in turn used to develop a **digital elevation model** (DEM). Further developments in remote sensing techniques are being applied today such as **light detection and ranging** (LIDAR), which is used to produce very accurate three-dimensional digital maps for use in the development of drainage area boundaries [American Society for Photogrammetry and Remote Sensing, 2003]. Regardless of the source, it is imperative that the drainage area map reflect the true pattern of the surface flow of rainfall runoff. Once these patterns and contributing drainage areas are known, the quantity of storm water runoff may be determined.

Prior to the determination of runoff quantities within a project area, it must first be established what is the particular design event for the project at hand. In most cases, urban storm drainage systems are designed for a particular **synthetic design event**. These synthetic events are usually based upon some compilation of weather data such as Technical Paper No. 40 (TP-40), which is a Rainfall Frequency Atlas of the United States [National Weather Service, 2003]. Design storm events are typically associated with a particular return frequency as shown in Table 94.1.

The most commonly used method for determining peak runoff rates for a particular urban project area is the Rational Method using the formula

$$Q = (CA) \cdot i \quad (94.1)$$

where Q = peak flow (cfs), C = runoff coefficient, i = rainfall intensity (in/hr), and A = drainage area (acres).

The Rational Method is simplistic in that it relies on the basic physical characteristics of a drainage area (i.e., size and runoff coefficient) multiplied by a rainfall intensity as based upon the design event being considered. The runoff coefficient, C , varies dramatically based upon the developed state. While many reference manuals have complete listings of runoff coefficients, Table 94.2 lists some commonly utilized runoff coefficients.

TABLE 94.2 Common Runoff Coefficients

| Land Use | Runoff Coefficient |
|-------------|--------------------|
| Residential | 0.35 to 0.55 |
| Multifamily | 0.65 to 0.80 |
| Business | 0.70 to 0.90 |
| Industrial | 0.60 to 0.85 |
| Unimproved | 0.10 to 0.30 |

FIGURE 94.2 Rational formula hyetograph and runoff hydrograph.

The rainfall intensity is a function of the return frequency or design event and the time-of-concentration (T_c). T_c is normally thought of as the time in minutes it takes for water to travel from the furthest hydraulically remote part of the drainage area to the point of consideration or design — in other words, how many minutes it takes for a water particle to travel the longest distance within a drainage area being considered. The basic fundamental assumption of T_c in the Rational Method is that the time-to-peak, T_p , is equal to T_c and that the runoff hydrograph for a project area has a simplified triangular relationship as shown in Figure 94.2, resulting from a constant rainfall intensity over the drainage area for a time period equal to T_c . Using sources relating total rainfall depth to a rainfall duration period (i.e., 6, 12, and 24 hr) such as TP-40, intensity-duration-frequency (IDF) curves may be developed which relate T_c , the design event or frequency, and the runoff intensity measured in inches per hour. Most major municipalities and state entities have such IDF curves readily available for use. Furthermore, these same entities typically specify the design event to be utilized on a given project. Typical IDF curves are illustrated in Figure 94.3.

Numerous reference materials deal with the above application of the Rational Method [Urbonas and Roesner, 1993; American Concrete Pipe Association, 2000; Mays, 2001]. Also, it should be noted that there are also several other methods for determining runoff rates for given drainage areas. A partial list of these other methods is included in Table 94.3.

The Rational Method is generally considered applicable to drainage areas less than 200 acres. When dealing with contributing drainage areas greater than 200 acres, other methods as tabulated in Table 94.3 may prove more applicable.

The actual design of urban storm sewers and open channels, or conduits, is a process of sizing the conveyance conduit to facilitate the estimated peak flow rate at that point in the system considering the upstream drainage area(s). In using the Rational Method, as the drainage areas are summed moving downstream along the new or proposed storm drainage conduit, T_c is naturally increased. This provides

FIGURE 94.3 IDF curves for Houston, Texas.

TABLE 94.3 Various Runoff Determination Methods

| Method | Description |
|--|---|
| Rational | Simplest and most commonly used method for urban storm drain systems; usually limited to watersheds of less than 200 acres |
| Area/runoff (Regional Regression Equations) | Usually used to estimate peak discharges for larger watersheds in a specific geographical region at an ungauged site |
| TR-20 | NRCS hydrology program for small- to large-ranging systems to estimate peak discharge and runoff hydrographs |
| HEC-HMS | Used in large complex drainage systems where storage; multiple tributaries; and hydraulic structures, such as dams, weirs, etc. come into play; and rainfall and runoff vary over both time and space |

some consideration for the dampening or attenuation of the storm flood wave as it propagates downstream through the conduits. To size the conduits themselves, it is common to use Manning's Equation as

$$Q = \frac{1.49}{n} AR^{\frac{2}{3}} S^{\frac{1}{2}} \quad (94.2)$$

where

Q = flow (cfs)

n = Manning's roughness coefficient = 0.011 to 0.013 for concrete and 0.020 to 0.035 for turf lined ditches

A = cross-sectional area (ft²)

R = A/P , the hydraulic radius (ft)

P = wetted perimeter (ft)

S = conduit slope (ft/ft)

In parallel with the sizing of the conduits, the relative position of the resultant water surface profile should be examined. This is achieved by the calculation of the **hydraulic grade line** (HGL), starting at the most downstream point in the system, typically the storm drainage system outlet. The resultant HGL represents the locus of elevations to which the storm water would rise if open to atmospheric pressure, such as within piezometer tubes, and can be used to evaluate the adequacy of the design and identify areas of potential surface flooding. The difference in elevation of the water surface in successive conduit reaches represents the friction and other minor losses in the conduits assuming gradually varied flow conditions. If the conduit has a slope equal to the friction slope, then the HGL would be parallel to the conduit. Considering Equation 94.2, the slope, S , is equal to the friction loss, h_f , divided by the length of conduit, L , ignoring minor losses. Solving for h_f , Equation 94.3 represents Manning's Equation as utilized for determining the friction head loss of a conduit reach.

$$h_f = L \left(\frac{Qn}{1.49AR^{\frac{2}{3}}} \right)^2 \quad (94.3)$$

where h_f = head loss in conduit reach (ft), L = length of conduit reach (ft), and other terms as previously stated.

It is also important for a designer to understand the relationship of the HGL to the **energy grade line** (EGL). The EGL represents the total energy head, or the HGL plus the velocity head, at any given point along a conduit computed by Equation 94.4.

$$EGL = HGL + \frac{V^2}{2g} \quad (94.4)$$

where V = velocity of flow (ft/sec) and g = gravitational constant (32.2 ft/sec²).

FIGURE 94.4 HGL and EGL representation.

In a physical sense, the EGL would be represented by a series of pitot tubes (small tubes with their end openings pointed upstream) intercepting the kinetic energy of the flow. Figure 94.4 represents an illustration of the relationship between the HGL, the EGL, and a conduit (in this case a storm sewer pipe). Notice that if the starting water surface elevation of the downstream outlet of a conduit is below the soffit of the conduit itself, then the conduit may be flowing partially full. Conversely, if the outlet is fully submerged, then the conduit will be under pressure, at least at the outlet, assuming that the conduit is a pipe. Open channels behave similarly as closed conduits except that there are no bounding physical conditions that would cause an open channel to become pressurized as does typically occur in a closed conduit such as a pipe. Further reference on the behavior of open and closed conduit systems is encouraged to fully understand the behavior of such systems [Brater and King, 1976; Chow, 1959].

The relationship of the HGL to the surrounding environment is critical in the design of a storm drainage system. In a common urban environment, storm drainage systems usually exist as roadside ditches, roadside ditches in combination with an underground storm sewer, or a depressed curb-and-gutter street with an underground storm sewer. When two physical drainage facilities exist in conjunction with each other such as with a depressed curb-and-gutter street and an underground storm sewer system, the storm sewer system acts as the primary drainage mechanism while the street acts as a secondary drainage mechanism (i.e., storm water flows within the street as an open channel). This relationship demonstrates the importance of the relative position of the primary drainage system HGL. For example, if a calculated HGL elevation is shown to be above the natural ground elevation along a project route, then surface flooding, even beyond the street, is indicated. The design of the inlet systems to provide connectivity between the primary and secondary drainage mechanisms is also extremely important, as discussed later within this chapter.

Figure 94.5 illustrates a typical storm sewer system design spreadsheet. Such a spreadsheet may be expanded to include other applicable data such as critical natural ground elevations for comparison to the HGL and other pertinent information. Once the fundamentals of the above equations are understood, the actual design development is rather straightforward. As can be seen from reference back to Figure 94.1, the drainage area map provides the fundamental basis of the design accuracy. The design proceeds from upstream to downstream, summing the combined $C \times A$ values from the Rational Method, thus providing a weighted $C \times A$ value to account for different C values along the project route, and realizing the changing T_c , the various intensity values are determined from IDF curves (or intensity formulas if they are available for the project locale). The flow rates, Q , are then calculated for each design reach and the conduit is sized accordingly using Equation 94.2.

After the conduits are sized, it is common to then calculate the HGL or water surface profile of the system. In closed conduit systems, this entails the computation of the friction losses through the storm sewers and adding those losses, on a reach-by-reach basis, to the starting water surface elevation at the outlet; hence, the importance of defining a proper starting water surface elevation at the outlet. Considering the design event utilized, the water surface elevation at the storm drainage system outlet must have

some relation and may be used as provided by other studies and analyses or as determined from approximations, if acceptable, using normal depth calculations within the outlet receiving channel. In many instances, the design criterion allows for simplified assumptions pertaining to starting water surface elevations at the outlet for the purposes of computing the HGL along a designed storm sewer system. This may be the soffit of the last reach of pipe at the outlet or even perhaps some arbitrary elevation, as prescribed by a governing flood control agency. In any case, the HGL is computed upstream throughout the storm sewer system to detect instances where significant head loss may exist. Increasing the size of the conduit increases the wetted perimeter of the conduit, thereby reducing the friction loss and the slope of the HGL. In cases where certain HGL criteria must be met, a trial-and-error type of approach is often exercised to finalize a design that satisfies the design intent.

Manhole and junction losses as well as bend losses may be considered in the development of the HGL profile [American Iron and Steel Institute, 1980]. In some cases, these losses are considered minor and insignificant; yet, in other cases, especially where relative velocities are rather high, the losses may need to be considered and added to the conduit friction losses at the junctions. Equations 94.5 and 94.6 represent the equations for the calculation of manhole/junction losses and bend losses, respectively. Notice that the primary influencing parameter in these equations is the velocity term. When the velocity is rather low, these losses are indeed very minor. In general, it is desirable to keep the minimum velocities within conduits above 3 ft/sec. Maximum velocities should not exceed 8 ft/sec without due consideration of the use of energy dissipation features to control the effects of high velocities such as erosion. Again, local design guidelines generally dictate this controlling criterion.

$$h_j = K_j \left(\frac{V^2}{2g} \right) \quad (94.5)$$

where h_j = manhole/junction loss without a curved deflector (ft), K_j = loss coefficient for manhole/junction = 0.05 for straight-through (no bend at junction) = 0.37 for 45° angle of storm sewers at junction = 1.33 for 90° angle of storm sewers at junction, and other terms as previously stated.

$$h_b = K_b \left(\frac{V^2}{2g} \right) \quad (94.6)$$

where h_b = bend loss (ft); K_b = loss coefficient for bend, 0.19 for 15°; 0.47 for 45°; 0.70 for 90°, and other terms as previously stated.

Equally important as the design of the conduits is the design of inlets and other storm water capture facilities. After all, the conduit system may be sized adequately for a certain design event, but if the storm water cannot enter the conduits at the rate designed for, then the hydraulic connectivity of the system is compromised. This is especially true of depressed curb-and-gutter street sections using conventional on-grade and sag inlets. Inlets work hand-in-hand with the surface streets in urbanized storm sewer systems. As previously mentioned, the storm sewers act as the primary drainage system, while the surface streets act as the secondary system. Those storm water flows not facilitated by the storm sewers are conveyed overland by the street system. Inlets provide the vital function of hydraulic connectivity between the primary and secondary systems. Much study has been done on the subject of inlet behavior, and these studies are still ongoing and evolving. The inlet capacity is designed based upon allowable street ponding widths, street gutter flow rates, street physical features such as slope and friction value, and the inlet physical features. It is highly recommended that inlet computations be precisely considered using established guidelines such as those developed by the Hydraulic Engineering Circular No. 22 (HEC 22) as published by the Federal Highway Administration (FHWA) [Federal Highway Administration, 2001].

Inlets act as weirs until submerged, and then they transition to act as orifices. In curb opening inlets, these two states transition at depths between 1.0 and 1.4 times the inlet opening height. In these cases, the inlet behavior should be analyzed using both the weir and orifice equations, and the lesser of these two capacities computed should be used in the design. Test studies have shown that inlet physical features such as inlet throat depressions and grate types greatly affect the actual performance of an inlet. For these reasons, it is recommended to refer to detailed guidelines as previously mentioned or check with local governing agencies that likely have published allowable inlet capacities for those types of inlets commonly utilized in the project area. Absent of these detailed procedures, inlet behavior may be approximated using weir and orifice equations as depicted in Equations 94.7 and 94.8; yet, due consideration must be given to the other parameters that may limit inlet capacities such as inlets on steep grades which induce the likelihood of substantial inlet bypass flow.

$$Q = C_w(L + 1.8W)h^{1.5} \quad (94.7)$$

where Q = weir condition inlet flow (cfs), C_w = weir coefficient = 3.087 (English) and 1.25 (metric), L = length of curb inlet opening (ft), h = head at inlet opening (ft), and W = lateral width of inlet throat depression (ft).

$$Q = C_o d_o L \sqrt{2gh} \quad (94.8)$$

where Q = orifice condition inlet flow (cfs), C_o = orifice coefficient = 0.67, L = length of curb opening (ft), d_o = depth of curb opening (ft), g = acceleration due to gravity (32.2 ft/sec²), and h = effective head at the center of the orifice throat.

The importance of the behavior of the primary and secondary drainage systems, working collectively, cannot be overemphasized. When surface flooding does occur, ponded sections within roadways and other areas act as storage junctions. These junctions detain storm water flows until the primary drainage system can facilitate that stored volume. In cases where there is insufficient storage volume on the surface for a particular storm event, then the water surface elevation (WSEL) of the flooded secondary system, commonly a street, increases to a point in which structural flooding of adjacent homes and buildings may occur. Furthermore, storm water typically flows overland between the surface storage junctions. This is a very common occurrence in urban drainage systems where overland flow is conveyed between surface storage junctions that may exist as street intersections, for example. In these cases, the relative position of the overland flow routes in a project area must be fully understood as to limit the potential for flooded WSELs building up to the point at which structural flooding of homes and businesses occurs. Such surface conduits (i.e., the streets) may be considered using weir equations or even calculated as conventional open channels. Mother Nature developed flow patterns along our surface topography long

before we imposed urbanized development upon our lands. These natural flow patterns must be recognized and respected, as there is always another natural storm that may or eventually will occur above and beyond that which was planned for in the design development of our urban drainage systems.

94.3 Routing and Flood Wave Propagation

The previous discussion pertaining to the design of urban storm water systems is based upon standard design practices using conventional steady state analyses based upon the simplified form of the continuity equation as

$$Q = V_1 A_1 = V_2 A_2 \tag{94.9}$$

where Q = flow (cfs), V = velocity (ft/sec), and A = cross-sectional area (ft²).

This approach has proven very applicable to most standard urban systems; yet, in reality, there is a recognized change in storage relative to time throughout the system. The recognition of the storage and time elements becomes increasingly important when dealing with large storm drainage systems or when considering the issues of adverse hydraulic impacts and pollutant transport, both discussed later in this chapter. The fundamentals of these applications are based upon a more dynamic approach to the continuity equation whereby

$$Q_{in} - Q_{out} = \frac{\Delta S}{\Delta t} \tag{94.10}$$

where Q_{in} = inflow (cfs), Q_{out} = outflow (cfs), ΔS = change in storage (ft³), and Δt = change in time (sec).

Given the importance of the behavior of storm drainage systems in our developed environments, the basic design procedures previously described must be coupled with the understanding of the dynamic system as it will actually exist. This includes the principles of flood wave propagation in storm sewers and open channels as well as the routing of flows through these systems. From a basic design standpoint, these analyses can be inherently complex, as the numerical process of calculating changes in storage in conjunction with elements of changes in momentum becomes very taxing for simplified design procedures. Invariably, computer models are used to account for these complex procedures, and it is important to understand the fundamentals of these basic routing concepts.

There are two basic categories of routing techniques: hydrologic and hydraulic. Hydrologic routing is more simplified and involves the basic application of the continuity equation, whereby inflow and outflow are balanced with the change in storage relative to time. Hydraulic routing is more complex and, if applied correctly, can provide more accurate results. The basic premise of full hydraulic routing involves the simultaneous computation of the continuity equation and the momentum equation for unsteady non-uniform flow solutions. This method of hydraulic routing is based upon the Saint Venant equations. For simplification purposes, the full Saint Venant equations may be shortened to account for a simplified continuity and uniform flow relationship commonly termed **kinematic wave routing** [Bedient and Huber, 2002]. Other routing methods exist as well, including the modified Puls, Muskingum, and Muskingum–Cunge methods. Table 94.4 illustrates the various forms of the momentum equation, and Table 94.5 lists various routing methods commonly applied.

TABLE 94.4 Forms of the Momentum Equation

| Type of Flow | Momentum Equation |
|---------------------------------|---|
| Kinematic wave (steady uniform) | $S_f = S_o$ |
| Diffusion (noninertia) model | $S_f = S_o - \partial y / \partial x$ |
| Steady nonuniform | $S_f = S_o - \partial y / \partial x - (v/g) \partial v / \partial x$ |
| Unsteady nonuniform | $S_f = S_o - \partial y / \partial x - (v/g) \partial v / \partial x - (1/g) \partial v / \partial t$ |

TABLE 94.5 Commonly Applied Routing Methods

| Title | Type |
|--|-------------------|
| Unsteady flow using St. Venant equations | Hydraulic method |
| Diffusion approximation of St. Venant equations (Muskingum–Cunge method) | Hydraulic method |
| Kinematic-wave approximation of St. Venant equations | Hydraulic method |
| Modified Puls | Hydrologic method |
| Muskingum | Hydrologic method |
| Combination of steady-state backwater computations and Modified Puls | Hydrologic method |

Kinematic waves assume that the gravity force of water is approximately balanced by the conduit bed friction, and these waves appear as uniform, unsteady flow with the water surfaces and conduit bed parallel to each other and to the energy grade line. Dynamic waves appear as gradually varied, unsteady flow with water surface profiles and the conduit bed not being parallel to each other. These two scenarios are best illustrated in Figure 94.6. In most cases dealing with open channel floodplain hydraulics, steady or gradually varied flow exists, making kinematic wave and diffusion approximations of the Saint Venant equations applicable. In urban closed conduit systems subject to rapid changes in flow and storage, unsteady flow analyses using the full Saint Venant equations provide a more exact solution given suitable and adequate input data.

In dealing with flood wave propagation and routing within our urban drainage systems, we are interested in such characteristics as wave timing, wave peaks, relative peak attenuation, and flood storage and discharge. These are some of the basic design variables that are of interest when confronted with issues above and beyond the standard base design as provided by simplified procedures. These other design issues typically include the identification and mitigation of adverse hydraulic impacts caused by a new storm drainage project or with issues pertaining to pollutant and sedimentation transport. In these cases, it is common to utilize computer models for computing the performance of a designed system.

FIGURE 94.6 Visualization of dynamic and kinematic flood waves. (From Bedient, P. B. and Huber, W. C. 2002. *Kinematic Wave Routing, Hydrology and Floodplain Analysis*, 3rd ed., 2002, chap. 4.6. With permission.)

TABLE 94.6 Commonly Applied Computer Models

| Model | Author | Description |
|---------|---------------------|--|
| HEC-HMS | HEC | Hydrologic modeling system (replace HEC-1) |
| HEC-RAS | HEC | River analysis system (replace HEC-2) |
| TR-20 | NRCS | Hydrologic simulation model |
| SWMM | Huber and Dickinson | Storm water management model |

The modeling tools that can be used in the design of urban storm water systems are varied. From simple spreadsheet functions to complex computer models, all types of modeling tools can prove very valuable to the successful development of a project. For open channel hydrology and hydraulics, the U.S. National Flood Insurance Program (NFIP), in conjunction with the Federal Emergency Management Agency (FEMA), utilizes the U.S. Army Corps of Engineers' HEC-HMS and RAS programs, which supercede the HEC-1 and 2 programs [Department of the Army, 2003]. For complex urban storm drainage systems, there exist various proprietary versions of the U.S. Environmental Protection Agency's Storm Water Management Model (SWMM) [U.S. Environmental Protection Agency, 2003], which facilitate the full design and analysis of closed and open conduit systems using fully dynamic conditions. In addition, several other public and proprietary software models exist with varying degrees of complexity that can aid in the design and analysis of urban drainage systems. Table 94.6 lists several of the more commonly used models and their application.

94.4 Hydraulic Impact Determination and Mitigation

The development of a given urban storm water management project within an existing watershed can consist of not only the construction of new facilities on raw land but also the alteration of existing impervious levels and drainage characteristics in previously developed areas. As such, new developments, channel modifications, roadway reconstructions, and other common civil works projects may lead to the creation of undesirable **hydraulic impacts**. The identification, quantification, and mitigation of such impacts to receiving outlet channels or conduits and adjoining properties have become a primary focus in a typical project development life cycle.

The term "impact" is used extensively in hydraulic engineering as related to a particular project's development. By strict definition, all changes to the behavior of existing storm water flows as routed from or through a project area could be deemed an impact. These impacts may be negative or positive. The alteration of an existing watershed's drainage characteristics, as caused by an urban storm water project, often leads to increased flow rates to the receiving outlet or downstream collection system. In many cases, these increased flow rates equate to rises in open channel water surface elevations or the surcharging of existing storm sewer systems, which in turn often directly relate to increased levels of surface flooding.

While the elimination or significant reduction of the increase of surface flooding is desired, not all increases in flow rates from a given project area negatively impact receiving outlet channels or closed conduit systems. This would be the case if an outlet system had sufficient capacity to facilitate these increased flows without any effect on or alteration to levels of surface flooding. Provided that no onsite, upstream, or downstream flooding conditions are created or worsened as caused by the increased discharges and any resultant rise in water surface elevations, it can be argued that no negative impacts have occurred. If an outlet system has no excess hydraulic capacity, and any increase in flows would result in surface flooding, possibly causing physical flood damage, then obviously an increase in flow rate and corresponding increase in water surface elevation would be considered a negative impact.

Considering this discussion on various baseline parameters for the identification of negative hydraulic impacts, the term *impact* actually implies *adverse impact*. An adverse impact would exist from a project development standpoint if the resultant increase in existing runoff flow rates caused by the alteration to the watershed characteristics directly results in increased surface flooding, erosion, or other such physi-

cally damaging phenomena. After a storm water management project is designed using either advanced or conventional means, the system should be analyzed to ascertain if any adverse hydraulic impacts do indeed exist as a result of the new or proposed improvements. If these impacts do exist, then mitigation measures should be undertaken. Typically, the determination and mitigation of hydraulic impacts usually entails a rather complex analysis utilizing some of the computer modeling tools described in the previous section. Simplified approaches are available in urbanized areas where storage coefficients or other such watershed parameters have been established to facilitate the development of storm water management improvements. This may be the case, for example, if detention basin requirements are simplified to per-acre-of-detention-needed versus the size of a given project area. As always, design engineers are encouraged to check local governing entities for such established criteria.

In most urbanized settings, even when some simplified guidelines have been established, hydraulic impacts must be analyzed to insure that no adverse effects will exist from the project's development. The basic steps in performing an impact analysis build upon the design procedure outlined in Section 94.2 as follows:

1. Perform the design of the storm water management improvements as based upon a particular design event or other such established criteria.
2. Model the existing conditions using computed contributing drainage areas and peak discharges.
3. Change the drainage area characteristics, if needed, for the proposed conditions.
4. Model the new or proposed conditions by incorporating all of the designed storm water facilities (ditches, storm sewers, streets, inlets, etc.) into the proposed model.
5. Compare the existing model results to those of the new or proposed model.
6. Identify adverse hydraulic impacts.
7. Determine and analyze mitigation methods (detention, in-line restriction, etc.).
8. Refine/change the base design within the new or proposed model to reflect the incorporated mitigation measures.
9. Remodel the new or proposed conditions to demonstrate the mitigation results.

The steps are rather straightforward and can vary given certain requirements of reviewing entities; however, the fundamental approach is simply to analyze the existing conditions, compare those hydraulic conditions to the new or proposed conditions that would result due to project improvements, and mitigate any impacts as required.

One of the more obvious means of identifying adverse hydraulic impacts from a storm water management project is the comparison of the existing condition outlet discharge hydrograph to that of the new or proposed condition outlet discharge hydrograph. The base design, as previously described, is usually performed using some sort of synthetic design recurrence interval (i.e., a 2-, 5-, 10-, 25-, or 50-year frequency event). Hydraulic impacts are commonly analyzed for not only the lesser storm frequency events but more importantly for the extreme storm frequency events such as the 100-year frequency event. This is to ensure that the project design performs adequately in such extreme events without inducing adverse hydraulic impacts, which would typically result in increased structural flooding in or near the project area.

One of the most common forms of mitigation employed is the utilization of a detention basin within the project design. There are numerous detailed references on detention design [Stahre and Urbonas, 1990], but the basic fundamental sizing of a detention basin is based on the comparison of the existing to proposed discharge hydrograph at the outlet whereby the needed storage volume is determined from the area under the proposed to the existing hydrograph as illustrated in [Figure 94.7](#).

[Figure 94.8](#) illustrates an actual overlay of an urban project area's existing condition discharge hydrograph at the outlet to the receiving river with that of the new or proposed condition discharge hydrograph. Noticeably, there is an increase in peak of the proposed hydrograph. This is not necessarily an indication of the induction of adverse hydraulic impacts in the receiving river, stream, or channel. By modeling the river flood wave in existing versus proposed conditions (using HEC-HMS and RAS for example) and taking into consideration the alteration of the inflow hydrograph for the project area, it could be documented that the increase in peak discharge from the project area occurs well ahead of the

FIGURE 94.7 Detention basin sizing.

FIGURE 94.8 Existing versus proposed discharge hydrographs.

propagating river flood wave in such a manner as to not result in any increased water surface elevations along the river. In this case, it was noticed that the peak discharge of the proposed conditions model at the outlet coincided fairly closely to the peak in the river flood wave, and thus, a rise in water surface elevation along the river was noticed for several river miles downstream of the project area. To address this adverse hydraulic impact, a detention basin was utilized within the project area, and after several iterations of sizing the basin, the peak of the proposed condition discharge hydrograph was reduced as seen in Figure 94.9 to mimic the existing conditions peak, and the proposed condition hydrograph was then input in the river hydrologic and hydraulic models and routed downstream to ensure that no rises in water surface elevations were caused by the project improvements.

FIGURE 94.9 Existing versus mitigated discharge hydrographs.

Mitigation measures are often not easily employed in densely developed urban areas. In many cases, available land for detention basins does not exist or available land is simply too costly. As is often the case, a complex balance of manipulating available storage within storm sewers, ditches, and even depressed curb-and-gutter streets in conjunction with adjusting the routing of flows within the storm drainage system is required to successfully mitigate adverse hydraulic impacts resulting from the proposed improvements. For these reasons, complex modeling techniques using sophisticated computer software are often required to properly analyze the project conditions, make an accurate determination of hydraulic impacts, and adequately design the needed mitigation measures.

94.5 Sediment and Pollutant Control

Effects of Urban Runoff

During a storm event, rain will fall over an urban watershed and will strike either a pervious (infiltration allowed) or an impervious (no infiltration) surface. Pervious area does not prevent urban runoff, rather some of the rainfall that strikes the area remains as runoff and a portion of the water that is infiltrated will take a subterranean path to a surface stream. On impervious surfaces nearly all rainfall becomes surface runoff that ends up in channels and/or streams. Urban watersheds are characterized by surface water runoff from impervious and pervious areas (mostly impervious) and efficient drainage systems. The increased volumes and flow rates of runoff produced under these conditions have a number of deleterious effects [Nix, 1994].

Developed areas and their drainage systems are usually very good at discharging runoff — so much so that they can cause flooding at downstream locations. On the other hand, older or inadequately designed drainage systems can themselves be overwhelmed by runoff from increased urbanization. The result is flooding at the “headwater” of the drainage system. The increased runoff accompanying urban development increases the bed load, or sediment-carrying, capacity of a stream [Whipple et al., 1983]. This increase of sediment in the stream is the result of stream bed and stream bank erosion. Increased runoff does not only affect the integrity of the stream itself, but the delicate ecosystem surrounding the stream. The runoff changes the habitats equilibrium and the thermal loads associated with runoff can also disrupt the ecosystem.

As rainfall moves vertically through the atmosphere, it may wash out air pollutants and carry them to the surface. Upon reaching the ground, rainfall will dislodge some particles and dissolve other materials. The freed and dissolved contaminants will either be carried to drainage systems by surface runoff, or infiltrate the soil at pervious areas that may threaten subterranean aquifers. The pollutants carried from the watershed surface come from a number of sources, as listed in [Table 94.7](#).

TABLE 94.7 Sources of Storm Water Pollutants

| |
|--|
| Transportation (tire and brake wear and exhaust dust) |
| Industrial activities (petroleum, chemical, energy, and manufacturing) |
| Decaying vegetation (leaf litter and lawn waste) |
| Soil erosion (especially from construction sites) |
| Animal wastes |
| Fertilizer/pesticide application on lawns and gardens |
| Deicing agents |
| General litter |

TABLE 94.8 Opportunities for Urban Runoff Pollution

| |
|--|
| Leaking sanitary sewers |
| Direct connections of sanitary sewer to storm sewers |
| Poorly operating septic systems |
| Illegal disposals of oils, paints, etc. to storm sewer systems |
| Accidental spills |
| Leaking underground storage tanks |
| Leachate from landfills |
| Leakage from hazardous waste sites |

Pollutants may also be contributed by the watershed's drainage system. Such a system may consist of natural or artificial channels as well as sewerage. A system that is designed exclusively for stormwater flows is known as a **separate sewer system** (most modern systems), and a system that is designed to carry both stormwater and sanitary sewer flows is known as a **combined sewer system** (seen throughout the older systems of the northeastern U.S.). The contamination of the urban water runoff can be enhanced by erosion of natural channels and sediment resuspension in artificial channels and sewer systems. Other opportunities for urban runoff are listed in Table 94.8. Figure 94.10 shows possible sources of urban runoff contamination in a typical urban area as well as the inlets and outlets of a typical drainage system.

The pollutants are carried in runoff at varying concentrations. Table 94.9 presents concentration ranges for some specific pollutants in urban runoff as compared to other wastewater streams. Urban stormwater is roughly characterized by a heavy suspended solid load and relatively low **BOD** and nutrient levels when compared to untreated sanitary sewage. Combined sewage, being a combination of sanitary sewage and stormwater runoff, has characteristics somewhere between the two. Table 94.10 summarizes the impacts associated with the various kinds of pollutants and Table 94.11 shows the EMCs for all the nationwide urban runoff program [Nix, 1994].

Urban Runoff Transport

A point source is a regulatory term meaning a source that is discharged through a pipe at a known position, whereas a nonpoint source originates from flow distributed over the land surface. To simplify matters, urban runoff is going to be considered a nonpoint source because it is a diffuse source of pollution and the flow follows the temporal and spatial characteristics of rainfall over a large area. If the concentration of the contaminant during a storm were constant, the mass versus time (loadograph) would match the hydrograph. What usually takes place is that the concentration versus time (pollutograph) exhibits a high concentration at the beginning of a storm; this is known as the first flush. The first flush is a phenomenon that is due to high rainfall intensities at the beginning of the storm creating higher runoff and larger sediment wash-off (due to buildup prior to runoff). The first flush can be readily seen in sewers where the solids were deposited during dry weather and washed away during the first storm event; it is less evident in highly urbanized areas where factors such as street cleaning, traffic, and wind remove the sediments just as fast as they are deposited. On pervious surfaces, buildup plays a lesser role, and entrainment of water quality constituents in runoff is due more to erosion and solution mechanisms. Constituents may be adsorbed onto particulate matter and thus be subject to transport as solids [Huber, 1992].

FIGURE 94.10 Typical urban stormwater system.

TABLE 94.9 Characteristics of Urban Wastewater Streams

| Wastewater Type | BOD ₅ (mg/L) | SS (mg/L) | Total N (mg/L) | Total P (mg/L) | Lead (mg/L) | Total Coliforms (MPN/100 mL) |
|----------------------------|-------------------------|-------------|----------------|----------------|-------------|------------------------------------|
| Stormwater | 10 to 250 ^c | 3 to 11,000 | 3 to 10 | 0.2 to 1.7 | 0.03 to 3.1 | 10 ³ to 10 ⁸ |
| CSOs ^a | 60 to 200 ^c | 100 to 1000 | 3 to 24 | 1 to 11 | 0.4 | 10 ⁵ to 10 ⁷ |
| Untreated sewage | 160 ^c | 235 | 35 | 10 | — | 10 ⁷ to 10 ⁹ |
| POTW ^b effluent | 20 | 20 | 30 | 10 | — | 10 ⁴ to 10 ⁶ |

^a Combined sewer overflows.

^b Publicly owned treatment works.

^c Single numbers are means. Others represent a range.

Source: Ellis, J.B. 1986. Pollution aspects of urban runoff, in *Urban Runoff Pollution*, Torno, H., J. Marsalek, and M. Desbordes, Eds., NATO ASI Series, Series G: Ecological Sciences, Vol. 10, Springer-Verlag, Berlin. p. 1.

TABLE 94.10 Summary of Urban Runoff Pollution Effects

| |
|---|
| Sediment (Sand, Silt, Clay in Colloidal Suspension) |
| Suspended sediment decreases recreational values, reduces fishery habitat, reduces sunlight penetration, thereby impairing photosynthesis of aquatic plants, adds to the mechanical wear of water supply pumps and distribution systems, and adds treatment costs for water supplies. |
| Nutrients (Phosphorus, Nitrogen) |
| Nutrient enrichment of surface waters may cause excessive algae and aquatic plant growth, choking open waters consuming oxygen (mainly through plant die-off). |
| Oxygen-Demanding Organics (Human, Animal Excreta; Decaying Plant, Animal Matter; Discarded Litter, Food Wastes) |
| Organic materials (natural or synthetic) may enter surface waters dissolved or suspended in runoff; natural decomposition of these materials may deplete dissolved oxygen supplies in the surface waters. |
| Toxic Substances (Heavy Metals, Pesticides, Oil, and Other Petroleum Products) |
| The principal concerns about toxic substances in surface water are their entry into the food chain, bioaccumulation, toxic effects on fish, wildlife, and microorganisms, and habitat degradation of public water supply sources; the ground water impacts are primarily related to water supply sources. |
| Pathogens (Bacteria, Viruses) |
| The principal concerns about pathogens are the survival and transmission of such organisms and their impacts on drinking water supplies, contact recreation waters, and fish and wildlife or domestic animals. |

The **event mean concentration** (EMC) is the total storm load (mass) divided by the total runoff volume. Mathematically,

$$EMC = C = \frac{M}{V} = \frac{\int C(t)Q(t)dt}{\int Q(t)dt} \tag{94.11}$$

where $C(t)$ = time-variable concentration, $Q(t)$ = time-variable flow, M = pollutant mass, and V = runoff volume.

TABLE 94.12 Water Quality Characteristics of Typical Urban Runoff

| Constituent | Units | Event-to-Event Variability in EMCs (Coefficient of Variation) | Site Median EMC | |
|---|-------|--|--------------------------|-----------------------------------|
| | | | For Median Urban Site | For 90th Percentile Urban Site |
| BOD ₅ | mg/L | 0.5 to 1.0 | 9 | 15 |
| COD | mg/L | 0.5 to 1.0 | 65 | 140 |
| TSS | mg/L | 1 to 2 | 100 | 300 |
| Total lead | µg/L | 0.5 to 1.0 | 144 | 350 |
| Total copper | µg/L | 0.5 to 1.0 | 34 | 93 |
| Total zinc | µg/L | 0.5 to 1.0 | 160 | 500 |
| TKN | µg/L | 0.5 to 1.0 | 1500 | 3300 |
| NO ₂ -N + NO ₃ -N | µg/L | 0.5 to 1.0 | 680 | 1750 |
| Total phosphorus | µg/L | 0.5 to 1.0 | 330 | 700 |
| Soluble phosphorus | µg/L | 0.5 to 1.0 | 120 | 210 |

Source: Environmental Protection Agency. 1986. *Results of the Nationwide Urban Runoff Program*, vol. I, Final Report, NTIS PB84-185552, Washington DC.

It is clear that the EMC results from a flow-weighted average, not simply a time average of concentration. Thus, when the EMC is multiplied by the runoff volume, an estimate of the loading and receiving water is provided. The instantaneous concentration during a storm can be higher or lower than the EMC, but the use of EMC as an event characterization replaces the actual time variation of C versus t in a storm with a pulse of constant concentration having equal mass and duration as the actual event. This ensures that mass loadings from storms will be correctly represented [Huber, 1992; Mustard et al., 1987].

Just as instantaneous concentrations vary within a storm, event mean concentrations vary from storm to storm and from site to site as well. The median or fiftieth percentile EMC at a site, estimated from a time series, is called the site median EMC. When site median EMCs from different locations are aggregated, their variability can be quantified by their median and coefficient of variation ($CV = \text{standard deviation divided by the mean}$) to achieve an overall description of the runoff characteristics of a constituent across various sites. An indication of this variability is shown for combined sewer overflows in Table 94.12.

When dealing with the quality of urban runoff, it is no longer necessary to design for large infrequent storms, rather design storms for quality control are generally storms less than the 1-year storm. The reason why these smaller storms are more important is because they are more frequent (causing more frequent flushes of contaminants) and also because capturing the 2-month storm (six overflows per year) in a basin designed to do so will treat about 90% of the runoff events. The runoff water that enters basins designed for smaller storm events will receive primary treatment as the flow passes through the basin. Along with designing controls for the smaller storm, there are four other basic factors involved in the control of urban runoff quality: preventing the deposition of pollutants, source control of pollutants, minimizing directly connected impervious areas, and using the treatment train concept [Urbonas and Roesner, 1992].

Preventing the deposition of pollutants is the best and theoretically the easiest way to prevent the contamination of urban stormwater systems, but it takes awareness and cooperation of the citizens to properly work. Examples of problems associated with the deposition of pollutants are draining motor oil, antifreeze, gasoline, pesticides, herbicides, paints, and solvents onto an empty lot or down storm sewers. It takes management practices as well as public awareness for this control procedure to work properly.

Source controls of pollutants involve the prevention of contaminants coming into contact with rainfall and runoff. These controls involve the covering of chemical storage areas, diking around chemical unloading and potential spill areas, minimizing the use of deicing chemicals, proper use and handling of herbicides and pesticides, and disconnecting illicit wastewater connections (wastewater sewers from buildings, drains from carwashes, and chemical storage) to storm sewers. Being aware of source pollutant potentials can decrease the amount of contaminants entering water runoff.

Minimizing directly connected impervious area means reducing the amount of impermeable area that drains directly into a gutter, ditch, or pipe. This is effective because it allows a longer traveling time of the stormwater, which creates an opportunity of maximum infiltration where the rainfall lands. Grassed areas not only allow permeable landscape, but also remove pollutants from the rainfall [Urbanas and Roesner, 1992].

The treatment methods used for the treatment train can be grouped into two categories: infiltration practices and detention. Infiltration practices can be further divided into three classes: swales and filter strips, percolation trenches, and infiltration basins. Swales and filter strips use vegetation such as grasses to minimize the amount of directly connected impervious area, which also reduces the runoff velocity and allows the water an extended amount of time to infiltrate the soil. A swale is a shallow trench seen along streets and highways, and a filter strip is a strip of land across that stormwater, from an impervious area, sheet flows before entering drainage. The vegetation acts as a filter, removing approximately 80% of the contaminants during runoff [Whalen and Callum, 1988].

Percolation trenches are devices used in areas of water runoff ranging in size up to 10 acres. There are two main types of percolation trenches, the open surface type and the underground type. The purpose of a percolation trench is to be able to store water runoff for 48 to 72 h, allowing infiltration through the bottom and sidewalls of the trench. The infiltration trench is a long dug-out trench that is lined with a filter cloth or granular filter media to prevent the adjacent soils from entering the trench; it is filled with stone aggregate to allow the storage of water in the pores of the media. The trench bottom must be 4 ft above the seasonal groundwater high and bedrock.

An infiltration basin is either constructed in a natural depression in the landscape or by an embankment that captures rainwater runoff and allows infiltration of the water into the soil in a maximum of 72 h. The basin must be constructed out of soil that is very permeable and the bottom must be at least 4 ft above the seasonal groundwater high or bedrock. Vegetation adds aesthetic beauty and also breaks up the surface soil, which keeps the surface area from getting plugged [Urbanas and Roesner, 1992].

The aforementioned water quality practices are good for very permeable soils that drain small areas, but if the area is impermeable or large, then the controls above will require too much land and be impractical. As a result, a detention pond is needed. Detention ponds can be classified either as an extended detention basin (dry detention basin) or a retention pond (wet detention pond). An extended detention basin completely empties between storm events, while a retention pond has a permanent pool of water and stores the storm water above its permanent water surface. Retention ponds are much more effective in removing pollutants and this is especially true for nutrients. Retention ponds remove two to three times more phosphorus and about two times more total nitrogen than extended detention basins do. Extended detention basins work by allowing the settling of pollutants, but since detention basins allow water to steadily pass, soluble pollutants are not effectively removed. Their efficiency is good if the detention time is greater than 24 h, but if the time is under 12 h, the efficiency is very poor. Since retention

TABLE 94.13 Potential Pollutant Removal Rates, in Percent, of Various Treatment Practices

| Type of Practice | Total Suspended | | | | | | |
|--------------------|-----------------|----------|----------|----------|----------|----------|----------|
| | Solids | Total P | Total N | Zinc | Lead | BOD | Bacteria |
| Porous pavement | 85 to 95 | 65 | 75 to 85 | 98 | 80 | 80 | N/A |
| Infiltration | 0 to 99 | 0 to 75 | 0 to 70 | 0 to 99 | 0 to 99 | 0 to 90 | 75 to 98 |
| Percolation trench | 99 | 65 to 75 | 60 to 70 | 95 to 99 | N/A | 90 | 98 |
| Retention ponds | 91 | 0 to 79 | 0 to 80 | 0 to 71 | 9 to 95 | 0 to 69 | N/A |
| Extended detention | 50 to 70 | 10 to 20 | 10 to 20 | 30 to 60 | 75 to 90 | — | 50 to 90 |
| Wetland | 41 | 9 to 58 | 21 | 56 | 73 | 18 | N/A |
| Sand filters | 60 to 80 | 60 to 80 | 0 | 10 to 80 | 60 to 80 | 60 to 80 | N/A |

ponds have a constant pool of water, they remove pollutants by settling and dissolved pollutants biochemically by phytoplankton growth. The pond must be designed so that the permanent pool is deep enough to allow minimal sunlight penetration at the bottom reducing weed growth, but not too deep or the bottom becomes anoxic. A depth of 3.5 to 12 ft appears to work best. In areas of dry climate, a retention pond is not feasible because such ponds cannot retain a permanent pool. A water budget must be performed on the area to make sure that evapotranspiration and exfiltration do not cause too great of a loss in the retention pond. Table 94.13 shows the potential percent removal of the different treatment methods [Stahre and Urbonas, 1990].

Defining Terms

- BOD** — The amount of oxygen that would be consumed if all the organics in volume of water were oxidized by bacteria and protozoa.
- Combined sewer system** — A system of conduits that carries storm runoff and domestic sewage together.
- Digital elevation model (DEM)** — An array of numbers representing the regularly spaced distribution of geographic elevations for a specific area horizontally referenced to either a UTM or geographic coordinate system in a digital form.
- Energy grade line (EGL)** — A line connecting the set of points along a conduit representing the total energy of the flow within the conduit referenced to a common elevation datum.
- Event mean concentration (EMC)** — The total storm load (mass) divided by the total runoff volume.
- Hydraulic impact** — The negative effect of developed project increased runoff rates, which directly results in increased flooding, erosion, or other such physically damaging phenomena.
- Hydraulic grade line (HGL)** — A line connecting the set of points along a conduit representing the elevation head and pressure head of the flow within the conduit referenced to a common elevation datum.
- Kinematic wave routing** — A simplified form of wave routing whereby the water surfaces, bed slope, and energy grade lines along a conduit are parallel.
- Light detection and ranging (LIDAR)** — An active sensory system that uses laser light to measure distances between an airborne platform and points on the ground, including trees, buildings, etc., to collect and generate densely spaced and highly accurate elevation data.
- Separate sewer system** — A system of conduits that carry storm runoff and domestic sewage separately.
- Synthetic design event** — A design storm whose properties such as total rainfall, intensity, duration, and distribution are empirically and statistically derived from the analysis of historical storm data for some defined geographic area.

Hydraulics deals with the principles that govern the behavior of liquids at rest and in motion. This is the study of the mechanics of water and its control by man. Hydraulics deals with pressurized systems and open channel flow, and includes principles of pressure and force, energy theorem, **flow** calculations and measurement, friction losses, pumps, and pumping applications.

95.1 Flow Characteristics

Laminar flow occurs at extremely low **velocity**; water molecules move in straight parallel lines called *laminae*, which slide upon each other as they travel, evidenced in groundwater flow; friction losses are minimal. *Turbulent flow*, normal pipe flow, occurs because of roughness encountered on the inner conduit walls. Outer layers of water are thrown into the inner layers; movement in different directions and at different velocities generates turbulence. *Steady-state flow* occurs if at any one point flow and velocity are unchanging. Hydraulic calculations almost always assume steady state flow. *Uniform flow* occurs when the magnitude and direction of velocity do not change from point to point.

95.2 Equation of Continuity

At a given flow, water velocity is dependent upon the cross-sectional area of the conduit. This statement expresses the most basic hydraulic equation, the equation of continuity:

$$Q = AV \tag{95.1}$$

where Q is the flow in cfs, A is the cross-sectional area in ft^2 , and V is the velocity in ft/sec .

FIGURE 95.1 Pressure gage.

95.3 Pressure Characteristics

Unit Pressure

Water **pressure** is due to its weight (62.4 lb/ft^3) and the depth of water above the point of measurement (equating pressure to depth, 0.433 psi/ft water depth, or 2.31 ft water depth/psi). Water pressure does not affect liquid density, and *Pascal's law* states that the pressure at any one point in a static liquid is exerted with equal intensity in all directions.

Pressure Measurement

The *piezometer* is an open-ended vertical tube inserted at the point of pressure measurement and is impractical for measuring anything but the smallest pressures. The *manometer* is a modification of the piezometer with internal liquid fill of a higher specific gravity, bent into a U shape for easy reading. When connected to two separate sources of pressure, the unity yields a differential reading.

The *pressure gage*, called a *Bourdon tube*, may read feet, psi, or inches of mercury. It provides a direct, easy-to-read, static connection to the source of pressure (Figure 95.1).

The earth's atmosphere, about 200 miles deep, exerts a pressure of 14.7 psi or the equivalent of 34 ft water pressure upon the surface of the earth at sea level, the standard reference point for all pressure measurements. *Gage pressure* (psig) is the pressure read on a gage above or below atmospheric. *Absolute pressure* (psia) includes atmospheric pressure in the reading and is employed when calculating pumping suction **heads**.

Total Pressure

Force is registered in pounds and is calculated as follows:

$$\text{Force} = \text{Pressure} \times \text{Area} \tag{95.2}$$

$$\text{lb} = \text{lb/ft}^2 \times \text{ft}^2$$

Components of Pressure

Pressure head (PH) is due to the depth of the water and is measured as feet of water or registered on a pressure gage. *Velocity head* (VH) is the distance the water can move due to velocity energy; it does not register on a pressure gage, but can be captured by a pitot gage (described later) and is calculated as follows:

$$VH = \frac{V^2(\text{ft/s})^2}{2g(\text{ft/s}^2)} \quad (95.3)$$

Elevation head (Z) is pressure due to elevation above the point of reference, measured as feet of water or registered on a pressure gage.

Bernoulli's Theorem

In a fluid system employing steady-state flow, the theoretical total energy is the same at every point in the path of flow, and the energies are composed of pressure head, velocity head, and elevation head (*Z*). Expressed in terms of actual energy change between two points in a dynamic system where a pressure decrease or head loss (HL) occurs,

$$PH_1 + VH_1 + Z_1 = PH_2 + VH_2 + Z_2 + HL \quad (95.4)$$

95.4 Effects of Pressure — Dynamic Systems

Water hammer (hydraulic shock) is the momentary increase in pressure that occurs in a moving water system when there is a sudden change in direction or velocity of the water. **Suppressors** are installed where water hammer is encountered frequently in order to minimize shock and protect piping and appurtenances. *Surge*, a less severe form of hammer, is a slow-motion mass oscillation of water caused by internal pressure fluctuations in the system; it can be controlled by surge suppressors or spring-loaded pressure relief valves. *Thrust*, caused by an imbalance of pressures, is the force that water exerts on a pipeline as it turns a corner. Its intensity is directly proportional to water **momentum** and acts perpendicular to the outside corner of the pipe, affecting bends, tees, reducers, and dead ends, pushing the coupling away from both sections of pipeline. To calculate total pounds of thrust,

$$\text{Thrust} = 2TA \times \sin \frac{1}{2}\theta \quad (95.5)$$

where *T* is the test pressure of system in psf, plus 100 psi for hammer, and *A* is the cross-sectional area of fitting.

For pipes using push-on or **mechanical joints**, thrust restraint is desired. *Thrust blocks* are concrete blocks cast in place onto the pipe and around the outside corner of the turn. Block-bearing face must be large enough so that its pressure does not exceed soil-bearing strength (variable, <1000 to 10,000 lb/ft², depending on soil type) (Figure 95.2).

To calculate bearing face area of the thrust block:

$$\text{Area} = \frac{\text{Total thrust (lb)}}{\text{Bearing strength of soil (lb/ft}^2\text{)}} \quad (95.6)$$

In locations where it is difficult to use thrust blocks, *restrained joint pipe* is an alternative. Extra locking rings stabilize the joint under thrust conditions and transfer the load from the pipe directly to the surrounding soil.

95.5 Pressure Loss

Major head loss occurs because of friction dropping pressure along the conduit length. *Minor head loss* is caused by extra turbulence at bends, fittings, and diameter changes in the pipeline. In open channel systems, slope equates to the amount of pipe incline, as feet of drop per foot of pipe length; it is designed

FIGURE 95.2 Thrust blocks.

TABLE 95.1 Hazen–Williams Roughness Coefficient (*C*) Value

| Type of Material | <i>C</i> Value |
|------------------------------|----------------|
| Asbestos cement | 140 |
| Brass | 140 |
| Brick sewer | 100 |
| Cast iron: 10 years old | 110 |
| 20 years old | 90 |
| Ductile iron (cement lined) | 140 |
| Concrete: Smooth | 140 |
| Rough | 110 |
| Copper | 140 |
| Fire hose (rubber lined) | 135 |
| Galvanized iron | 120 |
| Glass | 140 |
| Lead | 130 |
| Masonry conduit | 130 |
| Plastic | 150 |
| Steel: Coal-tar enamel lined | 150 |
| Unlined | 140 |
| Riveted | 110 |
| Vitrified | 120 |

to be just enough to overcome friction losses so that velocity will remain constant. In closed conduit systems under pressure, the pipe is taken as horizontal unless otherwise indicated, and slope relates directly to the loss of pressure per foot of pipe:

$$\text{Slope} = \frac{\text{Head loss}}{\text{Length}} \quad (95.7)$$

Head Loss — Physical Components

Interior pipe roughness is dependent upon pipe material and increases with corrosion and age, designated by the *C* factor, the roughness coefficient (Table 95.1).

Length, velocity head, and diameter (inversely) also affect pressure loss. A widely used formula for flow, velocity, or head loss calculation in a closed pipe system, derived from these physical components, was developed by Hazen and Williams:

$$Q = 0.435 \times C \times d^{2.63} \times s^{0.54} \quad (95.8)$$

For field use, a **nomograph** has become popular (Figure 95.3).

Variations of this formula are easily recognizable, and with any of them approximate values can be measured or calculated for flow, velocity, slope, or length. Accuracy is limited, however, by the roughness coefficient *C*, which can only be estimated based on pipe type and age and a knowledge of water quality.

Compound Pipe Systems

When pipes are laid in series, flow is continuous through the system, and head losses in the component segments are additive. Pipes laid in parallel split flow among the components; head loss in each is identical and is the same as the total head loss. Indirect solutions may be obtained by the equivalent pipe method, creating a single pipe with head loss equivalent to that in the compound set.

FIGURE 95.3 Hazen–Williams alignment chart.

Minor Head Loss

For determination of minor head loss, a standard nomograph is often used, with which each fitting is converted to an equivalent length of straight pipe of the same diameter. Head loss calculations using the new length of pipe will include both major and minor losses (Figure 95.4).

A few minor losses may be expressed in terms of velocity head ($V^2/2g$). Useful in calculations where Bernoulli's theorem is in use and a velocity head value is readily at hand, this method directly converts to head loss (ordinary exit: $HL = 1VH$; ordinary entrance: $HL = 0.5VH$; Borda entrance: $HL = 1VH$).

FIGURE 95.5 Hydraulic jump.

95.6 Open Channel Flow

In conduits where the water has a free surface exposed to atmospheric pressure, velocity head is the energy driving flow. The channel must be physically sloped enough to overcome friction losses so that velocity is maintained. In a properly sloped channel, at steady state flow, the water surface is parallel to the channel bottom and the hydraulic grade line follows. Energy loss is negated by the slope of the channel, and water depth remains constant throughout. In an open channel with a horizontal bottom, the water encounters friction and decreases in velocity, “piling up” behind; it produces the pressure head needed as a greater depth at the upstream end, and the slope of the water surface registers its progressive loss downstream. If the channel is sloped more than is necessary to overcome friction losses, velocity will increase and water depth will decrease; the steep slope creates extra velocity head. A stream bed that slopes sharply, then levels off, will carry water at a shallow depth where the slope is steep and velocity is high. Downstream, the water will be deeper, and the velocity slower (Figure 95.5).

In locations where waters of two different velocities meet, a short section of deeper water occurs; water level rises at the point of velocity change before the surface evens out again; there is extra turbulence at this point, and the water traps air and expands. Called *hydraulic jump*, the phenomenon occurs dramatically at dams and flumes, less so as shoreline waves or those created in a ship’s wake, or as ripples that form when a stone is thrown into water.

Manning’s formula is widely used for calculation of velocity or flow in open channels:

$$V = \frac{1.486}{n} \times R^{0.66} \times s^{0.5} \quad (95.9)$$

Manning’s formula employs a roughness coefficient, n , which is specialized for materials of which open channels are constructed (Table 95.2). In this equation, diameter has been replaced by hydraulic radius (R), making the formula flexible enough to adapt to all cross-sectional areas. R is a measure of the efficiency with which the conduit transmits water and is determined by dividing the cross-sectional area of the water by the wetted perimeter.

$$R = \frac{\text{Wetted area}}{\text{Wetted perimeter}} \quad (95.10)$$

For pipes less than full, wetted area and wetted perimeter are difficult to ascertain, and a hydraulic elements curve is an indirect but accurate method of obtaining the desired value based on its percentage of the full pipe value (Figure 95.6).

TABLE 95.2 Manning Roughness Coefficient (*n*) Value

| Type of Material | <i>n</i> Value |
|----------------------------|----------------|
| Pipe | |
| Cast iron: Coated | 0.012 to 0.014 |
| Uncoated | 0.013 to 0.015 |
| Wrought iron: Galvanized | 0.015 to 0.017 |
| Black | 0.012 to 0.015 |
| Steel: Riveted | 0.015 to 0.017 |
| Corrugated | 0.021 to 0.026 |
| Wood stave | 0.012 to 0.013 |
| Concrete | 0.012 to 0.017 |
| Vitrified | 0.013 to 0.015 |
| Clay, drainage tile | 0.012 to 0.014 |
| Lined Channels | |
| Metal: Smooth semicircular | 0.011 to 0.015 |
| Corrugated | 0.023 to 0.025 |
| Wood: Planed | 0.010 to 0.015 |
| Unplaned | 0.011 to 0.015 |
| Cement lined | 0.010 to 0.013 |
| Concrete | 0.014 to 0.016 |
| Cement rubble | 0.017 to 0.030 |
| Unlined Channels | |
| Earth: Uniform | 0.017 to 0.025 |
| Winding | 0.023 to 0.030 |
| Stony | 0.025 to 0.040 |
| Rock: Uniform | 0.025 to 0.035 |
| Jagged | 0.035 to 0.045 |

95.7 Flow Measurement

Orifice Meter

An orifice meter is a flat steel plate with a precisely sized small-diameter hole at the center that is installed between flanges in a pipeline; the pressure differential created across the orifice is measured by gages upstream and at the orifice discharge. Derived from Bernoulli's formula, calculation is based upon change in velocity head passing through the orifice:

$$Q = C_d A \sqrt{(PH_1 - PH_2) \times 2g} \quad (95.11)$$

where C_d = coefficient of discharge (0.6–0.9); A = area of the orifice (ft²); PH_1 = pressure head upstream; and PH_2 = pressure head at discharge.

Venturi Meter

The Venturi meter is the most accurate and widely used closed conduit pressure differential meter — a constricted tube, with converging section, throat, and longer diverging outlet section. Gages are placed just upstream from the convergence and at the throat; flow is smooth through the unit, and head loss is minimal ($C_d = 0.98$).

$$Q = C_d A \sqrt{\frac{(PH_1 - PH_2)}{1 - (d_2 / d_1)^4}} \times 2g \quad (95.12)$$

Pitot Gage

The Pitot gage is a flowmeter that relies on a direct measurement of velocity head. A pressure gage with a double sensing unit (or a differential manometer) is installed into the pipeline. One end is bent backwards into the flow to capture velocity head as well as pressure head. The differential reading is velocity head, which can be converted to flow.

Magnetic Flowmeter

A magnetic flowmeter consists of a set of magnetic coils that surround the pipe, creating an electromagnetic field; an opposed pair of electrodes mounted at right angles registers the induced voltage (converted to a current signal), which is directly proportional to the velocity of the water passing through the unit.

Ultrasonic Meter

The transmissive type of ultrasonic meter sends ultrasonic beams through the pipe from opposite transmitter/receivers mounted at a diagonal to the flow stream; beam differential is directly proportional to water velocity. The reflective type sends a single sonic beam into the water from a transmitter mounted on the pipe; the beam bounces off solids in the water and is picked up at a different frequency. The magnitude of frequency change is directly proportional to water velocity.

A variation sends a beam to the water surface from an overhead transmitter and relates the return time to water depth, which is convertible to flow.

Positive Displacement Meter

Positive displacement meters are service meters suitable for residential customers; the unit consists of a measuring chamber enclosing a disk or piston; with each pulse a magnetic contact is made to a register that totalizes flow.

Turbine Meter

Turbine meters consist of a measuring chamber with a rotor that turns in response to the velocity of the water. Large customer flows (hotels, industries) are recorded with turbine or the more efficient “turbo” meters.

Compound Meter

Compound meters are installed when accurate reading at both high and low flows is required for customer billing; this device consists of a turbine meter on the main line and a positive displacement meter on the bypass.

Weir

The weir is the least costly open-channel flow meter, a flat plate over which the flow passes. For a rectangular weir,

$$Q = 3.33 \times L \times h^{1.5} \quad (95.13)$$

where L is the width of the weir and h is the head on the weir. For a 90-degree V-notch weir,

$$Q = 2.5 \times h^{2.5} \quad (95.14)$$

Parshall Flume

The Parshall flume is widely used for wastewater and irrigation water flow measurement due to low head loss; this device has self-cleansing capacity and the ability to operate accurately over a significant flow range; it consists of an inlet, a downward-inclining throat, and a diverging outlet. Depth measurement is taken from a stilling well at the inlet. The following formula applies to throat widths of 1 to 8 ft and a medium range of flows:

$$Q = 4W \times H_a^{1.52} \times W^{0.026} \quad (95.15)$$

where W is the width of the throat and H_a is the depth in the stilling well upstream.

Parshall flume formulas are based on low flows; at higher flows, a hydraulic jump forms at the outlet, which may submerge the throat, restricting flow. Formulas will not yield a true flow value; a stilling well at the throat bottom measures downstream depth H_b , and with percent submergence, the correction graph (Figure 95.7) can be referred to.

95.8 Centrifugal Pump

Centrifugal pumps are mechanical devices that convert other forms of energy to hydraulic energy; these pumps create the pressure needed for flow to occur. Pumping technology was limited to positive displacement and screw devices until the nineteenth century, when the centrifugal pump was developed. This device is a small, efficient unit employing a rapidly revolving impeller; high water velocity is developed, which is then converted to pressure upon exit. The pressure developed, the horsepower required, and the resulting efficiency vary with the discharge. These values are diagrammed graphically for each pump on a pump characteristic curve (Figure 95.8), which has been developed from the formula

$$\frac{\text{gpm} \times \text{TDH}}{3960} = \frac{\text{WHP}}{\text{Pump efficiency}} = \text{BHP} \quad (95.16)$$

FIGURE 95.7 Corrections for Parshall flume.

FIGURE 95.8 Pump characteristic curve.

where TDH is the total dynamic head (the work the pump must do in overcoming lift and losses to move the water), WHP is the water horsepower (the power needed to move the water), and BPH is the brake horsepower (the power that must be available to the pump).

Each pump is built to operate at its *design point*, the head and flow at which it achieves maximum efficiency. The point at which it does operate is dependent upon the characteristics of the system — the arrangement of the pipes and appurtenances through which the flow must pass. A centrifugal pump will perform according to its characteristic curve. Pump characteristics, however, may be changed by adjusting the pumping speed (change rpm or impeller size), and oak tree curves are designed to demonstrate characteristics using various sizes of impellers.

Pumps installed in series increase the pumping head, as in booster pumping (multiple pumps) or high-pressure or deep well pumps (multiple impellers). Pumps arranged in parallel increase the flow; the head remains that of one pump working.

For further information on incompressible fluids, refer to [Chapter 35](#).

Defining Terms

Flow — The quantity of water passing a point in a given unit of time (gpd, gpm, cfs).

Force — The total pressure registered on an entire surface area (lb).

Head — Pressure, registered as feet of water.

Mechanical joint — Bell and spigot type; has an outer follower that bolts to the flanged end.

Momentum — Mass multiplied by velocity; responsible for extent of hammer, thrust, surge.

Nomograph — A specialized chart with three or more components that may yield an answer with one or more of its dimensions unknown.

Pressure — Force exerted on a unit area (psf, psi).

Suppressor — Air chamber or open container with small orifice connection to pipeline; allows temporary exit of some water when pressures are high.

Velocity — Speed at which the water travels (ft/sec).

Vijay P. Singh

Louisiana State University

Hydrology can be defined as the science that deals with occurrence, movement, distribution, and storage of water with respect to both its quantity and quality over and below the land surface in space, time, and frequency domains. Water quantity encompasses the physical aspects, and water quality, the chemical and biological aspects. One might sum up hydrology as the study of water in all aspects at macro and higher scales.

The study of hydrology originated in the design of hydraulic works. This historical underpinning continues to dominate the scope and the range of hydrologic investigations. It is therefore no surprise that most often civil engineering is the home of hydrology. With the changing environmental landscape, however, hydrology is beginning to establish its niche in the study of earth, environment, and ecology, and there are signs of hydrology becoming a geophysical science in its own right.

96.1 Classification of Hydrology

It is instructive to peruse the various classifications of hydrology [Singh, 1993, 1997a]. By definition, hydrology can be classified as physical hydrology, chemical hydrology, or biological hydrology; as water quantity hydrology or water quality hydrology; as surface-water hydrology or subsurface hydrology. Depending on the type of **watershed** for which the study of water is undertaken, it can be classified as agricultural hydrology, forest hydrology, urban hydrology, mountainous hydrology, desert hydrology,

wetlands hydrology, or coastal hydrology. Considering the form of water or where water occurs predominantly, this study can be classified as snow hydrology, ice and glacier hydrology, atmospheric hydrology, or lake hydrology. Depending on the particular emphasis on land phase or channel phase, it can be classified as watershed hydrology or river hydrology. Hydrology is also classified based on the tools employed for investigation of hydrologic systems. Parametric hydrology, theoretical hydrology, mathematical hydrology, statistical hydrology, probabilistic hydrology, stochastic hydrology, systems hydrology, and digital hydrology form this classification. The various classifications of hydrology are useful in that they point to its scope and the range of techniques and scales employed in its study.

96.2 Hydrologic Cycle

Water originates in the atmosphere when water vapors are transformed into droplets forming precipitation that falls on the land surface. Part of this precipitation, which eventually returns to the atmosphere through evaporation, is intercepted during its fall by vegetative canopy, buildings, and so on. Another part, which may fall on water surfaces such as streams, lakes, ponds, and seas, may either run off, evaporate, or get stored and finally evaporate. The remainder fills in the depressions on the ground, meets the infiltrative demand of the soil, and runs off the ground to form stream flow. The infiltrated water percolates down and recharges the groundwater and may eventually become stream flow. The final destination of all streams is the ocean, so stream flows finally reach the ocean. Part of the oceanic water returns to the atmosphere through evaporation. Part of the infiltrated water as well as of the surface flow returns to the atmosphere through evapotranspiration. Thus the cyclic movement of water from the atmosphere through precipitation to the land, through stream flow to the ocean, and through evapotranspiration back to the atmosphere is designated the **hydrologic cycle**. This movement, of course, follows devious paths. The study of the hydrologic cycle can then be defined as hydrology. A sketch of the hydrologic cycle [Ackermann et al., 1955], as shown in [Figure 96.1](#), is meaningful in that it brings out the complexity as well as the challenge encountered in the study of water.

96.3 Laws of Science

The laws that govern the movement of water and the constituents it carries with it over and below the ground are the laws of conservation of mass, momentum, and energy. These laws are supplemented by some flux laws. The conservation of mass is expressed as a continuity equation, and that of momentum as an equation of motion. Depending on the type of flow, these equations are expressed in a variety of forms, as will be clear from the following discussion.

Surface Flow

For simplicity, only the one-dimensional form of the governing equations using a control volume is given here. The continuity equation can be expressed as

$$\frac{\partial A}{\partial t} + \frac{\partial Q}{\partial x} = q(x,t) - i(x,t) - e(x,t) \quad (96.1)$$

the momentum equation as

$$\frac{\partial u}{\partial t} + u \frac{\partial u}{\partial x} + g \frac{\partial h}{\partial x} = g(S_0 - S_f) - \frac{(q-i)(u-v)}{A} \quad (96.2)$$

and the energy equation as

FIGURE 96.1 A schematic of hydrologic cycle. (From Ackermann, W. C., Colman, E. A., and Ogrosky, H. O. 1955. In *U.S. Department of Agriculture Yearbook 1955*, USDA, Washington, DC. pp. 41–51.)

$$\frac{\partial u}{\partial t} + u \frac{\partial u}{\partial x} + g \frac{\partial h}{\partial x} = g(S_0 - S_f) + \frac{u - v(v/u)}{2A} q \quad (96.3)$$

where A is flow cross-sectional area, Q is discharge (volumetric rate = $u \cdot A$), u is average flow velocity, h is depth of flow, S_0 is bed slope, S_f is frictional slope, q is lateral inflow per unit length of flow, i is infiltration per unit length, e is evaporation rate and other abstractions per unit length, v is velocity of lateral inflow in the longitudinal direction, x is distance in the longitudinal direction, and t is time. Except for the term expressing the influence of lateral inflow or outflow, Equation (96.2) and Equation (96.3) are equivalent.

Equation (96.1), in conjunction with either Equation (96.2) or Equation (96.3), can be employed to model **surface flows** on plains and/or in channels. Two popular approximations of Equation (96.2) are the diffusion-wave and kinematic-wave approximations [Lighthill and Whitham, 1955; Dooge, 1973; Singh, 1996], which can be expressed, respectively, as follows:

$$\frac{\partial h}{\partial x} = S_0 - S_f \quad (96.4)$$

$$S_0 = S_f \quad (96.5)$$

With use of a uniform flow formula such as Manning's or Chezy's, S_f can be expressed as

$$S_f = \beta \frac{u^2}{R^a} \quad (96.6)$$

where $\beta = 1/C^2$ and $a = 1$ for Chezy's equation; $\beta = n_m^2$ and $a = 4/3$ for Manning's equation; C is Chezy's roughness coefficient, n_m is Manning's roughness factor, and R is the hydraulic radius ($= A/P$, P = wetted perimeter).

Substitution of Equation (96.6) into Equation (96.5) and the assumption that R and h are uniquely related leads to

$$u = \alpha h^m, \quad m > 0 \quad \text{or} \quad Q = \alpha h^n, \quad n = m + 1 \quad (96.7)$$

where $m = 0.5$ and $\alpha = C(S_0)^{0.5}$ for Chezy's equation, and $m = 2/3$ and $\alpha = (S_0)^{0.5}/n_m$ for Manning's equation. Equation (96.7) is normally applied to wide rectangular cross-sections. Otherwise, Q can also be expressed in terms of A in place of h .

The kinematic-wave approximation hypothesizes a unique relationship between the flux (average velocity), concentration (depth), and position. Thus, this approximation can also be expressed in forms different from Equation (96.7), as shown by Beven [1979]. If the control volume is extended to the scale of a watershed or a channel segment, then the flow variables are lumped or integrated in space and only their temporal variability is retained. Thus, integration of Equation (96.1) in space leads to

$$\frac{dS}{dt} = Q - I(t) - f(t) - E(t) \quad (96.8)$$

where

$$S = \int_{x_1}^{x_2} A \, dx, \quad Q = Q(x_2, t), \quad I = Q(x_1, t) + \int_{x_1}^{x_2} q \, dx,$$

$$f = \int_{x_1}^{x_2} i \, dx, \quad E = \int_{x_1}^{x_2} e \, dx$$

where S is storage or volume and Q is discharge as volumetric rate. Equation (96.8) is a volume balance or water budget equation with two unknowns, S and Q . Its solution requires another equation relating S to Q , I , and/or other variables. A very general relation between S and I and Q is [Singh, 1988]:

$$S = \sum_{j=0}^M a(Q, I) \frac{d^j Q}{dt^j} + \sum_{i=0}^N b(Q, I) \frac{d^i I}{dt^i} \quad (96.9)$$

where a and b are coefficients, and M and N are some integers. A special case, involving one of the most frequently used relations in hydrology, is $S = S(Q)$:

$$S = KQ, \quad S = kQ^\beta \quad (96.10)$$

where K is the storage parameter (lag time for $\beta = 1$), and k and β are parameters.

Since Equation (96.8) is derived from Equation (96.1), Equation (96.10) can be derived from the momentum equation. As an example, consider Equation (96.7) with $n = 1$. By multiplying both sides by $\Delta x = x_2 - x_1$ and recalling that $S = \Delta x \cdot h \cdot 1$ and Q is volumetric flow rate, Equation (96.10) results immediately.

Unsaturated Flow

In an unsaturated porous medium, part of the pore space is occupied by air, so the degree of saturation is to be taken into account in dealing with unsaturated flow. The moisture content θ in the medium (volume of water per unit volume of porous medium) is a function of the capillary pressure $\psi < 0$, and likewise is the medium's hydraulic conductivity $K(\psi)$. The basic governing equations for **unsaturated flow** are the continuity equation and a flux law given by Darcy's equation in lieu of the momentum equation. This flux law can also be derived from energy conservation considerations. The three-dimensional continuity equation, under the assumption of incompressible water, can be written as

$$\frac{\partial q_x}{\partial x} + \frac{\partial q_y}{\partial y} + \frac{\partial q_z}{\partial z} = -\frac{\partial \theta}{\partial t} \quad (96.11)$$

and Darcy's equation as

$$q_s = -K_s(\psi) \frac{\partial h}{\partial s}, \quad s = x, y, z; \quad \vec{q} = \{q_x, q_y, q_z\} \quad (96.12)$$

where h is the hydraulic head and q_s is the flux in the s direction. Substituting Equation (96.12) into Equation (96.11) and recalling that $h = \psi + z$, one gets

$$\begin{aligned} \frac{\partial}{\partial x} \left(K_x(\psi) \frac{\partial \psi}{\partial x} \right) + \frac{\partial}{\partial y} \left(K_y(\psi) \frac{\partial \psi}{\partial y} \right) + \frac{\partial}{\partial z} \left(K_z(\psi) \frac{\partial \psi}{\partial z} + K_z(\psi) \right) &= C(\psi) \frac{\partial \psi}{\partial t}, \\ C(\psi) &= \frac{\partial \theta}{\partial \psi} \end{aligned} \quad (96.13)$$

where $C(\psi)$ is the specific moisture capacity. This is the well-known Richards equation [Richards, 1931]. Based on simplifications of porous media properties (anisotropy and heterogeneity) and the nature of flow, a number of simpler versions can be derived [Singh, 1997b]. On the other hand, if the control volume is extended to a soil element, then spatially lumped equations can be derived. For example, Equation (96.11) can be integrated over space and expressed in the form of a water balance equation as

$$\frac{dS(t)}{dt} = f_s(t) - f(t) \quad (96.14a)$$

where $S(t)$ is the potential water storage space in the soil element, $f_s(t)$ is the seepage rate from the element, and $f(t)$ is the infiltration rate. If the initial storage space available in the element is S_0 , then the amount of water storage at any time t is

$$W(t) = S_0 - S(t) = \int_0^t [f(t) - f_s(t)] dt \quad (96.14b)$$

which is an integral expression of continuity. Another relation in lieu of Equation (96.12) can be expressed [Singh and Yu, 1990] as

$$f(t) = f_s(t) + \frac{a[S(t)]^m}{[S_0 - S(t)]^n} \quad (96.15)$$

where a , m , and n are positive real constants.

Saturated Flow

The governing equations for **saturated flow** are the continuity equation and the flux law specified by Darcy's equation. A three-dimensional form of continuity equation for incompressible flow is

$$\frac{\partial q_x}{\partial x} + \frac{\partial q_y}{\partial y} + \frac{\partial q_z}{\partial z} = -S_s \frac{\partial h}{\partial t} \quad (96.16)$$

where S_s is the specific storage for confined formations, or specific yield divided by the saturated thickness for unconfined formations. Darcy's equation can be written as

$$q_s = -K_s \frac{\partial h}{\partial s}, \quad s = x, y, z; \quad \vec{q} = \{q_x, q_y, q_z\} \quad (96.17)$$

where K_s = the saturated hydraulic conductivity in the s direction. Substitution of Equation (96.17) into Equation (96.16) gives the general flow equation, which specializes — depending on the simplifications of porous media properties and the nature of flow — into a number of equations, such as the Laplace equation, the diffusion equation, the Theis equation, the Poisson equation, and the Boussinesq equation [Singh, 1997b].

Sediment Transport

The governing equations for transport of suspended sediment by convection and turbulent diffusion under gravity are the conservation of mass for sediment and the shallow-water equations of momentum and mass conservation for sediment-laden water. The latter two equations are Equation (96.1) and Equation (96.2). The three-dimensional form of sediment mass conservation can be expressed as

$$\frac{\partial C}{\partial t} + u \frac{\partial C}{\partial x} + v \frac{\partial C}{\partial y} + w \frac{\partial C}{\partial z} = w_s \frac{\partial C}{\partial z} + \frac{\partial}{\partial x} \left(\epsilon_x \frac{\partial C}{\partial x} \right) + \frac{\partial}{\partial y} \left(\epsilon_y \frac{\partial C}{\partial y} \right) + \frac{\partial}{\partial z} \left(\epsilon_z \frac{\partial C}{\partial z} \right) \quad (96.18)$$

where C is the concentration of sediment by volume; u , v , and w are velocity components in the x , y , and z directions; w_s is the particle fall velocity; and ϵ_s is the turbulent diffusion coefficient for sediment particle in the s direction ($s = x, y, z$). A number of simplifying assumptions are often made regarding the flow, which gives rise to simplifying sediment transport models [Yang, 1997]. For example, the flow is frequently assumed one-dimensional, and ϵ_s is considered constant or independent of the direction.

Solute Transport

The governing equations for solute transport are the conservation of solute mass and flux laws and the shallow water equations of conservation of mass and momentum of flow containing solute. For expressing the solute mass conservation, advection, diffusion, and dispersion fluxes; adsorption and desorption; and loss and gain of solute have to be expressed. If the medium is unsaturated with moisture content θ , then the solute-mass conservation can be expressed as

$$\frac{\partial}{\partial x} \left(\theta D_h \frac{\partial C}{\partial x} - qC \right) - \frac{\partial}{\partial t} (\theta C + \rho_s S) = \mu_w \theta C + \mu_s \rho_s S - \gamma_w \theta - \gamma_s \rho_s \quad (96.19)$$

where C is the solute concentration, q is Darcy's flux of water, ρ_s is the porous media bulk density, μ_w is the rate constant for first-order decay in the liquid phase, μ_s is the rate constant for first-order decay in the solid phase, γ_w is the rate constant for zero-order production in the liquid phase, γ_s is the rate constant for zero-order production in the solid phase, S is the adsorbed concentration, and D_h is the coefficient

of hydrodynamic dispersion. Depending on the nature of solute and flow, a number of models can be derived from simplification of Equation (96.19) [Singh, 1997b].

Microbial Transport

The fate of microorganisms in the subsurface environment depends on their survival and retention by soil particles. The governing equations for transport and retention of microorganisms are obtained from the conservation of microbial particles in porous media [Kommalapati et al., 1991–1992]. The first governing equation is for the deposited particles, which can be written as

$$\frac{\partial(\rho\sigma)}{\partial t} = K_c(\theta C) - k_d(\rho\sigma) - R_{dd} + R_{gd} \quad (96.20)$$

where R_{dd} and R_{gd} are decay and growth terms of the deposited microbes, ρ is density of microbial particles, σ is volume of deposited bacteria per unit volume of bulk soil, C is concentration of suspended microbial particles per unit volume of flowing suspension, and θ is effective porosity.

The second governing equation is the mass balance equation, including growth and decay terms:

$$\frac{\partial(\rho\sigma)}{\partial t} + \frac{\partial(\theta C)}{\partial t} = -\nabla[-\theta D \nabla C + \theta C(v_f + v_g + v_m)] + [\theta C + \rho\sigma](\mu - b) \quad (96.21)$$

where D is the coefficient of hydrodynamic dispersion, v_f is superficial longitudinal velocity of flow, v_g is settling velocity, v_m is migration velocity, μ is a specific growth term, and b is the specific decay rate.

The third governing equation is derived from the mass conservation for the organic matter:

$$\frac{\partial(\rho_s S_f)}{\partial t} + \frac{\partial(\theta C_f)}{\partial t} = -\nabla(-D_e \theta \nabla C_f) + \theta v_f C_f - \frac{\mu}{Y}(\theta C + \rho\sigma) \quad (96.22)$$

where ρ_s is the bulk mass density of dry soil, S_f is the mass of adsorbed substrate per unit mass of soil particles, C_f is the mass of the substrate per unit volume, D_e is the effective diffusivity coefficient, and Y is the true yield coefficient.

Depending upon the nature of flow, properties of porous media, and characteristics of microorganisms, a number of simplifications of Equation (96.20) through Equation (96.22) have been made, which then form the basis of simpler models.

Initial and Boundary Conditions

In hydrology, all three types of partial differential equations are involved. For example, Equation (96.1) and Equation (96.2) are nonlinear hyperbolic; Equation (96.11) and Equation (96.12) are nonlinear parabolic; and Equation (96.16), with unsteady state term dropped, and Equation (96.17) are nonlinear elliptic. Initial and boundary conditions are needed to obtain a unique solution to a given problem. As an example, for surface flow the usual initial condition is one of dry surface or zero flow, the upstream boundary condition is one of zero discharge, and the downstream boundary condition is specified based on the type of flow or the existence of a control. For subcritical flow in a channel, it may be given by a known control; for supercritical flow another upstream boundary is specified. In a similar manner, conditions are to be specified for unsaturated flow, saturated flow, sediment transport, solute transport, or biological transport.

96.4 Approaches to Hydrologic Problems

Hydrologic systems are analyzed in one or more of three domains: (1) time, (2) space, and (3) frequency. They are also analyzed at different space–time scales. Most of the approaches developed in hydrology

can be classified on the basis of domains and scales. Let us consider a hydrologic variable Y at any location (x, y, z) as a function of time. Then one can write

$$Y(t) = \bar{Y}(t) + \varepsilon(t) \quad (96.23)$$

where $\bar{Y}(t)$ represents the mean value of Y and ε the fluctuations around the mean. If Y is entirely deterministic, then ε vanishes and any approach for determination of Y is deterministic. If Y is entirely probabilistic, then Y is completely specified through modeling of ε and the approach is entirely probabilistic. If Y is part deterministic and part stochastic, the approach employed for determination of Y is mixed. Determination of \bar{Y} constitutes the subject matter of deterministic or mathematical hydrology, and that of ε the subject matter of statistical hydrology. All the deterministic approaches are either empirical, systems based, or physically based. Empirical approaches are based on data, systems approaches are based on the volume balance equation and a type of storage-discharge relation, and physically based approaches are based on the continuity equation together with an equation of motion or energy.

Methods for description of $\varepsilon(t)$ are statistical, probabilistic, or stochastic. Statistical methods are mostly empirical and yield certain moment characteristics or descriptors such as mean, variance, skewness, and so on. Probabilistic approaches employ certain axioms, conceptually or physically based, and proceed to derive the probabilistic structure of ε . The stochastic approaches, on the other hand, can be likened to systems approaches and strive to describe the entire time series of ε without, however, necessarily deriving its probabilistic structure. Time series analysis is an example of a stochastic approach where co-variance structure, correlogram, and spectral analysis are frequently employed. These approaches constitute the subject matter of statistical hydrology. Frequently, the terms *statistical*, *probabilistic*, and *stochastic* are used interchangeably in hydrology. In this chapter the term *statistical* will be used to mean all three types.

96.5 Tools for Hydrologic Analyses

With continuing evolution of hydrology and its expanding role in environmental studies, a greater range of scientific, mathematical, and statistical tools are becoming increasingly important. In addition to physical, chemical, and biological training, hydrologic analyses require a good level of training in mathematics (at the level of partial differential equations and finite element method), statistics (at the level of stochastic processes, time series analysis, reliability analysis, spectral analysis, and multivariate analysis), and operations research (at the level of dynamic programming). Furthermore, to take full advantage of this knowledge, hydrologists of today have to be conversant with GIS, database management, computer graphics and imaging, computer languages, and word processing. Methods of laboratory and field experimentation will receive increasing attention in the years to come. Hydrologic concepts and theories will have to be based more and more on what actually transpires in the field.

96.6 Components of Hydrology Cycle — Deterministic Hydrology

Precipitation

Precipitation forms input to hydrologic systems. It greatly varies in space and time and its space-time structure is highly random, especially at small time scales. The spatial and temporal variability of precipitation is sampled by a network of gages. These must be optimally located. An optimum number of rain gages N corresponding to an assigned percentage error ε in estimation of mean areal rainfall can be obtained as

$$N = \left(\frac{C_v}{\varepsilon} \right)^2, \quad C_v = \frac{100S_p}{P} \quad (96.24)$$

where C_v is the coefficient of variation of the rainfall values of the gages, S_p is the standard deviation of rainfall values, and \bar{P} is the mean of rainfall values.

Precipitation measurements are often inconsistent and incomplete. Methods for checking inconsistency are either graphical or statistical [Buishand, 1982, 1984]. One of the popular methods for correcting it is the double mass curve [Singh, 1989]. Statistical methods include the von Neumann ratio test, cumulative deviations, likelihood ratio test, Bayesian tests, and run test. A multitude of methods exist for filling in the missing values, including the normal ratio method, arithmetic average, isohyetal method, the inverse distance method (IDM), ratio method, and linear programming [Kruizinga and Yperlaan, 1978; Tung, 1983]. The IDM is quite popular and is based on the assumption that the dependence between any two gages is directly proportional to the inverse of some power (between 1.5 and 2.0) of the distance between them. Thus, the missing precipitation value at a gage x for a given time interval can be computed as

$$P(x) = \sum_{i=1}^m w_i P_i, \quad w_i = \frac{1/(D_i^a)}{\sum_{i=1}^m 1/(D_i^a)} \quad (96.25a)$$

where P_i is the precipitation at the i th gage, D_i is the distance between the gages x and i , m is the number of gages used in filling (usually between three and five), and w_i is the weight assigned to the i th gage.

For hydrologic modeling, mean areal precipitation \bar{P} is often needed and is obtained in a variety of ways [Singh and Birsoy, 1975; Singh and Chowdhury, 1986], including unweighted mean, grouped area-aspect weighted mean, Thiessen polygons, individual area-altitude weighted mean, triangular area weighted mean, Myers method, isohyetal method, trend surface analysis, reciprocal distance-squared method, two-axis method, double Fourier series, modified polygon method, finite element method, analysis of variance, and kriging. These methods can be expressed as

$$\bar{P} = \sum_{i=1}^N a_i P_i \quad (96.25b)$$

where P_i is the precipitation value at the i th gage, N is the number of gages, and a_i is the weight assigned to the i th gage. The various methods differ in computation of a_i values. For example, $a_i = 1/N$ for the arithmetic average, and $a_i = A_i/A$ for the Thiessen polygon method, where A_i is the area of the polygon surrounding the i th gage and A is the watershed area. For monthly and yearly values, all of these methods yield comparable results, but for short time intervals (e.g., hourly), isohyetal-type methods may be preferable.

An estimate of the mean areal rainfall is prone to random and systematic errors. Random errors are caused by storm characteristics, rain gage density, and the representativeness of gages, whereas systematic errors are due to improper siting, poor exposure, and change in observer and in gage. Statistical methods for estimating the error in \bar{P} have been reported by Zawadzki [1973] and Bras and Rodriguez-Iturbe [1976].

With improved satellite and radar technology, it is now possible to obtain the spatial field of precipitation for a given event. Such a description can be directly input to distributed hydrologic models [Singh and Frevert, 2002a, b]. To address complex water resources, environmental and ecological problems, distributed models are being increasingly utilized these days.

Evaporation and Transpiration

Evaporation is an energy exchange process through which water is transformed to vapor, and transpiration is the process by which plants transpire water. These are the only processes by which water is returned to the atmosphere to sustain the hydrologic cycle. Evaporation from a water body differs from that from land only if the latter has limited water that may be insufficient to satisfy the evaporative demand. The evaporation occurring from water bodies is referred to as *potential evaporation* (PE). If the soil has limited

water and evaporative demand is not fully satisfied, then the evaporation occurs at a rate less than the potential and is called *actual evaporation* (AE).

Evaporation from a water body depends upon atmospheric conditions such as temperature, pressure, humidity, radiation, sunshine, and wind velocity. As a result, a number of methods are available for estimating evaporation, some based on temperature, some on radiation, some on humidity, and some on combinations of the controlling factors [Jensen et al., 1990; Jones, 1992]. Perhaps the best known is the Penman–Monteith method [Penman, 1948; Monteith, 1981]. This method combines the mass-transfer and energy balance approaches, and can be expressed as

$$E = \frac{\Delta}{\Delta + \gamma}(R_n + G) + \frac{\gamma}{\Delta + \gamma} E_a \quad (96.26)$$

where Δ is the slope of the saturation vapor pressure curve for water, γ is the psychrometric constant, R_n is the net radiation, G is the sensible heat flux, and E_a is the evaporation due to water vapor saturation deficit at some height. Monteith [1981] incorporated aerodynamic and canopy resistance by modifying γ . Allen [1985] presents an account of several variants of the Penman method.

In addition to limiting soil moisture, evaporation from croplands is also affected by crop characteristics. In this case, evaporation from the soil and transpiration are combined to form *evapotranspiration* (ET). This phenomenon is also commonly referred to as *consumptive use*. One of the popular methods for its determination is the Jensen–Haise method [Jensen and Haise, 1963], expressed as

$$ET = C_T(T - T_x)R_s \quad (96.27)$$

where C_T is the temperature constant = 0.014 and T_x is the intercept axis = 26.5 for T in °F; and $C_T = 0.025$ and $T_x = -3$ for T in °C.

The Blaney–Criddle method [Blaney and Criddle, 1962] is also quite popular for computing ET:

$$ET = KF = \sum kf, \quad f = \frac{TP}{100} \quad (96.28)$$

where ET is the consumptive use in inches of water during the growing season, K is the seasonal consumptive use coefficient for a crop, F is the sum of monthly consumptive use factors, T is the mean monthly air temperature in °F, P is the mean monthly percentage of daytime hours, and k is the monthly consumptive use coefficient.

Extraction of water by plants is limited by the availability of soil moisture. Holmes and Robertson [1959] showed that the ratio of AE to PE varies with the drying of soil and that the nature of this variation depends upon the type of soil and vegetation as well as drying rate. Thus, PE is modulated to account for soil moisture stress for determining AE [Singh and Dickinson, 1975].

Infiltration and Soil Moisture

The process by which water enters into the soil at its surface is called *infiltration*. The subsequent downward movement of water is referred to as *percolation*. If water availability is not the limitation, then water will infiltrate the soil at the maximum rate, called *infiltration capacity*, f_p . Under water ponding, the soil's infiltration capacity declines exponentially in time. If availability of water is limited, then the infiltration rate, f , is less than the capacity rate. A number of factors affecting infiltration include soil characteristics, land use, vegetative cover, and rainfall characteristics [Smith, 2002].

A number of models for computing f_p are available. The physically based models are based on Equation (96.11) and Equation (96.12), the conceptual models on Equation (96.14a) and Equation (96.15), and empirical models on data [Smith, 2002]. Singh and Yu [1990] showed that a number of empirical models could be derived using the systems-theoretic framework based on Equation (96.14a) and Equation (96.15)

and that these are actually conceptual models. Examples of some well-known conceptual models are the Philip two-term model [Philip, 1969],

$$F = At + st^{0.5} \quad (96.29)$$

the Green–Ampt model [Green and Ampt, 1911],

$$Kt = F - \eta S \ln \left(\frac{\eta S + F}{\eta S} \right) \quad (96.30)$$

and the Horton model [Horton, 1940],

$$F = f_c t + \frac{1}{k} (f_0 - f_c) [1 - \exp(-kt)] \quad (96.31)$$

where F is cumulative infiltration, t is time, A is the coefficient \approx saturated hydraulic conductivity, s is sorptivity, η is wettable porosity, S is the capillary section at the setting front, K is hydraulic conductivity, f_0 is the initial infiltration rate, f_c is the steady infiltration rate, and k is a constant depending upon the soil type and initial condition. By coupling these models with a rainfall event, the actual infiltration can be determined for that event.

The downward movement of water permits determination of soil moisture. This moisture is evapotranspired, so the status of soil moisture is predicted with the use of an appropriate evapotranspiration model.

Surface Runoff

Surface runoff originates on the land surface and includes both overland flow and channel flow. Two fundamental problems in surface runoff are its time distribution for a specified rainfall event and the amount of surface runoff (also called *yield*) generated from it. A great deal of attention has historically been directed at these two problems, principally because of their ubiquitous application in the design of hydraulic works.

Surface Runoff Hydrograph

The physically based models of the hydrograph are based on Equation (96.1) and Equation (96.2) or Equation (96.4) and Equation (96.5). The most popular models for overland flow are based on the kinematic-wave approximation and those for channel flow on diffusion-wave approximation [Singh, 1990, 1996]. For realistic field conditions, equations are solved numerically [Liggett and Woolhiser, 1967].

The conceptual models most commonly employed in hydraulic design are based on Equation (96.8) and Equation (96.9). The fundamental assumptions made in these models are that rainfall and infiltration are combined, forming excess rainfall, and that the watershed may be represented fictitiously through a network of reservoirs and/or channels, or through a geomorphologic network of average channels and cumulative overland areas [Singh, 1988]. If the watershed is assumed linear, then it is sufficient to compute the *instantaneous unit hydrograph* (IUH) for a delta-function excess rainfall, which, for a watershed represented by a linear reservoir [Dooge, 1959], is

$$h(t) = \frac{1}{k} \exp(-t/k) \quad (96.32)$$

where k is the reservoir lag time. For any excess rainfall the surface runoff hydrograph is then given by the convolution integral:

$$Q(t) = \int_0^t I(\tau)h(t - \tau) d\tau \quad (96.33)$$

If the watershed is represented by a series of n equal reservoirs each with lag time k , as done by Nash [1957], then

$$h(t) = \frac{1}{K\Gamma(n)} \left(\frac{t}{k}\right)^n \exp(-t/k) \quad (96.34)$$

where $\Gamma(n)$ is the gamma function, with n as its argument. Convolution of this IUH with an excess rainfall yields the runoff hydrograph.

Surface Runoff Volume

Determination of runoff volume for a given event is rather complicated, for the determination of the exact amount of infiltration and other abstractions in a watershed has been elusive. One of the popular methods for estimating storm runoff from agricultural areas is the SCS–curve number (SCS–CN) method [Soil Conservation Service, 1971; Mishra and Singh, 2003]. This method is based on two main hypotheses:

1. The ratio of the actual amount of runoff to the potential amount of runoff is equal to the ratio of the actual amount of infiltration to the potential infiltration.
2. An initial amount of abstraction must be satisfied before commencement of any runoff, and that consists of interception, surface storage, and infiltration.

The SCS–CN method can be written as

$$\frac{V_p - V_r - V_Q}{V_R} = \frac{V_Q}{V_p - V_r} \quad (96.35a)$$

where V_R is maximum possible retention, V_r is initial abstraction, V_p is amount of rainfall, and V_Q is amount of runoff. Note that $V_r = aV_R$, $a \simeq 0.1$ to 0.2 . The term V_R depends upon the characteristics of soil cover complex and antecedent soil moisture conditions. SCS expresses V_R as

$$V_r = \frac{1000}{C_N} - 10 \quad (96.35b)$$

where C_N is the curve number on a scale of 10 to 100. For computation of daily, weekly, monthly, or yearly runoff, water balance models are employed. Such models are also employed for computation of storm runoff. Reviews of such models have been presented by Sorooshian [1983] and Renard et al. [1982], [Singh and Frevert, 2002a, b] among others.

Sediment Transport and Yield

Sediment has been characterized as the greatest carrier of pollutants. Sediment yield generated by a storm or on a daily, monthly, or yearly basis has been modeled in a number of ways [Singh, 1989]. By far the best known yield model for small watersheds is the *universal soil loss equation* (USLE) [Wischmeier and Smith, 1978], which can be written as

$$A = RKLSCP \quad (96.36)$$

where A is the soil loss per unit area, in the units of K and for the period of R ; R is the rainfall–runoff factor; K is the erodibility factor; L is the slope-length factor; S is the slope steepness factor; C is the cover

and management factor; and P is the support practice factor. The values of these factors have been extensively tabulated for a wide range of soil–vegetation–land use conditions.

The conceptual models of sediment discharge are derived based on the unit hydrograph concept [Singh, 1989; Singh et al., 1982; Williams, 1978; Sharma and Dickinson, 1980]. Consequently, a unit sediment graph for a watershed is defined as the graph of sediment discharge for a given duration that accumulates to 1 ton. The graph is generated by an effective sediment erosion intensity distributed uniformly in time and in space of the watershed. Singh [1989] has presented a comprehensive discussion of conceptual sediment yield models.

A large volume of literature on sediment transport exists [Vanoni, 1975]. For comprehensive sediment transport models, the entire transport continuum, comprising detachment, deposition, degradation, suspension, and bed-load transport, has to be taken into account. Many of these processes can be modeled using the kinematic-wave theory [Singh, 1997].

Solute Transport

The sources of water pollution can be distinguished as environmental, domestic, industrial, and agricultural. Depending upon the nature of the solute, the transport process in a hydrologic environment may entail advection, diffusion, dispersion, adsorption, desorption, decay of contaminants, chemical reactions, solubilization, precipitation, volatilization, particulate transport, and miscibility. The mechanisms for transport are advection, dispersion, diffusion, solute–solid interaction, chemical reactions, and decay phenomena. The process by which solute is transported by the bulk motion of flowing water is called *advection*. When a solute moves, it tends to spread out from its advection path. This spreading, called *hydrodynamic dispersion*, comprises mechanical dispersion and molecular diffusion. Mechanical dispersion is caused entirely by mixing during the motion of the fluid, which is impacted by the geometry of the conduit, initial and boundary conditions and the sources and sinks. In molecular diffusion, molecular constituents move under the influence of their thermal kinetic energy in the direction of their concentration gradient. Many solutes react with soil through the process of adsorption. This reaction results in partitioning of the solute into the mobile solution phase and the immobile soil surface phase. The reverse of adsorption is the process of dislodgement of chemicals from soil, called *desorption*.

The fundamental law governing the solute transport is the law of conservation of solute mass, which for one-dimensional flow through unsaturated porous media is given by Equation (96.19). Based on the consideration of sources and sinks, four groups of models can be identified [Singh, 1997b]:

1. Models with no production and no decay terms ($\gamma = \mu = 0$)
2. Models with zero production only ($\gamma \neq 0, \mu = 0$),
3. Models with first-order decay only ($\mu \neq 0, \gamma = 0$)
4. Models with zero-order production and first-order decay

If transport mechanisms constitute the basis of model classification, then they can be distinguished as kinematic-wave models and advection–dispersion models.

Microbial Transport

Contaminated soils pose one of the most serious threats to surface and groundwater quality. *In situ* bioremediation is being touted as a viable technology to remedy this problem. Fundamental to development of this technology is the modeling of microbial transport. When microbes are injected into the subsurface environment to augment degradation, one of the problems faced is the limited capacity to transport and disperse bacteria by the soil through the zone of soil contamination [Jackson et al., 1994]. The retention of bacteria by the soil matrix restricts transport of bacteria and is controlled by straining and adsorption. The models for bacterial transport are derived from Equation (96.20) through Equation (96.22). Kommalapati et al. (1991–1992) numerically solved the first two equations by assuming the absence of substrate for biological growth. In a similar manner, simplifications of these equations lead to a variety of simple models.

Models of Hydrologic Cycle

The models of hydrologic cycle are also the stream flow simulation models or the watershed hydrology models. These models are either event based or continuous-time. A large number of simulation models of both types are available. Singh [1989] has provided a short review of these models. A large number of these models are described in Singh (1995), and Singh and Frevert (2002 a, b).

96.7 Statistical Hydrology

Statistical analyses in hydrology have been developed along three lines, as mentioned previously. The following sections present short discussions of each.

Empirical Analyses

These analyses may involve determination of moments, regression and correlation, or entropy for given hydrologic data. If $x_i, i = 1, 2, \dots, N$ represents a set of observations, then the mean \bar{x} , the variance S_x^2 , and the skewness G are given, respectively, as

$$\bar{x} = \frac{1}{N} \sum_{i=1}^N x_i; \quad S_x^2 = \frac{1}{N} \sum_{i=1}^N (x_i - \bar{x})^2; \quad (96.37)$$

$$G = \frac{1}{(n-1)(n-2)} \sum_{i=1}^N (x_i - \bar{x})^3$$

The correlation coefficient r between two data sets of data $X = \{x_1, x_2, \dots, x_N\}$ and $Y = \{y_1, y_2, y_3, \dots, y_N\}$ is

$$r = \frac{\text{cov}(x, y)}{[\text{var}(x) \text{var}(y)]^{1/2}} = \frac{\sum_{i=1}^N (x_i - \bar{x})(y_i - \bar{y})}{NS_x S_y} = \frac{\sum_{i=1}^N x_i y_i - N\bar{x}\bar{y}}{NS_x S_y} \quad (96.38)$$

where $\text{cov}(x, y)$ is the covariance of X and Y , $\text{var}(\bullet)$ is the variance of (\bullet) , S_x is the standard deviation of X , and S_y is the standard deviation of Y . The coefficient of determination is the square of r and gives the amount of variability explained by the relationship between Y and X .

The regression analysis permits establishment of a relationship between the dependent variable Y and the set of independent variables $X_i, i = 1, 2, \dots, M$ as

$$Y = f(X_i, i = 2, \dots, M; a_i, i = 0, 1, 2, \dots, M) \quad (96.39)$$

where a_i values are parameters. The parameters appearing in Equation (96.39) are estimated using the least squares method.

Another empirical analysis frequently employed in hydrology involves finding a frequency distribution that best fits the given set of data [Rao and Hamed, 2000]. This can be done in three ways: (1) graphically, (2) testing the fit of an assumed distribution, and (3) applying the principle of maximum entropy subject to some information about the hydrologic system the data represent [Singh and Fiorentino, 1992]. A number of distributions have been used in hydrology, and entropy has been used to derive a number of these distributions [Singh, 1998]. Other examples of empirical analyses are pattern recognition-based analyses for in-filling of missing records, stream-flow forecasting, and so on [Unny, 1982; Panu, 1992].

Phenomenological Analyses

These analyses make certain postulates about the behavior of a random variable and employ them to derive the probability distribution of the random variable. Examples of such analyses are the extreme-

value analysis based on the random number of random variables [Todorovic, 1982], the point process theory of rainfall [Waymire et al., 1984], and the storage theory of reservoirs [Phatarford, 1976]. As an example, probabilistic models of floods employ such assumptions as independence, stationarity, and Markov property that concern the stochastic structure of the family of the random variables involved. A random number of random variables (RNRV) model considers flood exceedances above a threshold as a sequence of independent random variables, and the number of such exceedances within the selected time interval, say a year, also as a random variable. The choice of probability distributions or stochastic processes for these random variables leads to a number of RNRV-based flood models [Todorovic, 1982].

Stochastic Analyses

Stochastic analyses involve constructing the entire time series of a variable without explicitly knowing the probabilistic structure of the variable. Techniques based on time series analysis, spectral analysis, and so on belong to this class. As an example, consider a random variable X that is observed in a sequential manner as X_1, X_2, \dots , where the subscript may represent intervals of time, distance, and so forth. When the interval is time, this sequence is a time series and is stochastic. The set of random variables X_1, X_2, \dots , associated with its underlying probability distribution is a stochastic process. A time series model has a certain mathematical form and a set of parameters. A comprehensive discussion of time series models in hydrology is given by Salas et al. [1980].

96.8 Hydrologic Design

The type of project determines the need for a particular type of hydrologic information. Hydrologic design of many water resources projects is based on either peak discharge or the complete discharge hydrograph. The selection of a design flood for water resources projects such as dams and spillways involves selecting safety criteria and estimating the flood that meets these criteria. Depending upon the size of a water resources project, three types of design floods are recognized: (1) probable maximum flood (PMF), (2) standard project flood (SPF), and (3) frequency-based flood (FBF). Design of large dams is often based on the concepts of probable maximum precipitation (PMP) and probable maximum flood (PMF). These are either determined deterministically or statistically. Urban drainage is designed using design hydrographs and an acceptable level of risk. Reservoirs are designed using either the storage theory or flow duration curves. Methods of estimating a design flood can be distinguished, depending upon the data requirements, as rainfall-runoff methods, frequency-based methods, and risk-based methods.

Defining Terms

Hydrologic cycle — Denotes the endless movement of water among atmospheric, earth, and oceanic systems through the processes of precipitation, evaporation, infiltration, and stream flow.

Saturated flow — Includes the flow of water occurring in saturated geologic formations.

Surface flow — Includes flow of water occurring over the land.

Unsaturated flow — Includes the flow of water occurring in the vadose zone.

Watershed — Denotes the drainage area draining into an outlet; there is no flow across this area's boundaries. The magnitude of this area varies with the position of the outlet.

Sedimentation studies in water resources engineering require knowledge of and the ability to determine the yield of sediment from the land surface, the transport of sediment by streams, erosion and erosion control, and reservoir sedimentation. These studies require an understanding of **fluvial geomorphology**, sediment properties, hydraulics of open channel flow, river and sediment transport mechanics, and **bed forms** in alluvial channels.

97.1 Fluvial Geomorphology

Fluvial geomorphology is the science dealing with the profiles and planforms of streams and rivers. Rivers are dynamic — always changing their shape, position, and other morphological characteristics — with long- and short-term changes in water or sediment discharge, climate, and tectonic and humanity's activities. A local change in a river or stream, such as construction of a dam or bridge, causes modifications of a river both up- and downstream. With a dam, changes in water and sediment discharge can cause degradation downstream, and backwater can cause aggradation upstream. The fluvial geomorphology of a stream determines its mode of sediment transport and its response to changes in climate, tectonic activity, and man's activity, as well as changes in sediment and water discharge.

Geomorphic factors affecting stream morphology include stream size, flow habit (ephemeral, perennial but flashy, or perennial), bed and bank material, valley setting, flood plains, natural levies, apparent incision, channel boundaries, vegetation, stream planform, variability of width, and development of bars [Vanoni, 1975; Schumm, 1977; Simons and Senturk, 1992; and Richardson et al., 2001]. Stream planform is broadly classified as **meandering**, **straight**, **braided**, or **anabranching**. These broad classifications have been subclassified by geomorphologists and engineers, but for sedimentation studies these broad classifications normally will be sufficient.

Lane [1957, Richardson et al., 2001], studying the relationship between **slope**, S , **discharge**, Q , and **channel planform**, observed that, when $SQ^{1/4} < 0.0017$, a sand bed stream had a meandering planform. Also, when $SQ^{1/4} > 0.01$, a stream had a braided planform. A stream with a value between the two could have either a meandering or a braided planform. A meandering stream whose slope increased such that the value of $SQ^{1/4}$ is larger than 0.0017 might become a braided stream. Conversely, a braided stream that

has its discharge or slope decreased such that the value of $SQ^{1/4}$ is smaller than 0.01 might change to a meandering planform.

Lane [1955; Schumm, 1972] also proposed the following qualitative relationship to predict the response of a stream or river to changes in **water discharge**, Q , **slope**, S , **sediment discharge**, Q_s , and **median diameter** of the bed material, D_{50} :

$$QS \sim Q_s D_{50} \quad (97.1)$$

This relationship shows that, with a decrease in Q and no changes in the qualities on the right, the slope increases. The increase in slope results from deposition of Q_s . Changes in other qualities would induce a response to keep a balance between the left and right sides of the relationship. Richardson et al. [2001] give examples of the uses of this relationship and also expand on the effect of additional variables on the response of streams to change. Leopold and Maddock, Mackin, and others [Schumm, 1972, 1977] give additional insight into the response of streams to change and the importance of fluvial geomorphology in sedimentation.

97.2 Sediment Properties

Sediment properties of value in sedimentation are the physical size, fall velocity, and density of the particles and bulk properties of the bed and bank material and sediment deposits. Sediments are composed of clay (0.0002 to 0.004 mm), silt (0.004 to 0.062 mm), sand (0.062 to 0.2 mm), gravel (2.0 to 64 mm), cobble (64 to 250 mm), or boulder (250 to 4000 mm) material. Bulk properties are described by the size frequency distributions, specific weight, and porosity. Size distributions are determined by sieving, visual accumulation tube analysis, pebble count, and pipette methods. Size distributions are usually expressed as a percentage finer than a given size in the distribution. Also of major importance is the viscosity of suspensions with large concentrations of silts and clays. Sediment properties and methods to determine them are discussed in detail by Brown [1950], Vanoni [1975], Simons and Senturk [1992], and Richardson et al. [2001].

97.3 Beginning of Motion

Knowledge of the point at which fluid forces are large enough to move sediment particles is important in sediment transport, erosion, and design of riprap. Shields [Brown, 1950; Vanoni, 1975; Buffington, 1999; and Richardson, et al., 2001] experimentally determined a relationship at beginning of motion between the ratio of the **critical shear stress** τ_c to move a particle and its **submerged weight** expressed as $(S_s - 1)\gamma D$ and the shear velocity, particle size Reynolds number $[(gRS)^{0.5} D/\nu]$, where S_s is the specific gravity of the particle, γ is the unit weight of water, g is the acceleration of gravity, R is the hydraulic radius, D is the particle size, and ν is the kinematic viscosity. Lane, Fortier and Scobey, Keown, and others [Brown, 1950; Vanoni, 1975; and Richardson et al., 2001] give values for the critical shear or critical velocity for the beginning of motion of silts, clays, sand, and coarser particles. Equations for determining **shear stress** on a boundary are given in the above references. Richardson et al. [2001] and Richardson and Davis [2001] give the following equation for the critical velocity at the beginning of motion of a particle:

$$V_c = [K_s(S-1)D]^{1/2} \gamma^{1/6} / n \quad (97.2)$$

where V_c = critical velocity above which bed material of size D and smaller will be transported (ft/sec or m/sec), D = particle size (ft or m), K_s = Shields parameter for beginning of motion, S_s = specific gravity of bed material particles, γ = depth of flow (ft or m) and n = Manning n . Taking S_s equal to 2.65 — a typical value for sand — $K_s = 0.039$ and $n = 0.041 D^{1/6}$, Equation (97.2) in metric units reduces to

$$V_C = 6.19y^{1/6}D^{1/3} \quad (97.3)$$

97.4 Sediment Yield

Determining the amount of erosion (*sediment yield*) from the land has great significance in water resources engineering. Erosion is classified into overland processes and stream processes. Overland processes include sheet wash, rilling, and gullyng. Stream processes include bed and bank erosion and will be described later.

The *universal soil loss equation* (USLE), developed by the U.S. Department of Agriculture, is the most widely used regression equation for predicting sediment yield from overland flow [Vanoni, 1975; Simons and Senturk, 1992]. The five major factors used to determine the average annual soil loss A , in U.S. tons per acre, are the rainfall factor R , in inches per hour; soil erodibility factor k , in tons per acre per unit of rainfall factor R ; topography factors S for slope (land gradient) and L for length of slope; cropping and management factor C ; and erosion control practices factor P .

97.5 Bed Forms

Flow in sand and medium gravel alluvial channels (D_{50} from 0.062 to 16 mm) is divided into lower and upper flow regime, separated by a transition zone on the basis of the **bed form**, **resistance to flow**, and **bed material discharge**. In the lower flow regime the bed forms in natural channels are dunes, with large resistance to flow (Manning n ranges from 0.02 to 0.04) and low bed material discharge (concentrations ranging from 200 to 2000 ppm by weight). In the upper flow regime the bed forms are plane beds or antidunes, with low resistance to flow (Manning n ranging from 0.012 to 0.020) and large bed material discharge (concentrations of 1000 ppm and larger). In the transition between the two regimes the bed form, resistance to flow, and bed material discharge range between characteristics of the two. The bed form in an alluvial stream depends on the discharge, slope, depth of flow, size of bed material, and viscosity of the fluid [Simons and Richardson, 1963; Vanoni, 1975; Richardson et al., 2001].

Alluvial streams with steep slopes may flow in the upper flow regime all the time, whereas streams with lower slopes change from lower to upper flow regimes depending upon the discharge, bed material size, and fluid viscosity. This tendency results in streams that at low flow are in the lower flow regime and at high flow are in the upper flow regimes. These streams can have a dune bed form in the summer and washed-out dunes, plane beds, or antidunes in the fall and winter. An example is the Missouri River along the border between Nebraska and Iowa. In the summer, when the water temperature is high (70 to 80°F), the bed form is in the lower flow regime and the Manning n is 0.020; in the fall, water temperatures are much lower (35 to 65°F) and the bed form is in the transition and Manning n is 0.015 with, consequently, a lower depth and higher velocity for the same discharge (U.S. Army Corps of Engineers, 1969). These changes in flow regime with discharge and temperature produces discontinuous or shifting rating curves for many sand channel streams and affects the determination of discharge, depths of flow, velocity, and bed material discharge in these streams.

97.6 Sediment Transport

The quantity of sediment transported by a stream consists of the **bed material discharge** and the **fine material discharge (washload discharge)** from the watershed and banks. The bed material discharge is determined by the flow variables and fluid and sediment properties and is, with some degree of accuracy, subject to calculation. The fine sediment discharge depends on availability of fine sediment, is not transported at the capacity of the stream to transport it, is not functionally related to measurable hydraulic variables, and must be measured.

Bed material and fine material are transported in suspension by the turbulence of the stream (**suspended sediment discharge**) or by rolling along in contact with the bed (**contact sediment discharge**). Laursen [Richardson et al., 2001, Richardson and Davis, 2001] determined that, when the ratio of the shear velocity $[(gRS)^{0.5}]$ to the fall velocity (ω) of the bed material is less than 0.5, the bed material discharge is mostly contact bed material discharge; ratios between 0.5 and 2.0 suggest some suspended bed material discharge, and those larger than 2.0 suggest mostly suspended bed material discharge. When the bed material discharge is mostly in contact with the bed, the Meyer–Peter–Muller equation is normally used to determine bed material discharge. Suspended bed material discharge is measured or calculated by integrating the velocity and sediment concentration at a point through the vertical and across the stream. Suspended fine sediment discharge is measured by integrating the velocity and sediment concentration at a point through the vertical and across the stream using depth integrating samplers. To calculate suspended bed material discharge, an equation for the distribution of sediment particles in the vertical (developed by Rouse) is combined with a velocity distribution equation and integrated through the depth. Various investigators then combined the suspended bed material discharge with the contact bed material discharge to develop an equation to determine the total bed material discharge. To determine the total sediment discharge of a stream or river, the fine sediment discharge, which has to be measured, is added to the measured to calculated bed material discharge.

The Meyer–Peter–Muller, Einstein, modified Einstein (developed by Colby and Hembree), and other equations for calculating total bed material discharge are given by Brown [1950], Vanoni [1975], Richardson et al. [2001], and Simons and Senturk [1992].

Colby [1964] developed a very useful graphical method of determining total bed material discharge. The method is given in [Figure 97.1](#) and [Figure 97.2](#) and Equation (97.4) and Equation (97.5):

$$q_T = [1 + (K_1 K_2 - 1) K_3] q_n \quad (97.4)$$

$$Q_s = W q_T \quad (97.5)$$

where q_T is total bed material discharge per unit width (U.S. tons/day/ft), the K_s are correction coefficients determined from [Figure 97.2](#), q_n is the discharge of bed material determined from [Figure 97.1](#), and Q_s (U.S. tons/day) is the total bed material discharge for a channel of width W (ft).

The uncorrected total bed material discharge (q_n) is determined from [Figure 97.1](#) for a given velocity, median diameter of the bed material, and two depths that bracket the desired depth by interpolating on a logarithmic graph of depth versus q_n to obtain the bed material discharge per unit width. The corrected bed material discharge per unit width (q_T) is determined using Equation (97.4) and [Figure 97.2](#). The total bed material discharge is then obtained using Equation (97.5).

The modified Einstein method determines the **total bed material discharge** and **total sediment discharge** from measurements of the suspended sediment discharge to determine the **unmeasured sediment discharge** and, thus, is probably the most accurate of the methods used to calculate the total bed material discharge and the total sediment discharge of a stream. The **unmeasured sediment discharge** is composed of the contact bed material discharge and the suspended sediment discharge in the unmeasured zone. Suspended sediment samplers, except in special cases, only measure within a set distance to the bed (0.2 to 0.4 ft, depending on the sampler). Suspended sediment samplers that are used in very turbulent streams or in specially constructed turbulence flumes (all the bed material is in suspension, no contact discharge) or that traverse the total depth as at the nape of a weir measure the total sediment discharge of a stream. In fact, this method was used to obtain data for the development of the modified Einstein method and other equations. Suspended sediment samplers and measurement methods are described by Vanoni [1975], Simons and Senturk [1992], and Richardson et al. [2001]. Mathematical computer models have been developed to determine total bed material discharge using currently available equations. Models are described by Richardson et al. [2001] and Simons and Senturk [1992].

R. 1964. *Discharge of Sands and Mean-Velocity in Sand-Bed Streams*. U.S. Geological Survey Professional Paper 462-A. U.S. Geological Survey, Washington DC.)

97.7 Reservoir Sedimentation

The rate of depletion of reservoir storage from storage of sediment depends on:

1. The volume of the reservoir in relation to inflow
2. Sediment inflow
3. Reservoir trap efficiencies
4. The specific weight (density) of the sediment deposits

The distribution of the sediment in the reservoir can sometimes be important. Sedimentation damages a reservoir over time if it decreases storage volume to such an extent that it no longer can serve its design function.

Reservoirs with large storage volume in relation to average annual inflow of water have a lower rate of storage loss due to sedimentation than reservoirs that do not — even with the same trap efficiency [Richardson, 1996]. Lake Mead on the Colorado River and Lake Nasser on the Nile River have storage

FIGURE 97.2 Colby's correction curves for temperature and fine sediment (Source: Colby, B. R. 1964. *Discharge of Sands and Mean-Velocity in Sand-Bed Streams*. U.S. Geological Survey Professional Paper 462-A. U.S. Geological Survey Washington, DC.)

volumes that are about double their average annual inflow. Their trap efficiencies are almost 100%. Their rate of sediment depletion of storage is so low that their useful life expectancy is measured in thousands of years. The reservoir behind Tarbella Dam on the Indus River has a storage volume that is less than 20% of the average annual flow. Its trap efficiency is also about 100%. Its rate of storage depletion is so large that its useful life as a storage reservoir is less than 100 years. All three reservoirs have approximately the same annual sediment inflow. Of interest is the fact that the reservoir behind Old Aswan Dam on the Nile (downstream of Lake Nasser), with a storage-to-inflow ratio of less than 3%, has an infinite useful life. The reservoir stored water for over 50 years before Lake Nasser was created by the High Aswan Dam. Its trap efficiency is close to zero because (1) it has under-slucies across the total dam width, and (2) most of the annual flood passes through the reservoir, with only the tail of the flood stored.

The sediment inflow into a reservoir can be estimated by

1. Use of the recorded annual measured total sediment discharge of the stream
2. Computation by flow duration–sediment rating curve method
3. Estimating the sediment yield from the watershed

The use of recorded annual measured total sediment discharge of a stream is limited to those sites that have a historical record based on frequent sampling to establish a reliable estimate of the sediment inflow into the reservoir. Normally, the record of sediment inflow is less than the stream flow record and is only suspended sediment discharge. However, with studies, the suspended sediment record can be adjusted to obtain the total sediment discharge using methods described in the previous section.

The flow duration–sediment rating curve method, which extends the available total sediment discharge record to the historical stream flow record, is the most desirable. In this method, a sediment rating curve is made by relating the daily sediment discharge (normally expressed in tons per day) to the daily discharge. There will be a large scatter in the data, some of which may be seasonal, but with study a reliable set of curves can be developed. A flow duration curve is also prepared for the entire stream flow record. From these two sets of relationships the average annual sediment discharge is determined [Vanoni,

1975; Simons and Senturk, 1992; Albertson et al., 1996]. The sediment rating curve may be developed using measured suspended sediment discharge, measured total sediment discharge (suspended sediments plus unmeasured sediment discharge), or a measured suspended sediment discharge corrected for the unmeasured sediment discharge.

The sediment yield from a watershed is estimated using the universal soil loss equation given earlier. This value is then used with the appropriate trap efficiency to determine sedimentation rates in a reservoir. This method is often used for small reservoirs.

Trap efficiency is the measure of the percentage of the sediment inflow retained (trapped) in the reservoir. It depends on the velocity of flow through the reservoir as well as sediment size. The velocity of flow depends on the size of the reservoir, type of dam, and operating procedures. Reservoirs that are formed from large embankments (soil, concrete, or rock), with large storage volumes and over-year storage, and outlets that normally discharge less flow than the incoming floods have large trap efficiencies (close to 100%). These reservoirs may have some sediment removed by density currents or large velocities when the reservoir is low, but these amounts are ignored in consideration of the other approximations and uncertainties in the determination of the sediment inflow. Small reservoirs with large velocities or reservoirs with under-sluices that can pass large inflows will have low trap efficiencies. The Old Aswan Dam described earlier is an example of the latter. Operation of the dam to have a low pool with high velocities part of each year will decrease trap efficiency.

To determine trap efficiency, Churchill — from a study of TVA reservoirs — developed a relationship between the percentage of incoming silt passing through the reservoir and the ratio of period of retention divided by mean velocity; Brune developed a relationship between percentage of sediment trapped and a ratio of reservoir capacity divided by the mean annual inflow [Vanoni, 1975; Simons and Senturk, 1992]. In using these relations, engineering judgement must be used to determine trap efficiency for a particular reservoir.

The specific weight of the sediment deposited in a reservoir is needed to convert to volume the estimate of sediment deposited in the reservoir, which is normally given in terms of weight. The specific weight of the sediment deposits in the reservoir increases with time as they consolidate. Coarse sediments (sand and gravels) will consolidate faster than finer silts and clays and will reach their ultimate weight faster. Also, sediments consolidate faster if they are not always submerged. Vanoni [1975] and Simons and Senturk [1992] present methods for estimating the specific weight developed by Lane and Koelzer, which takes into account the type of sediment and degree of submergence.

The distribution of sediment deposits in reservoirs and/or movement of sediments through reservoirs depends on the size composition of the sediment flowing into a reservoir and the management of the outflow. Coarse sediments are deposited in the upper reaches of the reservoir and finer sediments farther down. If the water storage in the reservoir is managed so as to have a low water level part of the year, then the coarser materials are moved farther down into or even through the reservoir. Coarse sediment deposits at the upper end of the reservoir can increase the backwater effects upstream. Vanoni [1975], Simons and Senturk [1992] and Albertson et al. [1996] discuss the location of sediment deposits and present methods to evaluate the location.

Sediment deposits in reservoirs are measured using sonic sounders and surveying techniques to monitor the loss of storage with time. Vanoni [1975] and Albertson et al. [1999] describes methods for conducting these surveys.

Defining Terms

Anabranch — A stream whose flow is divided at normal or lower discharges by large, relatively permanent islands. The channels are more permanent and more widely and distinctly separated than those of a braided stream.

Bed form — A relief feature on the bed of a stream, such as dunes, plane bed, or antidunes. Also called *bed configuration*.

- Bed material** — Material found in the bed of a stream. May be transported in contact with the bed or in suspension.
- Bed material discharge** — The part of the total sediment discharge of a stream that is composed of grain sizes found in the bed and is equal to the transport capability of the flow.
- Braided stream** — A stream whose flow is divided at normal and low flow into several channels by bars, sandbars, or islands. The bars and islands change with time, sometimes with each runoff event. A braided stream may have the aspect of a single large channel at large flows.
- Contact sediment discharge** — Sediment that is transported in a stream by rolling, sliding, or skipping along in contact with the bed. Also called *bed load* or *contact load*.
- Critical shear stress** — The minimum amount of shear (force) exerted by the flow on a particle or group of particles that is required to initiate particle motion.
- Discharge** — Time rate of the movement of a quantity of water or sediment passing a given cross section of a stream or river.
- Fine sediment discharge (washload discharge)** — That part of the total sediment discharge of a stream that is not found in appreciable quantities in the stream bed. Normally, the fine sediment discharge in a sand bed stream is composed of particles finer than sand (0.062 mm). In coarse gravel, cobble, or boulder bed stream, silts, clays and sand could be fine sediment or washload discharge.
- Flow duration curve** — A graph indicating the percentage of time a given discharge is exceeded.
- Fluvial** — Related to stream or rivers.
- Geomorphology** — The branch of physiography and geology that deals with the general configuration (form) of the earth's surface and the changes that take place as the result of the forces of nature.
- Hydraulic radius** — The cross-sectional area of a stream, divided by its wetted perimeter. Equals the depth of flow when the width is larger than 10 times depth.
- Meandering stream** — A stream with sinuous S-shaped flow pattern.
- Median diameter** — The particle diameter at which 50% of a sample's particles are coarser and 50% are finer (D_{50}).
- Sediment yield** — The total sediment outflow from a unit of land (field, watershed, or drainage area) at a point of reference and per unit of time.
- Shear stress, tractive force** — The force or drag on the channel boundaries that is caused by the flowing water. For uniform flow, average shear stress is equal to the unit weight of water times the hydraulic radius times the slope. Usually expressed as force per unit area.
- Shear velocity** — The square root of the shear stress divided by the mass density of water, in units of velocity.
- Slope** — Fall per unit length of the channel bottom, water surface, or energy grade line.
- Suspended sediment** — Sediment particles that are suspended in the flow by the turbulence of the stream.
- Suspended sediment discharge** — The quantity of suspended sediment passing through a stream cross-section per unit of time.
- Total bed material discharge** — The sum of the suspended sediment bed material discharge (suspended load) and the contact sediment discharge (bed-load).
- Total sediment discharge** — The sum of the suspended sediment discharge and the contact sediment discharge, the sum of the bed material discharge and the washload discharge, or the sum of the measured sediment discharge and the unmeasured sediment discharge.
- Unmeasured sediment discharge** — The sediment discharge that is not measured by suspended sediment samplers. It consists of the suspended sediment discharge in the unsampled zone and the contact sediment discharge. Suspended sediment samplers normally do not measure to the bed of a stream.

Transfer Functions and Laplace Transforms

C. Nelson Dorny
University of Pennsylvania

- 98.1 Transfer Functions
- 98.2 The Laplace Transformation
- 98.3 Transform Properties
- 98.4 Transformation and Solution of a System Equation

We perceive a system primarily through its behavior. Therefore, our mental image of a system usually includes representative response **signals**. The *step response*, the behavior when we suddenly turn on the system, is such a system-characterizing signal. We should view the step response as a description of the system. The *impulse response* is another description of the system. For a system represented by linear differential equations, the unit-step response is the integral of the unit-impulse response.

Let us represent time differentiation (d/dt) by the *time-derivative operator*, p . Then we can denote the time derivative of a signal y by py , its second derivative by p^2y , its integral with respect to time by $(1/p)y$, and so on. This *operator notation* simplifies the expressions for differential equations. We shall use the expression *system equations* to mean a set of differential equations that determines fully the behaviors of the dependent variables that appear in those equations. We can reduce a *linear* set of system equations to a single **input-output system equation** by eliminating all but one dependent variable from the set. The *transfer function* associated with that dependent variable is a mathematical expression that contains all the essential information embodied in the system differential equation.

The Laplace transformation converts signals (functions of time) to functions of a *complex-frequency variable*, $s = \sigma + j\omega$. A one-to-one correspondence exists between a signal and its Laplace transform. We can retrieve the time function by inverse transformation. Laplace transformation produces images that have some properties that are more convenient than those of the original signals. In particular, time differentiating a signal corresponds to multiplying its Laplace transform by the complex-frequency variable s . Hence, the transformation converts linear constant-coefficient differential equations to linear algebraic equations. Such simplifications of time-domain operations make Laplace transformation useful.

The Laplace transformation also converts the impulse response of a system variable to the transfer function for that variable. As a consequence, we can view the differential equation that represents a linear system as an expression of the response of that system to an impulsive input.

98.1 Transfer Functions

The node displacements x_1 and x_2 and the compressive forces f_1 and f_2 within the branches of the lumped model of [Figure 98.1](#) are related to each other by the spring equations, the damper equation, and the balance of forces at node 2. The spring equation is $f_2 = k(x_1 - x_2)$. The equation for the damper is $f_1 =$

FIGURE 98.1 The lumped model of a mechanical system.

$b(px_1 - px_2)$. The balance of forces requires that $f_1 + f_2 = mp^2x_2$. These equations describe fully the behavior of the system if the spring and mass are unenergized. (If the mass were moving and/or the spring were compressed, we would have to express separately their initial energy states to describe fully the future relations among the variables.)

Eliminating f_1 and f_2 from the equations to obtain the operational equation:

$$(mp^2 + bp + k)x_2 = (bp + k)x_1 \quad (98.1)$$

This differential equation describes fully the **zero-state** relation between x_1 and x_2 . Rearrange Equation (98.1) to form the ratio

$$\frac{x_2}{x_1} = \frac{bp + k}{mp^2 + bp + k} \quad (98.2)$$

We call Equation (98.2) the *transfer function* from x_1 to x_2 . The transfer function focuses attention on the mathematical operations that characterize the behavioral relationships rather than on the particular natures of the variables. [Note that the transfer function from v_1 to v_2 where $v_1 = px_1$ and $v_2 = px_2$ is the same as the transfer function given by Equation (98.2).]

In general, suppose that y_1 and y_2 are two variables related (in operator notation) by the linear differential equation

$$y_2 = G(p)y_1 \quad (98.3)$$

We formally define the *transfer function* from y_1 to y_2 by

$$G(p) = \left. \frac{y_2}{y_1} \right|_{ZS} \quad (98.4)$$

where the notation ZS means **zero state**. If y_1 is an independent variable, then $G(p)$ is the *input-output transfer function* for the variable y_2 and accounts fully for its behavior owing to the **input signal** y_1 . We can determine from that transfer function the behavior of the system for any source waveform and any initial state.

98.2 The Laplace Transformation

The *one-sided Laplace transformation*, L , is an integral operator that converts a signal $f(t)$ to a complex-valued function $F(s)$ in the following fashion:

$$L[f(t)] \equiv F(s) \triangleq \int_0^{\infty} f(t)e^{-st} dt \quad (98.5)$$

We refer to the transformed function $F(s)$ as the *Laplace transform* of the signal $f(t)$. Picture the lower limit 0^- of the integral as a *specific* instant prior to but infinitesimally close to $t = 0$. It is customary to use a lowercase symbol (f) to represent a signal waveform and an uppercase symbol (F) to represent its Laplace transform. [Although we speak here of time signals, there is nothing in Equation (98.5) that requires $f(t)$ to be a function of time. The transformation can be applied to functions of any quantity t .]

We shall use the Laplace transformation to transform the signals of **time-invariant** linear systems. The behavior of such a system for $t \geq 0$ depends only on the input signal for $t \geq 0$ and on the prior **state** of the output variable (at $t = 0^-$).

The process of finding the time function $f(t)$ that corresponds to a particular Laplace transform $F(s)$ is called *inverse Laplace transformation*, and is denoted by L^{-1} . We also call $f(t)$ the *inverse Laplace transform* of $F(s)$. Since the one-sided Laplace transformation ignores $t < 0^-$, $F(s)$ contains no information about $f(t)$ for $t < 0^-$. Therefore, inverse Laplace transformation cannot reconstruct $f(t)$ for $t < 0^-$. We shall treat all signals as if they are defined only for $t \geq 0^-$. Then there is a one-to-one relation between $f(t)$ and $F(s)$.

To illustrate the Laplace transformation, we find the Laplace transform of the decaying exponential, $f(t) = e^{-\alpha t}$, $t \geq 0^-$. The transform is

$$\begin{aligned} F(s) &= \int_{0^-}^{\infty} e^{-\alpha t} e^{-st} dt = \left. \frac{e^{-(s+\alpha)t}}{-(s+\alpha)} \right|_{0^-}^{\infty} \\ &= \left. \frac{e^{-(\sigma+\alpha)t} e^{-j\omega t}}{-(s+\alpha)} \right|_{0^-}^{\infty} = \frac{1}{s+\alpha} \quad \text{for } \text{Re}[s] > -\alpha \end{aligned} \tag{98.6}$$

We must require $\sigma > -\alpha$, where σ is the real part of s , in order that the real-exponent factor converges to zero at the upper limit. (The magnitude of the complex-exponent factor remains 1 for all t .) Therefore, the Laplace transform of the decaying exponential is defined only for $\text{Re}[s] > -\alpha$. This restriction on the domain of F in the complex s plane is comparable to the restriction $t \geq 0^-$ on the domain of f .

The significant features of the complex-frequency function $1/(s + \alpha)$ are the existence of a single pole and the location of that pole, $s = -\alpha$ rad/sec. [The pole defines the left boundary of that region of the complex s plane over which the transform $1/(s + \alpha)$ is defined.] The significant features of the corresponding time function are the fact of decay and the rate of decay, with the exponent $-\alpha$ rad/sec. There are clear parallels between the features of $f(t)$ and $F(s)$. We should think of the whole complex-valued function F as representing the whole time waveform f .

As a second transformation example, let $f(t) = \delta(t)$, the unit impulse, essentially a unit-area pulse of very short duration. It acts at $t = 0$ — barely within the lower limit of the Laplace integral. It has value zero at $t = 0^-$. (Because we use 0^- as the lower limit of the defining integral, it does not matter whether the impulse straddles $t = 0$ or begins to rise at $t = 0$.) The impulse is nonzero only for $t \approx 0$, where $e^{-st} \approx 1$. Therefore, the Laplace transform is

$$\Delta(s) = \int_{0^-}^{\infty} \delta(t) e^{-st} dt \approx \int_{0^-}^{\infty} \delta(t) (1) dt = 1 \tag{98.7}$$

It is not necessary to derive the Laplace transform for each signal that we use in the study of systems. [Table 98.1](#) gives the transforms for some signal waveforms that are common in dynamic systems.

98.3 Transform Properties

A number of useful properties of the Laplace transformation L are summarized in [Table 98.2](#). According to the derivative property, the multiplier s acts precisely like the time-derivative operator, but in the domain of Laplace-transformed signals. When we Laplace transform the equation for an energy-storage element such as a mass or a spring, the derivative property automatically incorporates the prior energy

Table 98.1 Laplace Transform Pairs

| $f(t) = \mathcal{L}^{-1} [F(s)], t \geq 0^-$ | $F(s) = \mathcal{L} [f(t)]$ |
|--|--|
| 1. Unit impulse $\delta(t)$ | 1 |
| 2. Unit step $u_s(t)$ | $\frac{1}{s}$ |
| 3. $t^n, n = 1, 2, \dots$ | $\frac{n!}{s^{n+1}}$ |
| 4. $e^{-\alpha t}$ | $\frac{1}{s + \alpha}$ |
| 5. $t^n e^{-\alpha t}, n = 1, 2, \dots$ | $\frac{n!}{(s + \alpha)^{n+1}}$ |
| 6. $\sin(\omega_0 t)$ | $\frac{\omega_0}{s^2 + \omega_0^2}$ |
| 7. $\cos(\omega_0 t)$ | $\frac{s}{s^2 + \omega_0^2}$ |
| 8. $e^{-\alpha t} \sin(\omega_d t)$ | $\frac{\omega_d}{(s + \alpha)^2 + \omega_d^2}$ |
| 9. $e^{-\alpha t} \cos(\omega_d t)$ | $\frac{s + \alpha}{(s + \alpha)^2 + \omega_d^2}$ |

Source: Dorny, C. N. 1993. *Understanding Dynamic Systems*, Prentice Hall, Englewood Cliffs, NJ. p. 412. With permission.

state of the element — essentially the value of the variable at $t = 0^-$. When we Laplace transform the input-output system equation for a particular system variable, the derivative property automatically incorporates the whole prior system state. As a consequence, we can find the solution to the system equation without having to determine the initial conditions (at $t = 0^+$) — a considerable simplification of the solution process.

Since $F(s)$ contains all information about $f(t)$ for $t \geq 0^-$, it is possible to find some features of the signal $f(t)$ from the transform $F(s)$ without performing an inverse Laplace transformation. Properties 7 through 9 of Table 98.2 provide three of these features — namely, the initial value ($t \rightarrow 0^+$), the final value ($t \rightarrow \infty$), and the area under the waveform. The remaining properties in the table show the effect on the transform of various changes in the signal waveform.

The usual approach to finding inverse transforms is to use a table of transform pairs. That table might be stored in a software package such as CC, MATLAB, MAPLE, and so on. Table 98.1 demonstrates that transforms of typical system signals are ratios of polynomials in s . A ratio of polynomials can be decomposed into a sum of *simple* polynomial fractions — a process referred to as *partial fraction expansion*. Hence, the inversion process can be accomplished by a computer program that incorporates a brief table of transforms.

98.4 Transformation and Solution of a System Equation

Suppose that an independent external source applies a specific velocity pattern $v_1(t)$ to node 1 of Figure 98.1. To obtain the input-output system equation that relates the velocity v_2 of node 2 to the input signal v_1 , multiply Equation (98.2) by p and substitute v_1 for px_1 and v_2 for px_2 . The result is

$$(mp^2 + bp + k)v_2 = (bp + k)v_1 \tag{98.8}$$

TABLE 98.2 Properties of the Laplace Transformation, L

| | |
|-------------------------|---|
| 1. Magnification | $L[af(t)] = aF(s)$ |
| 2. Addition | $L[f_1(t) + f_2(t)] = F_1(s) + F_2(s)$ |
| 3. Derivative | $L[\dot{f}(t)] = sF(s) - f(0^-)$ |
| 4. Derivatives | $L[\ddot{f}(t)] = s^2F(s) - sf(0^-) - \dot{f}(0^-)$ |
| 5. Integral | $L\left[\int_0^t f(t)dt\right] = \frac{F(s)}{s}$ |
| 6. Convolution | $L\left[\int_0^b f_1(\lambda)f_2(t-\lambda)\right] = F_1(s)F_2(s)$ |
| 7. Initial value | $f(0^+) = \lim_{t \rightarrow 0^+} f(t) = \lim_{s \rightarrow \infty} sF(s)$ |
| 8. Final value | $f(\infty) = \lim_{t \rightarrow \infty} f(t) = \lim_{s \rightarrow 0} sF(s)$ if finite |
| 9. Definite integral | $\int_0^\infty f(t)dt = \lim_{s \rightarrow 0} F(s)$ if finite |
| 10. Exponential decay | $L[e^{-\alpha t}f(t)] = F(s + \alpha)$ |
| 11. Delay | $L[f(t-t_0)u_s(t-t_0)] = e^{-t_0 s} F(s)$ For $t_0 \geq 0$ |
| 12. Time multiplication | $L[tf(t)] = -\frac{dF(s)}{ds}$ |
| 13. Time division | $L\left[\frac{f(t)}{t}\right] = \int_s^\infty F(s)ds$ |
| 14. Time scaling | $L[f(at)] = \frac{F(s/a)}{a}$ |

Source: Dorny, C. N. 1993. *Understanding Dynamic Systems*, Prentice Hall, Englewood Cliffs, NJ. p. 413. With permission.

The two sides of Equation (98.8) are identical functions of time. Therefore, the Laplace transforms of the two sides of Equation (98.8) are equal. Since the Laplace transformation is linear (properties 1 and 2 of Table 98.2), and since the coefficients of the differential equation are constants, the Laplace transform can be applied separately to the individual terms of each side. The result is

$$m[s^2V_2(s) - sv_2(0^-) - \dot{v}_2(0^-)] + bsV_2(s) - v_2(0^-) + kV_2(s) = b[sV_1(s) - v_1(0^-)] + kV_1(s) \quad (98.9)$$

where the derivative properties of the Laplace transformation (properties 3 and 4 of Table 98.2) introduce the prior values $v_1(0^-)$, $v_2(0^-)$, and $\dot{v}_2(0^-)$ into the equation. According to Equation (98.9), to fully determine the transform $V_2(s)$ of the behavior $v_2(t)$, we must specify these prior values and also $V_1(s)$. It can be shown that specifying the three prior values is equivalent to specifying the energy states of the spring and mass.

Let us assume that the independent source applies the constant velocity $v_1(t) = v_c$ beginning at $t = 0$. The corresponding transform, by item 3 of Table 98.1 and property 1 of Table 98.2, is $V_1(s) = v_c/s$. Substitute the transform $V_1(s)$ into Equation (98.9) and solve for

$$V_2(s) = \frac{(bs+k)v_c + ms\dot{v}_2(0^-) + bs[v_2(0^-) - v_1(0^-)] + ms^2v_2(0^-)}{s(ms^2 + bs + k)} \quad (98.10)$$

We could find the output signal waveform $v_2(t)$ as a function of the model parameters m , k , b , the source-signal parameter v_c , and the prior state information $v_1(0^-)$, $v_2(0^-)$, and $\dot{v}_2(0^-)$, but the expression for the solution would be messy. Instead, we complete the solution process for specific numbers: $m = 2$

kg, $b = 4 \text{ N} \cdot \text{sec}/\text{m}$, $k = \text{N}/\text{m}$, $\dot{v}_2(0^-) = 0 \text{ m}/\text{sec}^2$, $v_1(0^-) = 0 \text{ m}/\text{sec}$, $v_2(0^-) = -1 \text{ m}/\text{sec}$, and $v_c = 1 \text{ m}/\text{sec}$. The partial-fraction expansion of the transform and the inverse transform, both obtained by a commercial computer program, are

$$V_2(s) = \frac{1}{s} - \frac{2s+2}{(s+1)^2 + 2^2} \quad (98.11)$$

$$v_2(t) = 1 - 2e^{-t} \cos(2t), \quad \text{for } t \geq 0 \quad (98.12)$$

We can take Laplace transforms of the system equations at any stage in their development. We can even write the equations directly in terms of transformed variables if we wish. The process of eliminating variables can be carried out as well in one notation as in another. For example, the operator $G(p)$ in Equation (98.3) represents a ratio of polynomials in the time-derivative operator p . Therefore, Laplace transforming the differential Equation (98.3) introduces the prior values of various derivatives of y_1 and y_2 . If the prior values of all these derivatives are zero, then the Laplace-transformed equation is

$$Y_2(s) = G(s)Y_1(s) \quad (98.13)$$

where the operator p in Equation (98.3) is replaced by the complex-frequency variable s in Equation (98.13). It is appropriate, therefore, to define the transfer function directly in terms of Laplace-transformed signals:

$$G(s) = \left. \frac{Y_2(s)}{Y_1(s)} \right|_{\text{PV}=0} \quad (98.14)$$

where $Y_1(s)$ and $Y_2(s)$ are the Laplace transforms of the signals $y_1(t)$ and $y_2(t)$, and the notation $\text{PV} = 0$ means that the prior values (at $t = 0^-$) of $y_1(t)$ and $y_2(t)$ and the various derivatives mentioned above in connection with Equation (98.13) are set to zero. The *frequency domain* definition [Equation (98.14)] is equivalent to the time *domain* definition [Equation (98.4)].

Suppose that the input signal $y_1(t)$ is the unit impulse $\delta(t)$. Then the response signal $y_2(t)$ is the unit-impulse response of the system. Since the Laplace transform of the unit impulse is $Y_1(s) = \Delta(s) = 1$ by entry 2 of Table 98.1, Equation (98.13) shows that the Laplace transform $Y_2(s)$ of the unit-impulse response is identical to the zero-state transfer function (expressed in the transform domain).

The transfer function for a linear system has two interpretations. Both interpretations characterize the system. In the frequency domain, the transfer function $G(s)$ is the multiplier that produces the response — by multiplying the source-signal transform, as in Equation (98.13). In the time domain, we use a representative response signal — the impulse response — to characterize the system. The transfer function $G(s)$ is the Laplace transform of that characteristic response.

Defining Terms

Input — An independent variable.

Input-output system equation — A differential equation that describes the behavior of a single dependent variable as a function of time. The dependent variable is viewed as the system output. The independent variable(s) are the inputs.

Output — A dependent variable.

Signal — An observable variable; a quantity that reveals the behavior of a system.

State — The state of an n th-order linear system corresponds to the values of a dependent variable and its first $n - 1$ time derivatives.

Time invariant — A system that can be represented by differential equations with constant coefficients.
Zero state — A condition in which no energy is stored or in which all variables have the value zero.

99.1 Introduction

Block diagrams are representations of physical systems using blocks. They are among the many representations such as transfer function representation, impulse response representation, difference equation representation, and state-space representation. Each of these representations, including the block diagram representation, gives a complete description of the system under consideration. Some of them are better than the others, and that depends on the system itself. Individual blocks can be put together to represent the physical system in block diagram form. Individual blocks can be the basic blocks or they can be subsystems. The discussion we will undertake will be applicable to discrete or analogue linear time-invariant systems. We will use analogue systems in the discussion in the Laplace domain with s being the Laplace domain variable. We will start by examining block diagrams that are built from the very basic components, and then we will look at block diagrams that are built from subsystems. We will also look at methods of reducing block diagrams with the main goal of obtaining the transfer function represen-

FIGURE 99.1 The ideal integrator block.

FIGURE 99.2 The adder block.

tations. We will also see in the coming discussion that block diagram representations are not unique. We can have many different block diagram representations, but the transfer function relating the inputs to the outputs is unique. Among the many block diagram representations, we are mainly concerned with about five. The first three are the canonical controllable, the canonical observable, and the diagonal or the Jordan forms. These three representations will be presented in block diagrams using the basic building blocks. The other two are the series and parallel forms and they will be built using subsystems. The first three representations are very important in the design of feedback and state estimators in the state-space domain. These three representations are also important in the process of building actual prototype circuits using operational amplifier. The series and the parallel representations are important in the process of building analogue or digital filters using first- and second-order transfer functions.

Every dynamical linear time-invariant system can be put in the transfer function representation form. Thus our starting point in building block diagrams will be the transfer function representation. Also we will deal with only causal and realizable systems. This requires that in the transfer function representation, the degree of the numerator is less than the degree of the denominator. Thus the transfer function is in the strictly proper form.

99.2 Basic Block Diagram Components

The Ideal Integrator

The integrator block diagram is seen in Figure 99.1.

The output in this case is

$$Y(s) = \frac{1}{s}X(s) \quad (99.1)$$

The Adder

The adder block diagram is seen in Figure 99.2.

The output in this case is

$$Y(s) = X_1(s) + X_2(s) \quad (99.2)$$

The Subtractor

The subtractor block diagram is seen in Figure 99.3.

The output in this case is

$$Y(s) = X_1(s) - X_2(s) \quad (99.3)$$

The Multiplier

The multiplier block diagram is seen in Figure 99.4.

FIGURE 99.3 The subtractor block.

FIGURE 99.4 The multiplier block.

The output in this case is

$$Y(s) = kX(s) \tag{99.4}$$

99.3 Block Diagrams as Interconnected Subsystems

We will look at four important configurations. These are the general transfer function representation, the series representation, the parallel representation, and the basic feedback representation.

The General Transfer Function Representation

A block diagram representation for a system with $x(t)$ as the input, $y(t)$ as the output, and $h(t)$ as the impulse response can be represented as shown in Figure 99.5. Mathematically we write

$$Y(s) = X(s)H(s) \tag{99.5}$$

The Parallel Representation

If we have two subsystems connected in parallel as shown in Figure 99.6, then the output is written as

$$Y(s) = X(s)[H_1(s) + H_2(s)] \tag{99.6}$$

If we have more subsystems connected the procedure is the same; you add all the individual transfer functions for the subsystems and multiply by the input $X(s)$ to get $Y(s)$. You can find the equivalent transfer function for the whole system as

$$H(s) = \frac{Y(s)}{X(s)} = H_1(s) + H_2(s) + H_3(s) + \dots \tag{99.7}$$

The Series Representation

If we have two subsystems connected in series as in Figure 99.7, then mathematically we write the output as

$$Y(s) = X(s)H_1(s)H_2(s) \tag{99.8}$$

FIGURE 99.5 The general transfer function representation.

FIGURE 99.6 The parallel representation.

FIGURE 99.7 The series representation.

FIGURE 99.8 Basic feedback block diagram.

If we have more subsystems connected, the procedure is the same; you multiply all the individual transfer functions for the subsystems first and then multiply the result by the input $X(s)$ to get $Y(s)$. You can find the equivalent transfer function for the whole system as

$$H(s) = \frac{Y(s)}{X(s)} = H_1(s)H_2(s)H_3(s)\dots \quad (99.9)$$

The Basic Feedback Representation

A very basic and fundamental feedback block diagram representation is shown in Figure 99.8.

From Figure 99.8 we have

$$E(s) = X(s) - F(s)Y(s) \quad (99.10)$$

and the output is

$$Y(s) = G(s)E(s) \quad (99.11)$$

If we substitute Equation (99.10) in Equation (99.11) we have

$$H(s) = \frac{G(s)}{1 + G(s)F(s)} \quad (99.13)$$

99.4 The Controllable Canonical Form (CCF) Block Diagrams with Basic Blocks

Consider the transfer function representation

$$\frac{Y(s)}{X(s)} = \frac{b_{n-1}s^{n-1} + b_{n-2}s^{n-2} + b_{n-3}s^{n-3} + \dots + b_0}{s^n + a_{n-1}s^{n-1} + a_{n-2}s^{n-2} + a_{n-3}s^{n-3} + \dots + a_0} \quad (99.14)$$

Let us multiply the numerator and the denominator in (99.14) by s^{-n} to get

$$\frac{Y(s)}{X(s)} = \frac{b_{n-1}s^{-1} + b_{n-2}s^{-2} + b_{n-3}s^{-3} + \dots + b_0s^{-n}}{1 + a_{n-1}s^{-1} + a_{n-2}s^{-2} + a_{n-3}s^{-3} + \dots + a_0s^{-n}} \frac{V(s)}{V(s)} \quad (99.15)$$

where $V(s)$ is introduced as an intermediate signal in the desired block diagram.

From (99.15) we can write two separate equations

FIGURE 99.9 Initial block for CCF diagram.

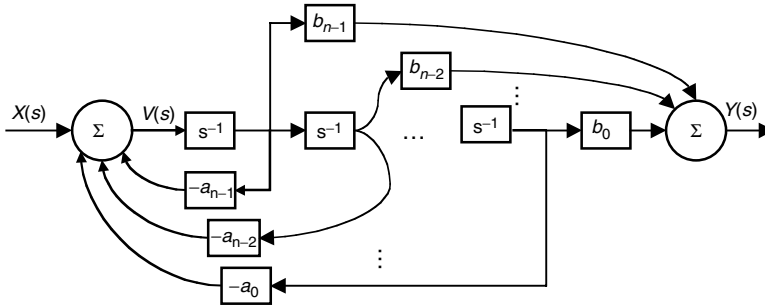

FIGURE 99.10 Final block for CCF diagram.

$$Y(s) = [b_{n-1}s^{-1} + b_{n-2}s^{-2} + b_{n-3}s^{-3} + \dots + b_0s^{-n}]V(s) \quad (99.16)$$

and

$$X(s) = [1 + a_{n-1}s^{-1} + a_{n-2}s^{-2} + a_{n-3}s^{-3} + \dots + a_0s^{-n}]V(s) \quad (99.17)$$

We can solve for the intermediate variable $V(s)$ from Equation (99.17) to get

$$V(s) = -a_{n-1}s^{-1}V(s) - a_{n-2}s^{-2}V(s) - a_{n-3}s^{-3}V(s) - \dots - a_0s^{-n}V(s) + X(s) \quad (99.18)$$

We can also solve for the output from Equation (99.16) to get

$$Y(s) = b_{n-1}s^{-1}V(s) + b_{n-2}s^{-2}V(s) + b_{n-3}s^{-3}V(s) + \dots + b_0s^{-n}V(s) \quad (99.19)$$

From Equation (99.18) we can draw the partial block diagram as shown in [Figure 99.9](#).

Note that we have n basic integrators in the diagram, where n is the order of the system or the number of states.

Next we can add to the diagram in [Figure 99.9](#) the equivalent of Equation (99.19) to get the final block diagram in the CCF as shown in [Figure 99.10](#).

Example 99.1

Consider the system

$$\frac{Y(s)}{X(s)} = \frac{2s + 10}{s^2 + 3s + 11}$$

Draw the CCF block diagram.

FIGURE 99.11 CCF diagram for Example 99.1.

Solution

Similar to Equation (99.18) and Equation (99.19) we have

$$V(s) = -3s^{-1}V(s) - 11s^{-2}V(s) + X(s)$$

and

$$Y(s) = 2s^{-1}V(s) + 10s^{-2}V(s)$$

The block diagram in the CCF is shown in Figure 99.11. The number of integrators is also n , which is the order of the system or the number of states.

99.5 The Observable Canonical Form (OCF) Block Diagrams with Basic Blocks

Consider Equation (99.15) again.

$$\frac{Y(s)}{X(s)} = \frac{b_{n-1}s^{-1} + b_{n-2}s^{-2} + b_{n-3}s^{-3} + \dots + b_0s^{-n}}{1 + a_{n-1}s^{-1} + a_{n-2}s^{-2} + a_{n-3}s^{-3} + \dots + a_0s^{-n}} \frac{V(s)}{V(s)} \quad (99.20)$$

Let us cross multiply to get

$$Y(s)[1 + a_{n-1}s^{-1} + a_{n-2}s^{-2} + a_{n-3}s^{-3} + \dots + a_0s^{-n}] = [b_{n-1}s^{-1} + b_{n-2}s^{-2} + b_{n-3}s^{-3} + \dots + b_0s^{-n}]X(s) \quad (99.21)$$

We can solve for the output $Y(s)$ from Equation (99.21) and write

$$Y(s) = [-a_{n-1}s^{-1} - a_{n-2}s^{-2} - a_{n-3}s^{-3} - \dots - a_0s^{-n}]Y(s) + [b_{n-1}s^{-1} + b_{n-2}s^{-2} + b_{n-3}s^{-3} + \dots + b_0s^{-n}]X(s) \quad (99.22)$$

From Equation (99.22) we can draw the block diagram in Figure 99.12.

Example 99.2

Consider the same system as in Example 99.1.

$$\frac{Y(s)}{X(s)} = \frac{2s + 10}{s^2 + 3s + 11}$$

Draw the OCF block diagram.

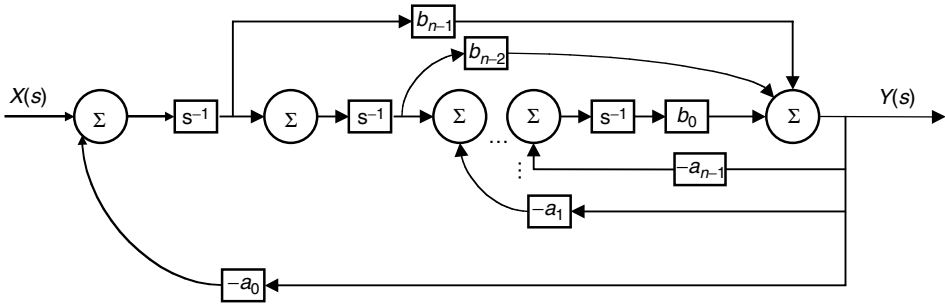

FIGURE 99.12 Final block for OCF diagram.

FIGURE 99.13 OCF diagram for Example 99.2

Solution

Similar to Equation (99.22), we have

$$Y(s) = [-3s^{-1} - 11s^{-2}]Y(s) + [2s^{-1} + 10s^{-2}]X(s)$$

and the block diagram is shown in Figure 9.13.

99.6 The Diagonal Form (DF) Block Diagrams with Basic Blocks

Distinct Roots Case

Consider the same transfer function we considered before

$$\frac{Y(s)}{X(s)} = \frac{b_{n-1}s^{n-1} + b_{n-2}s^{n-2} + b_{n-3}s^{n-3} + \dots + b_0}{s^n + a_{n-1}s^{n-1} + a_{n-2}s^{n-2} + a_{n-3}s^{n-3} + \dots + a_0} \quad (99.23)$$

The transfer function in Equation (99.23) can be written in partial fraction form as

$$\frac{Y(s)}{X(s)} = \frac{A_1}{s + p_1} + \frac{A_2}{s + p_2} + \frac{A_3}{s + p_3} + \dots + \frac{A_n}{s + p_n} \quad (99.24)$$

The output in this case can be written as the sum of all outputs obtained from each individual subsystem such as the subsystem

$$\frac{A_1}{s + p_1}$$

with $X(s)$ being the input to all subsystems.

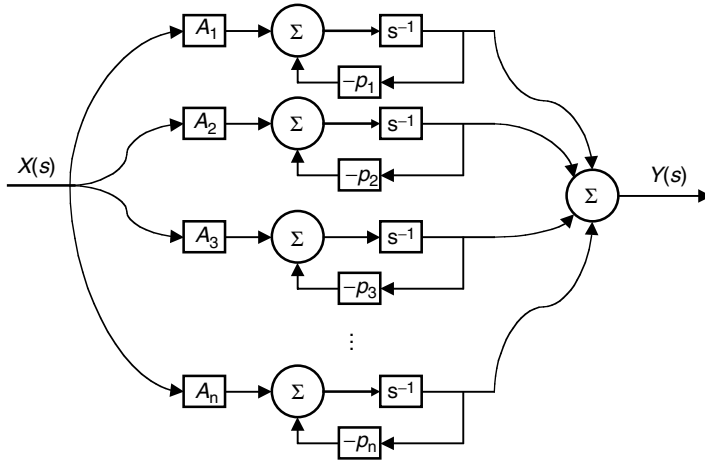

FIGURE 99.14 DF block diagram representation using basic integrators.

For the first subsystem

$$H_1(s) = \frac{A_1}{s + p_1} = \frac{Y_1(s)}{X(s)}$$

we have

$$Y_1(s)[s + p_1] = A_1 X(s) \tag{99.25}$$

If we take the inverse Laplace transform on Equation (99.25) we get

$$y_1'(t) = -p_1 y_1(t) + A_1 x(t) \tag{99.26}$$

For the second subsystem we also get

$$y_2'(t) = -p_2 y_2(t) + A_2 x(t) \tag{99.27}$$

We can get similar results for the second subsystem, the third subsystem, and so on.

For the n^{th} subsystem we have

$$y_n'(t) = -p_n y_n(t) + A_n x(t) \tag{99.28}$$

and the block diagram represented in what is called the diagonal form is shown in Figure 99.14.

Repeated Roots Case

This is best dealt with using an example. Consider the following transfer function representation in partial fraction form.

$$\frac{Y(s)}{X(s)} = \frac{1}{(s + p_1)^2(s + p_1)} = \frac{A_1}{(s + p_1)^2} + \frac{A_2}{s + p_1} + \frac{A_3}{s + p_2} \tag{99.29}$$

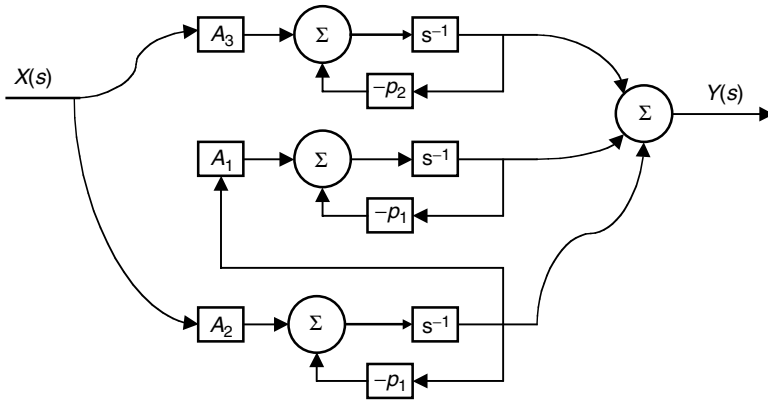

FIGURE 99.15 JF block diagram representation using basic integrators.

We will have three parallel subsystems, but it seems that we need four basic integrators to realize this system in the block diagram form. In fact, we can realize this system with three integrators where the integrator for

$$\frac{A_2}{s + p_1}$$

will be shared by

$$\frac{A_1}{(s + p_1)^2}$$

The block diagram is shown in Figure 99.15.

When we have repeated roots we call the representation in Figure 99.15 the Jordan form (JF) block diagram representation.

99.7 The Parallel Block Diagrams with Subsystems

Parallel block diagrams can arise frequently in implementing analogue or digital filters. We already have fixed designs for first- and second-order analogue or digital filters. If we are given a transfer function of order higher than two, we can simplify the transfer function and write it as the sum of first- or/and second-order filters. We will use second-order filters in the implementation when we have complex poles since it is difficult to realize a single-pole subsystem if the pole is complex. For real systems, complex poles come as complex conjugates, and thus the subsystem is second order with real coefficients.

Distinct Roots Case

Consider the same transfer function we considered before

$$\frac{Y(s)}{X(s)} = \frac{b_{n-1}s^{n-1} + b_{n-2}s^{n-2} + b_{n-3}s^{n-3} + \dots + b_0}{s^n + a_{n-1}s^{n-1} + a_{n-2}s^{n-2} + a_{n-3}s^{n-3} + \dots + a_0} \quad (99.30)$$

The transfer function in Equation (99.30) can be written in partial fraction form as

FIGURE 99.16 DF block diagram representation using subsystems.

$$\frac{Y(s)}{X(s)} = \frac{A_1}{s + p_1} + \frac{A_2}{s + p_2} + \frac{A_3}{s + p_3} + \dots + \frac{A_n}{s + p_n} \tag{99.31}$$

The output in this case can be written as the sum of all outputs obtained from each individual subsystem such as the subsystem

$$\frac{A_1}{s + p_1}$$

with $X(s)$ being the input to all subsystems. The output in this case is

$$Y(s) = X(s) \frac{A_1}{s + p_1} + X(s) \frac{A_2}{s + p_2} + X(s) \frac{A_3}{s + p_3} + \dots + X(s) \frac{A_n}{s + p_n}$$

The block diagram represented in what is called the diagonal form is shown in Figure 99.16.

Repeated Roots Case

This is best dealt with using an example. Consider the following transfer function representation in partial fraction form.

$$\frac{Y(s)}{X(s)} = \frac{1}{(s + p_1)^2(s + p_1)} = \frac{A_1}{(s + p_1)^2} + \frac{A_2}{s + p_1} + \frac{A_3}{s + p_2} \tag{99.32}$$

We will have three simple single-pole parallel subsystems, but it seems that we need four to realize this system in the block diagram form. In fact, we can realize this system with three simple single-pole subsystems where the output for subsystem

FIGURE 99.17 JF block diagram representation using subsystems.

$$\frac{A_2}{s + p_1}$$

will be the input to subsystem

$$\frac{A_1}{(s + p_1)^2}$$

The block diagram is shown in Figure 99.17.

When we have repeated roots, we call the representation in Figure 99.17 the Jordan form (JF) block diagram representation.

99.8 The Series Block Diagrams with Subsystems

Series or cascade block diagrams can arise frequently in implementing analogue or digital filters. We already have fixed designs for first- and second-order analogue or digital filters. If we are given a transfer function of order higher than two, we can simplify the transfer function and write it as the product of first- or/and second-order filters. We will use second-order filters in the implementation when we have complex poles since it is difficult to realize a single-pole subsystem if the pole is complex. For real systems, complex poles come as complex conjugates, and thus the subsystem is second order with real coefficients.

Distinct Real Roots Case

Consider the transfer function

$$\frac{Y(s)}{X(s)} = \frac{A_1}{s + p_1} \frac{A_2}{s + p_2} \frac{A_3}{s + p_3} \dots \frac{A_n}{s + p_n} \quad (99.33)$$

in the series or the cascade form. The block diagram is shown in Figure 99.18.

FIGURE 99.18 Series block diagram representation using real single-pole subsystems.

FIGURE 99.19 Series block diagram representation with complex-poles subsystems.

Mixed Complex and Real Roots Case

With mixed complex and real poles, let us consider the system

$$\frac{Y(s)}{X(s)} = \frac{A_1}{s+p_1} \frac{A_2}{s+p_2} \frac{A_3+sA_4}{s^2+as+b} \frac{A_5+sA_6}{s^2+cs+d}$$

where we have two simple real single-pole subsystems and two complex two-pole subsystems. All parameters in these subsystems are real, so they can easily be implemented. This case is shown in Figure 99.19.

99.9 Block Diagram Reduction Rules

Using the Reduction Rules

We list in Table 99.1 some techniques in reducing block diagrams. Other techniques were presented at the beginning of the chapter under series, parallel, and basic feedback block diagrams in Figure 99.6, Figure 99.7, and Figure 99.8.

TABLE 99.1 Equivalent Block Diagrams

| Original Block | Equivalent Block |
|----------------|------------------|
| | |
| | |
| | |

Using Mason's Rule

In using Mason's rule we will apply the following formula that relates any input to any output in a block diagram. The formula is

$$\frac{y}{x} = \frac{\sum_i p_i \Delta_i}{\Delta} \quad (99.34)$$

where x is any of the single inputs and y is any of the single outputs in the block diagram. The p_i is gain of the forward path that connects x to y . We can have i of these forward paths. The denominator in Equation 99.34 is given by

$$\Delta = 1 - (\text{sum of all loop gains in the diagram}) + (\text{sum of products of all 2-nontouching loops}) \\ - (\text{sum of products of all 3-nontouching loops}) + \dots \quad (99.35)$$

The Δ_i is the same as Δ but with setting the gains that the p_i path touches to zero.

99.10 Block Diagram Reduction Examples

In the following, we will give some examples where we will try to simplify the block diagrams and get the system in its transfer function form or its state-space representation form. If the system is given in state-space form with the matrices A , B , C , and D as

$$\begin{aligned} \dot{\mathbf{v}}(t) &= A\mathbf{v}(t) + B\mathbf{x}(t) \\ y(t) &= C\mathbf{v}(t) + D\mathbf{x}(t) \end{aligned} \quad (99.36)$$

then the transfer function representation is

$$H(s) = C(sI - A)^{-1}B + D \quad (99.37)$$

If the system in block diagram is given as an interconnection of simple integrators, constant gains, and summers, we will use state-variables in simplifying the diagram. Then we will use Equation 99.37 to get the transfer function. If the block diagram is given in terms of interconnected subsystems, then it is easier to use the block diagram reduction rules given in [Table 99.1](#) or Mason's formula to simplify the diagram and get the transfer function.

From Block Diagrams with Basic Block Components to Transfer Functions

Example 99.3

Consider the system in [Figure 99.26](#). What is the transfer function representation?

Solution

We assign the output of every integrator as one state variable. Thus the input of the integrator is the derivative of the state variable. Then from the block diagram we have

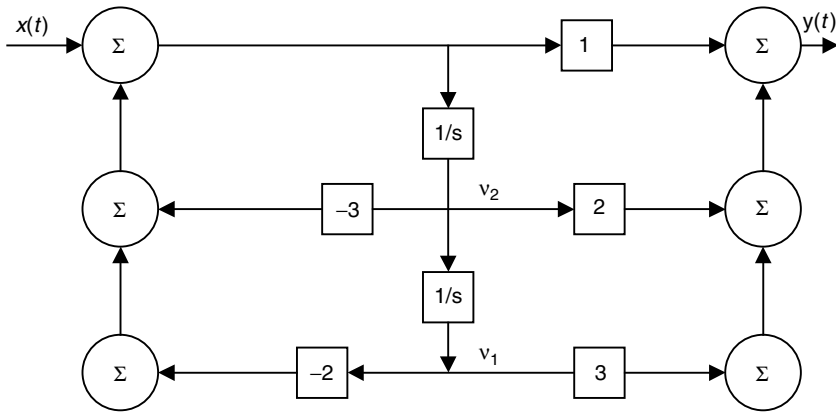

FIGURE 99.26 Block diagram for Example 99.3.

$$v_1'(t) = v_2(t)$$

$$v_2'(t) = x(t) - 2v_1(t) - 3v_2(t)$$

$$y(t) = x(t) - 2v_1(t) - 3v_2(t) + 2v_2(t) + 3v_1(t) = x(t) + v_1(t) - v_2(t)$$

Thus the state-space system is

$$\mathbf{v}'(t) = \begin{pmatrix} 0 & 1 \\ -2 & -3 \end{pmatrix} \mathbf{v}(t) + \begin{pmatrix} 0 \\ 1 \end{pmatrix} \mathbf{x}(t)$$

$$y(t) = (1 \quad -1) \mathbf{v}(t) + (1) \mathbf{x}(t)$$

The transfer function representation can be obtained using Equation 99.37 or using Matlab as in the script

```
A=[0 1; -2 -3];
B=[0;1];
C=[1 -1];
D=[1];
[num, den]=ss2tf(A,B,C,D)
```

The output of the script is

```
num = 1.0000 2.0000 3.0000
den = 1 3 2
```

The transfer function representation is then

$$H(s) = \frac{s^2 + 2s + 3}{s^2 + 3s + 2}$$

Example 99.4

Consider the system in Figure 99.27. What is the transfer function representation?

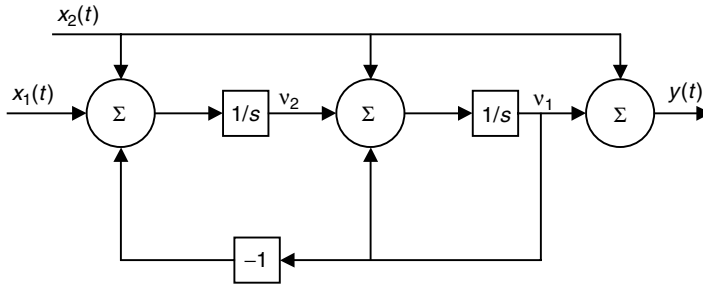

FIGURE 99.27 Block diagram for Example 99.4.

Solution

Again, we assign the output of every integrator as one state variable. Thus the input of the integrator is the derivative of the state variable. Then from the block diagram we have

$$\dot{v}_1(t) = x_2(t) + v_2(t) + v_1(t)$$

$$\dot{v}_2(t) = x_2(t) + x_1(t) - v_1(t)$$

$$y(t) = x_2(t) + v_1(t)$$

Thus the state-space system is

$$\dot{\mathbf{v}}(t) = \begin{pmatrix} 1 & 1 \\ -1 & 0 \end{pmatrix} \mathbf{v}(t) + \begin{pmatrix} 0 & 1 \\ 1 & 1 \end{pmatrix} \mathbf{x}(t)$$

$$y(t) = (1 \quad 0) \mathbf{v}(t) + (0 \quad 1) \mathbf{x}(t)$$

The transfer function representation can be obtained using Equation 99.37 or using Matlab as in the script

```
A=[1 1; -1 0];
B=[0 1; 1 1];
C=[1 0];
D=[0 1];
[num, den]=ss2tf(A,B,C,D,1)%1 for the first input x1(t)
```

The output of the script is

```
num = 0 0 1
den = 1.0000 -1.0000 1.0000
```

The transfer function representation is then

$$H_1(s) = \frac{Y(s)}{X_1(s)} = \frac{1}{s^2 - s + 1}$$

For the second transfer function we use the script

```
A=[1 1; -1 0];
B=[0 1; 1 1];
C=[1 0];
D=[0 1];
```

FIGURE 99.28 Block diagram for Example 99.5.

```
[num, den]=ss2tf(A,B,C,D,2)%1 for the second input x2(t) to get
num = 1 0 2
den = 1.0000 -1.0000 1.0000
with
```

$$H_2(s) = \frac{Y(s)}{X_2(s)} = \frac{s^2 + 2}{s^2 - s + 1}$$

From Block Diagrams with Interconnected Subsystems to Transfer Functions

Example 99.5

Consider the block diagram in Figure 99.28. Use the Mason's formula to find the transfer function representation.

Solution

From the figure we can see that we have only three forward paths from the only input $x(t)$ to the only output $y(t)$. They are

$$p_1 = G1 \quad p_2 = G2G4 \quad p_3 = G2G5G7$$

We also have two loops in the figure with the gains $G2G3$ and $G2G5G6$, and they are touching loops. In this case we have

$$\Delta = 1 - G2G3 - G2G5G6$$

All the forward paths touch the loops in the figure. Thus

$$p_1\Delta_1 = G1(1)$$

$$p_2\Delta_2 = G2G4(1)$$

$$p_3\Delta_3 = G2G5G7(1)$$

and the transfer function is

FIGURE 99.29 Block diagram for Example 99.6.

$$H(s) = \frac{G_1 + G_2G_4 + G_2G_5G_7}{1 - G_2G_3 - G_2G_5G_6}$$

If $G_1 = 1$, $G_2 = 1/s$, $G_3 = -3$, $G_4 = 2$, $G_5 = 1/s$, $G_6 = -2$, and $G_7 = 3$, then the transfer function becomes

$$H(s) = \frac{s^2 + 2s + 3}{s^2 + 3s + 2}$$

Example 99.6

Consider the block diagram in Figure 99.29. Use Mason's formula to find the transfer function representation.

Solution

From the figure we can see that we have two touching loops with the gains $G_1G_2G_3$ and G_2 . Thus we have

$$\Delta = 1 - G_1G_2G_3 - G_2$$

From the input $x_1(t)$ to the output $y(t)$, we have one forward path that touches all the loops in the figure. Thus we have $p_1 = G_1G_2$ and $\Delta_1 = 1$. The transfer function is then

$$H_1(s) = \frac{Y(s)}{X_1(s)} = \frac{G_1G_2}{1 - G_1G_2G_3 - G_2}$$

From the input $x_2(t)$ to the output $y(t)$ we have three forward paths. They are with the gains 1, G_2 , and G_1G_2 . The forward path with the unity gain does not touch any of the loops in the figure. Thus we have

$$p_1 = 1 \quad p_2 = G_2 \quad p_3 = G_1G_2$$

and

$$\Delta_1 = 1 - G_1G_2G_3 - G_2 \quad \Delta_2 = 1 \quad \Delta_3 = 1$$

The second transfer function is

$$H_1(s) = \frac{Y(s)}{X_2(s)} = \frac{1(1 - G_1G_2G_3 - G_2) + G_2(1) + G_1G_2(1)}{1 - G_1G_2G_3 - G_2} = \frac{1 - G_1G_2G_3 + G_1G_2}{1 - G_1G_2G_3 - G_2}$$

If $G_1 = 1/s$, $G_2 = 1/s$, and $G_3 = -1$ then the transfer functions become

$$H_1(s) = \frac{Y(s)}{X_1(s)} = \frac{1}{s^2 - s + 1}$$

and

$$H_2(s) = \frac{Y(s)}{X_2(s)} = \frac{s^2 + 2}{s^2 - s + 1}$$

Example 99.7

Consider the block diagram in Figure 99.30. Find the transfer function using the block diagram simplification rules.

Solution

In Figure 99.30 we have three loops, two inner loops and one outer. We can simplify the two inner loops (they are simple feedback loops) to get the intermediate simplified block in Figure 99.31.

The inner summer is of no importance. Now we still have a single simple feedback loop to simplify. The final block diagram is shown in Figure 99.32.

FIGURE 99.30 Block diagram for Example 99.7.

FIGURE 99.31 Block diagram for Example 99.7.

FIGURE 99.32 Final block diagram for Example 99.7.

FIGURE 99.33 Block diagram for Example 99.8.

Example 99.8

Consider the block diagram in Figure 99.33. Find the transfer function using the block diagram simplification rules.

Solution

We will start with the inner loops one at a time to get the intermediate diagram in Figure 99.34.

Now it looks like we have a parallel connection at the forward parallel paths with gains unity and $G1/(1 + G1)$. This section can be simplified, giving the diagram in Figure 99.35.

At this point we have a series connection between $[1 + G1/(1 + g1)]$ and $G2/(1 + G2)$. We can combine this series connection to get the product $G = [1 + G1/(1 + g1)] [G2/(1 + G2)]$. This product is now in parallel with the forward gain of unity. So we will have $1 + G$ as the result of combining G with the unity gain. The three summers in the diagram serve no purpose and we can eliminate them. The final block diagram is shown in Figure 99.36.

Signal flow graphs are a viable alternative to block diagrammatic representation of a system. What makes signal flow graphs attractive is that certain features from graph theory can be applied to the simplification and the synthesis of complex systems.

100.1 Introduction

The relationship between the input and output of a certain system can be represented in terms of a *block diagram*. The block diagram represents the operator that operates on the input to produce the output, and can be represented either in the time domain or in the Laplace domain for a time-dependent input and output. The relationship between the input and the output in the Laplace domain is called the *transfer function* of the system. In this case, the input is the independent variable and the output is the dependent variable. Sometimes, when there are intermediate dependent variables, the relationships between each other as well as the input(s) and output(s) can also be represented by block diagrams. Alternatively, instead of block diagrams, the dependent variables and the inputs can be denoted as *nodes*, and connections or *paths* between the nodes can denote the mathematical operator linking the two variables or nodes. This is used to draw what is called a *signal flow graph*. A simple diagram representing the similarities between a block diagram and a signal flow graph is shown in [Figure 100.1](#).

100.2 Signal Flow Graphs for Feedback Systems

In many systems, there is feedback (positive or negative) from the output to the input. Negative feedback makes a system more stable, while positive feedback causes a system to become unstable and is the principle behind the operation of oscillators. Feedback is depicted in a block diagram through a feedback transfer function $G(s)$ between the output and the input, as shown in [Figure 100.2](#). Note that in this case, $U(s)$ is the input, and the output $X_2(s)$ is fed back to the input through $G(s)$. The input $X_1(s)$ to $H(s)$ can be expressed as

$$X_1(s) = U(s) - X_2(s)G(s) \tag{100.1}$$

FIGURE 100.1 Connection between a block diagram and a signal flow graph.

FIGURE 100.2 Connection between a block diagram and a signal flow graph for a system with negative feedback.

where

$$X_2(s) = X_1(s)H(s) \quad (100.2)$$

The same is depicted in the signal flow graph drawn on the right. Note that upon manipulating Equation (100.1) and Equation (100.2), a direct relationship can be found between the input $U(s)$ and the output $X_2(s)$ as

$$X_2(s) = \frac{H(s)}{1 + G(s)H(s)} U(s) = H_{eq}(s) U(s) \quad (100.3)$$

In other words, the feedback system represented by the block diagram in Figure 100.2 can be reduced to a block diagram similar to Figure 100.1, where the input is now $U(s)$ and the transfer function relating the output $X_2(s)$ to the input is now $H_{eq}(s)$, defined in Equation (100.3). This is shown in Figure 100.3. The equivalent signal flow graph also reduces to a form similar to Figure 100.1, with $X_1(s)$ replaced by $U(s)$ and $H(s)$ replaced by $H_{eq}(s)$, as shown in Figure 100.3. This also suggests that in a signal flow graph, it may be possible to reduce the number of nodes through a systematic node elimination procedure. This is facilitated through using Mason's theorem for reduction of systems, to be described below.

In general, signal flow graphs may be more complicated and comprise nodes, paths, and loops. An example of a feedback loop appears in the signal flow graph of Figure 100.2; however, self-loops are possible as well. An example of a more complicated signal flow graph involving many loops is shown in Figure 100.4. This signal flow graph corresponds to the set of equations

$$\begin{aligned} X_1(s) &= U(s) - X_2(s)G_1(s), \\ X_2(s) &= X_1(s)H_1(s) + X_2(s)G_2(s), \end{aligned} \quad (100.4)$$

$$Y(s) = X_2(s)H_2(s).$$

FIGURE 100.3 Reduced block diagram and corresponding signal flow graph from Figure 100.2.

FIGURE 100.4 A more complicated signal flow graph corresponding to the system of equations showing feedback loops including self-loops.

FIGURE 100.5 Equivalence between signal flow graphs in Laplace and time domains.

One can readily go from the set of equations to the signal flow graph and vice versa.

In passing, we would like to point out that the second of the relations in Equation (100.4) above can be rewritten in the form

$$X_2(s) = X_1(s) \frac{H_1(s)}{1 - G_2(s)}$$

This implies that self-loops can be eliminated by dividing all incoming path gains by $1 - G_i(s)$, where $G_i(s)$ is the self-loop gain for the node X_i . Other types of simplification of signal flow graphs, such as *node elimination*, are discussed later. We would like to remind readers that signal flow graphs can be drawn for signals depicted in either the Laplace domain or the time domain. The time domain equivalent of the signal flow graph in Figure 100.4 would involve the same nodes and loops, except that the nodes would be depicted as $u(t), x_1(t), x_2(t), y(t)$, which are the inverse Laplace transforms of $U(s), X_1(s), X_2(s), Y(s)$, respectively, and the loops would correspond to operators in the time domain such as $h_1(t), h_2(t), g_1(t), g_2(t)$, which are the inverse Laplace transforms of $H_1(s), H_2(s), G_1(s), G_2(s)$, respectively. Figure 100.5 shows the equivalence between the signal flow graphs in the Laplace and time domains. It should be noted that multiplication in the Laplace domain corresponds to convolution in time, denoted as a * in Figure 100.5.

For instance, if $H_1(s) = s$, then $h_1(t) = d[\delta(t)]/dt$, and it can be shown from the properties of convolution that $h_1(t) * x_1(t) = [d[\delta(t)]/dt] * x_1(t) = dx_1(t)/dt$, so that the operator $h_1(t)* = d/dt$. If $H_1(s) = c$, a constant, then $h_1(t)* = c$, which is the same multiplicative constant.

100.3 Reduction of Signal Flow Graphs

We now enunciate *Mason's theorem* for reduction of a signal flow graph. It states that the equivalent transfer function from input $U(s)$ to output $Y(s)$ can be written as

$$H_{eq}(s) = Y(s)/U(s) = \sum_i P_i \Delta_i / \Delta \tag{100.5}$$

where

$$\Delta = 1 - \sum L_j + \sum L_k L_l - \sum L_m L_n L_o + \dots \tag{100.6}$$

is the determinant of the feedback configuration. The L_j s are loop gains; $\sum L_j$ is the sum of all loop gains; $\sum' L_k L_l$ is the sum of all pairs of different nontouching loop gains, etc. Two loops are nontouching if they have no nodes in common. The P_i s are the gain of direct transmittances from the input to the output. Also Δ_i is the system determinant after we have excluded all loops that touch the P_i path.

As an example, we will demonstrate the use of Mason's theorem to find the equivalent transfer function for the system shown in Figure 100.4. Here, $\sum L_j = -G_1 H_1 + G_2$, and all higher order sums in (100.6) are zero, so that $\Delta = 1 + G_1 H_1 - G_2$. Also, $P_1 = 1 \cdot H_1 H_2$ and $\Delta_1 = 1$, and there is only one direct path from the input to the output. Hence, using Equation (100.5),

$$H_{eq}(s) = Y(s)/U(s) = \frac{H_1 H_2}{1 - G_2 + G_1 H_1} \quad (100.7)$$

The reduced signal flow graph is shown in Figure 100.6.

In retrospect, Mason's theorem is equivalent to solving for the output $Y(s)$ in terms of the (known) input $U(s)$ from a set of linear algebraic equations of the form $\underline{AX} = \underline{B}$. According to Cramer's rule, the solution for the j -th component of the vector \underline{X} is $X_j = \frac{D_j}{\Delta}$, where the matrix D_j has \underline{B} as its j -th column, and the corresponding columns of $\underline{Y}(s)$ as its other columns. Upon applying this to the example depicted in Figure 100.4, we see that the dependent variables X_1, X_2, Y can be solved by first rewriting (100.4) in the form of a vector-matrix equation of the type $\underline{AX} = \underline{B}$ as

$$\begin{bmatrix} 1 & G_1 & 0 \\ H_1 & 1 - G_2 & 0 \\ 0 & H_2 & 1 \end{bmatrix} \begin{bmatrix} X_1 \\ X_2 \\ Y \end{bmatrix} = \begin{bmatrix} U \\ 0 \\ 0 \end{bmatrix} \quad (100.8)$$

the solution for Y , using Cramer's rule is

$$Y = \frac{\begin{vmatrix} 1 & G_1 & U \\ H_1 & 1 - G_2 & 0 \\ 0 & H_2 & 0 \end{vmatrix}}{\begin{vmatrix} 1 & G_1 & 0 \\ H_1 & 1 - G_2 & 0 \\ 0 & H_2 & 1 \end{vmatrix}} = \frac{H_1 H_2}{(1 - G_2) + H_1 G_1} U, \quad (100.9)$$

which yields the result for the equivalent transfer function identical to Equation (100.7) above.

The reduction of the signal flow graph shown above using Mason's theorem can also be achieved through a repeated *node elimination* process. The rules of elimination are as follows. Assume that we would like to eliminate the node X_2 . First, we need to eliminate the self-loop around X_2 . The self-loop of gain G_2 is eliminated by dividing all incoming transmittances by $1 - G_2$. This makes the transmittance from X_1 to X_2 equal to $H_1 / (1 - G_2)$. Now, in the reduced signal flow diagram, all nodes except X_2 are drawn, and all original branches not entering or leaving X_2 are inserted. Finally, we add branches representing every possible path (in the signal flow diagram without self-loops) through X_2 . For instance, we can go from X_1 to X_1 through $-H_1 G_1 / (1 - G_2)$, and X_1 to Y through $H_2 G_1 / (1 - G_2)$. The reduced signal flow graph is shown in Figure 100.7.

A similar procedure can be used to eliminate the node X_1 . As before, it entails first removing the self-node at X_1 , which makes the transmittance from U to X_1 equal to $(1 - G_2) / (1 - G_2 + H_1 G_1)$. Upon now eliminating X_1 , the transmittance from U to Y is $[(1 - G_2) / (1 - G_2 + H_1 G_1)] \times [H_2 G_1 / (1 - G_2)]$

FIGURE 100.6 Equivalent reduced signal flow graph derived from Figure 100.4.

FIGURE 100.7 Reduction of the signal flow graph in Figure 100.4 through elimination of node X_2 .

$= H_2G_1/(1 - G_2 + H_1G_1)$, which is identical to the equivalent transfer function $H_{eq}(s)$ in Equation (100.7) derived using Mason's theorem. The resulting signal flow graph is as shown in Figure 100.6.

100.4 Realization of Transfer Functions

Thus far, we have discussed procedures for simplifying signal flow graphs to derive the transfer function of the system. We will now turn our attention to synthesizing signal flow graphs given a particular transfer function. Using the $H_{eq}(s)$ in Equation (100.7) as an illustration, assume that

$$H_1(s) = s + a_1, H_2(s) = a_2, G_1(s) = s + b_1, G_2(s) = s + b_2. \quad (100.10)$$

Then

$$H_{eq}(s) = \frac{Y(s)}{U(s)} = \frac{a_2s + a_1a_2}{s^2 + (a_1 + b_1 - 1)s + (a_1b_1 - b_2 + 1)}. \quad (100.11)$$

As is often the case, the degree of the polynomial in the denominator is equal to or greater than the degree of the polynomial in the numerator. Then the degree of the polynomial in the denominator is defined as the *order* of the system, and is equal to the number of *states* of the system. We can therefore define two state variables $X_1(s), X_2(s)$ for the system, related through $X_1(s) = X_2(s)/s$, or equivalently, $X_2(s) = sX_1(s)$. In the time domain this implies that $\chi_2(t) = d\chi_1(t)/dt$, where $\chi_1(t), \chi_2(t)$ are the inverse Laplace transforms of $X_1(s), X_2(s)$, respectively. Conversely, $\chi_1(t)$ is the integral of $\chi_2(t)$.

For convenience, Equation (100.11) is reexpressed in the form

$$H_{eq}(s) = \frac{Y(s)}{U(s)} = \frac{a_2/s + a_1a_2/s^2}{1 + (a_1 + b_1 - 1)/s + (a_1b_1 - b_2 + 1)/s^2}. \quad (100.12)$$

Since this is a second-order system, one needs two integrators. The integrator outputs are called $X_1(s), X_2(s)$, and the integrator inputs are called $X_1'(s), X_2'(s)$, respectively, as shown in Figure 100.8.

The second step is the realization of the denominator in Equation (100.12). Since Mason's theorem states that all loops that touch have a $\Delta = 1 - \sum L_j$, it is convenient to construct loops incorporating feedback which have a node in common, viz., $X_1(s)$, and with feedback loop gains equal to $-(a_1 + b_1 - 1)/s$ and $-(a_1b_1 - b_2 + 1)/s^2$, as illustrated by the dashed lines in Figure 100.9. Finally, to construct the numerator, we ensure that all direct paths also pass through one node, viz., $X_1(s)$. The path gains are a_2/s and a_1a_2/s^2 , as illustrated by the dotted lines in Figure 100.9.

FIGURE 100.8 First step in the realization of the transfer function in Equation (100.12).

FIGURE 100.9 Signal flow graph for the transfer function in Equation (100.12).

The signal flow graph shown in Figure 100.9, also called *Type I* realization, is not unique. *Type II* is an alternate realization that assumes that all feedback loops and parallel paths go through $X_2'(s)$ rather than $X_1(s)$. Finally, *Type III* involves a realization that is based on first decomposing Equation (100.12) into partial fractions in the form

$$H_{eq}(s) = \sum a_i / (s + b_i), \quad b_i \in \Re \quad (100.13)$$

by first factorizing the denominator. This yields a realization of the transfer function in terms of parallel loops. In cases where the denominator has complex roots, it can be decomposed into partial fractions involving sums of terms as in Equation (100.11) and Equation (100.13). Details can be found in Truxal (1972).

100.5 Boundary Conditions and Signal Flow Graphs

Signal flow graphs can be suitably adapted to incorporate initial conditions imposed on a certain state. For instance, assume that in the time domain, states $x_1(t), x_2(t)$ are related through the set of coupled differential equations as

$$\begin{aligned} dx_1(t)/dt &= x_2, \\ dx_2(t)/dt &= -a_2x_1 - a_1x_2 \end{aligned} \quad (100.14)$$

where a_1, a_2 are constants. Equation (100.14) is the state variable formulation of a second order ODE of the form $d^2x/dt^2 + a_1dx/dt + a_2x = 0$. With the definitions $x_1 = x, x_2 = dx_1/dt$, this ODE can be rewritten as Equation (100.14). Note also that Equation (100.14) can be recast in the form

$$\frac{d}{dt} \begin{pmatrix} x_1 \\ x_2 \end{pmatrix} = \begin{bmatrix} 0 & 1 \\ -a_2 & -a_1 \end{bmatrix} \begin{pmatrix} x_1 \\ x_2 \end{pmatrix}, \quad (100.15)$$

which is a special case of the vector ODE

$$\underline{dx}/dt = \underline{Ax} + \underline{Bu} \quad (100.16a)$$

Together with the output equation

FIGURE 100.10 Signal flow diagram for realization of the system modeled by Equation (100.15).

$$\underline{y} = \underline{C}\underline{x} + \underline{D}\underline{u} \quad (100.16b)$$

one can describe the behavior of the entire linear system.

Upon Laplace transforming Equation (100.14), we get

$$\begin{aligned} sX_1(s) + X_2(s) &= x_1(0), \\ a_2X_1(s) + (s + a_1)X_2(s) &= x_2(0). \end{aligned} \quad (100.17)$$

Similar to the way the signal flow graph from the transfer function in Equation (100.12) was realized, we can draw the signal flow diagram for Equation (100.17), as shown in Figure 100.10.

100.6 Conclusion

We have summarized the salient points of signal flow graphs, their reduction, and their synthesis. As seen from the discussions above, they are an analogue to block diagrams in the analysis of linear systems. In some cases, signal flow graphs can give valuable information about the *controllability* and *observability* of linear systems as well. Loosely speaking, a state is controllable if it can be changed by an appropriate set of inputs. A state is observable if the output(s) depend on the particular state. However, formal tests for controllability and observability can be made on the basis of the matrices $\underline{A}, \underline{B}, \underline{C}, \underline{D}$ defined in Equation (100.16) above. This is outside the scope of this chapter.

101.1 State–Space Models

The general **state–space** model that we will consider for a continuous-time dynamical system consists of a system of n_x first-order differential equations of the form

$$\begin{aligned}\frac{dx_1}{dt} &= f_1(x_1, \dots, x_{n_x}, u_1, \dots, u_{n_u}) \\ &\vdots \\ \frac{dx_{n_x}}{dt} &= f_{n_x}(x_1, \dots, x_{n_x}, u_1, \dots, u_{n_u})\end{aligned}\tag{101.1}$$

where t denotes time; $\mathbf{x}(t) = [x_1 \dots x_{n_x}]^T$ is an n_x -dimensional **state vector**; $\mathbf{u} = [u_1 \dots u_{n_u}]^T$ is an n_u -dimensional control or **input vector**; and $[\cdot]^T$ denotes the transpose. Loosely speaking, the dimension of the state vector equals the number of initial conditions required to determine the motion, given the input — say $\mathbf{u}(t)$ or $\mathbf{u}(\mathbf{x}, t)$ — and the model of Equation (101.1). As an example, the motion of a point mass m satisfying Newton's equations may be described by

$$m \frac{d^2 \mathbf{y}}{dt^2} = \mathbf{F}$$

where $\mathbf{y} = [y_1 \ y_2 \ y_3]^T$ is the position vector and $\mathbf{F} = [F_1 \ F_2 \ F_3]^T$ is the applied force. This second-order system can be converted to first-order state–space form by, for example, taking the state vector as $\mathbf{x} = [y_1 \ y_2 \ y_3 \ dy_1/dt \ dy_2/dt \ dy_3/dt]^T$ and the input vector as $\mathbf{u} = (1/m)\mathbf{F}$, yielding

$$\dot{x}_1 = x_4$$

$$\dot{x}_2 = x_5$$

$$\dot{x}_3 = x_6$$

$$\dot{x}_4 = u_1$$

$$\dot{x}_5 = u_2$$

$$\dot{x}_6 = u_3$$

where $(\dot{\cdot}) = d(\cdot)/dt$. This state–space formulation makes it clear that the required initial conditions include not only the initial position $\mathbf{y}(t)$ but also the initial velocity $\dot{\mathbf{y}}(0)$. Writing dynamic system models as first-order differential equations also allows numerical analysts, for example, to focus on one type of numerical integration procedure, rather than having one scheme for first-order systems, another for second-order systems, and various other schemes for n th-order systems, since all systems of higher-order differential equations can be converted to equivalent systems of first-order differential equations, as illustrated in the preceding equations.

It should be noted that Equation (101.1) does not explicitly cover systems governed by partial differential equations, such as the vibration of a drumhead, in which the motion of the object is distributed over space as well as time. Nor does Equation (101.1) cover time-delay systems, in which the motion depends not only on the current state $\mathbf{x}(t)$ and current input $\mathbf{u}(t)$, but also on a history of past conditions, such as the state $\mathbf{x}(t - \tau)$ at some time τ seconds in the past. Both of these situations could be (and typically are) converted to state–space models of the form in Equation (101.1), by discretizing the spatial region for partial differential equations or discretizing the time-delay interval for time delay systems. In the limit as the discretization intervals become small the dimension of the state vector would become infinite.

In addition to the state and input vectors, there are typically various output or measurement quantities of interest, which are related to the state and input vectors by algebraic **output equations** of the general form

$$\begin{aligned} y_1 &= g_1(x_1, \dots, x_{n_x}, u_1, \dots, u_{n_u}) \\ &\vdots \\ &\vdots \\ y_{n_y} &= g_{n_y}(x_1, \dots, x_{n_x}, u_1, \dots, u_{n_u}) \end{aligned} \tag{101.2}$$

where $\mathbf{y} = [y_1 \dots y_{n_y}]^T$ is an n_y -dimensional **output vector**. For our point-mass example, taking the position vector as the output would correspond to the output equations

$$y_1 = x_1$$

$$y_2 = x_2$$

$$y_3 = x_3$$

In vector form the state equations [Equations (101.1)] and the output equations [Equations (101.2)] can be written as

$$\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x}, \mathbf{u}) \tag{101.3}$$

$$\mathbf{y} = \mathbf{g}(\mathbf{x}, \mathbf{u}) \tag{101.4}$$

where $(\dot{\cdot}) = d(\cdot)/dt$, $\mathbf{f} = [f_1 \dots f_{n_x}]^T$, and $\mathbf{g} = [g_1 \dots g_{n_y}]^T$. Systems in which time t appears explicitly in the right-hand sides of Equation (101.3) or Equation (101.4) can be handled, for example, either by including

such terms in the input vector \mathbf{u} or by treating t as a state variable, say $x_{n_x} = t$ with the differential equation $\dot{t} = 1$.

101.2 Linearization

For a system of the form

$$\dot{\mathbf{X}} = \mathbf{f}(\mathbf{X}, \mathbf{U}) \quad (101.5)$$

with output equations

$$\mathbf{Y} = \mathbf{g}(\mathbf{X}, \mathbf{U}) \quad (101.6)$$

let $\mathbf{U}(t) = \bar{\mathbf{U}}(t)$ be a reference input. For a given initial state $\bar{\mathbf{X}}(0)$ let $\bar{\mathbf{X}}(t)$ be the corresponding solution to Equation (101.5) generated by $\bar{\mathbf{U}}(t)$ and let $\bar{\mathbf{Y}}(t)$ be the resulting output, given by Equation (101.6). Let $\mathbf{x}(t)$, $\mathbf{y}(t)$, and $\mathbf{u}(t)$ denote small deviations from the reference state, output, and input, respectively. Substituting $\mathbf{X}(t) = \bar{\mathbf{X}}(t) + \mathbf{x}(t)$, $\mathbf{Y}(t) = \bar{\mathbf{Y}}(t) + \mathbf{y}(t)$, and $\mathbf{U}(t) = \bar{\mathbf{U}}(t) + \mathbf{u}(t)$ into Equation (101.5) and Equation (101.6), expanding the results using Taylor's theorem, and retaining only the first-order (linear) terms yields the time-varying **linear state equations**,

$$\dot{\mathbf{x}} = \mathbf{A}(t)\mathbf{x} + \mathbf{B}(t)\mathbf{u} \quad (101.7)$$

and the **linear output equations**

$$\mathbf{y} = \mathbf{C}(t)\mathbf{x} + \mathbf{D}(t)\mathbf{u} \quad (101.8)$$

where $\mathbf{A}(t) = [a_{ij}(t)] = [\partial f_i / \partial X_j]$, $i = \text{row}, j = \text{column}$ is an $n_x \times n_x$ matrix; $\mathbf{B}(t) = [\partial f_i / \partial U_j]$ is an $n_x \times n_u$ matrix; $\mathbf{C}(t) = [\partial g_i / \partial X_j]$ is an $n_y \times n_x$ matrix; $\mathbf{D}(t) = [\partial g_i / \partial U_j]$ is an $n_y \times n_u$ matrix; and all matrices are evaluated along the reference conditions $\bar{\mathbf{X}}(t)$, $\bar{\mathbf{U}}(t)$.

The most common occurrence of linear systems arises when the reference input is a constant $\bar{\mathbf{U}}(t) = \bar{\mathbf{U}}$ and the reference state is an equilibrium (i.e., constant) state $\bar{\mathbf{X}}(t) = \bar{\mathbf{X}}$. Then the reference output $\bar{\mathbf{Y}}(t) = \bar{\mathbf{Y}}$ is also constant. In this case the matrices in the linear model are also constant. This yields a constant-coefficient **multiple-input, multiple-output (MIMO)** linear state-space model, with linear state equations

$$\dot{\mathbf{x}} = \mathbf{A}\mathbf{x} + \mathbf{B}\mathbf{u} \quad (101.9)$$

and the linear output equations

$$\mathbf{y} = \mathbf{C}\mathbf{x} + \mathbf{D}\mathbf{u} \quad (101.10)$$

Henceforth we will be concerned only with constant-coefficient linear state-space models of the form given in Equation (101.9) and Equation (101.10).

For the special case of a single input u and a single output y ($n_u = n_y = 1$) we have a **single-input, single-output (SISO)** state-space system,

$$\dot{\mathbf{x}} = \mathbf{A}\mathbf{x} + \mathbf{B}u \quad (101.11)$$

$$y = \mathbf{C}\mathbf{x} + Du \quad (101.12)$$

where u and y are scalar variables, D is a scalar constant, $\mathbf{B} = [b_1 \dots b_{n_x}]^T$, and $\mathbf{C} = [c_1 \dots c_{n_x}]$.

101.3 Linear System Representations

The representation of a linear state–space system is generally not unique. For example, a change in the coordinate system for \mathbf{x} will change the matrices in the state–space representation. In addition, there are certain state–space representations and other types of representations that may be more convenient for various types of analyses.

State–Space Systems

There are several special representations for a state–space system that occur frequently in control systems analysis:

Decoupled Form

The simplest representation of a state–space system occurs when the state equations are decoupled, that is, when the \mathbf{A} matrix is in the diagonalized form,

$$\mathbf{A} = \text{diag} [\lambda_1, \dots, \lambda_{n_x}] = \begin{bmatrix} \lambda_1 & & \mathbf{0} \\ & \ddots & \\ \mathbf{0} & & \lambda_{n_x} \end{bmatrix} \quad (101.13)$$

so that the evolution of each state variable depends only on itself and the inputs, but not on the other state variables.

Block Diagonal Form

For a particular state–space system it may not be possible to completely diagonalize the \mathbf{A} matrix so that each state variable is decoupled from the others. In this case a generalization of the diagonal structure occurs where the \mathbf{A} matrix is in block diagonal form,

$$\mathbf{A} = \text{diag} [\mathbf{A}_1, \dots, \mathbf{A}_n] \quad (101.14)$$

in which the \mathbf{A}_i are square matrices on the diagonal of \mathbf{A} .

Companion Form

For a special class of SISO state–space systems, a representation exists that can lead to a description of the system in terms of a single higher-order differential equation. A single-input, single-output state–space system is said to be in companion form if the \mathbf{A} matrix is a companion matrix,

$$\mathbf{A} = \begin{bmatrix} 0 & 1 & 0 & \cdots & 0 \\ 0 & 0 & 1 & \cdots & 0 \\ & & & \ddots & \\ 0 & 0 & 0 & \cdots & 1 \\ -a_1 & -a_2 & -a_3 & \cdots & -a_{n_x} \end{bmatrix} \quad (101.15)$$

and the scalar control input enters only in the \dot{x}_{n_x} equation, with the column matrix \mathbf{B} of the form $\mathbf{B} = [0 \ 0 \ \dots \ 1]^T$. As we will see, a companion form representation has a particularly simple relationship to a representation involving a single n_x -order differential equation.

Input-Output Systems

Equations (101.11) and (101.12) are the general representation of a constant-coefficient SISO system. Another common representation for a special class of SISO systems is referred to as an **input-output (IO)** representation. Using the notation $y^{(n)} = d^n y/dt^n$, we call an SISO system an IO system if the system can be represented by a single n_x -order differential equation of the form

$$y^{(n_x)} + p_{n_x-1}y^{(n_x-1)} + \cdots + p_1\dot{y} + p_0y = q_0u + q_1\dot{u} + \cdots + q_{n_x}u^{(n_x)} \quad (101.16)$$

Note that the left-hand side of Equation (101.16) is expressed in terms of the output $y(t)$ and the right-hand side is expressed in terms of the input $u(t)$. In order for the output to depend on the input, at least one of the right-hand coefficients must be nonzero.

There is a close relationship between the state-space representation of an SISO system in companion form and the IO representation of the same system, provided that certain conditions are satisfied. For example, if the output is just the first state component — that is, the \mathbf{C} matrix is of the form $\mathbf{C} = [1 \ 0 \ \dots \ 0]$ and $D = 0$, with $\mathbf{B} = [0 \ \dots \ 0 \ 1]^T$ — then from Equation (101.11) and Equation (101.15) the last state equation can be written as

$$\dot{x}_{n_x} + a_{n_x}x_{n_x} + \cdots + a_2x_2 + a_1x_1 = u \quad (101.17)$$

Since $x_1 = y$, it follows from the other state equations of Equation (101.11) and Equation (101.15), $\dot{x}_i = x_{i+1}$ for $i = 1, \dots, n_x - 1$, that

$$\begin{aligned} x_2 &= \dot{x}_1 = \dot{y} \\ x_3 &= \dot{x}_2 = \ddot{y} \\ &\vdots \\ x_{n_x} &= \dot{x}_{n_x-1} = y^{(n_x-1)} \end{aligned}$$

Thus Equation (101.17) becomes

$$y^{(n_x)} + a_{n_x}y^{(n_x-1)} + \cdots + a_2\dot{y} + a_1y = u$$

which is in the IO format.

If the output is not just the first state component, then it may not be possible to convert an SISO system in companion form to an equivalent IO representation. In the next section we will discuss a general requirement that, when satisfied, will guarantee that a state-space SISO system (whether in companion form or not) can be converted to an equivalent IO representation.

101.4 Transforming System Representations

For the remainder of this chapter we will be concerned with transforming between various types of representations of constant-coefficient linear systems. It turns out that two fundamental concepts, controllability and observability, govern whether or not certain equivalent representations can be achieved.

Controllability and Observability

Controllability is concerned with whether a control input $\mathbf{u}(t)$ exists that will transfer the state $\mathbf{x}(t)$ from a given initial point $\mathbf{x}(0)$ to a specified final state $\mathbf{x}(t_f)$ in some finite time interval $0 \leq t \leq t_f$. A linear

constant-coefficient system of the form in Equation (101.9) is completely controllable (from any initial state to any final state) if and only if the Kalman controllability criterion, $\text{rank } [\mathbf{P}] = n_x$, is satisfied, where the $n_x \times n_x n_u$ matrix,

$$\mathbf{P} = [\mathbf{B}, \mathbf{AB}, \mathbf{A}^2\mathbf{B}, \dots, \mathbf{A}^{n_x-1}\mathbf{B}] \quad (101.18)$$

is called the *controllability matrix*. Here, $\text{rank } [\mathbf{P}]$ is the maximum number of linearly independent rows (or columns) in \mathbf{P} and is equal to the size of the largest nonzero square determinant obtained by deleting various rows and/or columns of \mathbf{P} . For a single-input system, \mathbf{P} is square and the controllability criterion requires $|\mathbf{P}| \neq 0$, where $|\mathbf{P}|$ denotes the determinant of \mathbf{P} .

Observability is concerned with the problem of determining the state based on the measured outputs. In particular, a linear state–space system is observable if it is possible to uniquely determine the initial state $\mathbf{x}(0)$ given the output and input histories $\mathbf{y}(t)$ and $\mathbf{u}(t)$ over a finite time interval $0 \leq t \leq t_f$. A linear constant-coefficient system of the form in Equation (101.9) and Equation (101.10) is completely observable (over any nonzero time interval) if and only if the Kalman observability criterion, $\text{rank } [\mathbf{Q}] = n_x$, is satisfied, where the $n_x n_y \times n_x$ matrix,

$$\mathbf{Q} = \begin{bmatrix} \mathbf{C} \\ \mathbf{CA} \\ \mathbf{CA}^2 \\ \vdots \\ \mathbf{CA}^{n_x-1} \end{bmatrix} \quad (101.19)$$

is called the *observability matrix*. For a single-output system, \mathbf{Q} is square and the observability criterion requires $|\mathbf{Q}| \neq 0$.

State–Space Transformations

As indicated previously, the state–space representation of a linear system is not unique. Let \mathbf{M} be any constant nonsingular $n_x \times n_x$ matrix with inverse \mathbf{M}^{-1} . Then the coordinate transformation $\mathbf{z} = \mathbf{M}^{-1}\mathbf{x}$ transforms the system given in Equation (101.9) and Equation (101.10) into

$$\dot{\mathbf{z}} = \hat{\mathbf{A}}\mathbf{z} + \hat{\mathbf{B}}\mathbf{u} \quad (101.20)$$

$$\mathbf{y} = \hat{\mathbf{C}}\mathbf{z} + \mathbf{D}\mathbf{u} \quad (101.21)$$

where

$$\hat{\mathbf{A}} = \mathbf{M}^{-1}\mathbf{A}\mathbf{M}, \quad \hat{\mathbf{B}} = \mathbf{M}^{-1}\mathbf{B}, \quad \hat{\mathbf{C}} = \mathbf{C}\mathbf{M} \quad (101.22)$$

Diagonalization

For $i = 1, \dots, n_x$ let λ_i denote the scalar **eigenvalues** of \mathbf{A} , with corresponding **eigenvectors** $\boldsymbol{\xi}_i \neq \mathbf{0}$. That is,

$$\mathbf{A}\boldsymbol{\xi}_i = \lambda_i\boldsymbol{\xi}_i \quad (101.23)$$

where the eigenvalues satisfy the n_x -order polynomial characteristic equation

$$0 = |\lambda \mathbf{I} - \mathbf{A}| = \mathcal{P}(\lambda) = \lambda^{n_x} + p_{n_x-1} \lambda^{n_x-1} + \dots + p_1 \lambda + p_0 \quad (101.24)$$

Suppose that the n_x eigenvectors are linearly independent. A sufficient condition for this, from linear algebra, is that the eigenvalues be distinct ($\lambda_i \neq \lambda_j$ for $i \neq j$). Then the eigenvector matrix (also called the *modal matrix*),

$$\mathbf{M} = [\boldsymbol{\xi}_1 \dots \boldsymbol{\xi}_{n_x}] \quad (101.25)$$

whose columns are the eigenvectors of \mathbf{A} , has an inverse. Using the eigenvector matrix and the coordinate transformation $\mathbf{z} = \mathbf{M}^{-1}\mathbf{x}$ applied to the system given in Equation (101.9) and Equation (101.10) yields the transformed system of Equation (101.20) and Equation (101.21), in which $\hat{\mathbf{A}} = \mathbf{M}^{-1}\mathbf{A}\mathbf{M}$ is a diagonal matrix, with eigenvalues on the main diagonal in the same order as the eigenvector columns of \mathbf{M} . That is, the state equations become decoupled in the new state variables.

In component form the decoupled state equations are

$$\dot{z}_i = \lambda_i z_i + \hat{\mathbf{b}}_i^T \mathbf{u}, \quad i = 1, \dots, n_x \quad (101.26)$$

and the output equations can be written as

$$\mathbf{y} = z_1 \hat{\mathbf{c}}_1 + \dots + z_{n_x} \hat{\mathbf{c}}_{n_x} + \mathbf{D}\mathbf{u} \quad (101.27)$$

where $\hat{\mathbf{b}}_i^T$ is the i th row of $\hat{\mathbf{B}} = \mathbf{M}^{-1}\mathbf{B}$ and $\hat{\mathbf{c}}_i$ is the i th column of $\hat{\mathbf{C}} = \mathbf{C}\mathbf{M}$.

In terms of the decoupled system equations, we have direct alternate tests for controllability and observability. The system of Equation (101.9) and Equation (101.10) is controllable if and only if $\hat{\mathbf{B}}$ contains no zero row, so that \mathbf{u} affects each eigenstate z_i . Similarly, the system of Equation (101.9) and Equation (101.10) is observable if and only if $\hat{\mathbf{C}}$ contains no zero column, so that \mathbf{y} reflects each eigenstate z_i .

Block Diagonalization

If the n_x eigenvectors of \mathbf{A} are not linearly independent, then it is not possible to transform \mathbf{A} to a diagonal matrix. That is, we cannot find a coordinate system in which each state variable is decoupled from the other state variables. However, we can always find a coordinate transformation matrix \mathbf{M} so that $\mathbf{z} = \mathbf{M}^{-1}\mathbf{x}$ transforms \mathbf{A} to an $n_x \times n_x$ block diagonal *Jordan matrix*,

$$\mathbf{J} = \text{diag} [\mathbf{J}_1, \mathbf{J}_2, \dots, \mathbf{J}_n] \quad (101.28)$$

where n is the number of linearly independent eigenvectors and each Jordan block \mathbf{J}_j , associated with an eigenvalue λ_j , \mathbf{A} , is either a 1×1 matrix $[\lambda_j]$ for distinct eigenvalues or, for repeated eigenvalues, a square submatrix in upper triangular form with λ_j on the diagonal, ones above and adjacent to the diagonal, and zeroes elsewhere:

$$\mathbf{J}_i = \begin{bmatrix} \lambda_i & 1 & & & \\ & \lambda_i & 1 & 0 & \\ & & \lambda_i & \ddots & \\ & 0 & & \ddots & 1 \\ & & & & \lambda_i \end{bmatrix} \quad (101.29)$$

The resulting transformed system, of the form

$$\dot{z}_i = \mathbf{J}_i z_i + \mathbf{B}_i \mathbf{u} \quad (101.30)$$

will be composed of block-decoupled subsystems, whose state variables are decoupled from those of the other subsystems.

The development of the matrix \mathbf{M} , so that $\mathbf{z} = \mathbf{M}^{-1}\mathbf{x}$ transforms \mathbf{A} to Jordan block diagonal form, is essentially the same as in the case of complete diagonalization. The difference is that in order for the matrix \mathbf{M} to have an inverse, any linearly dependent eigenvectors of \mathbf{A} are replaced by “generalized eigenvectors” to form an \mathbf{M} matrix with n_x linearly independent columns. For a repeated eigenvalue λ with eigenvector $\hat{\boldsymbol{\xi}}$, a *generalized eigenvector* $\hat{\boldsymbol{\xi}}$ is a nonzero solution to the equation

$$[\lambda_i \mathbf{I} - \mathbf{A}]\hat{\boldsymbol{\xi}} = -\boldsymbol{\xi} \quad (101.31)$$

This equation can be used repeatedly, if necessary, with the right-hand side being either an eigenvector or a previously generated generalized eigenvector.

Let $\lambda_1, \dots, \lambda_{n_x}$ and $\boldsymbol{\xi}_1, \dots, \boldsymbol{\xi}_{n_x}$ be the eigenvalues and the associated linearly independent eigenvectors or generalized eigenvectors. Order them such that each generalized eigenvector $\boldsymbol{\xi}_i$ is generated from $\boldsymbol{\xi}_{i-1}$ by

$$[\lambda_i \mathbf{I} - \mathbf{A}]\boldsymbol{\xi}_i = -\boldsymbol{\xi}_{i-1} \quad (101.32)$$

whereas each eigenvector $\boldsymbol{\xi}_1$ satisfies

$$[\lambda_i \mathbf{I} - \mathbf{A}]\boldsymbol{\xi}_i = \mathbf{0} \quad (101.33)$$

Then the transformation $\mathbf{z} = \mathbf{M}^{-1}\mathbf{x}$, with $\mathbf{M} = [\boldsymbol{\xi}_1 \dots \boldsymbol{\xi}_{n_x}]$, converts \mathbf{A} to a Jordan block diagonal form $\mathbf{J} = \mathbf{M}^{-1}\mathbf{A}\mathbf{M}$, since $\mathbf{M}\mathbf{J} = \mathbf{A}\mathbf{M}$. For more details on block diagonalization see Brogan [1982, p. 143].

Instead of block diagonalization, one can employ a matrix perturbation technique and only consider the case where the eigenvalues of \mathbf{A} are distinct, so that the eigenvectors are linearly independent and complete diagonalization is possible. This technique is based on the fact that distinct eigenvalues can always be achieved by making a small perturbation ε in the elements of \mathbf{A} that cause repeated eigenvalues [Luenberger, 1979, p. 149]. After any ensuing analysis has been performed — for example, for the solution $\mathbf{x}(t, \varepsilon)$ — the results can be examined in the limit as $\varepsilon \rightarrow 0$.

Companion Form Systems

An SISO state–space system such as in Equation (101.11) and Equation (101.12) can be transformed to a unique companion form if, and only if, the system is controllable. By way of construction, we note from Equation (101.11) and Equation (101.15) that in companion form the state variables z_i all follow from z_1 in a cascade: $z_{i+1} = \dot{z}_i$, $i = 1, \dots, n_x - 1$. Thus we can construct the transformation matrix by finding an n_x -dimensional vector $\boldsymbol{\rho}$ such that, by choosing $z_1 = \boldsymbol{\rho}^T \mathbf{x}$, repeated differentiation yields a system in companion form. In particular, we choose

$$\begin{aligned} z_1 &= \boldsymbol{\rho}^T \mathbf{x} \\ z_2 &= \dot{z}_1 = \boldsymbol{\rho}^T \mathbf{A} \mathbf{x} && \text{with } \boldsymbol{\rho}^T \mathbf{B} = \mathbf{0} \\ z_3 &= \dot{z}_2 = \boldsymbol{\rho}^T \mathbf{A}^2 \mathbf{x} && \text{with } \boldsymbol{\rho}^T \mathbf{A} \mathbf{B} = \mathbf{0} \\ &\vdots \\ z_{n_x} &= \dot{z}_{n_x-1} = \boldsymbol{\rho}^T \mathbf{A}^{n_x-1} \mathbf{x} && \text{with } \boldsymbol{\rho}^T \mathbf{A}^{n_x-2} \mathbf{B} = \mathbf{0} \\ \dot{z}_{n_x} &= \boldsymbol{\rho}^T \mathbf{A}^{n_x} \mathbf{x} + \mathbf{u} && \text{with } \boldsymbol{\rho}^T \mathbf{A}^{n_x-1} \mathbf{B} = \mathbf{1} \end{aligned} \quad (101.34)$$

From the left-hand sides of Equation (101.34) and $\mathbf{z} = \mathbf{M}^{-1}\mathbf{x}$, we have

where $\mathbf{Y}(s) = \mathcal{L}[\mathbf{y}(t)]$ and $\mathbf{U}(s) = \mathcal{L}[\mathbf{u}(t)]$ are the Laplace transforms of $\mathbf{y}(t)$ and $\mathbf{u}(t)$, respectively, and

$$\mathbf{G}(s) = \mathbf{C}[s\mathbf{I} - \mathbf{A}]^{-1}\mathbf{B} + \mathbf{D} \quad (101.39)$$

is the $n_y \times n_u$ transfer matrix. Suppose that the transfer matrix is known, perhaps from experimental results, and is given by

$$\mathbf{G}(s) = \frac{1}{\mathcal{P}(s)} = \begin{bmatrix} \mathcal{Q}_{11}(s) & \dots & \mathcal{Q}_{1n_u}(s) \\ \vdots & \ddots & \vdots \\ \mathcal{Q}_{n_y,1}(s) & \dots & \mathcal{Q}_{n_y,n_u}(s) \end{bmatrix} \quad (101.40)$$

where each $\mathcal{P}_j(s)$ is a polynomial of order less than or equal to the order n_x of the characteristic polynomial $\mathcal{P}(s) = |s\mathbf{I} - \mathbf{A}|$. We wish to construct a state-space model from the transfer matrix model.

We will first obtain a decoupled model in which the \mathbf{A} matrix is diagonal. Then a suitable coordinate transformation is applied to yield a state-space representation having specified properties, such as a desired set of eigenvectors or an \mathbf{A} matrix that is in companion form.

We compute the eigenvalues from the n_x -order characteristic equation $\mathcal{P}(\lambda) = 0$. Assuming that these eigenvalues are distinct, we define the diagonalized state matrix as $\hat{\mathbf{A}} = \text{diag}[\lambda_1, \dots, \lambda_{n_x}]$. The next step is to determine an $n_x \times n_u$ matrix $\hat{\mathbf{B}}$, an $n_y \times n_x$ matrix $\hat{\mathbf{C}}$, and an $n_y \times n_u$ matrix $\hat{\mathbf{D}}$ such that the following conditions hold:

1. The transfer matrix corresponds to a state-space system, that is, $\mathbf{G}(s) = \hat{\mathbf{C}}[s\mathbf{I} - \hat{\mathbf{A}}]^{-1}\hat{\mathbf{B}} + \hat{\mathbf{D}}$.
2. $\hat{\mathbf{B}}$ has no zero rows (controllability is satisfied).
3. $\hat{\mathbf{C}}$ has no zero columns (observability is satisfied).

Usually, the system of equations that result from equating like powers of s in condition 1 involves fewer equations than unknowns in $\hat{\mathbf{B}}$, $\hat{\mathbf{C}}$, and $\hat{\mathbf{D}}$, so there is some degree of freedom in choosing the elements of $\hat{\mathbf{B}}$, $\hat{\mathbf{C}}$, and $\hat{\mathbf{D}}$. The resulting decoupled state-space system is

$$\begin{aligned} \dot{\mathbf{z}} &= \hat{\mathbf{A}}\mathbf{z} + \hat{\mathbf{B}}\mathbf{u} \\ \mathbf{y} &= \hat{\mathbf{C}}\mathbf{z} + \hat{\mathbf{D}}\mathbf{u} \end{aligned} \quad (101.41)$$

From the diagonalized representation, which may have complex-valued matrices, we can change to a final set of state variables $\mathbf{x} = \mathbf{M}\mathbf{z}$ by choosing a set of desired linearly independent eigenvectors as the columns of the transformation matrix $\mathbf{M} = [\boldsymbol{\xi}_1 \dots \boldsymbol{\xi}_{n_x}]$. This transformation yields

$$\begin{aligned} \dot{\mathbf{x}} &= \mathbf{A}\mathbf{x} + \mathbf{B}\mathbf{u} \\ \mathbf{y} &= \mathbf{C}\mathbf{x} + \mathbf{D}\mathbf{u} \end{aligned} \quad (101.42)$$

where $\mathbf{A} = \mathbf{M}\hat{\mathbf{A}}\mathbf{M}^{-1}$, $\mathbf{B} = \mathbf{M}\hat{\mathbf{B}}$, and $\mathbf{C} = \hat{\mathbf{C}}\mathbf{M}^{-1}$. The matrix \mathbf{A} will have eigenvalues λ_i and the chosen eigenvectors. For real-valued final matrices, complex conjugate eigenvectors should be chosen for any corresponding conjugate eigenvalues.

As an example, consider the IO system,

$$\dot{y} + 3\dot{y} + 2y = u_1 + 3u_2 + \dot{u}_2$$

that has the transfer matrix representation

$$\mathbf{Y}(s) = \begin{bmatrix} 1 & s+3 \\ s^2+3s+2 & s^2+3s+2 \end{bmatrix} \begin{bmatrix} U_1(s) \\ U_2(s) \end{bmatrix} = \mathbf{G}(s)\mathbf{U}(s)$$

The characteristic equation $\lambda^2 + 3\lambda + 2 = 0$ yields the eigenvalues $\lambda_1 = -1, \lambda_2 = -2$. Thus the diagonalized state equations will have the $\hat{\mathbf{A}}$ matrix given by

$$\hat{\mathbf{A}} = \begin{bmatrix} -1 & 0 \\ 0 & -2 \end{bmatrix}$$

The condition $\mathbf{G}(s) = \hat{\mathbf{C}} [s\mathbf{I} - \hat{\mathbf{A}}]^{-1} \hat{\mathbf{B}} + \mathbf{D}$ yields

$$\frac{[1 \ s+3]}{s^2+3s+2} = [\hat{c}_1 \ \hat{c}_2] \begin{bmatrix} \frac{1}{s+1} & 0 \\ 0 & \frac{1}{s+2} \end{bmatrix} \begin{bmatrix} \hat{b}_{11} & \hat{b}_{12} \\ \hat{b}_{21} & \hat{b}_{22} \end{bmatrix} + [d_1 \ d_2]$$

Thus the elements of $\hat{\mathbf{B}}$, $\hat{\mathbf{C}}$, and \mathbf{D} must satisfy

$$\begin{aligned} 1 &= d_1 s^2 + (\hat{c}_1 \hat{b}_{11} + \hat{c}_2 \hat{b}_{21} + 3d_1) s + (2\hat{c}_1 \hat{b}_{11} + \hat{c}_2 \hat{b}_{21} + 2d_1) \\ s+3 &= d_2 s^2 + (\hat{c}_1 \hat{b}_{12} + \hat{c}_2 \hat{b}_{22} + 3d_2) s + (2\hat{c}_1 \hat{b}_{12} + \hat{c}_2 \hat{b}_{22} + 2d_2) \end{aligned}$$

Equating like powers of s and solving the resulting equations yields

$$d_1 = d_2 = 0, \quad \hat{c}_1 \hat{b}_{11} = -1, \quad \hat{c}_2 \hat{b}_{21} = -1, \quad \hat{c}_1 \hat{b}_{12} = 2, \quad \hat{c}_2 \hat{b}_{22} = -1$$

The observability condition in 3 requires that $\hat{c}_1 \neq 0$ and $\hat{c}_2 \neq 0$. Therefore, these results can be solved for the \hat{b}_{ij} in terms of \hat{c}_1 and \hat{c}_2 . The resulting \hat{b}_{ij} are all nonzero, so the controllability condition in 2 is also satisfied. For this example, we choose $\hat{c}_1 = \hat{c}_2 = 1$, yielding the decoupled system of Equation (101.41) with

$$\hat{\mathbf{A}} = \begin{bmatrix} -1 & 0 \\ 0 & -2 \end{bmatrix}, \quad \hat{\mathbf{B}} = \begin{bmatrix} 1 & 2 \\ -1 & -1 \end{bmatrix}, \quad \hat{\mathbf{C}} = [1 \ 1], \quad \mathbf{D} = [0 \ 0]$$

Since the eigenvalues were all real, the diagonalized state-space model is real, so further transformation is not required. However, to complete the example, suppose we want to change from this diagonal form to a state-space system having a specified set of eigenvectors, such as $\boldsymbol{\xi}_1 = [1 \ -1]^T$ and $\boldsymbol{\xi}_2 = [1 \ -2]^T$. As a final step, we employ a coordinate transformation $\mathbf{x} = \mathbf{Mz}$, where $\mathbf{M} = [\boldsymbol{\xi}_1 \ \boldsymbol{\xi}_2]$. This yields a state-space system as in Equation (101.42), with

$$\mathbf{A} = \begin{bmatrix} 0 & 1 \\ -2 & -3 \end{bmatrix}, \quad \mathbf{B} = \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}, \quad \mathbf{C} = [1 \ 0], \quad \mathbf{D} = [0 \ 0]$$

Note that our choice of eigenvectors happened to produce an \mathbf{A} matrix in companion form, with the same eigenvalues as $\hat{\mathbf{A}}$, but with different eigenvectors. If our objective had been to directly produce an \mathbf{A} matrix in companion form, we could have chosen $\boldsymbol{\xi}_1 = [1 \ \alpha]^T$ and $\boldsymbol{\xi}_2 = [1 \ \beta]^T$ as variables, computed $\mathbf{A} = \mathbf{M}\hat{\mathbf{A}}\mathbf{M}^{-1} = [a_{ij}]$, and then solved for the parameters α and β to satisfy the two companion matrix conditions $a_{11} = 0$ and $a_{12} = 1$.

Defining Terms

Cause and effect — In this context for the IO formulation, a condition that requires that the order of any derivative in the input be less than or equal to the highest order of derivative in the output.

Controllability — The ability to drive a system from an arbitrary initial state to an arbitrary final state in finite time.

Eigenvalue — Any scalar λ satisfying the equation $\det[\lambda\mathbf{I} - \mathbf{A}] = 0$, where \mathbf{A} is an $n_x \times n_x$ matrix and \mathbf{I} is the identity matrix; alternately, a scalar λ satisfying the equation $\mathbf{A}\boldsymbol{\xi} = \lambda\boldsymbol{\xi}$, where $\boldsymbol{\xi}$ is an n_x -dimensional eigenvector.

Eigenvector — Any nonzero n_x -dimensional vector $\boldsymbol{\xi}$ satisfying the equation $\mathbf{A}\boldsymbol{\xi} = \lambda\boldsymbol{\xi}$, where \mathbf{A} is an $n_x \times n_x$ dimensional matrix and λ is an eigenvalue.

Input-output (IO) model — A representation of a dynamic system in terms of a single n_x -order differential equation relating the output $y(t)$ to the input $u(t)$.

Input vector — An n_u -dimensional column vector consisting of the variable quantities, other than state variables, that affect the evolution of the state of a dynamic system.

Linear output equations — A set of algebraic equations defining the output variables in terms of linear combinations of the state and input variables.

Linear state equations — A set of first-order differential equations that model the behavior of a physical system in terms of a linear combination of the state and input variables.

Multiple-input, multiple-output (MIMO) model — A state-space model with an input vector, \mathbf{u} , of dimension n_u , greater than one and output vector, \mathbf{y} , of dimension n_y , greater than one.

Observability — The ability to determine a system's initial state given the output and input histories over a finite time interval.

Output equations — A set of algebraic equations defining the output variables as functions of the state variables and the input variables.

Output vector — An n_y -dimensional column vector whose elements model the measurements of a physical system.

Single-input, single-output (SISO) model — A state-space model with a single scalar input, u , and single scalar output, y .

State equations — A set of first-order differential equations that model the behavior of a physical system.

State space — A geometric space with dimension n_x equal to the number of state variables. Any possible state of a dynamic model can be represented as a point in state space.

State variables — The smallest set of time-differentiated variables whose initial conditions, along with the inputs and the model, allow complete prediction of the behavior of a dynamic system. It is possible to define more than one set of state variables for any particular model. However, the number of state variables is a unique quantity for a system.

State vector — An n_x -dimensional column vector consisting of the state variables of a model.

102.1 Frequency Response Plotting

Linear Plots • Bode Diagrams

102.2 A Comparison of Methods

Frequency response in stable, linear systems is defined as “the frequency-dependent relation in both gain and phase difference between steady-state sinusoidal inputs and the resultant steady-state sinusoidal outputs” [IEEE, 1988]. The frequency response characteristics of a system can be found analytically from its transfer function. They are also commonly measured in laboratory or field tests. A single-input/single-output linear time-invariant system is shown in [Figure 102.1](#).

For systems with no time delay, the transfer function $H(s)$ is in the form of a ratio of polynomials in the complex frequency s ,

$$H(s) = K \frac{N(s)}{D(s)}$$

where K is a frequency-independent constant. For a system in the sinusoidal steady state, s is replaced by the sinusoidal frequency $j\omega$ ($j = \sqrt{-1}$) and the system function becomes

$$H(j\omega) = K \frac{N(j\omega)}{D(j\omega)} = |H(j\omega)|e^{j\angle H(j\omega)}$$

$H(j\omega)$ is a complex quantity. Its magnitude $|H(j\omega)|$ and its angle or argument $\angle H(j\omega)$ relate, respectively, the amplitudes and phase angles of sinusoidal steady-state input and output signals. Referring to [Figure 102.1](#), if the input and output signals are

$$x(t) = X \cos(\omega t + \theta_x)$$

$$y(t) = Y \cos(\omega t + \theta_y)$$

then the output’s magnitude Y and phase angle θ_y are related to those of the input by the two equations

$$Y = |H(j\omega)|X$$

$$\theta_y = \angle H(j\omega) + \theta_x$$

FIGURE 102.1 A single-input/single-output linear system.

The phrase *frequency response characteristic* usually implies a complete description of a system's sinusoidal steady-state behavior as a function of frequency. Because $H(j\omega)$ is complex, frequency response characteristics cannot be graphically displayed as a single curve plotted with respect to frequency. Instead, the magnitude and angle of $H(j\omega)$ can be separately plotted as functions of frequency. It is often advantageous to plot frequency response curves on other-than-linearly scaled Cartesian coordinates. **Bode diagrams** (developed in the 1930s by H.W. Bode of Bell Labs) use a logarithmic scale for frequency and a decibel measure for magnitude. In **Nyquist plots** (from Harry Nyquist, also of Bell Labs), $H(j\omega)$ is displayed in Argand (polar) diagram form on the complex number plane, with $\text{Re}[H(j\omega)]$ on the horizontal axis and $\text{Im}[H(j\omega)]$ on the vertical. Frequency is a parameter of such curves. It is sometimes numerically identified at selected points of the curve and sometimes omitted. The **Nichols chart** (developed by N. B. Nichols) graphs magnitude versus phase for the system function, frequency again being a parameter of the curve.

Frequency response techniques are most obviously applicable to topics such as communications and electrical filters in which the frequency response behaviors of systems are central to an understanding of their operations. It is, however, in the area of control systems that frequency response techniques are most fully developed as analytical and design tools. The Nichols chart, for instance, is used exclusively in the analysis and design of classical feedback control systems. Although frequency response concepts are perhaps most often associated with electrical engineering, they are also commonly used in other branches of engineering and the natural sciences. Two nonelectrical examples are given in [Figure 102.2](#) and [Figure 102.3](#), which show a frequency response test of a scale model of the suspension system of a truck and the modulation transfer function (MTF) of a photographic film. MTFs provide an accurate description of the quality of photographic systems and have largely replaced more subjective parameters, such as resolving power, sharpness, and acutance. Note that frequency response concepts are equally applicable to problems involving temporal ([Figure 102.2](#)) and spatial ([Figure 102.3](#)) frequencies.

102.1 Frequency Response Plotting

Frequency response plots are prepared by computing the magnitude and angle of $H(j\omega)$.

Linear Plots

In linear plots $|H(j\omega)|$ and $\angle H(j\omega)$ are shown in separate diagrams as functions of frequency (either f or ω). Cartesian coordinates are used, and all scales are linear.

Example 102.1

Consider the transfer function

$$H(s) = \frac{160000}{s^2 + 220s + 160000}$$

The complex frequency variable s is replaced by the sinusoidal frequency $j\omega$ and the magnitude and angle are found.

$$H(j\omega) = \frac{160000}{(j\omega)^2 + 220(j\omega) + 160000}$$

$$|H(j\omega)| = \frac{160000}{\sqrt{(160000 - \omega^2)^2 + (220\omega)^2}}$$

$$\angle H(j\omega) = -\tan^{-1} \frac{220\omega}{160000 - \omega^2}$$

The plots of magnitude and angle are shown in [Figure 102.4](#). Linear plots are most useful when the frequency range of interest is small, as is commonly the case for mechanical systems. Such plots give a straightforward representation of system response.

FIGURE 102.4 Linear frequency response curves of $H(j\omega)$.

The peaking of the magnitude curve near $\omega = 400$ rad/s in [Figure 102.4](#) is a reflection of the phenomenon of **resonance**. Resonance may exist in lightly damped second- or higher-order systems. Examples of resonance are common in both the natural and manmade worlds. Organ pipes, for example, are designed to resonate at desired pitches. Resonances can have undesirable effects, such as when the steering mechanism of a vehicle with misaligned front wheels shimmies at certain operating speeds. Two well-known examples of the destructive effects of resonance are the Tacoma Narrows suspension bridge, which underwent catastrophic failure during a moderate windstorm in 1940, and the 1981 collapse of an elevated walkway in the lobby of a Kansas City hotel under the load of a crowd of dancers. All mechanical systems resonate at certain critical frequencies. The careful design engineer makes sure that vibrations that might affect the system's structural integrity are well outside the service range.

Bode Diagrams

A Bode diagram consists of plots of the gain and angle of a transfer function, each with respect to logarithmically scaled frequency axes. In addition, the gain of the transfer function is scaled in **decibels (dB)** according to the definition

$$H_{dB} = 20 \log_{10} |H(j\omega)|$$

Bode diagrams have the advantage of clearly identifying system features even if they occur over wide ranges of frequency and dynamic response. Before constructing a Bode diagram, the transfer function is normalized so that each pole or zero term (except those at $s = 0$) has a DC gain of one. For instance,

$$H(s) = K \frac{s + \omega_z}{s(s + \omega_p)} = \frac{K\omega_z}{\omega_p} \frac{s/\omega_z + 1}{s(s/\omega_p + 1)} = K' \frac{s\tau_z + 1}{s(s\tau_p + 1)}$$

It is common to draw Bode diagrams directly from $H(s)$ without making the formal substitution $s = j\omega$.

When drawn by hand, Bode magnitude and angle curves are developed by adding the individual contributions of the factored terms of the transfer function's numerator and denominator. In general, these factored terms may include (1) a constant K , (2) a simple s term corresponding to either a zero or a pole at the origin, (3) a term such as $(s\tau + 1)$ corresponding to a real-valued (nonzero) pole or zero, and (4) a quadratic term with a possible standard form of $[(s/\omega_n)^2 + 2\zeta(s/\omega_n) + 1]$ corresponding to a pair of complex conjugate poles or zeros and for which $0 < \zeta < 1$. With the exception of quadratic terms having small ζ (**damping ratio**), the Bode magnitude and angle curves for all such expressions can be reasonably approximated by a series of straight line segments. Detailed procedures for drawing Bode diagrams from these basic forms are described in many references. Examples are given in [Figure 102.5](#), which shows straight-line approximations for both a numerator-factored term $(s/\omega_z + 1)$ and a denominator-factored term, $1/(s/\omega_p + 1)$. The approximations are shown as dotted lines. The exact curves are shown as solid lines.

Note in [Figure 102.5](#) that both decibel magnitude and angle are plotted semilogarithmically. The frequency axis is logarithmically scaled so that every tenfold, or **decade**, change in frequency occurs over an equal distance. The magnitude axis is given in decibels. Positive decibel magnitudes correspond to amplifications between input and output that are greater than one (output amplitude larger than input). Negative decibel gains correspond to attenuation between input and output (output amplitude smaller than input). Notice in [Figure 102.5](#) that at low and high frequencies the straight-line approximations are virtually identical to the exact curves. The straight-line approximations differ most greatly from the exact curves at points where the approximations change slope. In magnitude curves these are called **breakpoints**. At breakpoints the straight-line approximation and the exact curve differ by 3dB for each pole or zero.

FIGURE 102.5 Bode curves for (1) a pole at $s = -\omega_p$ and (2) a zero at $s = -\omega_z$.

Bode diagrams are easily constructed by hand because, with the exception of lightly damped quadratic terms, each contribution can be reasonably approximated with straight lines. Also, the overall frequency response curve is found by adding the individual contributions. Today, many commercially available mathematical analysis software packages have built-in utilities for creating Bode diagrams. These have rendered the plotting of Bode diagrams by hand nearly obsolete. Still, there is benefit in understanding the traditional methods because they give insight into the meanings of Bode diagram features. Break-points, for instance, can be related to the locations of poles and/or zeros and slopes can be related to the numbers of poles and/or zeros. Two examples of Bode diagram construction follow.

Example 102.2

$$A(s) = \frac{10^4 s}{s^2 + 1100s + 10^5} = \frac{10^4 s}{(s + 100)(s + 1000)} = 10^{-1} \frac{s}{(s/100 + 1)(s/1000 + 1)}$$

In [Figure 102.6](#), the individual contributions of the four factored terms of $H(s)$ are shown as dotted lines. The overall straight-line approximations for gain and angle are shown with dashed lines. The exact curves are plotted with solid lines.

Example 102.3

$$G(s) = \frac{1000(s + 500)}{s^2 + 70s + 1000} = \frac{50(s/500 + 1)}{(s/100)^2 + 2(.35)(s/100) + 1}$$

Note that, for the quadratic term in the denominator, the damping ratio is 0.35, an indication of resonance. For small damping ratios the straight-line approximations of Bode magnitude and phase plots can vary significantly from the exact curves. For improved accuracy the approximations would have to be adjusted near the frequency of $\omega = 100$ rad/sec. This is not a consideration when a computer is used to generate a Bode diagram. [Figure 102.7](#) shows the exact gain and angle frequency response curves for $G(s)$.

102.2 A Comparison of Methods

This chapter ends with the frequency response of a simple system plotted in three different ways.

Example 102.4

$$T(s) = \frac{10^7}{(s + 100)(s + 200)(s + 300)}$$

[Figure 102.8](#) shows linear frequency response curves for $T(s)$. Corresponding Bode and Nyquist diagrams are shown in [Figure 102.9](#) and [Figure 102.10](#), respectively. The information contained in the three sets of diagrams is the same.

Defining Terms

Bode diagram — A frequency response plot of 20-log gain and phase angle on a log-frequency base.

Breakpoint — A point of abrupt change in slope in the straight-line approximation of a Bode magnitude curve.

FIGURE 102.6 Bode diagram curves for $G(j\omega)$.

FIGURE 102.7 Bode diagram curves for $A(j\omega)$.

FIGURE 102.8 Linear frequency response curves for $T(j\omega)$.

FIGURE 102.9 Bode diagram curves for $T(j\omega)$.

FIGURE 102.10 Nyquist plot of $T(j\omega)$.

Damping ratio — The ratio between a system's damping factor (measure of rate of decay of response) and the damping factor when the system is critically damped.

Decade — Power of ten. In context, a tenfold change in frequency.

Decibel — A measure of relative size. The decibel gain between voltages V_1 and V_2 is $20 \log_{10}(V_1/V_2)$.

Frequency response — The frequency-dependent relation in both gain and phase difference between steady-state sinusoidal inputs and the resultant steady state sinusoidal outputs.

Nichols chart — A plot showing magnitude contours and phase contours of the closed-loop transfer function referred to ordinates of logarithmic loop gain and abscissas of loop phase.

Nyquist plot — A parametric frequency response plot with the real part of the transfer function on the abscissa and the imaginary part of the transfer function on the ordinate.

Resonance — The enhancement of the response of a physical system to the steady-state sinusoidal input when the excitation frequency is near a natural frequency of the system.

103

Convolution Integral

Rodger E. Ziemer

University of Colorado, Colorado Springs

103.1 Fundamentals

Continuous-Time Convolution • Discrete-Time Convolution

103.2 Properties of the Convolution Operation

103.3 Applications of the Convolution Integral

Filtering • Spectral Analysis • Correlation or Matched Filtering

103.4 Two-Dimensional Convolution

103.5 Time-Varying System Analysis

The mathematical operation of **convolution** is defined in the first sections of this chapter, both for **continuous-time** and **discrete-time signals**. Properties of convolution are given and illustrated. Several applications are then enumerated and illustrated. Further discussions and illustrations of convolution are given in Ziemer et al. [1998] and Phillips and Parr [1999]. A good reference on engineering mathematics — including many of the system analysis tools arising in linear systems where the convolution integral arises — is Kreyszig [1998].

103.1 Fundamentals

Continuous-Time Convolution

Let $x(t)$ and $h(t)$ be two continuous-time signals defined for $-\infty < t < \infty$. Their **continuous-time convolution** is defined as the integral operation

$$y(t) = \int_{-\infty}^{\infty} x(\tau)h(t - \tau) d\tau \quad (103.1)$$

With the change of variables $\lambda = t - \tau$, Equation (103.1) can be written in the equivalent form

$$y(t) = \int_{-\infty}^{\infty} x(t - \lambda)h(\lambda) d\lambda \quad (103.2)$$

Inspection of Equation (103.1) reveals that the convolution operation is composed of four steps with respect to the variable of integration:

1. **Shifting** of $h(\tau)$, represented by replacing τ by $\tau - t$
2. Reversal with respect to the independent variable, also known as **folding**, which gives the signal $h(t - \tau)$

3. Multiplication by the second signal to produce the integrand $x(\tau)h(t-\tau)$
4. Integration of the product with respect to τ for all values of the delay variable t , which is the independent variable of the new signal $y(t)$

Example 103.1

Consider the convolution of the following two signals:

$$x(t) = \begin{cases} \exp(-\alpha t), & t \geq 0, & \alpha > 0 \\ 0, & t < 0 \end{cases} \quad (103.3)$$

$$h(t) = \begin{cases} \exp(-\beta t), & t \geq 0, & \alpha \neq \beta > 0 \\ 0, & t < 0 \end{cases} \quad (103.4)$$

The convolution of these two signals, using Equation (103.1), is given by

$$\begin{aligned} y(t) &= \int_0^t \exp(-\alpha\tau) \exp[-\beta(t-\tau)] d\tau \\ &= \exp(-\beta t) \int_0^t \exp[-(\alpha-\beta)\tau] d\tau \\ &= \frac{\exp(-\beta t) - \exp(-\alpha t)}{\alpha - \beta}, \quad t \geq 0 \end{aligned} \quad (103.5)$$

where the lower limit on the integral is 0, by virtue of $x(\tau) = 0$ for $\tau < 0$, and the upper limit is t , by virtue of $h(t-\tau) = 0$ for $t-\tau < 0$ or $\tau > t$. Figure 103.1(a-d) illustrates the factors in the integrand for various values of t ; the final result of the full convolution is shown in Figure 103.2 for $0 \leq t \leq 6$.

FIGURE 103.1 Steps in the convolution of two exponential signals ($\alpha = 2$ and $\beta = 2$).

FIGURE 103.2 Final result for the convolution of two exponential signals ($\alpha = 2$ and $\beta = 2$).

Convolution is often used to find the output of a **linear time-invariant system** to an input signal. (The linearity property means that superposition holds; that is, an arbitrary linear combination of two inputs applied to a linear system results in the same linear combination of outputs due to the inputs applied separately. *Time invariant* means that if a given input results in a certain output, the output due to the input delayed is the original output delayed by the same amount as the input.) When used in this context, Equation (103.1) or Equation (103.2) involves the following functions or **signals**: the input signal $x(t)$, the output signal $y(t)$, and the **impulse response**, $h(t)$, which is the response of the system to a unit impulse function applied at time zero. The latter completely characterizes the system. A system is **causal** if its output does not anticipate the application of an input, which is manifested in the impulse response being zero for $t < 0$. The system is **stable** if every bounded input results in a bounded output, which is manifested by the impulse response being **absolutely integrable**.

Discrete-Time Convolution

Given two discrete-time signals $x(n)$ and $h(n)$ defined for $-\infty < n < \infty$, their **discrete-time convolution** (sum) is

$$y(n) = \sum_{k=-\infty}^{\infty} x(k)h(n-k) \quad (103.6)$$

With the change of variables $j = n - k$, this can be written as

$$y(n) = \sum_{j=-\infty}^{\infty} x(n-j)h(j) \quad (103.7)$$

Discrete-time convolution involves the same operations as continuous-time convolution except that integration is replaced by summation.

TABLE 103.1 Discrete-Time Convolution

| $h(-n)$ | $x(n)$ | | | | | $n =$ | $y(n)$ |
|---------|--------|---|---|---|---|-------|--------|
| | 1 | 1 | 1 | 0 | 0 | | |
| 0 3 2 1 | 0 | | | | | -1 | 0 |
| 0 3 2 | 1 | 0 | | | | 0 | 1 |
| 0 3 | 2 | 1 | 0 | | | 1 | 3 |
| 0 | 3 | 2 | 1 | 0 | | 2 | 6 |
| | 0 | 3 | 2 | 1 | 0 | 3 | 5 |
| | 0 | 0 | 3 | 2 | 1 | 4 | 3 |
| | 0 | 0 | 0 | 3 | 2 | 5 | 0 |
| | 0 | 0 | 0 | 0 | 3 | 6 | 0 |

Example 103.2

Consider the convolution of the following two discrete-time signals:

$$x(n) = \begin{cases} 1, & n = 0, 1, 2 \\ 0, & n < 0 \quad \text{and} \quad n > 2 \end{cases} \tag{103.8}$$

$$h(n) = \begin{cases} 0, & n \leq 0 \quad \text{and} \quad n > 3 \\ 1, & n = 1 \\ 2, & n = 2 \\ 3, & n = 3 \end{cases} \tag{103.9}$$

The discrete-time convolution can be carried out as shown in Table 103.1. Note that the duration of $x(n)$ is 3, that of $h(n)$ is 3, and that of $y(n)$ is $3 + 3 - 1 = 5$.

103.2 Properties of the Convolution Operation

Several convenient **properties of convolution** can be proved. These are listed in [Table 103.2](#). Hints at proving these properties are given in the right-hand column.

103.3 Applications of the Convolution Integral

Filtering

From property 7 of Table 103.2, it follows that

$$\begin{aligned} |Y(f)| &= |H(f)||X(f)| \\ \angle Y(f) &= \angle H(f) + \angle X(f) \end{aligned} \tag{103.10}$$

where $f = \omega/2\pi$ is frequency in hertz. The first equation shows that the magnitude of the spectral content of $x(t)$ is enhanced or attenuated by the magnitude of $H(f)$, which is known as the **amplitude response** of the system. Similarly, the phase components of the spectrum of $x(t)$ are shifted by the argument of $H(f)$, which is known as the **phase response** of the system. Standard design techniques can be used to design filters to modify the amplitude and phase components of $x(t)$ as desired. Similar statements can be applied to a discrete-time system where $H(e^{j2\pi fT})$ plays a role similar to $H(f)$.

TABLE 103.2 Properties of the Convolution Integral

| Number | Property | Comments on Proof |
|--------|--|--|
| 1 | $x(t) * h(t) = h(t) * x(t)$ or $x(n) * h(n) = h(n) * x(n)$ (commutative) | Compare Equation (103.1) and Equation (103.2) or Equation (103.6) and Equation (103.7). |
| 2 | $x(t) * [\alpha h(t)] = \alpha[x(t) * h(t)]$ or $x(n) * [\alpha h(n)] = \alpha[x(n) * h(n)]$ α constant | Convolution is an integral from which the constant α can be taken outside. |
| 3 | $x(t) * [y(t) * z(t)] = [x(t) * y(t)] * z(t)$ or $x(n) * [y(n) * z(n)] = [x(n) * y(n)] * z(n)$ (associative) | Write the two convolution operations as integrals and reverse the orders of integration. |
| 4 | $x(t) * [y(t) + z(t)] = x(t) * y(t) + x(t) * z(t)$ or $x(n) * [y(n) + z(n)] = x(n) * y(n) + x(n) * z(n)$ (distributive) | Separate the integral involving the convolution of $x(t)$ with the sum of the other two signals into the sum of two convolution integrals. |
| 5 | If the duration of $x(t)$ is T_1 and the duration of $y(t)$ is T_2 then the duration of their convolution is $T_1 + T_2$. For discrete-time sequences, the length of the convolution is $N_1 + N_2 - 1$, where $x(n)$ has length N_1 and $y(n)$ has length N_2 . | Evident by sketching time-limited versions of the integrand or summand factors and considering the overlap. |
| 6 | $x(t) * \delta(t - \tau) = x(t - \tau)$, τ constant $x(n) * \delta(n - n_0) = x(n - n_0)$, n_0 constant | Use the sifting property of the delta function inside convolution integral, or the sifting property of the unit pulse function inside the convolution sum. |
| 7 | $\mathcal{F} [x(t) * h(t)] = \mathcal{F} [x(t)] \mathcal{F} [h(t)]$ $\mathcal{L} [x(t) * h(t)] = \mathcal{L} [x(t)] \mathcal{L} [h(t)]$ $\mathcal{F} [x(n) * h(n)] = \mathcal{F} [x(n)] \mathcal{F} [h(n)]$ $\mathcal{F} (\cdot) =$ Fourier transform $\mathcal{L} (\cdot) =$ Laplace transform $\mathcal{F} (\cdot) = z$ transform | Write the Fourier or Laplace transform integrals and interchange the order of transforming and convolution. For the z transform, interchange the order of the z transform and convolution sums. |
| 8 | $x(t) * y(-t) = \int_{-\infty}^{\infty} x(\lambda) y(t + \lambda) d\lambda$ = correlation of $x(t)$ and $y(t)$ | Write out the convolution integral with the argument of the second signal negated. A similar expression holds for discrete-time sequences. |
| 9 | $x(t) * e^{j\omega t} = H(j\omega) e^{j\omega t}$ where $H(j\omega) = \int_{-\infty}^{\infty} h(t) e^{j\omega t} dt$ $x(n) * e^{jm\omega T} = H(e^{jm\omega T}) e^{jm\omega T}$ where $H(e^{j\omega T}) = \sum_{k=-\infty}^{\infty} h(k) e^{jk\omega T}$ | Do a direct substitution into the convolution integral, factor out the term $\exp(j\omega t)$, and use the given definition of $H(j\omega)$. A similar derivation holds for discrete-time sequences. |

Spectral Analysis

The approach for determining the presence of spectral components in a signal is similar to filtering, where now the amplitude response function of the filter is designed to pass the desired spectral components of the signal. In the case of random signals, spectral analysis requires the averaging of the Fourier transforms of several segments of the random signal in order to decrease the variance of the estimates at specific frequencies [Oppenheim and Schaffer, 1999].

Correlation or Matched Filtering

An important problem in signal detection involves maximizing the peak signal-to-rms-noise ratio at the output of a filter at a certain time. The filter that does this is called the **matched filter** for the particular signal under consideration. Its impulse response is the time reverse of the signal to which it is matched, or, for a signal $s(t)$, the matched filter impulse response is

$$h_m(t) = s(t_0 - t) \quad (103.11)$$

where t_0 is the time at which the output peak signal-to-rms-noise ratio is a maximum. The constant t_0 is often chosen to make the impulse response of the matched filter causal. In this case **causality** can be taken to mean that the impulse response is zero for $t < 0$. If $x(t) = 0$ outside of the interval $[0, T]$, Equation (103.1) can be used to write the output of a matched filter to signal alone at its input as

$$y(t) = \int_0^T s(\tau)s(t_0 - t + \tau)d\tau \quad (103.12)$$

If $t_0 = T$ and the output is taken at $t = T$, Equation (103.12) becomes the energy in the signal:

$$y(T) = \int_0^T s(\tau)s(\tau) d\tau = \int_0^T s^2(\tau) d\tau = E \quad (103.13)$$

The peak output signal squared-to-mean-square noise ratio can be shown to be

$$\text{SNR}_{\text{out}} = \frac{2E}{N_0} \quad (103.14)$$

where N_0 is the single-sided power spectral density of the white input noise.

103.4 Two-Dimensional Convolution

Convolution of two-dimensional signals, such as images, is important for several reasons, including pattern recognition and image compression. This topic will be considered briefly here in terms of discrete-spatial-variable signals. Consider two-dimensional signals defined as $x(m, n)$ and $h(m, n)$. Their **two-dimensional convolution** is defined as

$$y(m, n) = \sum_{j=-\infty}^{\infty} \sum_{k=-\infty}^{\infty} x(j, k)(h(m-j, n-k)) \quad (103.15)$$

A double change of summation variables permits this to also be written as

$$y(m, n) = \sum_{j=-\infty}^{\infty} \sum_{k=-\infty}^{\infty} x(m-j, n-k)h(j, k) \quad (103.16)$$

Properties similar to those shown for the one-dimensional case can also be given.

Example 103.3

The shift property given in Table 103.2 (generalized to two dimensions) and superposition will be used to convolve the two-dimensional signals given in the table that follows (assumed zero outside of its definition array), with

$$h(m, n) = \delta(m-1, n-1) + \delta(m-2, n-1) \quad (103.17)$$

Let $x(m, n)$ be given by

$$x(m,n) = \begin{bmatrix} 2 & 2 & 1 & 0 & 0 \\ 2 & 1 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \end{bmatrix}$$

The two-dimensional convolution of these two signals is given by

$$y(m, n) = x(m-1, n-1) + x(m-2, n-1) \quad (103.18)$$

The result of the two-dimensional convolution is given in the table that follows, for $y(m, n)$:

$$x(m,n) = \begin{bmatrix} 0 & 0 & 0 & 0 & 0 \\ 0 & 2 & 2 & 1 & 0 \\ 0 & 2 & 1 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \end{bmatrix} + \begin{bmatrix} 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 2 & 2 & 1 & 0 \\ 0 & 2 & 1 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 \end{bmatrix} = \begin{bmatrix} 0 & 0 & 0 & 0 & 0 \\ 0 & 2 & 2 & 1 & 0 \\ 0 & 4 & 3 & 1 & 0 \\ 0 & 3 & 1 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 \end{bmatrix}$$

103.5 Time-Varying System Analysis

The form of the convolution integral given in Equation (103.1), when applied to finding the output of a system to a given input, assumes that the system is time-invariant — that is, its properties do not change with time. In this context $x(t)$ is viewed as the input to the system, $y(t)$ its output, and $h(t)$ the response of the system to a delta function applied at time zero. The generalization of Equation (103.1) to time-varying (i.e., *not* time-invariant) systems is

$$y(t) = \int_{-\infty}^{\infty} x(\tau)h(t, \tau) d\tau \quad (103.19)$$

where now $h(t, \tau)$ is the response of the system at time t to a delta function applied at time τ .

Defining Terms

Amplitude response — The amount of attenuation or amplification given to a steady state sinusoidal input by a filter or time-invariant linear system. This is the magnitude of the Fourier transform of the impulse response of the system at the frequency of the sinusoidal input.

Causal — A property of a system stating that the system does not respond to a given input before that input is applied. Also, for a linear time-invariant system, **causality** implies that its impulse response is zero for $t < 0$.

Continuous-time signal (system) — A signal for which the independent variable — quite often time — takes on a continuum of values. When applied to a system, continuous time refers to the fact that the system processes continuous-time signals.

Convolution — The process of taking two signals, reversing one in time and shifting it, then multiplying the signals point by point and integrating the product (**continuous-time convolution**). The result of the convolution is then a signal whose independent variable is the shift used in the operation. When done for all shifts, the resulting convolution then produces the output signal for all values of its independent variable, usually time. When convolving discrete-time signals,

the integration of continuous-time convolution is replaced by summation and referred to as the **convolution sum** or **discrete-time convolution**.

Discrete-time signal (system) — A signal for which the independent variable takes on a discrete set of values. When applied to a system, discrete time refers to the fact that the system processes discrete-time signals.

Folding — The process of reversing one of the signals in the convolution integral or sum.

Impulse response — The response of an LTI system (see below) to a unit impulse function applied at time zero. For a system that is linear but not time invariant, the impulse response, $h(t, \tau)$, is the response of the system at time t to a unit impulse function applied at time τ .

Linear time-invariant (LTI) system — A system for which superposition holds and for which the output is invariant to time shifts of the input.

Matched filter — An LTI system whose impulse response is the time reverse of the signal to which it is matched.

Phase response — The amount of phase shift given to a steady state sinusoidal input by a filter or linear time-invariant system. This is the argument of the Fourier transform of the impulse response of the system at the frequency of the sinusoidal input.

Properties of convolution — Properties of the convolution operation given in [Table 103.2](#) result from the form of the defining integral (continuous-time case) or sum (discrete-time case). They can be used to simplify application of the convolution integral or sum.

Signal — Usually a function of time, but also may be a function of spatial and time variables. Signals can be classified in many different ways. Two classifications used here are continuous time and discrete time.

Shifting — An operation used in evaluating the convolution integral or sum. It consists of time-shifting the folded signal.

Stable — A system is stable if every bounded input results in a bounded output. For an LTI system, stability means that the impulse response is **absolutely integrable**.

Superposition — A term that can refer to the superposition integral or sum, which is identical to the convolution integral or sum except that it refers to the response of an LTI system or can apply to the property of superposition that defines a linear system.

Time-invariant system — A system whose properties do not change with time. When expressed in terms of the impulse response of a time-invariant linear system, this means that the impulse response is a function of a single variable, because the unit impulse function that is applied to give the impulse response can be applied at time zero.

Two-dimensional convolution — The process of convolution applied to signals dependent on two variables, usually spatial.

Further Information

The convolution integral finds application in linear system analysis and signal processing. In the book by Ziemer, Tranter, and Fannin [1998], Chapter 2 is devoted to the convolution integral and its application to continuous-time linear system analysis, whereas Chapter 8 includes material on the discrete-time convolution sum.

The *IEEE Signal Processing Magazine* has tutorial articles on various aspects of signal processing, whereas the *IEEE Transactions on Signal Processing* include research papers on all aspects of signal processing. One notable and timely application of convolution is to wavelet transform theory, which has many potential applications including signal and image compression. The April 1992 issue of the *IEEE Signal Processing Magazine* contains a tutorial article on wavelet transforms.

California State University, Long
Beach

104.1 Response Components

104.2 Internal (Asymptotic) and External (BIBO)
Stability

104.3 Unstable and Marginally Stable Responses

104.4 Structural Integrity and Design Implications

The output response of a linear system has two important components: the zero-state response caused by the input and the zero-input response caused by the initial conditions. It is desirable that each of those responses be well behaved. The speed of an automobile, for example, must provide a comfortable ride for the passengers. The term *stability* refers to how those two response components behave. The following sections define types of stability, relationships between stability types, and methods of determining the type of stability for a given system. Several response examples are provided. Some practical design considerations are given.

104.1 Response Components

Figure 104.1 shows two important response components for a linear system. The **zero-state** component occurs when the initial condition vector x_0 is zero and the input r is nonzero. Conversely, the **zero-input** response occurs when the input r is zero but some part of the initial condition vector x_0 is nonzero. Then, when both inputs are nonzero, the response contains both zero-input and zero-state responses.

Table 104.1 shows the Laplace transform and resulting time response where the zero-state and zero-input responses are defined using classical mathematics (based on transfer functions) and state variable mathematics (based on system matrices). In the time domain the state variable-based description is

$$dx/dt = Ax + Br \quad (104.1)$$

$$y = Cx \quad (104.2)$$

The classical transfer function can be related to the (A, B, C) system by

$$H(s) = Y(s)/R(s) = C[sI - A]^{-1}B \quad (104.3)$$

An important type of zero-state response is the **impulse response** in which the input r is a unit impulse function $\delta(t)$ whose Laplace transform $R(s)$ equals 1. Notice in Table 104.1 the close relationship between the form of the zero-state impulse response $C\Phi(t)B$ and the zero-input response $C\Phi(t)x_0$. Thus stability definitions based on the impulse response bear a close relationship to stability definitions based on the zero-input response.

a. Zero-state response

b. Zero-input response

c. Total response

FIGURE 104.1 Zero-state and zero-input components.

TABLE 104.1 Classical and State Variable Forms for Zero-State and Zero-Input Responses

| | Laplace | Time |
|--------------------------|-------------------------------------|---------------------------------------|
| Zero State | | |
| Classical (general) | $H(s)R(s) = \frac{N(s)}{D(s)}R(s)$ | $\int_0^t h(\tau)r(t-\tau) d\tau$ |
| Classical (impulse) | $H(s)$ | $h(t)$ |
| State variable (general) | $C\Phi(s)BR(s)$ | $\int_0^t \phi(\tau)Br(t-\tau) d\tau$ |
| State variable (impulse) | $C\Phi(s)B$ | $C\phi(t)B$ |
| Zero Input | | |
| Classical | $H_1(s) = \frac{N_1(s, x_0)}{D(s)}$ | $h_1(t)$ |
| State variable | $C\Phi(s)x_0$ | $C\phi(t)x_0$ |

Note: Transfer function = $H(s) = C\Phi(s)B$; resolvent matrix = $H(s) = \Phi(s) = [sI - A]^{-1}$; characteristic polynomial = $D(s) = |sI - A|$; initial state vector = x_0 .

104.2 Internal (Asymptotic) and External (BIBO) Stability

Stability definitions relate either to the zero-input response (**internal stability**) or to the zero-state response (**external stability**). The latter is called *external* because performance depends on the external input as it influences the external output (internal performance is ignored). Table 104.2 contains two commonly used stability definitions: **asymptotic stability** relates to zero-input (internal) stability, whereas the **bounded-input, bounded-output (BIBO)** stability relates to zero-state (external) stability.

Asymptotic stability implies that the zero-input response tends to zero for all initial conditions. A necessary and sufficient condition for asymptotic stability is that all the eigenvalues A are in the left half plane (LHP). BIBO stability implies that all bounded inputs will cause the output to be bounded. A

TABLE 104.2 Stability Definitions for Linear Systems

| Type of Stability | Requirement | Necessary and Sufficient Condition |
|---------------------------------------|---|---|
| Asymptotic (internal) (zero input) | $C\phi(t)x_0 \rightarrow 0$ as $t \rightarrow \infty$ for all x_0 | All eigenvalues of A (closed-loop poles) are in the LHP |
| BIBO (external) (zero state) | If $ r(t) \leq M_1 < \infty$ then $ y(t) \leq M_2 < \infty$ | $\int_0^{\infty} h(t) dt \leq M_2 < \infty$ (all poles of $H(s)$ are in the LHP) |

a. Classical form

b. State variable form

FIGURE 104.2 Condition 1 (BIBO stable but asymptotically unstable).

necessary and sufficient condition for BIBO stability is that the integral of the magnitude of the impulse response is bounded, which occurs if all the poles of $H(s)$ are in the LHP. These two stability definitions will result in different conclusions when there are right half plane (RHP) poles that are cancelled by RHP zeros of $H(s)$, obscuring internal responses that may not be bounded.

Figure 104.2 shows a system in both classical form and state variable form. From either form of the second-order system, notice that the transfer function $H(s) = 1/(s + 3)$ is actually first order, because an RHP pole at -2 is cancelled by an RHP zero at the same location. The impulse response of $y(t)$ is e^{-3t} (whose integral is bounded), causing the system to be BIBO (externally) stable. However, for an impulse input, $X_2(s)$ is $1/(s - 2)$ and $x_2(t)$ is e^{2t} , which is not bounded. An example would be an aircraft with a malfunctioning component that (fortunately) does not influence output response, perhaps velocity, under the current flight condition, which does not activate that component. Should the flight condition change, causing the zero to become -1 , for example, the component is activated, causing $H(s)$ to become $(s - 1)/[(s - 2)(s + 3)]$. Unfortunately, the aircraft velocity would be unbounded, possibly causing the aircraft to crash unless the component is disconnected quickly and control is reestablished.

That potentially undesirable effect is easily revealed by the state variable description

$$A = \begin{bmatrix} -3 & 1 \\ 0 & 2 \end{bmatrix}, \quad B = \begin{bmatrix} 0 \\ 1 \end{bmatrix}, \quad C = [-5 \quad 1] \quad (104.4)$$

Although $H(s) = C[sI - A]^{-1}B = 1/(s + 3)$, passing the test for BIBO stability, the eigenvalues of A are -3 and 2 , failing the test for asymptotic stability.

TABLE 104.3 Equivalence of Stability Types

| Equivalence | Requirement |
|-------------------------------|--|
| Asymptotic \rightarrow BIBO | Always |
| BIBO \rightarrow asymptotic | No cancellation of RHP poles in $H(s)$ |

a. Classical form

b. State variable form

FIGURE 104.3 Condition 2 (BIBO stable and asymptotically stable).

Table 104.3 shows that asymptotic (internal) stability always implies BIBO (external) stability but that BIBO stability implies asymptotic stability only if no RHP poles cancel from the transfer function. For example, Figure 104.3 shows another system in both classical form and state variable form. From either form, notice that $H(s) = 1/(s + 3)$ (no RHP poles cancel this time, just one LHP pole), so the impulse response of $y(t)$ is e^{-3t} (whose integral is bounded), causing the system to be BIBO (externally) stable. Now, for an impulse input, $X_2(s)$ is $1/(s + 2)$ and $x_2(t)$ is e^{-2t} , which is also bounded. From the state variable description,

$$A = \begin{bmatrix} -3 & 1 \\ 0 & -2 \end{bmatrix}, \quad B = \begin{bmatrix} 0 \\ 1 \end{bmatrix}, \quad C = [-1 \quad 1] \quad (104.5)$$

As before, $H(s) = C[sI - A]^{-1}B = 1/(s + 3)$, passing the test for BIBO stability; but now the eigenvalues of A are -3 and -2 , also passing the test for asymptotic stability.

Figure 104.4 shows three stable $H(s)$ functions and the corresponding impulse responses $h(t)$. Respectively, $H(s)$ has one real LHP pole, complex conjugate LHP poles, and double real LHP poles. A bounded input produces a bounded output in each case.

104.3 Unstable and Marginally Stable Responses

A system that does not pass the test for asymptotic stability and/or BIBO stability may be classified as **unstable** or **marginally stable** as regards the appropriate type of stability, as in Table 104.4. As before, BIBO and asymptotic stability may differ if zeros at the same place cancel certain poles of $H(s)$. An unstable system has a BIBO response that is unbounded for all bounded inputs and a zero-input response that diverges for at least one initial condition. A system is unstable in the BIBO sense if there is at least one RHP pole of $H(s)$ and/or there are repeated poles along the imaginary axis (IA). A system is asymptotically unstable if there is at least one RHP eigenvalue of A and/or there are repeated eigenvalues

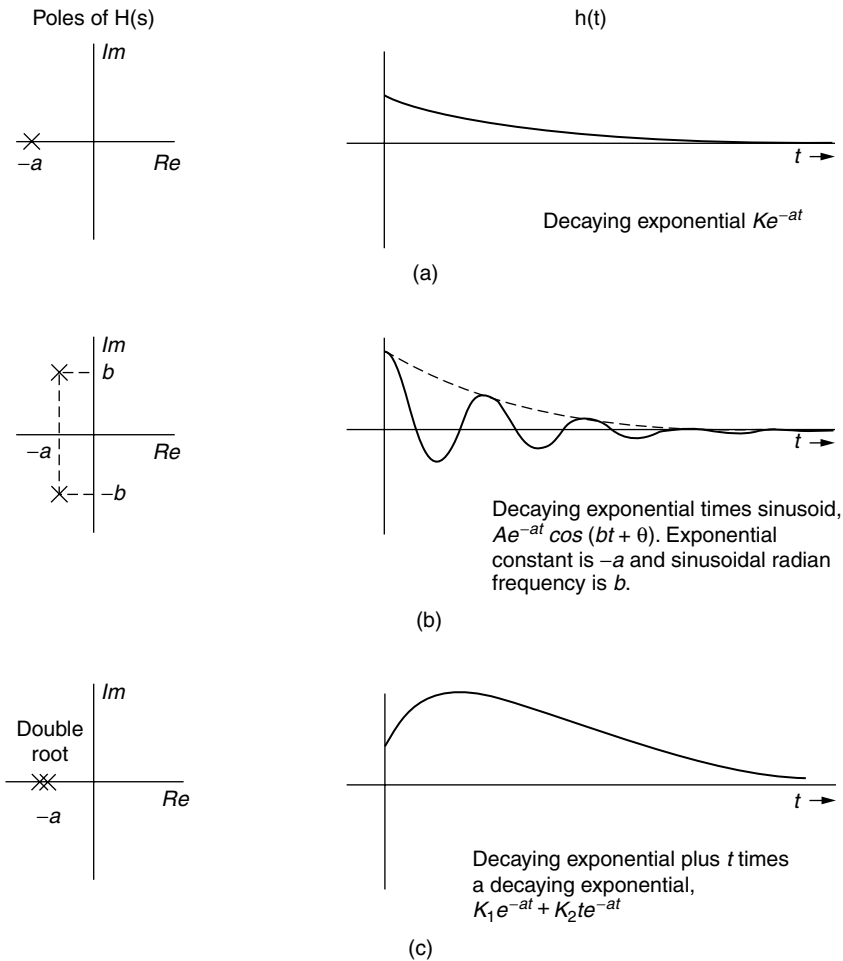

FIGURE 104.4 Impulse response of stable BIBO systems. (Adapted from Stefani, R. T., Savant, C. J., Shahian, B., and Hostetter, G. H. 2002. *Design of Feedback Control Systems*, 4th ed. Oxford University Press, New York.)

TABLE 104.4 Unstable and Marginally Stable Definitions for Linear Systems

| Type of Stability | Requirement | Necessary and Sufficient Condition |
|--------------------------------|---|---|
| Unstable (asymptotic) | $C\phi(t)x_0 \rightarrow \infty$ as $t \rightarrow \infty$ for at least one x_0 | At least one eigenvalue of A in RHP and/or repeated IA |
| Unstable (BIBO) | If $ r(t) \leq M_1 < \infty$ then $ y(t) \rightarrow \infty$ | At least one pole of $H(s)$ in RHP and/or repeated IA |
| Marginally stable (asymptotic) | $C\phi(t)x_0 \rightarrow C_0$ $0 < C_0 < \infty$ as $t \rightarrow \infty$ for all x_0 | One eigenvalue of A at 0 and/or nonrepeated complex conjugated IA; the rest are LHP |
| Marginally stable (BIBO) | For some but not all $ r(t) \leq M_1 < \infty$ then $ y(t) \leq M_2 < \infty$ | One pole of $H(s)$ at 0 and/or nonrepeated complex conjugated IA; the rest are LHP |

along the imaginary axis (IA). Figure 104.5 shows five examples of unstable (BIBO) $H(s)$ functions and the corresponding impulse responses $h(t)$. Respectively, there is one real RHP pole, one pair of complex conjugate RHP poles, double poles at the origin, double complex conjugate poles along the IA and double RHP real poles. Clearly, the impulse response is unbounded in each case. Notice in Figure 104.5(b) and Figure 104.5(d) that although the response goes to zero periodically, the response passes through zero instantaneously and reaches a peak that increases with each cycle.

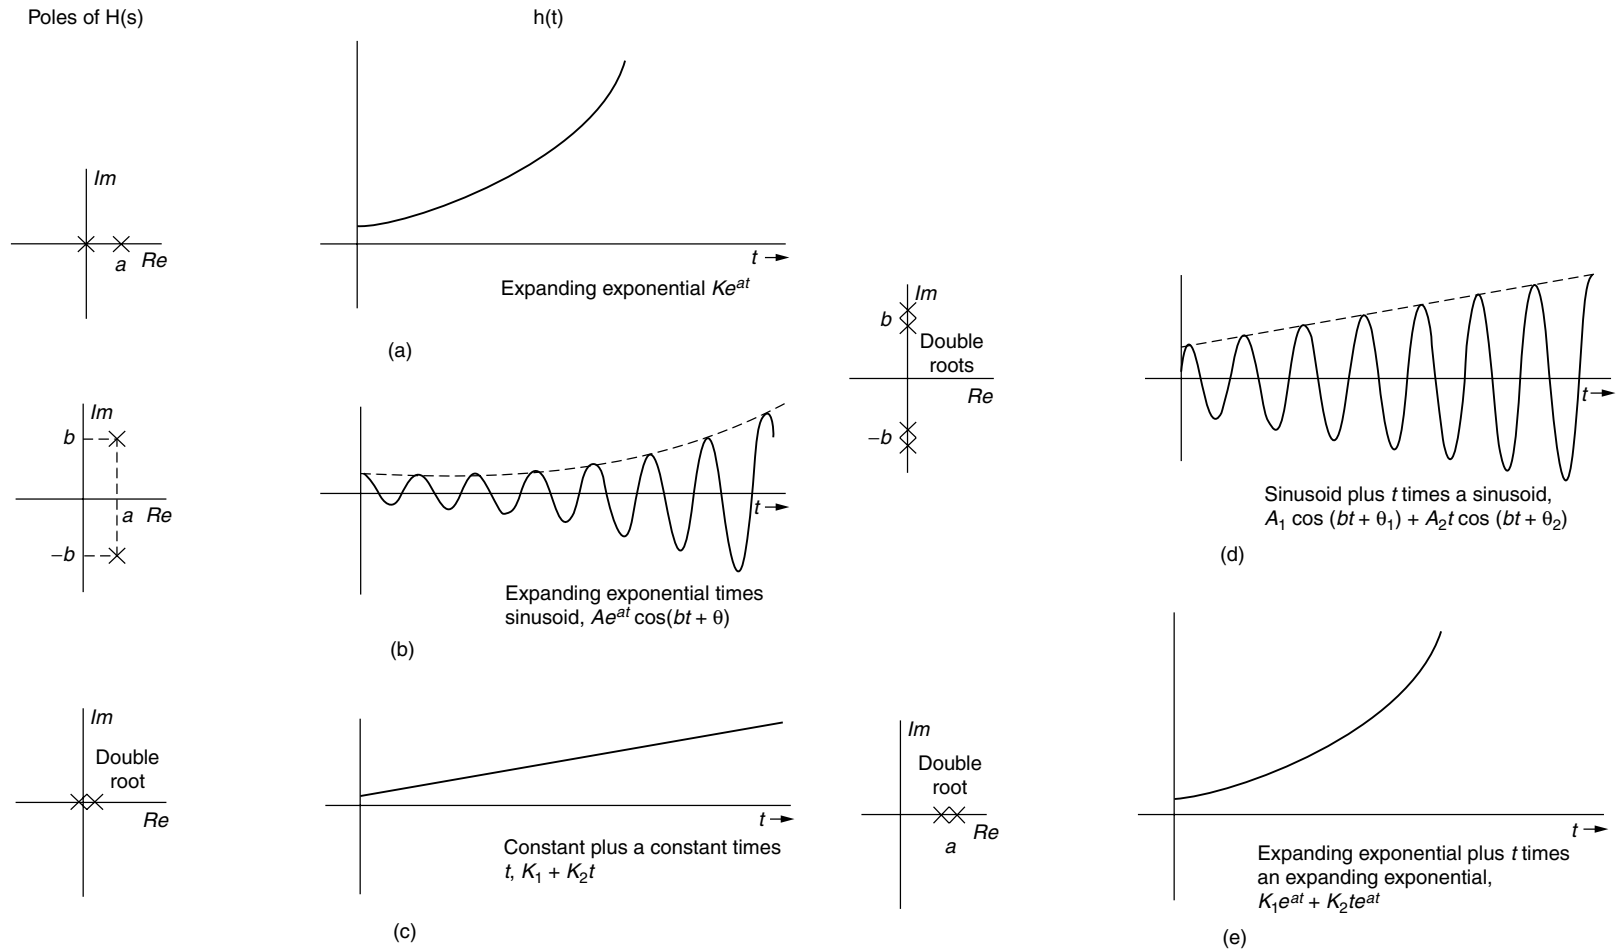

FIGURE 104.5 Impulse response of unstable BIBO systems. (Adapted from Stefani, R. T., Savant, C. J., Shahian, B., and Hostetter, G. H. 2002. *Design of Feedback Control Systems*, 4th ed. Oxford University Press, New York.)

FIGURE 104.6 Impulse response of marginally stable BIBO systems. (Adapted from Stefani, R. T., Savant, C. J., Shahian, B., and Hostetter, G. H. 2002. *Design of Feedback Control Systems*, 4th ed. Oxford University Press, New York.)

A marginally stable system has a BIBO response that is bounded for some inputs but unbounded for others and a zero-input response that is bounded (going neither to zero nor infinity) for all initial conditions. A system is marginally stable for closed loop poles (BIBO) and eigenvalues (asymptotic) that are IA and nonrepeated. Figure 104.6 shows two marginally stable (BIBO) $H(s)$ functions and the corresponding impulse responses $h(t)$. For Figure 104.6(a), $H(s) = 1/s$, so the zero-state impulse response is a constant (which is bounded). However, if the input is a step, the zero-state response becomes $1/s^2$ and the time response for this case is the same as the impulse response in Fig. 104.5(c), which is obviously unbounded. Similarly, the example of Figure 104.6(b) has a bounded sinusoidal impulse response for IA poles of $H(s)$, but if the bounded $r(t)$ is also sinusoidal and the IA poles of $R(s)$ are at the same place as for $H(s)$, then the multiple IA poles of $Y(s)$ create a time response like that of Figure 104.5(d), which is unbounded.

104.4 Structural Integrity and Design Implications

Assuming a bounded input, a stable BIBO system always has a bounded output response. That bounded response can sometimes have a very large and undesirable value when multiple (LHP) poles are present [as in Figure 104.4(c)]. In such cases, even though the output should tend toward zero thereafter, assuming the system operates in a linear region, structural integrity can be compromised, followed by nonlinear behavior. For example, a bridge over Tacoma Narrows collapsed in 1939 because winds created a lift/drag force with an $R(s)$ having poles near the bridge's $H(s)$ poles. Similarly, there are many examples of earthquakes providing a shaking motion having an $R(s)$ with poles near some poles of a structure's $H(s)$. The oscillating vertical motion, with an upper containing envelope similar to Figure 104.4(c), can exceed the structural tolerance and the ensuing failure can have tragic consequences. The design solution is to reinforce the structure, moving the poles of $H(s)$ away from those of $R(s)$, thus maintaining the response within structural limits. An engineer must examine more than just stability when ensuring that a design results in a satisfactory time response.

In summary, it should concern any designer when RHP eigenvalues occur for A . Active control and redesign should then be applied to move the RHP eigenvalues into the LHP, creating a system that is both BIBO and asymptotically stable. If the system is marginally stable from either BIBO or asymptotic

viewpoints, the designer should at least ensure that no input would create an unbounded zero-state response. Again, it is best if active control and redesign creates a system that is asymptotically stable.

Defining Terms

External stability — Stability based on the bounded-input, bounded-output relationship, ignoring the performance of internal states. This stability is based on the poles of the transfer function, which may contain RHP pole cancellations.

Impulse response — The zero-state response of a system to a unit impulse input whose Laplace transform is 1.

Internal stability — Stability based on the performance of all the states of the system, and therefore on all the eigenvalues of the system. This type of stability will differ from external stability if RHP poles cancel from the transfer function.

Marginally stable — For external stability, the response is bounded for some but not all bounded inputs.

Unstable — For external stability, the output is unbounded for all bounded inputs.

Zero input — Response component calculated by setting the input to zero.

Zero state — Response component calculated by setting the initial state to zero.

Rolf Johansson
Lund University

A digital system (or discrete-time system or sampled-data system) is a device such as a digital controller or a digital filter or, more generally, a system intended for digital computer implementation and usually with some periodic interaction with the environment and with a supporting methodology for analysis and design. Of particular importance for modeling and analysis are recurrent algorithms — for example, difference equations in input-output data — and the z transform is important for the solution of such problems.

The **z transform** is being used in the analysis of linear time-invariant systems and discrete-time signals — for example, for digital control or filtering — and may be compared to the Laplace transform as used in the analysis of continuous-time signals and systems, a useful property being that the convolution of two time-domain signals is equivalent to multiplication of their corresponding z transforms. The z transform is important as a means to characterize a linear time-invariant system in terms of its pole-zero locations, its transfer function and Bode diagram, and its response to a large variety of signals. In addition, it provides important relationships between temporal and spectral properties of signals. The z transform generally appears in the analysis of difference equations as used in many branches of engineering and applied mathematics.

105.1 The z Transform

The z transform of the sequence $\{x_k\}_{-\infty}^{+\infty}$ is defined as the generating function

$$X(z) = \mathcal{L}\{x\} = \sum_{k=-\infty}^{\infty} x_k z^{-k} \quad (105.1)$$

where the variable z has the essential interpretation of a forward shift operator so that

$$\mathcal{L}\{x_{k+1}\} = z\mathcal{L}\{x_k\} = zX(z) \quad (105.2)$$

The z transform is an infinite power series in the complex variable z^{-1} where $\{x_k\}$ constitutes a sequence of coefficients. As the z transform is an infinite power series, it exists only for those values of z for which this series converges and the *region of convergence* of $X(z)$ is the set of z for which $X(z)$ takes on a finite value. A sufficient condition for existence of the z transform is convergence of the power series

$$\sum_{k=-\infty}^{\infty} |x_k| \cdot |z^{-k}| < \infty \quad (105.3)$$

The region of convergence for a finite-duration signal is the entire z plane except $z = 0$ and $z = \infty$. For a one-sided infinite-duration sequence $\{x_k\}_{k=0}^{\infty}$, a number r can usually be found so that the power series converges for $|z| > r$. Then, the *inverse z transform* can be derived as

$$x_k = \frac{1}{2\pi i} \oint X(z)z^{k-1} dz \quad (105.4)$$

where the contour of integration encloses all singularities of $X(z)$. In practice it is standard procedure to use tabulated results; some standard z transform pairs are to be found in Table 105.1.

TABLE 105.1 Properties of the z Transform

FIGURE 105.1 A continuous-time signal $x(t)$ and a sampling device that produces a sample sequence $\{x_k\}$.

105.2 Digital Systems and Discretized Data

Periodic sampling of signals and subsequent computation or storing of the results requires the computer to schedule sampling and to handle the resulting sequences of numbers. A measured variable $x(t)$ may be available only as periodic observations of $x(t)$ as sampled with a time interval T (the sampling period). The sample-sequence can be represented as

$$\{x_k\}_{-\infty}^{\infty}; \quad x_k = x(kT) \quad \text{for} \quad k = \dots, -1, 0, 1, 2, \dots \quad (105.5)$$

and it is important to ascertain that the sample sequence adequately represents the original variable $x(t)$; see Figure 105.1. For ideal sampling it is required that the duration of each sampling be very short, and the sampled function may be represented by a sequence of infinitely short impulses $\delta(t)$ (the Dirac impulse). Let the sampled function of time be expressed thus:

$$x_{\Delta}(t) = x(t) \cdot T \sum_{k=-\infty}^{\infty} \delta(t - kT) = x(t) \cdot \sqcup_T(t) \quad (105.6)$$

where

$$\sqcup_T(t) \triangleq T \sum_{k=-\infty}^{\infty} \delta(t - kT) \quad (105.7)$$

and where the sampling period T is multiplied to ensure that the averages over a sampling period of the original variable x and the sampled signal x_{Δ} , respectively, are of the same magnitude. A direct application of the discretized variable $x_{\Delta}(t)$ in Equation (105.6) verifies that the spectrum of x_{Δ} is related to the z transform $X(z)$ as

$$X_{\Delta}(i\omega) = \mathcal{F}\{x(t) \sqcup_T(t)\} = T \sum_{k=-\infty}^{\infty} x_k \exp(-i\omega kT) = TX(e^{i\omega T}) \quad (105.8)$$

Obviously, the original variable $x(t)$ and the sampled data are not identical, and thus it is necessary to consider the distortive effects of discretization. Consider the spectrum of the sampled signal $x_{\Delta}(t)$ obtained as the Fourier transform

$$X_{\Delta}(i\omega) = \mathcal{F}\{x_{\Delta}(t)\} = \mathcal{F}\{x(t)\} * \mathcal{F}\{\sqcup_T(t)\} \quad (105.9)$$

where

$$\mathcal{F}\{\mathbb{1}_{T}(t)\} = \sum_{k=-\infty}^{\infty} \delta\left(\omega - \frac{2\pi}{T}k\right) = \frac{T}{2\pi} \mathbb{1}_{2\pi/T}(\omega) \quad (105.10)$$

so that

$$X_{\Delta}(i\omega) = \mathcal{F}\{x(t)\} * \mathcal{F}\{\mathbb{1}_{T}(t)\} = \sum_{k=-\infty}^{\infty} X\left[i\left(\omega - \frac{2\pi}{T}k\right)\right] \quad (105.11)$$

Thus, the Fourier transform X_{Δ} of the sampled variable has a periodic extension of the original spectrum $X(i\omega)$ along the frequency axis with a period equal to the sampling frequency $\omega_s = 2\pi/T$. There is an important result based on this observation known as the *Shannon sampling theorem*, which states that the continuous-time variable $x(t)$ may be reconstructed from the samples $\{x_k\}_{-\infty}^{+\infty}$ if and only if the sampling frequency is at least twice that of the highest frequency for which $X(i\omega)$ is nonzero. The original variable $x(t)$ may thus be recovered as

$$x(t) = \sum_{k=-\infty}^{\infty} x_k \frac{\sin \frac{\pi}{T}(t-kT)}{\frac{\pi}{T}(t-kT)} \quad (105.12)$$

The formula given in Equation (105.12) is called *Shannon interpolation*, which is often quoted though it is valid only for infinitely long data sequences and though it would require a noncausal filter to reconstruct the continuous-time signal $x(t)$ in real-time operation. The frequency $\omega_n = \omega_s/2 = \pi/T$ is called the *Nyquist frequency* and indicates the upper limit of distortion-free sampling. A nonzero spectrum beyond this limit leads to interference between the sampling frequency and the sampled signal (*aliasing*); see [Figure 105.2](#).

The Discrete Fourier Transform

Consider a finite length sequence $\{x_k\}_{k=0}^{N-1}$ that is zero outside the interval $0 \leq k \leq N-1$. Evaluation of the z transform $X(z)$ at N equally spaced points on the unit circle $z = \exp(i\omega_k T) = \exp[i(2\pi/NT)kT]$ for $k = 0, 1, \dots, N-1$ defines the *discrete Fourier transform* (DFT) of a signal x with a sampling period h and N measurements

$$X_k = \text{DFT}\{x(kT)\} = \sum_{l=0}^{N-1} x_l \exp(-i\omega_k lT) = X(e^{i\omega_k T}) \quad (105.13)$$

Notice that the discrete Fourier transform $\{X_k\}_{k=0}^{N-1}$ is only defined at the discrete frequency points

$$\omega_k = \frac{2\pi}{NT}k, \quad \text{for } k = 0, 1, \dots, N-1 \quad (105.14)$$

In fact, the discrete Fourier transform adapts the Fourier transform and the z transform to the practical requirements of finite measurements. Similar properties hold for the discrete Laplace transform with $z = \exp(sT)$, where s is the Laplace transform variable.

FIGURE 105.2 Illustration of aliasing appearing during sampling of a sinusoid $x(t) = \sin 2\pi \cdot 0.9 t$ at the insufficient sampling frequency 1 Hz (sampling period $T = 1$) (*upper graph*). The sampled signal exhibits aliasing with its major component similar to a signal $x(t) = \sin 2\pi \cdot 0.1 t$ sampled with the same rate (*lower graph*).

105.3 The Transfer Function

Consider the following discrete-time linear system with input sequence $\{u_k\}$ (stimulus) and output sequence $\{y_k\}$ (response). The dependency of the output of a linear system is characterized by the convolution-type equation and its z transform,

$$y_k = \sum_{m=0}^{\infty} h_m u_{k-m} + v_k = \sum_{m=-\infty}^k h_{k-m} u_m + v_k, \quad k = \dots, -1, 0, 1, 2, \dots \quad (105.15)$$

$$Y(z) = H(z)U(z) + V(z)$$

where the sequence $\{v_k\}$ represents some external input of errors and disturbances and with $Y(z) = \mathcal{L}\{y\}$, $U(z) = \mathcal{L}\{u\}$, $V(z) = \mathcal{L}\{v\}$ as output and inputs. The *weighting function* $h(kT) = \{h_k\}_{k=0}^{\infty}$, which is zero for negative k and for reasons of causality is sometimes called *pulse response* of the digital system (compare *impulse response* of continuous-time systems). The pulse response and its z transform, the *pulse transfer function*,

$$H(z) = \mathcal{L}\{h(kT)\} = \sum_{k=0}^{\infty} h_k z^{-k} \quad (105.16)$$

determine the system's response to an input $U(z)$; see [Figure 105.3](#). The pulse transfer function $H(z)$ is obtained as the ratio

FIGURE 105.3 Block diagram with an assumed transfer function relationship $H(z)$ between input $U(z)$, disturbance $V(z)$, intermediate $X(z)$, and output $Y(z)$.

$$H(z) = \frac{X(z)}{U(z)} \quad (105.17)$$

and provides the frequency domain input-output relation of the system. In particular, the Bode diagram is evaluated as $|H(z)|$ and $\arg H(z)$ for $z = \exp(i\omega_k T)$ and for $|\omega_k| < \omega_n = \pi/T$ — that is, when $H(z)$ is evaluated for frequency points up to the Nyquist frequency ω_n along the unit circle.

State–Space Systems

Alternatives to the input-output representations by means of transfer functions are the state–space representations. Consider the following finite dimensional discrete state–space equation with a state vector $x_k \in \mathbb{R}^n$, input $u_k \in \mathbb{R}^p$, and observations $y_n \in \mathbb{R}^m$.

$$\begin{cases} x_{k+1} = \Phi x_k + \Gamma u_k, \\ y_k = C x_k + D u_k \end{cases}, \quad k = 0, 1, \dots \quad (105.18)$$

with the pulse transfer function

$$H(z) = C(zI - \Phi)^{-1} \Gamma + D \quad (105.19)$$

and the output variable

$$Y(z) = C \sum_{k=0}^{\infty} \Phi^k z^{-k} x_0 + H(z)U(z) \quad (105.20)$$

where possible effects of initial conditions x_0 appear as the first term. Notice that the initial conditions x_0 can be viewed as the net effects of the input in the time interval $(-\infty, 0)$.

105.4 Digital Systems Described by Difference Equations (ARMAX Models)

An important class of nonstationary stochastic processes is one in which some deterministic response to an external input and a stationary stochastic process are superimposed. This is relevant, for instance, when the external input cannot be effectively described by some probabilistic distribution. A discrete-time model can be formulated in the form of a difference equation with an external input $\{u_k\}$ that is usually considered to be known:

$$y_k = -a_1 y_{k-1} - \dots - a_n y_{k-n} + b_1 u_{k-1} + \dots + b_n u_{k-n} + w_k + c_1 w_{k-1} + \dots + c_n w_{k-n} \quad (105.21)$$

Application of the z transform permits formulation of Equation (105.21) as

$$A(z^{-1})Y(z) = B(z^{-1})U(z) + C(z^{-1})W(z) \quad (105.22)$$

where

$$\begin{aligned} A(z^{-1}) &= 1 + a_1 z^{-1} + \cdots + a_n z^{-n} \\ B(z^{-1}) &= 1 + b_1 z^{-1} + \cdots + b_n z^{-n} \\ C(z^{-1}) &= 1 + c_1 z^{-1} + \cdots + c_n z^{-n} \end{aligned} \quad (105.23)$$

Stochastic models including the A polynomial, according to Equation (105.22) and Equation (105.23), are known as **autoregressive models** (AR), and models including the C polynomial are known as **moving-average** models (MA), whereas the B polynomial determines the effects of the external input (X). Notice that the term *moving average* is here somewhat misleading, as there is no restriction that the coefficients should add to 1 or that the coefficients are nonnegative. An alternative description is *finite impulse response* or *all-zero filter*.

Thus, the full model of Equation (105.22) is an **autoregressive moving average model** with external input (ARMAX) and its pulse transfer function $H(z) = B(z^{-1})/A(z^{-1})$ is stable if and only if the *poles* — that is, the complex numbers z_1, \dots, z_n solving the equation $A(z^{-1}) = 0$ — are strictly inside the unit circle, that is, $|z_i| < 1$. The *zeros* of the system — that is, the complex numbers z_1, \dots, z_n solving the equation $B(z^{-1}) = 0$ — may take on any value without any instability arising, although it is preferable to obtain zeros located strictly inside the unit circle, that is, $|z_i| < 1$ (*minimum-phase zeros*). By linearity, $\{y_k\}$ can be separated into one purely deterministic process $\{x_k\}$ and one purely stochastic process $\{v_k\}$:

$$\begin{cases} A(z^{-1})X(z) = B(z^{-1})U(z) \\ A(z^{-1})V(z) = C(z^{-1})W(z) \end{cases} \quad \text{and} \quad \begin{cases} y_k = x_k + v_k \\ Y(z) = X(z) + V(z) \end{cases} \quad (105.24)$$

The type of decomposition [Equation (105.24)] that separates the deterministic and stochastic processes is known as the *Wold decomposition*.

105.5 Prediction and Reconstruction

Consider the problem of predicting the output d steps ahead when the output $\{y_k\}$ is generated by the ARMA model,

$$A(z^{-1})Y(z) = C(z^{-1})W(z) \quad (105.25)$$

which is driven by a zero-mean white noise $\{w_k\}$ with covariance $\mathcal{E}\{w_i w_j\} = \sigma_w^2 \delta_{ij}$. In other words, assuming that observations $\{y_k\}$ are available up to the present time, how should the output d steps ahead be predicted optimally? Assume that the polynomials $A(z^{-1})$ and $C(z^{-1})$ are mutually prime with no zeros for $|z| \geq 1$. Let the C polynomial be expanded according to the *Diophantine equation*,

$$C(z^{-1}) = A(z^{-1})F(z^{-1}) + z^{-d} G(z^{-1}) \quad (105.26)$$

which is solved by the two polynomials

$$\begin{aligned} F(z^{-1}) &= 1 + f_1 z^{-1} + \cdots + f_{n_f} z^{-n_f}, & n_f &= d - 1 \\ G(z^{-1}) &= g_0 + g_1 z^{-1} + \cdots + g_{n_g} z^{-n_g}, & n_g &= \max(n_A - 1, n_C - d) \end{aligned} \quad (105.27)$$

Interpretation of z^{-1} as a *backward shift operator* and application of Equation (105.25) and Equation (105.26) permit the formulation

$$y_{k+d} = F(z^{-1})w_{k+d} + \frac{G(z^{-1})}{C(z^{-1})}y_k \quad (105.28)$$

Let us, by $\hat{y}_{k+d|k}$, denote linear d -step predictors of y_{k+d} based upon the measured information available at time k . As the zero-mean term $F(z^{-1})w_{k+d}$ of Equation (105.28) is unpredictable at time k , it is natural to suggest the following d -step predictor

$$\hat{y}_{k+d|k} = \frac{G(z^{-1})}{C(z^{-1})}y_k \quad (105.29)$$

The prediction error satisfies

$$\begin{aligned} \varepsilon_{k+d} &= (\hat{y}_{k+d|k} - y_{k+d}) \\ &= \frac{G(z^{-1})}{C(z^{-1})}y_k - \frac{A(z^{-1})F(z^{-1}) + z^{-d}G(z^{-1})}{C(z^{-1})}y_{k+d} \\ &= -F(z^{-1})w_{k+d} \end{aligned} \quad (105.30)$$

Let $\mathcal{E}\{\cdot|\mathcal{F}_k\}$ denote the *conditional mathematical expectation* relative to the measured information available at time k . The conditional mathematical expectation and the covariance of the d -step prediction relative to available information at time k is

$$\begin{aligned} \mathcal{E}\{\hat{y}_{k+d|k} - y_{k+d}|\mathcal{F}_k\} &= \mathcal{E}\{-F(z^{-1})w_{k+d}|\mathcal{F}_k\} = 0 \\ \mathcal{E}\{(\hat{y}_{k+d|k} - y_{k+d})^2|\mathcal{F}_k\} &= \mathcal{E}\{[-F(z^{-1})w_{k+d}]^2|\mathcal{F}_k\} \\ &= \mathcal{E}\{(w_{k+d} + f_1w_{k+d-1} + \dots + f_{d-1}w_{k+1})^2|\mathcal{F}_k\} \\ &= (1 + f_1^2 + \dots + f_{n_f}^2)\sigma_w^2 = 0 \end{aligned} \quad (105.31)$$

It follows that the predictor of Equation (105.29) is unbiased and that the prediction error only depends on future, unpredictable noise components. It is straightforward to show that the predictor of Equation (105.29) achieves the lower bound of Equation (105.31) and that the predictor of Equation (105.29) is optimal in the sense that the prediction error variance is minimized.

Example 105.1 — An Optimal Predictor for a First-Order Model

Consider for the first-order ARMA model

$$y_{k+1} = -a_1y_k + w_{k+1} + c_1w_k \quad (105.32)$$

The variance of a one-step-ahead predictor $\mathcal{E}\{\hat{y}_k$ is

$$\begin{aligned} \mathcal{E}\{(\hat{y}_{k+1|k} - y_{k+1})^2|\mathcal{F}_k\} &= \mathcal{E}\{(\hat{y}_{k+1|k} + a_1y_k - c_1w_k)^2|\mathcal{F}_k\} + \mathcal{E}\{w_{k+1}^2|\mathcal{F}_k\} \\ &= \mathcal{E}\{(\hat{y}_{k+1|k} + a_1y_k - c_1w_k)^2|\mathcal{F}_k\} + \sigma_w^2 \geq \sigma_w^2 \end{aligned} \quad (105.33)$$

The optimal predictor satisfying the lower bound in Equation (105.33) is obtained from Equation (105.33) as

$$\hat{y}_{k+1|k}^o = -a_1 y_k + c_1 w_k \quad (105.34)$$

which, unfortunately, is not realizable as it stands because w_k is not available to measurement. Therefore, the noise sequence $\{w_k\}$ has to be substituted by some function of the observed variable $\{y_k\}$, and Equation (105.25) suggests that $W(z)$ be chosen by the filtering relationship $C^{-1}(z^{-1})A(z^{-1})Y(z)$ which, in turn, gives Equation (105.29). Accordingly, a linear predictor is

$$\hat{y}_{k+1|k} = \frac{G(z^{-1})}{C(z^{-1})} y_k = \frac{c_1 - a_1}{1 + c_1 z^{-1}} y_k \quad (105.35)$$

105.6 The Kalman Filter

Consider the linear state-space model

$$\begin{aligned} x_{k+1} &= \Phi x_k + v_k, \quad x_k \in \mathbb{R}^n \\ y_k &= C x_k + w_k, \quad y_k \in \mathbb{R}^m \end{aligned} \quad (105.36)$$

where $\{v_k\}$ and $\{w_k\}$ are assumed to be independent zero-mean white-noise processes with covariances Σ_v and Σ_w , respectively. It is assumed that $\{y_k\}$ but not $\{x_k\}$ is available to measurement and that it is desirable to predict $\{x_k\}$ from measurements of $\{y_k\}$.

Introduce the state predictor,

$$\begin{aligned} \hat{x}_{k+1|k} &= \Phi \hat{x}_{k|k-1} - K_k (\hat{y}_k - y_k), \quad \hat{x}_{k|k-1} \in \mathbb{R}^n \\ \hat{y}_k &= C \hat{x}_{k|k-1}, \quad y_k \in \mathbb{R}^m \end{aligned} \quad (105.37)$$

The predictor of Equation (105.37) has the same dynamics matrix Φ as the state-space model of Equation (105.36) and, in addition, there is a correction term $K_k (\hat{y}_k - y_k)$ with a factor K_k to be chosen. The prediction error is

$$\tilde{x}_{k+1|k} = \hat{x}_{k+1|k} - x_{k+1} \quad (105.38)$$

The prediction-error dynamics is

$$\tilde{x}_{k+1} = (\Phi - K_k C) \tilde{x}_k + v_k - K_k w_k \quad (105.39)$$

The mean prediction error is governed by the recursive equation

$$\mathcal{E}\{\tilde{x}_{k+1}\} = (\Phi - K_k C) \mathcal{E}\{\tilde{x}_k\} \quad (105.40)$$

and the mean square error of the prediction error is governed by

$$\begin{aligned} \mathcal{E}\{\tilde{x}_{k+1} \tilde{x}_{k+1}^T\} &= \mathcal{E}\{[(\Phi - K_k C) \tilde{x}_k + v_k - K_k w_k][(\Phi - K_k C) \tilde{x}_k + v_k - K_k w_k]^T\} \\ &= (\Phi - K_k C) \mathcal{E}\{\tilde{x}_k \tilde{x}_k^T\} (\Phi - K_k C)^T + \Sigma_v + K_k \Sigma_w K_k^T \end{aligned} \quad (105.41)$$

If we denote

$$\begin{aligned} P_k &= \mathcal{E}\{\tilde{x}_k \tilde{x}_k^T\} \\ Q_k &= \Sigma_w + CP_k C^T \end{aligned} \quad (105.42)$$

then Equation (105.41) is simplified to

$$P_{k+1} = \Phi P_k \Phi^T - K_k C P_k \Phi - \Phi^T P_k C^T K_k^T + \Sigma_v + K_k Q_k K_k^T \quad (105.43)$$

By completing squares of terms containing K_k we find

$$P_{k+1} = \Phi P_k \Phi^T + \Sigma_v - \Phi P_k C^T Q_k^{-1} C P_k \Phi^T + (K_k - \Phi P_k C^T Q_k^{-1}) Q_k (K_k - \Phi P_k C^T Q_k^{-1})^T \quad (105.44)$$

where only the last term depends on K_k . Minimization of P_{k+1} can be done by choosing K_k such that the positive semidefinite K_k -dependent term in Equation (105.44) disappears. Thus P_{k+1} achieves its lower bound for

$$K_k = \Phi P_k C^T (\Sigma_w + C P_k C^T)^{-1} \quad (105.45)$$

and the *Kalman filter* (or *Kalman–Bucy filter* for continuous-time systems) takes the form

$$\begin{aligned} \hat{x}_{k+1|k} &= \Phi \hat{x}_{k|k-1} - K_k (\hat{y}_k - y_k) \\ \hat{y}_k &= C \hat{x}_{k|k-1} \\ K_k &= \Phi P_k C^T (\Sigma_w + C P_k C^T)^{-1} \\ P_{k+1} &= \Phi P_k \Phi^T + \Sigma_v - \Phi P_k C^T (\Sigma_w + C P_k C^T)^{-1} C P_k \Phi^T \end{aligned} \quad (105.46)$$

which is the optimal predictor in the sense that the mean square error [Equation (105.41)] is minimized in each step.

Example 105.2 — Kalman Filter for a First-Order System

Consider the state–space model

$$\begin{aligned} x_{k+1} &= 0.95x_k + v_k \\ y_k &= x_k + w_k \end{aligned} \quad (105.47)$$

where $\{v_k\}$ and $\{w_k\}$ are zero-mean white-noise processes with covariances $\mathcal{E}\{v_k^2\}=1$ and $\mathcal{E}\{w_k^2\}=1$, respectively.

The Kalman filter takes on the form

$$\begin{aligned} \hat{x}_{k+1|k} &= 0.95 \hat{x}_{k|k-1} - K_k (\hat{x}_{k|k-1} - y_k) \\ K_k &= \frac{0.95 P_k}{1 + P_k} \\ P_{k+1} &= 0.95^2 P_k + 1 - \frac{0.95^2 P_k^2}{1 + P_k} \end{aligned} \quad (105.48)$$

FIGURE 105.4 Kalman filter applied to one-step-ahead prediction of x_{k+1} in Equation (105.47). The observed variable $\{y_k\}$, the state $\{x_k\}$, and the predicted state $\{\hat{x}_k\}$, the estimated variance $\{P_k\}$ and $\{K_k\}$, and the prediction error $\{\tilde{x}_k\}$ are shown in a 100-step realization of the stochastic process. (Source: Johansson, R. 1993. *System Modeling and Identification*, Prentice Hall, Englewood Cliffs, NJ.)

The result of one such realization is shown in Figure 105.4.

Defining Terms

Autoregressive model (AR) — An autoregressive time series of order n is defined via $y_k = -\sum_{m=1}^n a_m y_{k-m} + w_k$. The sequence $\{w_k\}$ is usually assumed to consist of zero-mean identically distributed stochastic variables w_k .

Autoregressive moving average model (ARMA). An autoregressive moving average time series of order n is defined via $y_k = -\sum_{m=1}^n a_m y_{k-m} + \sum_{m=0}^n c_m w_{k-m}$. The sequence $\{w_k\}$ is usually assumed to consist of zero-mean identically distributed stochastic variables w_k .

Discrete Laplace transform. The discrete Laplace transform is counterpart to the Laplace transform with application to discrete signals and systems. The discrete Laplace transform is obtained from the z transform by means of the substitution $z = \exp(sT)$, where T is the sampling period.

Moving average process (MA). A moving average time series of order n is defined via $y_k = \sum_{m=0}^n c_m w_{k-m}$. The sequence $\{w_k\}$ is usually assumed to consist of zero-mean identically distributed stochastic variables w_k .

Rational model — AR, MA, ARMA, and ARMAX are commonly referred to as rational models.

Time series — A sequence of random variable $\{y_k\}$, where k belongs to the set of positive and negative integers.

z transform — A generating function applied to sequences of data and evaluated as a function of the complex variable z with interpretation of frequency.

Further Information

Early theoretical efforts developed in connection with servomechanisms and radar applications [Hurewicz, 1947]. Tsytkin [1950] introduced the discrete Laplace transform, and the formal z transform definition was introduced by Ragazzini and Zadeh [1952] with further developments by Jury [1956]. Much of prediction theory was originally developed by Kolmogorov [1939] and Wiener [1949], whereas state-space methods were forwarded by Kalman and Bertram [1958]. Pioneering textbooks on time-series analysis and spectrum analysis are provided by Box and Jenkins [1970] and Jenkins and Watts [1968].

Passive Components

Henry Domingos
Clarkson University

106.1 Resistors
106.2 Capacitors
106.3 Inductors

Passive components such as resistors, capacitors, and inductors can be an integral part of a more complex unit such as an operational amplifier, digital integrated circuit, or microwave circuit. However, this chapter deals with discrete components purchased as individual parts. Their importance lies in the fact that virtually every piece of electronic equipment incorporates a multitude of discrete passive components, and sale of these components parallels the fortunes of the electronics industry as a whole.

Although passive components have been in use for hundreds of years, one should not assume they represent a static industry: There is a continuing evolution in the design and fabrication of these parts to make them smaller and cheaper with better performance and better reliability. In fact, the useful life of modern components exceeds by far that of the electronic equipment in which they are used. Failure is more often the result of misapplication. The continuous improvement in quality, price, performance, and general usefulness contributes to greater convenience and functionality for consumers at a lower and lower price.

106.1 Resistors

Resistance is a property of a device that relates the current through the device with the voltage or electric potential across it. It is a dissipative property in that energy is converted from electrical energy to heat. The resistance of a device is directly related to the **resistivity** of the material of which it is composed. The resistivity is a relative property that varies from that of good conductors such as aluminum or copper (resistivity $\approx 10^{-6}$ ohm-cm) to semiconductors such as silicon ($\approx 10^{-3} - 10^{+3}$ ohm-cm) to that of good insulators such as alumina ($\approx 10^{14}$ ohm-cm). The resistance of a device is determined by its resistivity and its geometry. [Figure 106.1](#) and Equation (106.1) show the relationship for objects of uniform resistivity and cross-sectional area.

$$R = \rho \frac{L}{A} \quad (106.1)$$

In Equation (106.1), R is the resistance in ohms, ρ is the resistivity in ohm-cm, L is the length in cm, and A is the cross-sectional area in cm^2 . For example, #12 AWG copper wire has a diameter of 0.0808 in. and a resistivity of $1.724 \cdot 10^{-6}$ ohm-cm. Using Equation (106.1) and converting units as appropriate, the resistance of 1000 feet of wire is 1.588 ohms.

FIGURE 106.1 The resistance of a conductor with uniform resistivity and cross-section is given by Equation (106.1).

When resistive films are deposited on substrates or impurities are implanted in layers in silicon devices, the resistivity is not uniform and/or the thickness of the layer may not be known accurately. It is convenient then to define a **sheet resistance** that takes into account the average resistivity and the thickness so that the resistance is given by

$$R = R_s \frac{L}{W} \quad (106.2)$$

where R_s is the sheet resistance in ohms per square (the “square” is dimensionless), L is the length of the film, and W its width. Suppose, for example, a resistor ink is silk-screened onto a ceramic substrate and fired so that its sheet resistance is 100 ohms per square. If the width of the resistor is 10 mil (a mil is one one-thousandth of an inch), the length required to make a 1500-ohm resistor is, from Equation (106.2), $L = 150$ mil.

Using the concepts of resistivity and sheet resistance, a discrete resistor can be fabricated in a variety of ways. The common types are carbon composition resistors, wire-wound resistors, and film resistors. Carbon composition resistors were at one time the most popular type. They are low priced, high in reliability, and available in a wide range of resistance values. The drawbacks are poor long-term stability and tolerance of only 5% or larger. The resistor is fabricated from a silica-loaded resin with resistivity controlled by the addition of carbon particles. Axial leads are inserted and the outer shell, of the same material as the core, minus the carbon granules, insulates the assembly.

Wire-wound resistors are power wire wounds or precision wire wounds. In either case the resistance wire is either a nickel-chromium alloy with a resistivity of $1.33 \cdot 10^{-4}$ ohm-cm for high resistance values, or a copper-nickel alloy with a resistivity of $5 \cdot 10^{-5}$ ohm-cm for lower resistances. Power wire wounds are intended to operate at higher power dissipation and are composed of single layers of bare wire with substrates and packages of high-temperature materials. Precision resistors are stable, highly accurate components. The wire is multilayered, and therefore must be insulated, and all materials can be low temperature. The main disadvantages of wire-wound resistors are the high cost and low operating frequency.

Film-type resistors are made from various resistive materials deposited on an insulating substrate. Film thicknesses range from 0.005 micrometers deposited by evaporation for precision film resistors to as much as 100 micrometers deposited as a resistive ink. Sheet resistances range from 10 to 10,000 ohms per square. The final resistance value can be adjusted by cutting a spiral path through the resistive film until the desired value is reached. The resistors are stable, accurate, and low cost and are the most popular types today. Resistor networks, chip resistors, and film resistors deposited directly on a hybrid substrate provide a wide selection of styles.

The important specifications for a resistor are the resistance value, the tolerance, and the power rating. For carbon composition resistors the resistance value and tolerance are indicated by the familiar color code in [Table 106.1](#). Values range from 1 ohm to 100 megohms. Power rating ranges from 1/20 to 2 W. The power rating is somewhat misleading since the temperature rise is the crucial variable, not the power dissipation. A 2 W resistor cannot dissipate 2 W if it is conformably coated and situated where cooling

FIGURE 106.2 At high frequencies, the effects of parasitic capacitance and inductance of a resistor must be accounted for. This shows one possible equivalent representation.

air is restricted. On the other hand, if a suitable heat sink is provided and forced air cooling is available, the rating could be higher than specified. Under pulse conditions, the instantaneous power can be orders of magnitude larger than its nominal rating.

No resistance is ideal, and over wide frequency ranges the parasitic inductance and capacitance limit the usefulness. Figure 106.2 shows a common equivalent circuit for a resistor. The series inductance can be large for wire-wound resistors and limits their usefulness to frequencies less than about 50 to 100 kHz. For other resistors the leads constitute the main source of inductance, estimated to be of the order of 20 nH per inch. In general, low values of resistance and thin films tend to have lower inductance. Capacitance tends to dominate at high frequencies and with higher values of resistance. Figure 106.3 illustrates typical variation of impedance of a resistor with frequency.

Other resistor characteristics include temperature coefficient, voltage coefficient, stability, and noise. For a discussion of these the reader is referred to Dorf [1993] and Harper [1977].

106.2 Capacitors

Capacitance is a property that exists between two conductors separated by a **dielectric**. With equal but opposite charges on the two conductors a potential difference can be measured between them, and the capacitance is defined by the equation

$$C = \frac{Q}{V} \tag{106.3}$$

FIGURE 106.3 Variation of total impedance of a resistor with frequency for a typical film resistor.

C is the capacitance in farads, Q is the magnitude of the charge on either plate in coulombs, and V is the voltage between the plates in volts. The capacitance in the ideal case of two plane-parallel plates is given by

$$C = \epsilon \frac{A}{d} \quad (106.4)$$

where ϵ is the **permittivity** of the dielectric in farads per meter, A is the area of each plate in meters squared, and d is the plate separation in meters. ϵ is equal to $\epsilon_r \epsilon_0$, where ϵ_r is the relative permittivity (sometimes referred to as the *dielectric constant*, k) = 1 for vacuum, ≈ 1 for air, and ranging from 2 to 10 for common dielectrics. ϵ_0 is the permittivity of free space, equal to $8.854 \cdot 10^{-12}$ farads per meter. All **capacitors** use appropriate values of ϵ , A , and d in Equation (106.4) to achieve the wide range of values available in commercial capacitors.

The constitutive relationship between voltage and current in a capacitor is

$$v(t) = v_0 + \frac{1}{C} \int_0^t i \, dt \quad (106.5)$$

where $v(t)$ is the instantaneous voltage across the capacitor, v_0 is the initial voltage on the capacitor at $t = 0$, and i is the instantaneous current through the capacitor. By differentiating Equation (106.5),

$$i(t) = C \frac{dv}{dt} \quad (106.6)$$

Unlike a resistor, an ideal capacitor does not dissipate energy. Instead, it accumulates energy during the charging process and releases energy to the electrical circuit as it discharges. The energy stored on a capacitor is given by

$$W = \frac{1}{2} CV^2 = \frac{1}{2} \frac{Q^2}{V} \quad (106.7)$$

where W is in joules.

There are two main classes of capacitors — electrolytic and electrostatic. Electrolytic capacitors include aluminum and tantalum types, used in applications where large capacitance values are needed. Electrostatic

capacitors include plastic, ceramic disk, ceramic chip, mica, and glass. Aluminum electrolytics are constructed from high-purity aluminum foils that are chemically etched to increase the surface area, then anodized to form the dielectric. The thickness of this anodized layer determines the voltage rating of the capacitor. If only one foil is anodized, the capacitor is a polarized unit, and the instantaneous voltage cannot be allowed to reverse polarity. Porous paper separates the two foils and is saturated with a liquid electrolyte; therefore, the unit must be sealed, and leakage is a common failure mode. During extended periods of storage, the anodized layer may partially dissolve, requiring the unit to be reformed before rated voltage can be applied. Aluminum electrolytics exhibit a large series inductance, which limits the useful range of frequencies to about 20 kHz. They also have a large leakage current. Nevertheless, because of low cost and very large values of capacitance (up to 1 F), they are a popular choice for filtering applications.

Tantalum electrolytics are available in foil, wet slug, and solid varieties. All types require a tantalum electrode to be anodized, but the means used to make electrical contact to the plates differs in each case. The overall characteristics are superior to those of aluminum, but the cost is greater. Because of their small physical size and large capacitance, they are used for the same applications as aluminum electrolytics.

The common type of plastic capacitor is the metalized film type, made by vacuum deposition of aluminum a fraction of a micron thick directly onto a plastic dielectric film. Common film types include polyester, polycarbonate, polypropylene, and polysulfone. Although the relative permittivity is low, the films can be made extremely thin, resulting in a large capacitance per unit volume. This type of capacitor exhibits an interesting self-healing feature. If breakdown should happen to occur — for instance, at a defect in the film or during a momentary electrical overstress — the metalization around the breakdown site will act like a fuse and vaporize, clearing the breakdown and restoring operation to an equal or higher voltage capability.

Plastic film capacitors have good electrical characteristics and are capable of operation at higher voltages and much higher frequencies than are electrolytic capacitors. They have found wide application in filtering, bypassing, coupling, and noise suppression.

Ceramic capacitors employ ferroelectric dielectrics — commonly, barium titanate — that have an extremely high relative permittivity, 200 to 100,000. For disk capacitors the appropriate combination of powders is mixed, pressed into disks, and sintered at high temperatures. Electrodes are silk-screened on, leads are attached, and a protective coating applied. By varying the area, thickness (limited, to maintain mechanical strength), and especially the dielectric formulation, wide ranges of capacitance value are achieved. Very high voltage capability is also an option that can be achieved by increasing the thickness.

Ceramic chip capacitors are made from a slurry containing the dielectric powder and cast onto stainless-steel or plastic belts. After drying, electrodes are printed on the sheets, which are then arranged in a stack and fired. Electrodes are attached and the unit is encapsulated. By adjusting the number of plates and the plate area, a wide range of values can be obtained. The extremely small size makes this type especially useful in hybrid integrated circuits and on printed circuit boards.

Mica and glass capacitors are used whenever high quality and excellent stability with respect to temperature and aging are required, and where high frequency operation is required. They are used in tuning circuits and for coupling where high performance and reliability are essential. Mica capacitors are made from sheets of mica that are alternately stacked with foils. Alternate foils are extended and folded over the ends. After leads are attached, the unit is encapsulated. Glass capacitors are made from glass ribbons that are stacked alternately with foils. Leads are attached, and the entire assembly is sealed in glass at high temperature and pressure.

Capacitors used in power system applications employ oil-impregnated paper as a dielectric. Because of the very high voltage ratings, these capacitors are shipped and stored with a shorting bar across the terminals as a safety precaution. Even though a capacitor has been discharged after high voltage operation or testing, it is possible for charge and voltage to reaccumulate by a phenomenon known as *dielectric absorption*.

[Figure 106.4](#), [Figure 106.5](#), and [Figure 106.6](#) show ranges of capacitance values, voltage ratings, and frequency ranges for the different capacitors described in this section.

All capacitors dissipate a small amount of power due to resistive losses in the conductors, leakage current across the dielectric, and losses in the dielectric under AC operation. If the capacitor is represented

FIGURE 106.4 Range of values for various types of capacitors.

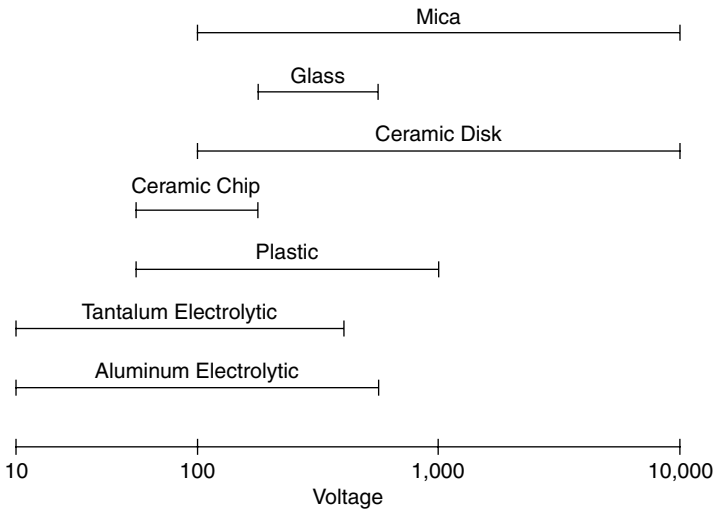

FIGURE 106.5 Voltage ratings of various capacitors.

FIGURE 106.6 Frequency range of various capacitors.

by its capacitance value in series with a resistor to simulate these losses, the resistance is called the **equivalent series resistance (ESR)**. Capacitance bridges often measure the **dissipation factor (DF)**, which is given by

$$DF = 2\pi f C_s R_s \quad (106.8)$$

where C_s is the series capacitance, f is the frequency in hertz, and R_s is the ESR. The reciprocal of the dissipation factor is the **quality factor (Q)** of the capacitor.

106.3 Inductors

Inductance is the property of a device that relates a magnetic field to the current that produces it. In Figure 106.7, the current I flowing in a counterclockwise direction in the coil produces, by the right-hand rule, a magnetic flux. The inductance of the coil is defined by

$$L = \frac{\Phi}{I} \quad (106.9)$$

where L is the inductance in henrys, Φ is the flux in webers, and I is the current in amperes.

In an **inductor** the instantaneous voltage and current are related by the equation

$$v(t) = L \frac{di}{dt} \quad (106.10)$$

where $v(t)$ is the instantaneous voltage in volts and di/dt is the rate of change of current with respect to time in amperes per second. Alternatively,

$$i(t) = i_0 + \frac{1}{L} \int_0^t v dt \quad (106.11)$$

where i_0 is the initial current through the inductor at $t = 0$.

The energy stored in an inductor is

$$W = \frac{1}{2} I^2 L \quad (106.12)$$

FIGURE 106.7 Magnetic flux produced by a current-carrying conductor. The inductance is defined by Equation (106.9).

Since the finite resistance of the wire in an inductor causes some energy loss, the quality factor, or Q , of an inductor — relating energy stored and energy dissipated — is an important quantity. It is given by

$$Q = \frac{2\pi fL}{R} \quad (106.13)$$

where f is the frequency in hertz and R is the series resistance of the inductor.

In general, it is not possible to find an exact analytical expression for the inductance of a configuration. A number of empirical formulas are given as follows, and some general principles can be stated.

1. The inductance is proportional to the size of the coil. Thus, larger loops have larger inductance.
2. Inductance is proportional to the number of turns squared. In [Figure 106.7](#), if there are two turns, the flux is doubled; if the flux is changing, then twice the induced voltage will appear in each turn, for a total of four times the voltage in a one-turn loop.
3. The inductance is proportional to the permeability of the surrounding medium. Most materials have a permeability μ_0 very close to that of free space; $\mu_0 = 4 \cdot 10^{-7}$ henrys per meter. Magnetic materials have a permeability ranging from about 100 to 100,000 times μ_0 . They are used to concentrate and intensify the flux in transformers, motors, relays, and inductors.

Approximate formulas for the inductance of several configurations can be given. The internal inductance per unit length of a round solid wire is

$$L = \frac{\mu_0}{8\pi} \quad (106.14)$$

The inductance per unit length of two parallel wires carrying current in opposite directions is

$$L = 0.4 \cdot 10^{-6} \ln\left(\frac{2D}{d}\right) \quad (106.15)$$

where D is the center-to-center spacing of the wires and d is the diameter of the wire. For a coaxial cable the inductance per unit length is

$$L = \frac{\mu_0}{2\pi} \ln\left(\frac{r_b}{r_a}\right) \quad (106.16)$$

where the subscripts b and a refer to the radius of the outer and inner conductors, respectively. For a circular loop of wire,

$$L = \mu_0 a \left(\ln\left(\frac{8a}{r}\right) - 1.75 \right) \quad (106.17)$$

where a is the radius of the loop and r is the radius of the wire. For a solenoid consisting of a single layer of turns,

$$L = \frac{\mu_0 N^2 A}{0.45d + l} \quad (106.18)$$

where N is the number of turns, A is the cross-sectional area of the solenoid, d is the diameter of the solenoid, and l is its length.

In many cases the objective is to minimize the parasitic inductance of a layout. To achieve this, one should minimize the area of current-carrying loops and use rectangular or flat conductors.

Defining Terms

Capacitance — A property of an arrangement of two conductors equal to the charge on a conductor divided by the voltage between them.

Capacitor — An electronic component that accumulates charge and energy in an electric circuit.

Dielectric — An insulating material, for example, between the plates of a capacitor.

Dissipation factor (DF) — The ratio of the energy dissipated per cycle to two times the maximum energy stored at a given frequency. The lower the DF, the more nearly ideal the capacitor.

Equivalent series resistance (ESR) — The resistance in series with a capacitor that accounts for energy loss in a nonideal capacitor.

Inductance — The property of a conductor arrangement that relates the magnetic flux to the current in the conductor.

Inductor — A passive component that stores energy in its magnetic field whenever it is conducting a current.

Permittivity — The property of a material that relates the electric field intensity to the electric flux density. The capacitance between two conductors is directly proportional to the permittivity of the dielectric between them.

Quality factor (Q) — A value equal to two times the ratio of the maximum stored energy to the energy dissipated per cycle at a given frequency in a capacitor or inductor. The larger the value of Q , the more nearly ideal the component. For a capacitor, Q is the inverse of DF.

Resistivity — The property of a material that relates current flow to electric field. The current density is equal to the electric field divided by the resistivity.

Sheet resistance — Sheet resistance (or sheet resistivity) is the average resistivity of a layer of material divided by its thickness. If the layer has the same length as width, the resistance between opposite edges of the “square” is numerically equal to the sheet resistance, regardless of the size of the square.

Circuits that contain only resistive elements can be described by a set of algebraic equations that are obtained by systematically applying Kirchhoff's current and voltage laws to the circuit. When a circuit contains energy storage elements — that is, inductors and capacitors — Kirchhoff's laws are still valid, but their application leads to a differential equation (DE) model of the circuit instead of an algebraic model. A DE model can be solved by classical DE methods, by time-domain convolution, and by Laplace transform methods.

107.1 RL Circuits

A series RL circuit can be analyzed by applying Kirchhoff's voltage law to the single loop that contains the elements of the circuit. For example, writing Kirchhoff's voltage law for the circuit in [Figure 107.1](#) leads to the following first-order DE stating that the voltage drop across the inductor and the resistor must equal the voltage drop across the voltage source:

$$L \frac{di}{dt} + i(t)R = v_g(t) \quad (107.1)$$

This DE belongs to a family of linear, constant-coefficient, ordinary differential equations. Various approaches can be taken to find the solution for $i(t)$, the current through the elements of the circuit. The first is to solve the DE by classical (time-domain) methods; the second is to solve the equation by using Laplace transform theory. A third approach, waveform convolution, will not be considered here (see Ziemer et al. [1993].)

The complete time-domain solution to the DE is formed as the sum of two parts, called the **natural solution** and the **particular solution**:

$$i(t) = i_N(t) + i_P(t) \quad (107.2)$$

FIGURE 107.1 Series RL circuit.

The natural solution, $i_N(t)$, is obtained by solving the (homogeneous) DE with the sources (or forcing functions) turned off. The circuit in this example has the following homogeneous DE:

$$L \frac{di}{dt} + i(t)R = 0 \quad (107.3)$$

The solution to this equation is the exponential form: $i_N(t) = Ke^{st}$, where K is an arbitrary constant. To verify this solution, substitute Ke^{st} into Equation (107.3) and form

$$LKse^{st} + RKe^{st} = 0 \quad (107.4)$$

Rearranging gives:

$$[sL + R]Ke^{st} = 0 \quad (107.5)$$

The factor Ke^{st} can be canceled because the factor e^{st} is nonzero, and the constant K must be nonzero for the solution to be nontrivial. This reduction leads to the characteristic equation

$$sL + R = 0 \quad (107.6)$$

The **characteristic equation** of this circuit specifies the value of s for which $i_N(t) = Ke^{st}$ solves Equation (107.3). By inspection, $s = -R/L$ solves Equation (107.6), and $i_N(t) = Ke^{-t/\tau}$ satisfies Equation (107.3), and $\tau = L/R$ is called the *time constant* of the circuit. The value $s = -R/L$ is called the **natural frequency** of the circuit.

In general, higher-order circuits (those with higher-order differential equation models and corresponding higher-order algebraic characteristic equations) will have several natural frequencies, some of which may have a complex value — that is, $s = \sigma + j\omega$ — where σ is an exponential damping factor and ω is the undamped frequency of oscillation. The natural frequencies of a circuit play a key role in governing the dynamic response of the circuit to an input by determining the form and the duration of the transient waveform of the response [Ciletti, 1988].

The particular solution of this circuit's DE model is a function $i_p(t)$ that satisfies Equation (107.1) for a given source $v_g(t)$. For example, the constant input signal $v_g(t) = V$ has the particular solution $i_p(t) = V/R$. [This can be verified by substituting this expression into Equation (107.1).] The complete solution to the differential equation when $v_g(t) = V$ is given by

$$i(t) = Ke^{(-R/L)t} + V/R = Ke^{-t/\tau} + V/R \quad (107.7)$$

The sources that excite physical circuits are usually modeled as being turned off before being applied at some specific time, say t_0 , and the objective is to find a solution to its DE model for $t \geq t_0$. This leads to consideration of boundary conditions that constrain the behavior of the circuit and determine the unknown parameters in the solution of its DE model. The boundary conditions of the DE model of a physical circuit are determined by the energy that is stored in the circuit when the source is initially

FIGURE 107.2 Waveforms of $v(t)$ and $i(t)$ in the series RL circuit.

applied. For example, the inductor current in [Figure 107.1](#) could have the constraint given as $i(t_0) = i_0$, where i_0 is a constant. If a circuit is modeled by a constant-coefficient DE, the time of application can be taken to be $t_0 = 0$ without any loss in generality. (Note: The physical conditions that created i_0 are not of concern.)

The value of the parameter K in Equation (107.7) is specified by applying the given boundary condition to the waveform of Equation (107.7), as follows:

$$i(0^+) = i_0 = K + V/R \quad (107.8)$$

and so $K = i_0 - V/R$.

The response of the circuit to the applied input signal is the complete solution of the DE for $t \geq 0$ evaluated with coefficients that conform to the boundary conditions. In the RL circuit example, the complete response to the applied step input is

$$i(t) = [i_0 - V/R]e^{-t/\tau} + V/R, \quad t \geq 0 \quad (107.9)$$

The waveforms of $i(t)$ and $v(t)$, the inductor voltage, are shown in [Figure 107.2](#) for the case in which the circuit is initially at rest, that is, $i_0 = 0$. The time axis in the plot has been normalized by τ .

The physical effect of the inductor in this circuit is to provide inertia to a change in current in the series path that contains the inductor. An inductor has the physical property that its current is a continuous variable whenever the voltage applied across the terminals of the inductor has a bounded waveform (that is, no impulses). The current flow through the inductor is controlled by the voltage that is across its terminals. This voltage causes the accumulation of magnetic flux, which ultimately determines the current in the circuit. The initial voltage applied across the inductor is given by $v(0^+) = V - i(0^+)R$. If the inductor is initially relaxed — that is, $i(0^-) = 0$ — the continuity property of the inductor current dictates that $i(0^+) = i(0^-) = 0$. So $v(0^+) = V$. All of the applied voltage initially appears across the inductor. When this voltage is applied for an interval of time, a magnetic flux accumulates, and current is established through the inductor. Mathematically, the integration of this voltage causes the current in the circuit. The current waveform in [Figure 107.2](#) exhibits exponential growth from its initial value of 0 to its final (steady state) value of V/R . The inductor voltage decays from its initial value to its steady state value of 0, and the inductor appears to be a “short circuit” to the steady state DC current.

107.2 RC Circuits

A capacitor acts like a reservoir of charge, thereby preventing rapid changes in the voltage across its terminals. A capacitor has the physical property that its voltage must be a continuous variable when its current is bounded. The DE model of the parallel RC circuit in [Figure 107.3](#) is described according to Kirchhoff’s current law by

FIGURE 107.3 Parallel RC circuit.

$$C \frac{dv}{dt} + \frac{v}{R} = i_g(t) \quad (107.10)$$

Taking the one-sided Laplace transform [Ziemer, 1993] of this differential equation gives

$$sCV(s) - Cv(0^-) + \frac{V(s)}{R} = I_g(s) \quad (107.11)$$

where $V(s)$ and $I_g(s)$ denote the Laplace transforms of the related time-domain variables. (Note that the Laplace transform of the derivative of a variable explicitly incorporates the initial condition of the variable into the model of the circuit's behavior.) Rearranging this algebraic equation gives the following:

$$V(s) = \frac{I_g(s)}{sC + 1/R} + \frac{Cv(0)}{sC + 1/R} \quad (107.12)$$

$$V(s) = I_g(s)H(s) + \frac{v(0)}{s + 1/(RC)} \quad (107.13)$$

where the s -domain function

$$H(s) = \frac{1}{sC + (1/R)} = \frac{1/C}{s + (1/RC)} \quad (107.14)$$

is called the input/output **transfer function** of the circuit. The expression in Equation (107.13) illustrates an important property of linear circuits: the response of a linear RLC circuit variable is the superposition of the effect of the applied source and the effect of the initial energy stored in the circuit's capacitors and inductors. Another important fact is that the roots of the denominator polynomial of $H(s)$ are the natural frequencies of the circuit (assuming no cancellation between numerator and denominator factors).

If a circuit is initially relaxed — that is, all capacitors and inductors are deenergized [set $v(0^-) = 0$ in Equation (107.13)], then the transfer function defines the ratio of the Laplace transform of the circuit's response to the Laplace transform of its stimulus. Alternatively, the transfer function and the Laplace transform of the input signal determine the Laplace transform of the output signal according to the simple product

$$V(s) = I_g(s)H(s) \quad (107.15)$$

The transfer function of a circuit can define a voltage ratio, a current ratio, a voltage-to-current ratio (impedance) or a current-to-voltage ratio (admittance). In this circuit, $H(s)$ relates the output (response of the capacitor voltage) to the input (i.e., the applied current source). Thus, $H(s)$ is actually a generalized impedance function. If a circuit is initially relaxed its transfer function contains all of the information necessary to determine the response of the circuit to any given input signal.

Suppose that the circuit has an initial capacitor voltage and that the applied source in Equation (107.13) is given by $i_g(t) = Iu(t)$, a step of height I . The Laplace transform [Ciletti, 1988] of the step waveform is given by $I_g(s) = I/s$, so the Laplace transform of $v(t)$, denoted by $V(s)$, is given by

$$V(s) = \frac{I/(sC)}{s + 1/(RC)} + \frac{v(0^-)}{s + 1/(RC)} \quad (107.16)$$

This expression for $V(s)$ can be expanded algebraically into partial fractions as

$$V(s) = \frac{IR}{s} - \frac{IR}{s + 1/(RC)} + \frac{v(0^-)}{s + 1/(RC)} \quad (107.17)$$

Associating the s -domain Laplace transform factor $1/(s + a)$ with the time-domain function $e^{-at}u(t)$ and taking the inverse Laplace transform of the individual terms of the expansion gives

$$v(t) = IR + [v(0^-) - IR]e^{-t/(RC)}, \quad t \geq 0 \quad (107.18)$$

When the source is applied to this circuit, the capacitor charges from its initial voltage to the steady state voltage given by $v(\infty) = IR$. The response of $v(t)$ is shown in Figure 107.4 with $\tau = RC$ and $v_0 = v(0^-)$. The capacitor voltage follows an exponential transition from its initial value to its steady state value at a rate determined by its time constant, τ . A similar analysis would show that the response of the capacitor current is given by

$$i(t) = [I - v(0^-)/R]e^{-t/RC}, \quad t \geq 0 \quad (107.19)$$

Capacitors behave like short circuits to sudden changes in current. The initial capacitor voltage determines the initial resistor current by Ohm's law: $v(0^+)/R$. Any initial current supplied by the source in excess of this amount will pass through the capacitor as though it were a short circuit. As the capacitor builds voltage, the resistor draws an increasing amount of current and ultimately conducts all of the current supplied by the constant source. In steady state the capacitor looks like an open circuit to the constant source — $i(\infty) = 0$ — and it conducts no current.

FIGURE 107.4 Step response of an initially relaxed RC circuit.

FIGURE 107.5 Parallel RLC circuit.

107.3 RLC Circuits

Circuits that contain inductors and capacitors exhibit dynamical effects that combine the inductor's inertia to sudden changes in current with the capacitor's inertia to sudden changes in voltage. The topological arrangement of the components in a given circuit determines the behavior that results from the interaction of the currents and voltages associated with the individual circuit elements.

The parallel RLC circuit in Figure 107.5(a) has an s -domain counterpart [see Figure 107.5(b)], sometimes referred to as a *transformed circuit*, that is obtained by replacing each time-domain variable by its Laplace transform, and each physical component by a Laplace transform model of the component's voltage-current relationship. Here, for example, the physical capacitor is replaced by a model that accounts for the impedance of the capacitor and the capacitor's initial voltage. The additional sources account for the possibly nonzero initial values of capacitor voltage and inductor current. Algebraic expressions of Kirchhoff's laws are written from the Laplace model of the circuit. Applying Kirchhoff's current law to the circuit of Figure 107.5 gives

$$sCV(s) + \frac{V(s)}{sL} + \frac{V(s)}{R} = I_g(s) + Cv(0^-) - i(0^-) \quad (107.20)$$

Algebraic manipulation of this expression gives

$$V(s) = \frac{(s/C)I_g(s)}{s^2 + (s/RC) + (1/LC)} + \frac{s/C[Cv(0^-) - i(0^-)]}{s^2 + (s/RC) + (1/LC)} \quad (107.21)$$

The transfer function relating the source current to the capacitor voltage is obtained directly from Equation (107.21), with $v(0^-) = 0$ and $i(0^-) = 0$:

$$H(s) = \frac{s/C}{s^2 + (s/RC) + (1/LC)} \quad (107.22)$$

Because $V(s)$ represents the response of a second-order circuit, the form of its partial fraction expansion depends on the natural frequencies of the circuit. These are obtained by solving for the roots of the characteristic equation:

$$s^2 + \frac{s}{RC} + \frac{1}{LC} = 0 \quad (107.23)$$

The roots are

$$s_1 = \frac{-1}{2RC} + \sqrt{\left[\frac{1}{2RC}\right]^2 - \frac{1}{LC}} \quad (107.24)$$

$$s_2 = \frac{-1}{2RC} - \sqrt{\left[\frac{1}{2RC}\right]^2 - \frac{1}{LC}} \quad (107.25)$$

To illustrate the possibilities of the second-order response, we let $i_g(t) = u(t)$, and $I_g(s) = 1/s$.

Case 1: Overdamped Circuit

If both roots of the second-order characteristic equation are real valued the circuit is said to be *overdamped*. The physical significance of this term is that the circuit response to a step input exhibits exponential decay and does not oscillate. The form of the step response of the circuit's capacitor voltage is

$$v(t) = K_1 e^{s_1 t} + K_2 e^{s_2 t} \quad (107.26)$$

and K_1 and K_2 are chosen to satisfy the initial conditions imposed by $v(0^-)$ and $i(0^-)$.

Case 2: Critically Damped Circuit

When the two roots of a second-order characteristic equation are identical, the circuit is said to be *critically damped*. The circuit in this example is critically damped when $s_1 = s_2 = -1/(2RC)$. In this case, Equation (107.21) becomes

$$V(s) = \frac{1/C}{[s+(1/2RC)]^2} + \frac{s [Cv(0^-) - i(0^-)]}{C [s+(1/2RC)]^2} \quad (107.27)$$

The partial fraction expansion of this expression is

$$V(s) = \frac{1/C}{[s+(1/2RC)]^2} + \frac{1 [Cv(0^-) - i(0^-)]}{C [s+(1/2RC)]} - \frac{1 [Cv(0^-) - i(0^-)]}{2RC^2 [s+(1/2RC)]^2} \quad (107.28)$$

Taking the inverse Laplace transform of $V(s)$ gives

$$v(t) = \frac{1}{C} t e^{-t/(2RC)} + \frac{1}{C} [Cv(0^-) - i(0^-)] e^{-t/(2RC)} - \frac{1}{2RC^2} [Cv(0^-) - i(0^-)] t e^{-t/(2RC)} \quad (107.29)$$

The behavior of the circuit in this case is called *critically damped* because a reduction in the amount of damping in the circuit would cause the circuit response to oscillate.

Case 3: Underdamped Circuit

The component values in this case are such that the roots of the characteristic equation are a complex conjugate pair of numbers. This leads to a response that is oscillatory, having a damped frequency of oscillation, ω_d , given by

$$\omega_d = \sqrt{\frac{1}{LC} - \left[\frac{1}{2RC}\right]^2} \quad (107.30)$$

and a damping factor, α , given by

FIGURE 107.6 Overdamped, critically damped, and underdamped responses of a parallel RLC circuit with a step input.

FIGURE 107.7 A comparison of current in series RL, RC, and RLC circuits.

$$\alpha = \frac{1}{2RC} \quad (107.31)$$

The form of the response of the capacitor voltage to a unit step input current source is

$$v(t) = 2|K|e^{-\alpha t} \sin(\omega_d t + \phi) \quad (107.32)$$

where the parameters K (a nonnegative constant) and ϕ are chosen to satisfy initial conditions.

A comparison of overdamped, critically damped, and underdamped responses of the capacitor voltage is given in Figure 107.6 for a unit step input, with the circuit initially relaxed. Additional insight into the behavior of RL, RC, and RLC circuits can be obtained by examining the response of the current in the series RL, RC, and RLC circuits for corresponding component values. For example, Figure 107.7 shows the waveforms of the step response of $i(t)$ for the following component values: $R = 4 \Omega$, $L = 1 \text{ H}$, and $C = 1 \text{ F}$. The RL circuit has a time constant of 0.25 sec, the RC circuit has a time constant of 2.00 sec, and the overdamped RLC circuit has time constants of 0.29 and 1.69 sec. The inductor in the RL circuit blocks the initial flow of current, the capacitor in the RC circuit blocks the steady-state flow of current, and the RLC circuit exhibits a combination of both behaviors. Note that the time constants of the RLC circuit are bounded by those of the RL and RC circuits.

RLC Circuit — Frequency Response

A circuit's transfer function defines a relationship between the frequency-domain (spectral) characteristics of any input signal and the frequency-domain characteristics of its corresponding output signal. In many engineering applications, circuits are used to shape the spectral characteristics of a signal. For

FIGURE 107.8 Magnitude and phase response of a parallel RC circuit.

example, in a communications application the frequency response could be chosen to eliminate noise from a signal. The frequency response of a circuit consists of the graphs of $|H(j\omega)|$ and $\theta(j\omega)$, the magnitude response and the phase response, respectively, of the transfer function of a given circuit voltage or current. The term $|H(j\omega)|$ determines the ratio of the amplitude of the *sinusoidal steady-state response* of the circuit to a sinusoidal input, and $\theta(j\omega)$ determines the phase shift (manifest as a time-axis translation) between the input and the output waveforms. Values of $|H(j\omega)|$ and $\theta(j\omega)$ are obtained by taking the magnitude and angle, respectively, of the complex value $H(j\omega)$.

The magnitude and phase responses play an important role in filter theory, where for distortionless transmission (i.e., the filter output waveform is a scaled and delayed copy of the input waveform) it is necessary that $|H(j\omega)| = K$, a constant (flat response), and $\theta(j\omega)$ be linear over the pass band of a signal that is to be passed through a filter.

In the parallel RC circuit of [Figure 107.3](#), the transfer function relating the capacitor voltage to the current source has

$$H(j\omega) = \frac{R}{1 + j\omega RC} \quad (107.33)$$

The arithmetic of complex numbers gives the following:

$$|H(j\omega)| = \frac{R}{\sqrt{1 + \omega^2 R^2 C^2}} \quad (107.34)$$

$$\theta(j\omega) = \angle H(j\omega) = -\tan^{-1}(\omega RC) \quad (107.35)$$

The graphs of $|H(j\omega)|$ and $\theta(j\omega)$ are shown in [Figure 107.8](#). The capacitor voltage in the parallel RC circuit has a “low pass” filter response, meaning that it will pass low frequency sinusoidal signals without significant attenuation provided that $\omega < \omega_0$ [$\omega_0 = 1/RC$], the cutoff frequency of the filter. The approximate linearity of the phase response within the passband is also evident.

A filter’s component values determine its cutoff frequency. An important design problem is to determine the values of the components so that a specified cutoff frequency is realized by the circuit. Here, increasing the size of the capacitor lowers the cutoff frequency, or, alternatively, reduces the bandwidth of the filter. Other typical filter responses that can be formed by RL, RC, and RLC circuits (with and without op amps) are high-pass, band-pass, and band-stop filters.

Defining Terms

Characteristic equation — The equation obtained by setting the denominator polynomial of a transfer function equal to zero. The equation defines the natural frequencies of a circuit.

Generalized impedance — An s -domain transfer function in which the input signal is a circuit's current and the output signal is a voltage in the circuit.

Natural frequency — A root of the characteristic polynomial. A natural frequency corresponds to a mode of exponential time-domain behavior.

Natural solution — The solution to the unforced differential equation.

Particular solution — The solution to the differential equation for a particular forcing function.

Steady-state response — The response of a circuit after sufficient time has elapsed to allow the transient response to become insignificant.

Transient response — The response of a circuit prior to its entering the steady state.

Transfer function — An s -domain function that determines the relationship between an exponential forcing function and the particular solution of a circuit's differential equation model. It also describes a relationship between the s -domain spectral description of a circuit's input signal and the spectral description of its output signal.

Node Equations and Mesh Equations

James A. Svoboda
Clarkson University

[108.1 Node Equations](#)
[108.2 Mesh Equations](#)

Node equations and mesh equations are sets of simultaneous equations that are used to analyze electric circuits. Engineers have been writing and solving node equations and mesh equations for a long time. For example, procedures for formulating node equations and mesh equations are found in textbooks from the late 1950s and 1960s [Seshu and Balabanian, 1959; Seshu and Reed, 1961; Desoer and Kuh, 1969]. This longevity is likely due to two facts. First, node equations and mesh equations are easy to write. Second, node equations and mesh equations are both relatively small sets of simultaneous equations.

Electric circuits are interconnections of electrical devices, for example, resistors, independent and dependent sources, capacitors, inductors, op amps, and so on. Circuit behavior depends both on how the devices work and on how the devices are connected together. **Constitutive equations** describe how the devices in the circuit work. Ohm's law is an example of a constitutive equation. The Kirchhoff's law equations describe how the devices are connected together to form the circuit. Both the node equations and the mesh equations efficiently organize the information provided by the constitutive equations and the Kirchhoff's law equations.

In order to better appreciate the advantages of using node and mesh equations, an example will be performed without them. The constitutive equations and Kirchhoff's law equations comprise a set of simultaneous equations. In this first example, illustrated in [Figure 108.1](#), these equations are used to analyze an electric circuit. This example also illustrates the use of MathCAD to solve simultaneous equations. The availability of such a convenient method of solving equations influences the way that node equations and mesh equations are formulated.

The circuit shown in [Figure 108.1](#) consists of six devices. Two variables — a branch current and a voltage — are associated with each branch. There are 12 variables associated with this small circuit. The constitutive equations describe each of the six devices:

$$\begin{aligned}v_1 &= 3i_1, & v_2 &= 4i_2, & v_3 &= 5i_3, \\v_4 &= 12, & i_5 &= 2i_2, & v_6 &= 5v_1\end{aligned}\tag{108.1}$$

Kirchhoff's laws provide six more equations:

$$\begin{aligned}i_1 + i_2 + i_4 &= 0, & -i_2 + i_3 + i_5 &= 0, & -i_1 - i_3 + i_6 &= 0, \\v_1 - v_3 - v_2 &= 0, & v_2 + v_5 - v_4 &= 0, & v_3 + v_6 - v_5 &= 0\end{aligned}\tag{108.2}$$

Solving a Circuit using Branch Equations

Guess the values of the branch voltages and currents. Any guess will do. A good guess is not required. In this example, V_4 is known to be 12. Zero is a suitable guess for the other branch voltages and currents.

$I_1 := 0$ $V_1 := 0$ $I_2 := 0$ $V_2 := 0$
 $I_3 := 0$ $V_3 := 0$ $I_4 := 0$ $V_4 := 12$
 $I_5 := 0$ $V_5 := 0$ $I_6 := 0$ $V_6 := 0$

Enter the equations describing the branches of the network. The word "Given" marks the beginning of these equations.

Given

Enter the Kirchhoff's Current Law (KCL) equations. (Use <ALT> = for the wiggly equal signs.)

$I_1 + I_2 + I_4 \approx 0$ $-I_2 + I_3 + I_5 \approx 0$ $-I_1 - I_3 + I_6 \approx 0$

Enter the Kirchhoff's Voltage Law (KVL) equations.

$V_1 - V_3 - V_2 \approx 0$ $V_2 + V_5 - V_4 \approx 0$ $V_3 + V_6 - V_5 \approx 0$

Enter the Constitutive Equations.

$V_1 \approx 3 \cdot I_1$ $V_2 \approx 4 \cdot I_2$ $V_3 \approx 5 \cdot I_3$ $V_4 \approx 12$
 $I_5 \approx 2 \cdot I_2$ $V_6 \approx 5 \cdot V_1$

Ask MathCAD to solve these equations. The word "Find" marks the end of the equations.

Find ($I_1, I_2, I_3, I_4, I_5, I_6, V_1, V_2, V_3, V_4, V_5, V_6$) =

FIGURE 108.1 Example illustrating the use of MathCAD to solve simultaneous equations.

FIGURE 108.2 Expressing branch voltages and currents as functions of node voltages.

Although it is not practical to solve 12 equations in 12 unknowns by hand, these equations can easily be solved using a personal computer with appropriate software. Figure 108.1 includes a screen dump that illustrates the use of MathCAD [Wieder, 1992] to solve these equations.

Writing all of these equations is tedious, and the process becomes more tedious as the size of the circuit increases. It would be convenient to use a smaller set of simultaneous equations, hence the interest in node equations and mesh equations. The size of the set of simultaneous equations is very important when the equations must be solved by hand. Most contemporary treatments of node equations and mesh equations [Dorf, 1993; Irwin, 1993; Nilsson, 1993] describe procedures that result in as small a set of equations as possible. The availability of the personal computer with appropriate software reduces, but does not eliminate, the importance of the size of the set of equations.

108.1 Node Equations

This section describes a procedure for obtaining node equations to represent a connected circuit. This procedure is based on the observation that an independent set of equations can be obtained by applying Kirchhoff's current law (KCL) at all of the nodes of the circuit except for one node [Seshu and Balabanian, 1959; Seshu and Reed, 1961; Desoer and Kuh, 1969]. The node at which KCL is not applied is called the **reference node**.

The voltage at any node, with respect to the reference node, is called the **node voltage** at that node. Figure 108.2 shows that the current in a resistor can be expressed in terms of the voltages at the nodes of the resistor. This is accomplished in three steps. First, in Figure 108.2(a), the node voltages corresponding to the nodes of the resistor are labeled. Next, in Figure 108.2(b), the branch voltage is expressed in terms of the node voltages (notice the polarities of the voltages). Finally, in Figure 108.2(c), Ohm's law is used to express the branch current in terms of the node voltages (notice the polarities of the branch voltage and current).

Consider writing simultaneous equations to represent the circuit shown in Figure 108.3. When the reference node is selected as shown in Figure 108.3, the node voltages are v_1 , v_2 , and v_3 . The resistor currents have been expressed in terms of the node voltages using the technique described in Figure 108.2. Since all of the branch currents have been labeled, a set of simultaneous equations can now be obtained by applying KCL at all of the nodes except for the reference node.

$$\begin{aligned}
 .001 &= \frac{v_1 - v_2}{2000} + \frac{v_1 - v_3}{1000} \\
 .002 &= .003 + \frac{v_1 - v_2}{2000} \\
 \frac{v_1 - v_3}{1000} &= .003 + \frac{v_3}{3000}
 \end{aligned}
 \tag{108.3}$$

FIGURE 108.3 A circuit consisting of resistors and current sources.

The independent variables in these equations are node voltages, and so this set of simultaneous equations is called the *node equations*. Representing the branch voltages and branch currents as functions of the node voltages made it possible to represent this circuit by a smaller set of variables, the node voltages.

Consider again the circuit shown in Figure 108.1. This circuit contains two voltage sources (one independent and one dependent). In general, there is no easy way to express the current in a voltage source as a function of the node voltages. Since the size of the set of simultaneous equations is not of critical importance, it is appropriate to add the currents of the voltage sources to the list of independent variables. The circuit has been redrawn in Figure 108.4. A reference node has been selected and labeled. The independent variables, that is, the node voltages and currents in the voltage sources, have been labeled.

The voltage across each voltage source can be expressed in two ways. The source voltage is given by the constitutive equation. The branch voltage is the difference of the node voltages at the nodes of the voltage source. These expressions must be equivalent so the branch voltage can be equated to the source voltage. In Figure 108.4 this means that

$$v_4 = 12 \text{ and } v_6 = 5(v_4 - v_6) \tag{108.4}$$

The circuit in Figure 108.4 contains two dependent sources. Dependent sources will not be a problem if the controlling variables of the dependent sources are first expressed as functions of the independent variables of the circuit. In Figure 108.4 this means that i_2 and v_1 must be expressed as functions of v_4 , v_5 , v_6 , i_4 , and i_6 .

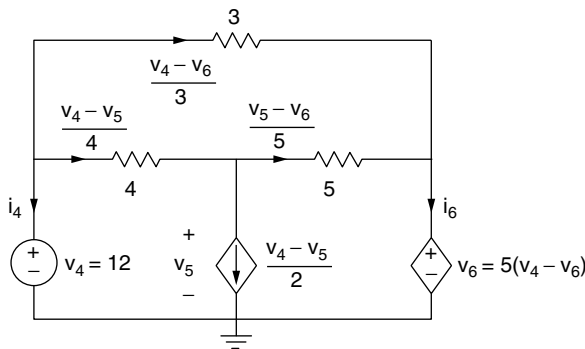

FIGURE 108.4 Writing node equations for the circuit from Figure 108.1.

$$i_2 = \frac{v_4 - v_5}{4} \quad \text{and} \quad v_1 = v_4 - v_6 \quad (108.5)$$

Next, the controlled variables of the dependent source can be expressed as functions of the independent variables of the circuit:

$$i_5 = 2\left(\frac{v_4 - v_5}{4}\right) = \frac{v_4 - v_5}{2} \quad \text{and} \quad v_6 = 5(v_4 - v_6) \quad (108.6)$$

Now all of the branch currents have been labeled. Apply KCL at all of the nodes except the reference node to get

$$\begin{aligned} \frac{v_4 - v_6}{3} + \frac{v_4 - v_5}{4} + i_4 &= 0 \\ -\frac{v_4 - v_5}{4} + \frac{v_4 - v_5}{2} + \frac{v_5 - v_6}{5} &= 0 \\ -\frac{v_5 - v_6}{5} - \frac{v_4 - v_6}{3} + i_6 &= 0 \end{aligned} \quad (108.7)$$

Equation (108.4) and Equation (108.7) comprise the node equations representing this circuit.

In summary, the following procedure is used to write node equations:

1. Choose and label the reference node. Label the independent variables: node voltages and voltage source currents.
2. Express branch currents as functions of the independent variables and the input variables.
3. Express the branch voltage of each voltage source as the difference of the node voltages at its nodes. Equate the branch voltage to the voltage source voltage.
4. Apply KCL at each node except for the reference node.

108.2 Mesh Equations

Mesh equations are formulated by applying Kirchhoff's voltage law (KVL) to each **mesh** of a circuit. A **mesh current** is associated with each mesh. Figure 108.5 shows how to express the branch voltage and branch current of a resistor as functions of the mesh currents.

The procedure for formulation of mesh equations is analogous to the procedure for formulating node equations:

1. Label the independent variables: mesh currents and current source voltages.
2. Express branch voltages as functions of the independent variables and the input variables.

FIGURE 108.5 Expressing branch voltages and currents as functions of mesh currents.

↓mesh_eqn.MCD↓ 23 77

Solving a Circuit using Mesh Equations

Guess the values of the mesh currents and current source voltage. Any guess will do. A good guess is not required.

$$i_1 := 0 \quad i_2 := 0 \quad i_3 := 0 \quad v_5 := 0$$

Given

$$\text{branch current} = i_2 - i_3 \approx 2 \cdot (i_2 - i_1) = \text{current source current}$$

Apply KVL to each mesh.

$$-4 \cdot (i_2 - i_1) + 3 \cdot i_1 - 5 \cdot (i_3 - i_1) \approx 0 \quad -12 + 4 \cdot (i_2 - i_1) + v_5 \approx 0$$

$$-v_5 + 5 \cdot (i_3 - i_1) + 15 \cdot i_1 \approx 0$$

$$\text{Find } (i_1, i_2, i_3, v_5) = \begin{bmatrix} 0.667 \\ -1.333 \\ 2.667 \\ 20 \end{bmatrix}$$

FIGURE 108.6 Writing mesh equations for the circuit from Figure 108.1.

3. Express the branch current of each current source as the difference of the mesh currents of its meshes. Equate the branch current to the current source current.
4. Apply KVL to each mesh.

As an example, consider again the circuit shown in Figure 108.1. This circuit is redrawn in Figure 108.6 to show the mesh currents i_1 , i_2 , and i_3 . The branch voltage of the current source, v_5 , is also labeled, because it will be added to the list of independent variables. In Figure 108.6, the branch voltages have been expressed as functions of the independent variables i_1 , i_2 , i_3 , and v_5 .

The current in the dependent current source can be expressed in two ways. This source current is given by the constitutive equation. This branch current is also the difference of two mesh currents. These expressions must be equal so

$$i_2 - i_3 = 2(i_2 - i_1) \tag{108.8}$$

Next, apply KVL to each mesh to get

$$\begin{aligned} -4(i_2 - i_1) + 3i_1 - 5(i_3 - i_1) &= 0 \\ -12 + 4(i_2 - i_1) + v_5 &= 0 \\ -v_5 + 5(i_3 - i_1) + 15i_1 &= 0 \end{aligned} \tag{108.9}$$

Equation (108.8) and Equation (108.9) comprise the mesh equations. Figure 108.6 illustrates the use of MathCAD to solve the circuit using mesh equations.

Defining Terms

Constitutive equations — Equations that describe the relationship between the branch current and branch voltage of an electric device. Ohm's law is an example of a constitutive equation.

Mesh — A loop that does not contain any branch in its interior. Only planar circuits have meshes. Redrawing a planar circuit can change the meshes [Seshu and Reed, 1961; Desoer and Kuh, 1969].

Mesh current — A current associated with a mesh. This current circulates around the mesh.

Node voltage — The voltage at any node, with respect to the reference node.

Reference node — An independent set of equations can be obtained by applying KCL at all of the nodes of the circuit except for one node. The node at which KCL is not applied is called the *reference node*. Any node of the circuit can be selected to be the reference node. In electronic circuits, where one node of the network is the ground node of the power supplies, the reference node is almost always selected to be the ground node.

Sinusoidal Excitation and Phasors

Muhammad H. Rashid
Purdue University

109.1 Sinusoidal Source

109.2 Phasor

109.3 Passive Circuit Elements in Phasors Domain

Resistor • Inductor • Capacitor • Sinusoidal Responses

A sinusoidal forcing function known as a **sinusoid** is one of the most important excitations. In electrical engineering, the carrier signals for communications are sinusoids, and the sinusoid is also the dominant signal in the power industry. Sinusoids abound in nature, as, for example, in the motion of a pendulum, in the bouncing of a ball, and in the vibrations of strings and membranes.

Because of the importance of sinusoids, the output response of a circuit due to a sinusoidal input signal is an important criterion in determining the performance of the circuit. In this section, we will define a sinusoidal function, represent it in a phasor form, and then illustrate the techniques for determining the sinusoidal responses.

109.1 Sinusoidal Source

A sinusoidal source (independent or dependent) produces a signal that varies sinusoidally with time. In electrical engineering, it is normally a voltage or a current. A sinusoid can be expressed as a sine function or a cosine function. There is no clear-cut choice for the use of either function. However, the sine function is more commonly used. Using a sine function, the instantaneous voltage, which is shown in Figure 109.1, can be represented by

$$v(t) = V_m \sin \omega t \quad (109.1)$$

where V_m is the maximum amplitude, and ω is the *angular* or *radian frequency* in rad/sec.

A sinusoid is a *periodic* function defined generally by the property

$$v(t + T) = v(t) \quad (109.2)$$

where T is the period, the time for one complete cycle. That is, the function goes through one complete cycle every T seconds and is then repeated. The period T is related to the angular frequency ω by

$$T = \frac{2\pi}{\omega} \quad (109.3)$$

FIGURE 109.1 Three sinusoids with different phase angles.

In 1 sec, the function goes through $1/T$ cycles, or periods. The *frequency* is then

$$f = \frac{1}{T} = \frac{\omega}{2\pi} \quad (109.4)$$

The number of cycles per second, or *hertz* (abbreviated Hz), named for the German physicist Heinrich R. Hertz (1857–1894), is the standard unit of frequency. The frequency and the angular frequency are related by

$$\omega = 2\pi f \quad (109.5)$$

So far, we have assumed that a sinusoid starts at $t = 0$. However, it could be phase shifted by an angle ϕ and has the more general expression given by

$$v(t) = V_m \sin(\omega t + \phi) \quad (109.6)$$

where ϕ is the *phase angle*, or simply *phase*. Since ωt is in radians, ϕ should also be expressed in radians. However, it is often convenient to specify ϕ in degrees. That is,

$$v(t) = V_m \sin\left(\omega t + \frac{\pi}{3}\right) \quad (109.7)$$

or

$$v(t) = V_m \sin(\omega t + 60^\circ) \quad (109.8)$$

is acceptable, although Equation (109.8) is mathematically inconsistent. While computing the value of $\sin(\omega t + \phi)$, one should use the same units (radians or degrees) for both ωt and ϕ . If ϕ has a positive value, the sinusoid is said to have a *leading phase angle*. If ϕ has a negative value, it is said to have a *lagging phase angle*.

109.2 Phasor

A **phasor** is a complex number that represents the amplitude and phase angle of a sinusoidal function. It transforms a sinusoidal function from time domain to the complex number domain. The phasor concept, which is generally credited to electrical engineer Charles Proteus Steinmetz (1865–1923), is based on the Euler's exponential function of the trigonometric function

$$e^{j\theta} = \cos\theta + j \sin\theta \quad (109.9)$$

FIGURE 109.2 Rotating phasor.

Thus, a cosine function may be regarded as the real part of the exponential function and a sine function as the imaginary part of the exponential function. That is,

$$\cos\theta = \text{Re}(e^{j\theta}) \quad (109.10)$$

$$\sin\theta = \text{Im}(e^{j\theta}) \quad (109.11)$$

Therefore, we can write the sinusoidal voltage function of Equation (109.6) as

$$v(t) = V_m \sin(\omega t + \phi) \quad (109.12)$$

$$= V_m \text{Im}\{e^{j(\omega t + \phi)}\} = \text{Im}\{(V_m e^{j\phi})e^{j\omega t}\} \quad (109.13)$$

which indicates that the coefficient of the exponential $e^{j\omega t}$ is a complex number. It is the *phasor representation*, or *phasor transform*, of the sinusoidal function and is represented by a boldface letter. Thus, the phasor \mathbf{V} becomes

$$\mathbf{V} = V_m e^{j\phi} \text{ (exponential form)} \quad (109.14)$$

$$= V_m \cos\theta + jV_m \sin\theta \text{ (polar form)} \quad (109.15)$$

Since phasors are used extensively in analysis of electrical engineering circuits, the exponential function $e^{j\phi}$ is abbreviated in a shorthand notation for the sake of simplicity as

$$e^{j\phi} = 1\angle\phi \quad (109.16)$$

A graphical relationship between a phasor and sinusoid is shown in Figure 109.2. A unit phasor may be regarded as a unit vector having an initial phase displacement of ϕ and rotating in the counterclockwise direction at an angular speed of ω .

109.3 Passive Circuit Elements in Phasors Domain

If we want to find the response of an electrical circuit due to a sinusoidal forcing function, first we need to establish the relationship between the phasor voltage across and the phasor current through passive elements such as the resistor, inductor, and capacitor.

Resistor

Let us assume that a sinusoidal current of

FIGURE 109.3 Voltage-current relationships of a resistor.

$$i(t) = I_m \sin(\omega t + \theta) \quad (109.17)$$

where I_m is the maximum amplitude of the current in amperes, and θ is the phase angle of the current.

Using Ohm's law for the resistor in Figure 109.3(a), the instantaneous voltage across the terminals of the resistor is related to its instantaneous current by

$$v(t) = Ri(t) = R\{I_m \sin(\omega t + \theta)\} = RI_m \sin(\omega t + \theta) \quad (109.18)$$

which can be represented as a phasor by

$$\mathbf{V} = RI_m e^{j\theta} = RI_m \angle \theta \quad (109.19)$$

Since $I_m \angle \theta = \mathbf{I}$ is the phasor representation of the current, we can write

$$\mathbf{V} = R\mathbf{I} \quad (109.20)$$

That is, the phasor voltage across the terminals of a resistor is the resistor times the phasor current. Figure 109.3(b) shows the \mathbf{V} and \mathbf{I} relationship of a resistor. A resistor has no phase shift between the voltage and its current. The current is said to be in time phase with the voltage, as shown in Figure 109.3(c).

Inductor

Assuming a sinusoidal current of $i = I_m \sin(\omega t + \theta)$, the voltage across an inductor shown in Figure 109.4(a) is related to its current by

$$v = L \frac{di}{dt} = \omega LI_m \cos(\omega t + \theta) \quad (109.21)$$

Using the trigonometric identity of $\cos A = \sin(A + \pi/2)$, Equation (109.21) can be rewritten as

FIGURE 109.4 Voltage-current relationships of an inductor.

$$v = \omega L I_m \sin\left(\omega t + \theta + \frac{\pi}{2}\right) \quad (109.22)$$

The phasor representation of the voltage given by Equation (109.22) is

$$\begin{aligned} \mathbf{V} &= \omega L I_m e^{j(\theta + \pi/2)} = \omega L I_m \angle(\theta + \pi/2) \\ &= \omega L I_m e^{j\theta} e^{j\pi/2} \\ &= \omega L I_m e^{j\theta} (\cos \pi/2 + j \sin \pi/2) \\ &= j\omega L I_m e^{j\theta} = j\omega L \mathbf{I} \end{aligned} \quad (109.23)$$

Thus, the phasor voltage across the terminals of an inductor equals $j\omega L$ times the phasor current. Since the operator j gives a phase shift of $+90^\circ$, then $j\mathbf{I} = jI\angle\theta = I_m\angle(\theta + \pi/2)$. That is, the current lags behind the voltage by 90° , or the voltage leads the current by 90° . The voltage and current relationship in the phasor domain is shown in Figure 109.4(b) and in the time domain in Figure 109.4(c).

Capacitor

Assuming a sinusoidal voltage of $v = V_m \sin(\omega t + \phi)$, the current through a capacitor shown in Figure 109.5(a) is related to its voltage by

$$i = C \frac{dv}{dt} = j\omega C V_m \cos(\omega t + \phi) \quad (109.24)$$

Using the trigonometric identity, Equation (109.24) can be rewritten as

FIGURE 109.5 Voltage-current relationships of a capacitor.

$$i = \omega CV_m \sin\left(\omega t + \phi + \frac{\pi}{2}\right) \quad (109.25)$$

The phasor representation of the current given by Equation (109.25) is

$$\mathbf{I} = j\omega C\mathbf{V} \quad (109.26)$$

Thus, the phasor current through a capacitor equals $j\omega C$ times the phasor voltage. That is, the voltage lags behind the current by 90° , or the current leads the voltage by 90° . The voltage and current relationship in the phasor domain is shown in Figure 109.5(b) and in the time domain in Figure 109.5(c).

Sinusoidal Responses

We can conclude from the previous discussions that the phasor relationship between the voltage and the current of an element takes the general form of

$$\mathbf{V} = \mathbf{Z}\mathbf{I} \quad (109.27)$$

where \mathbf{Z} is the **impedance** of the circuit element. That is, the impedance of a resistor is R , the impedance of an inductor is $j\omega L$, and the impedance of a capacitor is $1/j\omega C$. Thus, for a circuit having L and/or C , the impedance \mathbf{Z} will be a complex number with a real part R and an imaginary part X such that

$$\mathbf{Z} = R + jX = Z\angle\theta \quad (109.28)$$

where

$$Z = [R^2 + X^2]^{1/2} \quad (109.29)$$

and

FIGURE 109.6 A series RLC circuit.

$$\theta = \tan^{-1}(X/R) \quad (109.30)$$

If the Kirchhoff's voltage law for a set of n sinusoidal voltages in the time domain is given by

$$v_1 + v_2 + v_3 + v_4 + \cdots + v_n = 0 \quad (109.31)$$

then the equivalent statement in the phasor domain can be written as

$$\mathbf{V}_1 + \mathbf{V}_2 + \mathbf{V}_3 + \mathbf{V}_4 + \cdots + \mathbf{V}_n = 0 \quad (109.32)$$

Similarly, if the Kirchhoff's current law for a set of n sinusoidal currents in the time domain is given by

$$i_1 + i_2 + i_3 + i_4 + \cdots + i_n = 0 \quad (109.33)$$

then the equivalent statement in the phasor domain can be written as

$$\mathbf{I}_1 + \mathbf{I}_2 + \mathbf{I}_3 + \mathbf{I}_4 + \cdots + \mathbf{I}_n = 0 \quad (109.34)$$

Let us consider the RLC circuit shown in [Figure 109.6](#). We will use the phasor concept in finding its current in response to an input source voltage of $v_s = V_m \sin(\omega t + \phi)$. We use the phasor notation

$$\mathbf{V}_s = V_m \angle \phi \quad (109.35)$$

Applying the Kirchhoff's voltage law, we get

$$\mathbf{V}_s = (R + j\omega L + 1/j\omega C)\mathbf{I} = \mathbf{Z}\mathbf{I} \quad (109.36)$$

where \mathbf{Z} is the total impedance of the series loop formed by R , L , and C . That is,

$$\begin{aligned} \mathbf{Z} &= R + j(\omega L - 1/\omega C) = [R^2 + (\omega L - 1/\omega C)^2]^{1/2} \angle \theta \\ &= Z \angle \theta \end{aligned} \quad (109.37)$$

where Z is the impedance magnitude and is given by

$$Z = [R^2 + (\omega L - 1/\omega C)^2]^{1/2} \quad (109.38)$$

and θ is the impedance angle given by

$$\theta = \tan^{-1}\left(\frac{\omega L - 1/\omega C}{R}\right) \quad (109.39)$$

FIGURE 109.7 A parallel RLC circuit.

Dividing the phasor voltage by the phasor impedance gives the phasor current as

$$\mathbf{I} = \frac{\mathbf{V}_s}{\mathbf{Z}} = \frac{V_s \angle \phi}{Z \angle \theta} = \frac{V_s \angle \phi - \theta}{Z} \quad (109.40)$$

which indicates that the current lags the input voltage by an angle of θ . Converting to the time domain, the current is given by

$$i = \frac{V_m}{\sqrt{R^2 + (\omega L - 1/\omega C)^2}} \sin(\omega t + \phi - \theta) \quad (109.41)$$

Let us consider the parallel RLC circuit shown in Figure 109.7. Applying the Kirchhoff's current law at the node a , we get

$$\mathbf{I} = \mathbf{I}_1 + \mathbf{I}_2 + \mathbf{I}_3 \quad (109.42)$$

Since the three impedances are $\mathbf{Z}_R = R$, $\mathbf{Z}_1 = R_1 + j\omega L$, and $\mathbf{Z}_C = 1/j\omega C$, we can substitute for \mathbf{I} by using Ohm's law. That is,

$$\begin{aligned} \mathbf{I} &= \frac{V_s \angle \phi}{R} + \frac{V_s \angle \phi}{R_1 + j\omega L} + \frac{V_s \angle \phi}{1/j\omega C} \\ \mathbf{I} &= V_s \angle \phi \left[\frac{1}{R} + \frac{1}{\sqrt{R_1^2 + (\omega L)^2}} \angle \theta_1 + j\omega C \right] \end{aligned} \quad (109.43)$$

where θ_1 is the impedance angle of R_1 and L , and it is given by

$$\theta_1 = \tan^{-1} \frac{\omega L}{R_1} \quad (109.44)$$

Equation (109.42) can be written as

$$\mathbf{I} = V_s \angle \phi Y \angle -\theta = V_s Y \angle (\phi - \theta) \quad (109.45)$$

where $Y \angle -\theta$ is the equivalent admittance of R , R_1 , and L such that it is related to the equivalent impedance \mathbf{Z} by

$$Y \angle -\theta = \frac{1}{Z \angle \theta} = \frac{1}{R} + \frac{1}{R_1 + j\omega L} + j(\omega C) \quad (109.46)$$

Equation (109.43) can be written in the time domain as

$$i(t) = V_m Y \sin(\omega t + \phi - \theta) \quad (109.47)$$

where θ is the impedance angle of $(R_1 + j\omega L)$, which is in parallel with R and $1/j\omega C$. In converting from the phasor domain to the time domain, we have assumed that the maximum amplitude of a sinusoid is the magnitude of its phasor representation. However, in practice, the magnitude of a sinusoid is normally quoted in its root-mean-square (rms) value, which is defined by

$$V_{\text{rms}} = \sqrt{\frac{1}{T} \int V_m^2 \cos^2(\omega t + \phi) dt} \quad (109.48)$$

which, after completing the integration and simplification, becomes

$$V_{\text{rms}} = \frac{V_m}{\sqrt{2}} \quad (109.49)$$

Thus, $v = V_m \sin(\omega t + \phi) = \sqrt{2} V_{\text{rms}} \sin(\omega t + \phi)$, and it will be represented in a phasor form by $V_{\text{rms}} \angle \phi$. For example, $170 \sin(\omega t + \phi) \equiv (170 / \sqrt{2}) \angle \phi = 120 \angle \phi$.

Defining Terms

Impedance — An impedance is a measure of the opposition to a current flow due to a sinusoidal voltage source. It is a complex number and has a real and an imaginary part.

Phasor — A phasor is the vector representation of a sinusoid in the complex domain. It represents the amplitude and the phase angle of a sinusoid.

Sinusoid — A sinusoid is a sinusoidal time-dependent periodic forcing function which has a maximum amplitude and can also have a phase delay.

Three-Phase Circuits

110.1 Relationships between Voltages and Currents

110.2 Line Voltages

110.3 Power Relationship

110.4 Balanced Source and Balanced Load

110.5 Other Types of Interconnections

Norman Balabanian

University of Florida, Gainesville

A very important use of electricity is the driving of industrial equipment, such as electric motors, in the AC steady state. Suppose that the instantaneous AC voltage and current of such a load is given by

$$v(t) = \sqrt{2}|V|\cos(\omega t + \alpha) \tag{110.1}$$

$$i(t) = \sqrt{2}|I|\cos(\omega t + \beta)$$

Then the power to the load at any instant of time is

$$p(t) = |V||I|[\cos(\alpha - \beta) + \cos(2\omega t + \alpha + \beta)] \tag{110.2}$$

The instantaneous power has a constant term and a sinusoidal term at twice the frequency. The quantity in brackets fluctuates between a minimum value of $\cos(\alpha - \beta) - 1$ and a maximum value of $\cos(\alpha - \beta) + 1$. This fluctuation of power delivered to the load has a great disadvantage when the load is an electric motor. A motor operates by receiving electric power and transmitting mechanical (rotational) power at its shaft. If the electric power is delivered to the motor in spurts, the motor is likely to vibrate. For satisfactory operation in such a case, a physically larger motor, with a larger shaft and flywheel, will be needed to provide more inertia for smoothing out the fluctuations than would be the case if the delivered power were constant.

This problem is overcome in practice by the use of what is called a *three-phase* system. This chapter will provide a brief discussion of three-phase power systems.

Consider the circuit in [Figure 110.1](#). This is an interconnection of three AC sources to three loads connected in such a way that each source/load combination shares the return connection from O to N. The three sources can be viewed collectively as a single source, and the three loads — which are assumed to be identical — can be viewed collectively as a single load. Each of the individual sources and loads is referred to as one *phase* of the three-phase system.

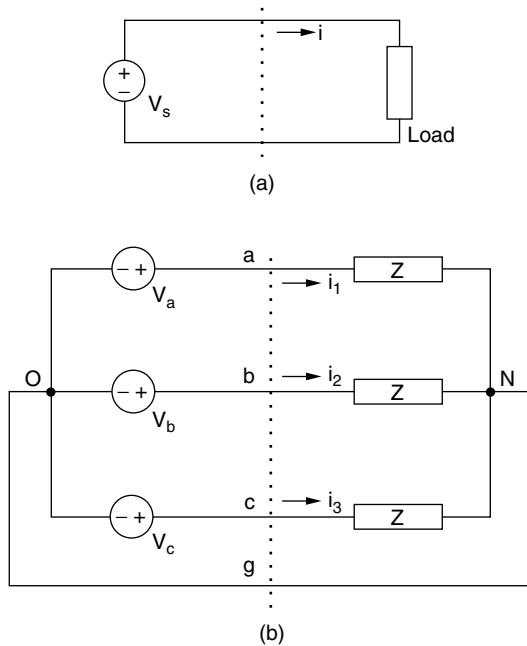

FIGURE 110.1 Flow of power from source to load.

110.1 Relationships between Voltages and Currents

The three sources are assumed to have the same frequency; for this reason, they are said to be *synchronized*. It is also assumed that the three phase voltages have the same rms values and that the phase difference between each pair of voltages is $\pm 120^\circ$ ($2\pi/3$ rad). Thus, the voltages can be written:

$$\begin{aligned}
 v_a &= \sqrt{2}|V|\cos(\omega t + \alpha_1) \leftrightarrow V_a = |V|e^{j0^\circ} \\
 v_b &= \sqrt{2}|V|\cos(\omega t + \alpha_2) \leftrightarrow V_b = |V|e^{-j120^\circ} \\
 v_c &= \sqrt{2}|V|\cos(\omega t + \alpha_3) \leftrightarrow V_c = |V|e^{j120^\circ}
 \end{aligned}
 \tag{110.3}$$

The **phasors** representing the sinusoids have also been shown. For convenience the angle v_a has been chosen as the reference for angles; v_b lags v_a by 120° and v_c leads v_a by 120° .¹

There are two options for choosing the sequence of the phases. Once the particular phase that is to be the reference for angles is chosen and named, “a,” there are two possible sequences for the other two: either “abc” or “acb.” This fact is hardly earthshaking; all it means is that the leading and lagging angles can be interchanged. Obviously, nothing fundamental is different in the second sequence. Hence, the discussion that follows is limited to the abc *phase sequence*.

Because the loads are identical, the rms values of the three currents shown in Figure 110.1 will also be the same, and the phase difference between each pair of them will be $\pm 120^\circ$. Thus, the currents can be written as

¹Observe that the principal value of the angle lying between $\pm 180^\circ$ is used. One could add 360° to the negative angle and use the value 240° instead.

$$\begin{aligned}
 i_1 &= \sqrt{2}|I|\cos(\omega t + \beta_1) \leftrightarrow I_1 = |I|e^{j\beta_1} \\
 i_2 &= \sqrt{2}|I|\cos(\omega t + \beta_2) \leftrightarrow I_2 = |I|e^{j(\beta_1 - 120^\circ)} \\
 i_3 &= \sqrt{2}|I|\cos(\omega t + \beta_3) \leftrightarrow I_3 = |I|e^{j(\beta_1 + 120^\circ)}
 \end{aligned}
 \tag{110.4}$$

Perhaps a better form of visualizing the voltages and currents is a graphical one. Phasor diagrams for the voltages and the currents are shown separately in Figure 110.2. The value of angle β_1 will depend on the load. Something significant is clear from these diagrams. First, V_2 and V_3 are each the other's conjugate. So if they are added, the imaginary parts cancel and the sum will be real, as illustrated by the construction in the voltage diagram. Furthermore, the construction shows this sum to be negative and equal in magnitude of V_1 . Hence, *the sum of the three voltages is zero*. The same is true of the sum of the three currents, as can be established graphically by a similar construction. The same results can be confirmed analytically by converting the phasor voltages and currents into rectangular form.

By Kirchhoff's current law applied at node N in Figure 110.1, we find that the current in the return line is the sum of the three currents in Equation (110.4). But since this sum was found to be zero, *the return line carries no current*. Hence, it can be removed entirely without affecting the operation of the system. The resulting circuit is redrawn in Figure 110.3. It can be called a *three-wire* three-phase system. Because of its geometrical form, this connection of both the sources and the loads is said to be a **wye (Y) connection**, even though *t* is an upside-down Y.

Notice that the circuit in Figure 110.3 is planar, with no lines crossing any other lines. That simplicity has been achieved at a price. Notice how the sequence (abc) of sources has been laid out geometrically.

FIGURE 110.2 Voltage and current phasor diagrams.

FIGURE 110.3 Wye-connected three-phase system.

Clearly, with the connections shown, the sequence of the loads is not the same as that of the sources. Having the same sequence would require interchanging the connections of the b and c sources with the bottom two loads. Doing that would result in one branch crossing another. However, nothing fundamental would change with either connection, assuming equal loads.

110.2 Line Voltages

In the three-wire three-phase system in [Figure 110.3](#), the neutral point O is not accessible, so phase voltages cannot be measured. The voltages that *are* available for measurement are the *line-to-line* or simply the *line* voltages: V_{ab} , V_{bc} , and V_{ca} . By Kirchhoff's voltage law,

$$\begin{aligned} V_{ab} &= V_a - V_b = |V| - |V|e^{-j120^\circ} = \sqrt{3}|V|e^{j30^\circ} \\ V_{bc} &= V_b - V_c = |V|e^{-j120^\circ} - |V|e^{j120^\circ} = \sqrt{3}|V|e^{-j90^\circ} \\ V_{ca} &= V_c - V_a = |V|e^{j120^\circ} - |V| = \sqrt{3}|V|e^{j150^\circ} \end{aligned} \quad (110.5)$$

The interesting result is that all the line-voltage magnitudes are equal at $\sqrt{3}$ times the phase-voltage magnitude. Thus, a 220 V line voltage corresponds to a phase voltage of 127 V. The line-voltage angles have the same mutual relationships as the phase-voltage angles; they are separated by $\pm 120^\circ$.

110.3 Power Relationship

The instantaneous power delivered by each of the sources has the form given in Equation (110.2), consisting of a constant term representing the average power and a double-frequency sinusoidal term. The latter, being sinusoidal, can be represented by a phasor also. The only caveat is that a different frequency is involved here, so this power phasor should not be mixed with the voltage and current phasors in the same diagram or calculations. Let $|S| = |V||I|$ be the apparent power delivered by each of the three sources, and let the three power phasors be S_a , S_b , and S_c , respectively. Then,

$$\begin{aligned} S_a &= |S|e^{j(\alpha_1 + \beta_1)} = |S|e^{j\beta_1} \\ S_b &= |S|e^{j(\alpha_2 + \beta_2)} = |S|e^{j(-120^\circ + \beta_1 - 120^\circ)} = |S|e^{j(\beta_1 + 120^\circ)} \\ S_c &= |S|e^{j(\alpha_3 + \beta_3)} = |S|e^{j(120^\circ + \beta_1 + 120^\circ)} = |S|e^{j(\beta_1 - 120^\circ)} \end{aligned} \quad (110.6)$$

It is evident that the phase relationships between these three phasors are the same as the ones between the voltages and the currents. That is, the second leads the first by 120° and the third lags the first by 120° . Hence, just as with the voltages and the currents, the sum of these three power phasors will also be zero. This is a very significant result. It constitutes the motivation for using three-phase power over the pulsating power of a single-phase system. Although the instantaneous power delivered by each load has a constant component and a sinusoidal component, when the three powers are added, the sinusoidal components add to zero, leaving only the constants. Thus, the total power delivered to the three loads is constant.

To determine the value of this constant power, let us use Equation (110.2) as a model. The contribution of the k th source to the total (constant) power is $|S| \cos(\alpha_k - \beta_k)$. It can be easily verified that $\alpha_k - \beta_k = \alpha_1 - \beta_1 = -\beta_1$. The first equality follows from the relationships between the α values from Equation (110.3) and between the β values from Equation (110.4). The choice of $\alpha_1 = 0$ leads to the last equality. Hence, each phase contributes an equal amount to the total average power. If P is the total average power, then

$$P = P_a + P_b + P_c = 3P_a = 3|V||I|\cos(\alpha_1 - \beta_1) \quad (110.7)$$

Although the angle α_1 has been set equal to zero, it is shown in this equation for the sake of generality.

A similar result can be obtained for the reactive power. The reactive power of the k th phase is $|S|\sin(\alpha_k - \beta_k) = |S|\sin(\alpha_1 - \beta_1)$. If Q is the total reactive power, then

$$Q = 3|S|\sin(\alpha_1 - \beta_1)$$

110.4 Balanced Source and Balanced Load

What has just been described is a *balanced* three-phase three-wire power system. The three sources in practice are not three independent sources but consist of three different parts of the same generator. The same is true of the loads.¹ What has been described is ideal in a number of ways. First, the circuit can be *unbalanced* — for example, by the loads being somewhat unequal. Second, since the real devices whose ideal model is a voltage source are coils of wire, each source should be accompanied by a branch consisting of the coil inductance and resistance. Third, since the power station (or the distribution transformer at some intermediate point) may be at some distance from the load, the parameters of the physical line carrying the power (the line inductance and resistance) must also be inserted in series between the source and the load.

The analysis of this chapter does not apply to an unbalanced system. An entirely new analytical technique is required to do full justice to such a system.² An understanding of balanced circuits is a prerequisite to tackling the unbalanced case.

The last two of the conditions that make the circuit less than ideal (winding and line impedances) introduce algebraic complications but change nothing fundamental in the preceding theory. If these two conditions are taken into account, the appropriate circuit takes the form shown in [Figure 110.4](#). Here the internal impedance of a source (the winding impedance labeled Z_w) and the line impedance Z_l connecting that source to its load are both connected in series with the corresponding load. Thus, instead of the impedance in each phase being Z , it is $Z + Z_w + Z_l$. Hence, the rms value of each current is

$$|I| = \frac{|V|}{|Z + Z_w + Z_l|} \quad (110.8)$$

instead of $|V|/|Z|$. All other previous results remain unchanged — namely, that the sum of the phase currents adds to zero and that the sum of the phase powers is a constant. The detailed calculations just become a little more complicated.

¹An AC power generator consists of (a) a *rotor* that is rotated by a *prime mover* (say a turbine) and produces a magnetic field that also rotates, and (b) a *stator* on which is wound one or more coils of wire. In three-phase systems the number of coils is three. The rotating magnetic field induces a voltage in each of the coils. The frequency of the induced voltage depends on the number of magnetic poles created on the rotor and the speed of rotation. These are fixed so as to “synchronize” with the 60 Hz frequency of the power system. The 120° leading and lagging phase relationships between these voltages are obtained by distributing the conductors of the coils around the circumference of the stator so that they are separated geometrically by 120°. Thus, the three sources described in the text are in reality a single physical device, a single generator. Similarly, the three loads might be the three windings on a three-phase motor, again a single physical device. Or they might be the windings of a three-phase transformer.

²The technique for analyzing unbalanced circuits utilizes what are called *symmetrical components*.

FIGURE 110.4 Three-phase circuit with nonzero winding and line impedances.

110.5 Other Types of Interconnections

All of the preceding development was based on both the sources and the loads being connected in a wye connection. Although the upside-down Y structure looks geometrically a little different from an upside-down tee circuit, electrically, the two are exactly the same. The wye is not, however, the only possible way to connect the phases of a three-phase system. Another possibility, the **delta connection**, so named because it looks like the Greek letter Δ , is shown in Figure 110.5. (In this figure the boxes can represent either sources or impedances.)

By proper choice of the branch parameters, a tee can be made equivalent to a pi (Π) at the terminals. We note that the delta is just an upside-down pi. As a pi, the junction between A and B is usually extended as the common terminal of a two-port.

If the structures in Figure 110.5 are to be equivalent, the line voltages V_{ab} , V_{bc} , and V_{ca} should be the same in both circuits. Similarly, the currents into the terminals should be the same in both. Note that, in the delta connection, the phase voltages are not evident; the only voltages available are the line voltages. Thus the voltages in the delta are the line voltages given in Equation (110.3). In the wye, the phase currents are also the currents in the lines. For the delta, however, the line currents are the difference between two phase currents, as noted in Figure 110.5. For the line currents, a set of equations similar to Equation (110.5) can be written in terms of the phase currents. Since the same 120° difference of angle exists between the phase currents as between the phase voltages, we would expect that the result for currents would be similar to the result for voltages in Equation (110.5) — namely, that the line-current magnitudes in a delta connection would be $\sqrt{3}$ times the phase-current magnitudes.

In a three-phase circuit the sources, the loads, or both can be replaced by a delta equivalent; four different three-phase circuits can therefore be imagined: wye-wye, wye-delta, delta-wye, and delta-delta. There are no fundamental differences in analyzing each of these four circuits.

FIGURE 110.5 Wye connection and delta connection.

Example

A balanced, 120 V, three-wire, three-phase transmission system in a wye-wye connection is represented by the circuit in [Figure 110.4](#). Assume that the winding impedances are negligible but that the line impedances are given by $Z_l = 0.1 + j0.2 \Omega$. Each load impedance is $Z = 20 + j5 \Omega$. The following quantities are to be determined: (a) the line current magnitude; (b) the magnitude of the voltage across each load; (c) the average power, reactive power, and apparent power delivered to the load by each phase; (d) the average power, reactive power, and apparent power delivered by each source; and (e) the fraction of the power delivered by the system that is lost in the lines.

Solution

The solution is completely straightforward. First, the line current is found by dividing the phase voltage by the sum of the load and line impedances; the load voltage follows from the product of the load impedance by the line current. Thus,

$$|I| = \frac{120}{\sqrt{(20+0.1)^2 + (5+0.2)^2}} = 5.78 \text{ A}$$

$$|V_L| = |I||Z| = 5.78\sqrt{20^2 + 5^2} = 119.16 \text{ V}$$

The power calculations then follow:

$$|S_L| = |V_L||I| = 119.16(5.78) = 688.7 \text{ VA or}$$

$$|S_L| = |I|^2|Z_L| = 5.78^2\sqrt{20^2 + 5^2} = 688.7 \text{ VA}$$

$$P_L = R_L|I|^2 = 20(5.78)^2 = 668.2 \text{ W}$$

$$Q_L = X_L|I|^2 = 5(5.78)^2 = 167.0 \text{ VAR}$$

$$= \sqrt{|S_L|^2 - P_L^2} = \sqrt{688.7^2 - 668.2^2} = 166.8 \text{ VAR}$$

Perhaps the best way to find the power delivered by the sources is to determine the power lost in the line and then add this to the load power. Carrying out this approach leads to the following result:

$$P_l = 0.1|I|^2 = 3.34 \text{ W} \qquad P_s = 3.34 + 668.2 = 671.5 \text{ W}$$

$$Q_l = 0.2|I|^2 = 6.68 \text{ VAR} \qquad Q_s = 6.68 + 167.0 = 173.7 \text{ VAR}$$

Finally, the fraction of the source power that is lost in the line is $3.34/671.5 = 0.005$ or 0.5%.

Defining Terms

Delta connection — The sources or loads in a three-phase system connected end-to-end, forming a closed path, like the Greek letter Δ .

Phasor — A complex number representing a sinusoid; its magnitude and angle are the rms value and the phase of the sinusoid, respectively.

Wye connection — The three sources or loads in a three-phasor system connected to have one common point, like the letter Y.

[Simple RL and RC Filters](#) • [Simple RLC Filters](#) • [Compound Filters](#) • [Constant- \$k\$ Filters](#) • [\$m\$ -Derived Filters](#)

A **filter** is a frequency-sensitive two-port circuit that transmits with or without amplification signals in a band of frequencies and rejects (or attenuates) signals in other bands. The electric filter was invented during the First World War by two engineers working independently of each other — the American engineer G. A. Campbell and the German engineer K. W. Wagner. O. Zobel followed in the 1920s. These devices were developed to serve the growing areas of telephone and radio communication. Today, filters are found in all types of electrical and electronic applications from power to communications. Filters can be both active and passive. In this section we will confine our discussion to those filters that employ no active devices for their operation. The main advantage of passive filters over active ones is that they require no power (other than the signal) to operate. The disadvantage is that they often employ inductors that are bulky and expensive.

111.1 Fundamentals

The basis for filter analysis involves the determination of a filter circuit's sinusoidal steady state response from its transfer function $T(j\omega)$. Some references use $H(j\omega)$ for the transfer function. The filter's transfer function $T(j\omega)$ is a complex function and can be represented through its gain $|T(j\omega)|$ and phase $\angle T(j\omega)$ characteristics. The gain and phase responses show how the filter alters the amplitude and phase of the input signal to produce the output response. These two characteristics describe the *frequency response* of the circuit since they depend on the frequency of the input sinusoid. The signal-processing performance of devices, circuits, and systems is often specified in terms of their frequency response. The gain and phase functions can be expressed mathematically or graphically as *frequency-response* plots. Figure 111.1 shows examples of gain and phase responses versus frequency, ω .

The terminology used to describe the frequency response of circuits and systems is often based on the form of the gain plot. For example, at high frequencies the gain in Figure 111.1 falls off so that output signals in this frequency range are reduced in amplitude. The range of frequencies over which the output is significantly attenuated is called the *stopband*. At low frequencies the gain is essentially constant and there is relatively little attenuation. The frequency range over which there is little attenuation is called a *passband*. The frequency associated with the boundary between a passband and an adjacent stopband is called the *cutoff frequency* ($\omega_c = 2\pi f_c$). In general, the transition from the passband to the stopband, called the *transition band*, is relatively gradual, so the precise location of the cutoff frequency is a matter of definition. The most widely used approach defines the cutoff frequency as the frequency at which the gain has decreased by a factor of $1/\sqrt{2} = 0.707$ from its maximum value in the passband.

FIGURE 111.1 Low-pass filter characteristics showing passband, stopband, and the cutoff frequency, ω_c .

This particular definition is based on the fact that the power delivered to a resistor by a sinusoidal current or voltage waveform is proportional to the square of its amplitude. At a cutoff frequency the gain is reduced by a factor of $1/\sqrt{2}$ and the square of the output amplitude, and thusly also its power, is reduced by a factor of one half. For this reason the cutoff frequency is also called the *half-power frequency*.

There are four prototypical filters. These are *low pass* (LP), *high pass* (HP), *band pass* (BP), and *bandstop* (BS). Figure 111.2 shows how the amplitude of an input signal consisting of three separate equal-amplitude frequencies is altered by each of the four-prototypical filter responses. The low-pass filter passes frequencies below its cutoff frequency ω_c , called its *passband*, and attenuates the frequencies above the cutoff, called its *stopband*. The high-pass filter passes frequencies above the cutoff frequency ω_c and attenuates those below. The band-pass filter passes those frequencies that lie between two cutoff frequencies, ω_{c1} and ω_{c2} , its passband, and attenuates those frequencies that lie outside the passband. Finally, the bandstop filter attenuates those frequencies that lie in its reject or stopband, between ω_{c1} and ω_{c2} , and passes all others.

The *bandwidth* of a gain characteristic is defined as the frequency range spanned by its passband. For the band-pass case in Figure 111.2, the bandwidth is the difference in the two cutoff frequencies.

$$BW = \omega_{c2} - \omega_{c1} \quad (111.1)$$

This equation applies to the low-pass response with the lower cutoff frequency ω_{c1} set to zero. In other words, the bandwidth of a low-pass circuit is equal to its cutoff frequency ($BW = \omega_c$). The bandwidth of a high-pass characteristic is infinite since the upper cutoff frequency ω_{c1} is infinity. For the bandstop case, Equation (111.1) defines the bandwidth of the stopband rather than the passbands.

Frequency-response plots are usually made using logarithmic scales for the frequency variable because the frequency ranges of interest often span several orders of magnitude. A logarithmic frequency scale compresses the data range and highlights important features in the gain and phase responses. The use of a logarithmic frequency scale involves some special terminology. A frequency range whose end points have a 2:1 ratio is called an *octave* and one with 10:1 ratio is called a *decade*. Straight-line approximations

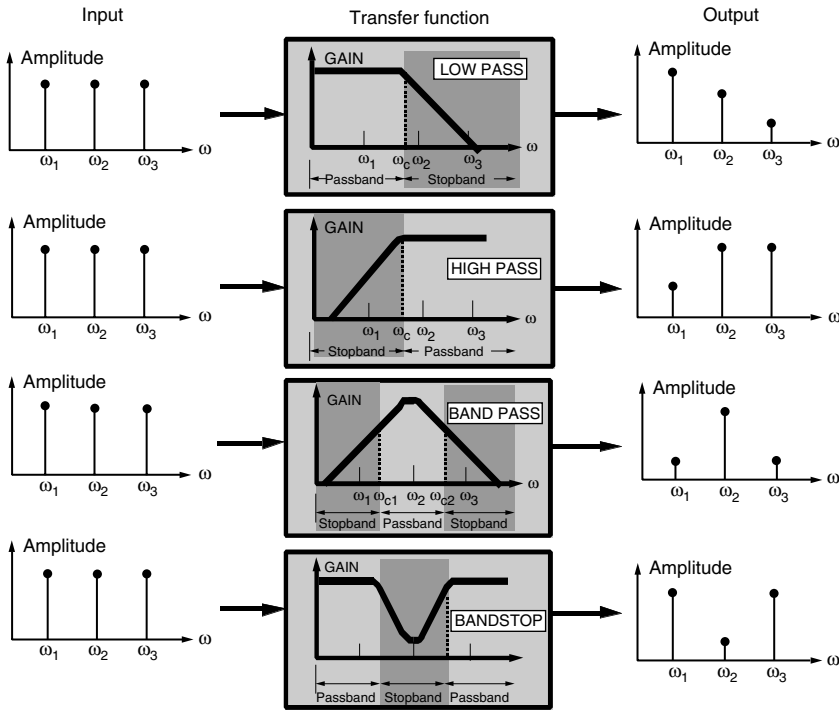

FIGURE 111.2 Four prototype filters and their effects on an input signal consisting of three frequencies.

of these plots, called Bode (Bow-dee) plots, are often used to describe the general behavior of the devices, circuits, or systems.

In frequency-response plots the gain $|T(j\omega)|$ is often expressed in *decibels* (dB), defined as

$$|T(j\omega)|_{\text{dB}} = 20 \log_{10} |T(j\omega)| \quad (111.2)$$

Gains expressed in decibels can be either positive, negative, or zero. A gain of zero dB means that $|T(j\omega)| = 1$ — that is, the input and output amplitudes are equal. A positive dB gain means the output amplitude exceeds the input since $|T(j\omega)| > 1$, whereas a negative dB gain means the output amplitude is smaller than the input since $|T(j\omega)| < 1$. A cutoff frequency usually occurs when the gain is reduced from its maximum passband value by a factor $1/\sqrt{2}$ or 3 dB.

Figure 111.3 shows the asymptotic gain characteristics of ideal and real low-pass filters. The gain of the *ideal filter* is unity (0 dB) throughout the passband and zero ($-\infty$ dB) in the stopband. It also has an infinitely narrow transition band. The asymptotic gain responses of real low-pass filters show that we can only approximate the ideal response. As the order of the filter or number of poles n increases, the approximation improves since the asymptotic slope or “rolloff” in the stopband is $-20 \times n$ dB/decade. On the other hand, adding poles requires additional stages in a cascade realization, so there is a trade-off between (1) filter complexity and cost and (2) how closely the filter gain approximates the ideal response.

Figure 111.4 shows how low-pass filter requirements are often specified. To meet the specification, the gain response must lie within the unshaded region in the figure, as illustrated by the two responses shown in Figure 111.4. The parameter T_{max} is the *passband gain*. In the passband the gain must be within 3 dB of T_{max} and must equal $T_{\text{max}}/\sqrt{2}$ at the cutoff frequency ω_c . In the stopband the gain must decrease and remain below a gain of T_{min} for all $\omega \geq \omega_{\text{min}}$. A low-pass filter design requirement is usually defined by specifying values for these four parameters. The parameters T_{max} and ω_c define the passband response, whereas T_{min} and ω_{min} specify how rapidly the stopband response must decrease.

FIGURE 111.3 The effect of increasing the order n of a filter relative to an ideal filter.

FIGURE 111.4 Parameters for specifying low-pass filter requirements.

111.2 Applications

Simple RL and RC Filters

A first-order LP filter has the following transfer function:

$$T(s) = \frac{K}{s + \alpha} \quad (111.3)$$

FIGURE 111.5 Single-pole LP filter realizations: (a) RL, (b) RC.

FIGURE 111.6 Single-pole HP filter realizations: (a) RL, (b) RC.

where for a passive filter $K \leq \alpha$ and $\alpha = \omega_c$. This transfer function can be realized in several ways including using either of the two circuits shown in Figure 111.5.

For sinusoidal response the respective transfer functions are

$$T(j\omega)_{RL} = \frac{R/L}{j\omega + (R/L)}; \quad T(j\omega)_{RC} = \frac{1/RC}{j\omega + (1/RC)} \quad (111.4)$$

For these filters the passband gain is equal to one and the cutoff frequency is determined by R/L for the RL filter and $1/RC$ for the RC filter. The gain $|T(j\omega)|$ and phase $\angle T(j\omega)$ plots of these circuits are shown back in Figure 111.1.

A first-order HP filter is given by the following transfer function:

$$T(s) = \frac{Ks}{s + \alpha} \quad (111.5)$$

where, for a passive filter, $K \leq 1$ and α is the cutoff frequency. This transfer function can also be realized in several ways including using either of the two circuits shown in Figure 111.6. For sinusoidal response the respective transfer functions are

$$T(j\omega)_{RL} = \frac{j\omega}{j\omega + (R/L)}; \quad T(j\omega)_{RC} = \frac{j\omega}{j\omega + (1/RC)} \quad (111.6)$$

For the LP filters the passband gain is one and the cutoff frequency is determined by R/L for the RL filter and $1/RC$ for the RC filter. The gain $|T(j\omega)|$ and phase $\angle T(j\omega)$ plots of these circuits are shown in Figure 111.7.

FIGURE 111.7 High-pass filter characteristics showing passband, stopband, and the cutoff frequency, ω_c .

Simple RLC Filters

Simple second-order LP, HP, or BP filters can be made using series or parallel RLC circuits. Series or parallel RLC circuits can be connected to produce the following transfer functions:

$$\begin{aligned}
 T(j\omega)_{LP} &= \frac{K}{-\omega^2 + 2\zeta\omega_0 j\omega + \omega_0^2} \\
 T(j\omega)_{HP} &= \frac{-K\omega^2}{-\omega^2 + 2\zeta\omega_0 j\omega + \omega_0^2} \\
 T(j\omega)_{BP} &= \frac{Kj\omega}{-\omega^2 + 2\zeta\omega_0 j\omega + \omega_0^2}
 \end{aligned} \tag{111.7}$$

where for a series RLC circuit $\omega_0 = \sqrt{LC}$ and $\zeta = \frac{R}{2} \sqrt{\frac{C}{L}}$. ω_0 is called the undamped natural frequency and is related to the cutoff frequency in the HP and LP case and is the center frequency in the BP case. ζ is called the damping ratio and determines the nature of the roots of the equation that translates to how quickly a transition is made from the passband to the stopband. ζ in the BP case helps define the bandwidth of the circuit, that is, $Bw = 2\zeta\omega_0$. Figure 111.8 shows how a series RLC circuit can be connected to achieve the transfer functions given in Equation 111.7. The gain $|T(j\omega)|$ and phase $\angle T(j\omega)$ plots of these circuits are shown in Figure 111.9 through Figure 111.11.

FIGURE 111.8 RLC circuit connections to achieve LP, HP, or BP responses.

FIGURE 111.9 Second-order low-pass gain responses.

FIGURE 111.10 Second-order band-pass gain responses.

FIGURE 11.11 Second-order high-pass gain responses.

Compound Filters

Compound filters are higher-order filters obtained by cascading lower-order designs. *Ladder circuits* are an important class of compound filters. Two of the more common passive ladder circuits are the *constant- k* and the *m -derived* filters (either of which can be configured using a *T-section*, *π -section*, or *L-section*, or combinations thereof), the **bridge-T network** and **parallel-T network**, and the **Butterworth** and **Chebyshev** realizations. Only the first two known as image-parameter filters will be discussed in this section. Figure 11.12(a) shows a standard ladder network consisting of two impedances, Z_1 and Z_2 , organized as an L-section filter. Figure 11.12(b) and Figure 11.12(c) show how the circuit can be redrawn to represent a T-section or Π -section filter, respectively.

T- and Π -section filters (also referred to as “full sections”) are usually designed to be symmetrical so that either can have its input and output reversed without changing its behavior. The “L-section” (also known as a “half section”) is unsymmetrical, and orientation is important. Since cascaded sections “load” each other, the choice of termination impedance is important. The *image impedance*, Z_i , of a symmetrical filter is the impedance with which the filter must be terminated in order to “see” the same impedance at its input terminals. In general the image impedance is the desired load or source impedance to which the filter matches. The image impedance of a filter can be found from

$$Z_i = \sqrt{Z_{10}Z_{1s}} \quad (111.8)$$

where Z_{10} is the input impedance of the filter with the output terminals open circuited, and Z_{1s} is its input impedance with the output terminals short-circuited. For symmetrical filters the output and input can be reversed without any change in its image impedance — that is,

$$Z_{1i} = \sqrt{Z_{10}Z_{1s}} \quad \text{and} \quad Z_{2i} = \sqrt{Z_{20}Z_{2s}} \quad (111.9)$$

$$Z_{1i} = Z_{2i} = Z_i$$

The concept of matching filter sections and terminations to a common image impedance permits the development of symmetrical filter designs.

The image impedances of T- and Π -section filters are given as

$$Z_{iT} = \sqrt{Z_{10}Z_{1s}} = \sqrt{\frac{1}{4}Z_1^2 + Z_1Z_2}$$

FIGURE 11.12 Ladder networks: (a) standard L-section, (b) T-section, (c) Π -section.

and

$$Z_{i\Pi} = \sqrt{Z_{10}Z_{1s}} = \frac{Z_1Z_2}{\sqrt{(1/4)Z_1^2 + Z_1Z_2}} \quad (111.10)$$

These expressions also describe the input (or output) impedance when the filter's output (or input) is terminated with appropriate image impedance, i.e., Z_i or Z_T .

The image impedance of an L-section filter, being unsymmetrical, depends on the terminal pair being calculated. For the L-section shown in Figure 11.12(a), image impedances are

$$Z_{iL} = \sqrt{\frac{1}{4}Z_1^2 + Z_1Z_2} = Z_{iT} \quad \text{and} \quad Z_{2iL} = \frac{Z_1Z_2}{\sqrt{(1/4)Z_1^2 + Z_1Z_2}} = Z_{i\Pi} \quad (111.11)$$

These equations show that the image impedance of an L-section at its input is equal to the image impedance of a T-section, whereas the image impedance of an L-section at its output is equal to the image impedance of a Π -section. This relationship is important in achieving an optimum termination when cascading L-sections with T- and/or Π -sections to form a composite filter.

Since Z_1 and Z_2 vary significantly with frequency, the image impedances of T- and Π -sections will also change. This condition does not present any particular problem in combining any number of equivalent filter sections together, since their impedances vary equally at all frequencies. But this does make it difficult to terminate these filters exactly, causing a limitation of these types of filters. However, there is a frequency within the filter's passband where the image impedance becomes purely resistive. It is useful

FIGURE 111.13 Circuit for determining the transfer function of a T-section filter.

to terminate the filter with this value of resistance since it provides good matching over much of the filter's passband.

To develop the theory of constant- k and m -derived filters, consider the circuit of Figure 111.13. The current transfer function in the sinusoidal steady state is given by $T(j\omega) = |T(j\omega)| \angle T(j\omega) = I_2/I_1$:

$$T(j\omega) = |T(j\omega)| \angle T(j\omega) \tag{111.12}$$

$$= \frac{I_2(j\omega)}{I_1(j\omega)} = e^{-\alpha} e^{-j\beta} = e^{-\gamma}$$

where α is the attenuation in dB, β is the phase shift in radians, and γ is the image transfer function.

For the circuit shown in Figure 111.13, the following relationship can be derived:

$$\tanh \gamma = \sqrt{Z_{1S} / Z_{1O}} \tag{111.13}$$

This relationship and those in Equation (111.12) will be used to develop the constant- k and m -derived filters.

Constant- k Filters

During the 1920s O. Zobel developed an important class of symmetrical filters called *constant- k filters* with the conditions that Z_1 and Z_2 are purely reactive — that is, $\pm X(j\omega)$ and

$$Z_1 Z_2 = k^2 = R^2 \tag{111.14}$$

In modern references an R replaces the k . Note that the units of k are ohms. The advantage of this type of filter is that the image impedance in the passband is a pure resistance, whereas in the stopband it is purely reactive. Hence if the termination is a pure resistance and equal to the image impedance, all the power will be transferred to the load since the filter itself is purely reactive. Unfortunately, the value of the image impedance varies significantly with frequency, and any termination used will result in a mismatch except at one frequency.

In LC constant- k filters, Z_1 and Z_2 have opposite signs, so that $Z_1 Z_2 = \pm jX_1 \mp jX_2 = +X_1 X_2 = R^2$. The image impedances become

$$Z_{iT} = R \sqrt{1 - (-Z_1 / 4Z_2)} \quad \text{and} \quad Z_{i\Pi} = \frac{R}{\sqrt{1 - (-Z_1 / 4Z_2)}} \tag{111.15}$$

Therefore, in the stopband and passband, we have the following relations for standard T- or Π -sections, where n represents the number of identical sections:

FIGURE 11.14 Normalized plots of attenuation and phase angle for various numbers of sections n .

FIGURE 11.15 Typical sections: (a) LP Π -section, (b) HP T-section, (c) BP T-section.

| Stopband | Passband | |
|---|---|----------|
| $\alpha = 2n \cosh^{-1} \sqrt{-Z_1 / 4Z_2}$ | $\alpha = 0$ | (111.16) |
| $\beta = \pm n \pi, \pm 3n \pi, \dots$ | $\beta = 2n \sin^{-1} \sqrt{-Z_1 / 4Z_2}$ | |

The ultimate roll-off of constant- k filters is 20 dB per decade per reactive element or 60 dB per decade for the T- or Π -section, 40 dB per decade per L-section. Figure 11.14 shows normalized plots of α and β versus $\sqrt{-Z_1 / 4Z_2}$. These curves are generalized and apply to low-pass, high-pass, band-pass, or band-reject filters. Figure 11.15 shows examples of a typical LP Π -section, an HP T-section, and a BP T-section.

***m*-Derived Filters**

The need to develop a filter section that could provide high attenuation in the stopband near the cutoff frequency prompted the development of the m -derived filter. O. Zobel developed a class of filters that had the same image impedance as the constant- k but had a higher attenuation near the cutoff frequency. The impedances in the m -derived filter were related to those in the constant- k as

FIGURE 11.16 m -derived filters: (a) T-section, (b) Π -section.

$$Z_{1m} = mZ_{1k} \quad \text{and} \quad Z_{2m} = \left(\frac{1-m^2}{4m} \right) Z_{1k} + \frac{1}{m} Z_{2k} \quad (111.17)$$

where m is a positive constant ≤ 1 . If $m = 1$ then the impedances reduce to those of the constant- k . Figure 11.16 shows generalized m -derived T- and Π -sections.

The advantage of the m -derived filter is that it gives rise to infinite attenuation at a selectable frequency, ω , just beyond cutoff, ω_c . This singularity gives rise to a more rapid attenuation in the stopband than can be obtained using constant- k filters. Equation 111.18 relates the cutoff frequency to the infinite attenuation frequency.

$$m = \sqrt{1 - \frac{\omega_c^2}{\omega_\infty^2}} \quad (111.18)$$

Figure 11.17 shows the attenuation curve for a single m -derived LP stage for two values of m . The smaller m becomes, the steeper the attenuation near the cutoff, but also the lesser the attenuation at higher frequencies.

Constant- k filters have image impedance in the passband that is always real but that varies with frequency, making the choice of an optimum termination difficult. The impedance of an m -derived filter also varies, but how it varies depends on m . Figure 11.18 shows how the impedance varies with frequency (both normalized) and m . In most applications, m is chosen to be 0.6, keeping the image impedance nearly constant over about 80% of the passband.

FIGURE 11.17 Attenuation curves for a single-stage filter with $m = 0.6$ and $m = 0.9$.

FIGURE 11.18 Z_{iR}/R and Z_{iT}/R versus normalized frequency for various values of m .

Defining Terms

Bridge-T network — A two-port network that consists of a basic T-section and another element connected so as to “bridge across” the two arms. Such networks find applications as band rejection filters, calibration bridges, and feedback networks.

Butterworth filters — Ladder networks that enjoy a unique passband frequency response characteristic that remains very constant until near the cutoff, hence the designation “maximally flat.” This

filter has its critical frequency remain fixed regardless of the number of stages employed. It obtains this characteristic by realizing a transfer function built around a Butterworth polynomial.

Chebyshev filters — A variant of the Butterworth design that achieves a significantly steeper transition band about its critical frequency for the same number of poles. Although the Chebyshev filter also maintains the integrity of its critical frequency regarding the number of poles, it trades the steeper roll-off for a fixed ripple — usually specified as 1 dB or 3 dB — in the passband. Chebyshev filters are also called *equal-ripple* or *stagger-tuned* filters. They are designed by realizing a transfer function using a Chebyshev polynomial.

Parallel-T networks — A two-port network that consists of two separate T-sections in parallel with only the ends of the arms and the stem connected. Parallel-T networks have applications similar to those of the bridge-T but can produce narrower attenuation bandwidths.

112.5 Operations

The function of power distribution is to deliver to consumers economic, reliable, and safe electrical energy in a manner that conforms to regulatory standards. Power distribution systems receive electric energy from high-voltage transmission systems and deliver energy to consumer service-entrance equipment. Systems typically supply alternating current at voltage levels ranging from 120 V to 46 kV.

Figure 112.1 illustrates aspects of a distribution system. Energy is delivered to the distribution substation (shown inside the dashed line) by three-phase transmission lines. A transformer in the substation steps the voltage down to the distribution primary system voltage — in this case, 12.47 kV. Primary distribution lines leave the substation carrying energy to consumers. The substation contains a breaker that may be opened to disconnect the substation from the primary distribution lines. If the breaker is opened, outside the substation there is normally an open supervisory switch that may be closed in order to provide an alternate source of power for the customers normally served by the substation. The substation also contains a capacitor bank used for either voltage or power factor control.

Four types of customers, along with representative distribution equipment, are shown in Figure 112.1. A set of loads requiring high reliability of service is shown being fed from an underground three-phase secondary network cable grid. A single fault does not result in an interruption to this set of loads. A residential customer is shown being supplied from a two-wire, one-phase overhead lateral. Commercial and industrial customers are shown being supplied from the three-phase, four-wire, overhead primary feeder. At the industrial site, a capacitor bank is used to control the power factor. Except for the industrial customer, all customers shown have 240/120 V service. The industrial customer has 480Y/277 V service.

For typical electric utilities in the U.S., investment in distribution ranges from 35 to 60% of total capital investment.

112.1 Equipment

Figure 112.1 illustrates a typical arrangement of some of the most common equipment. Equipment may be placed into the general categories of transmission, protection, and control.

Arresters protect distribution system equipment from transient over-voltages due to lightning or switching operations. In over-voltage situations the arrester provides a low-resistance path to ground for currents to follow.

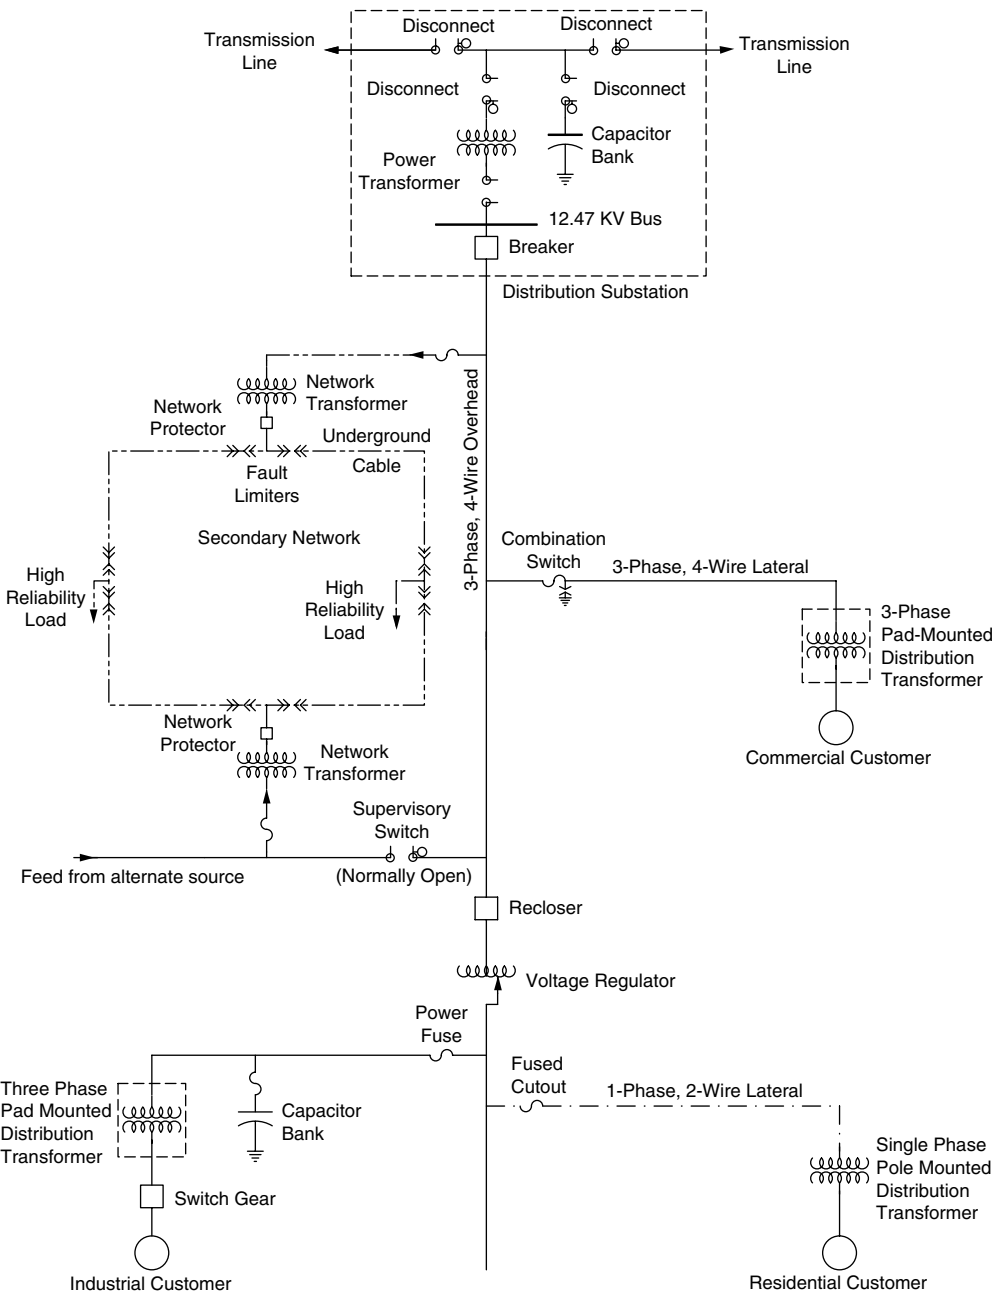

FIGURE 112.1 Distribution system schematic.

Capacitor banks are energy storage devices primarily used to control voltage and power factor. System losses are reduced by the application of capacitors.

Conductors are used to transmit energy and may be either bare or insulated. Bare conductors have better thermal properties and are generally used in overhead construction where contact is unlikely. Insulated cables are used in underground/conduit construction and in overhead applications where minimum right-of-way is available. Concentric neutral and tape-shielded cables provide both a phase conductor and a return path conductor in one unit.

Distribution lines are made up of conductors and are classified according to primary voltage, the number of phases, number of conductors, and return path. The three-phase, four-wire, multi-grounded system is the most common primary system, where one conductor is installed for each of the three phases and the fourth conductor is a neutral that provides a return current path. Multi-grounded means that the neutral is grounded at many points, so that the earth provides a parallel path to the neutral for return current. Three-phase, three-wire primary systems, or delta-connected systems, are rarely used because faults therein are more difficult to detect. A lateral is a branch of the system that is shorter in length, more lightly loaded, or has a smaller conductor size than the primary feeder.

Distribution transformers step the voltage down from the primary circuit value to the customer utilization level, thus controlling voltage magnitude. Sizes range from 1.5 to 2500 kVA. Distribution transformers are installed on poles, ground-level pads, or in underground vaults. A specification of 7200/12,470Y V for the high-voltage winding of a single-phase transformer means the transformer may be connected in a line-to-neutral “wye” connection for a system with a line-to-line voltage of 12,470 V or in a line-to-line “delta” connection for a system with a line-to-line voltage of 7200 V. A specification of 240/120 V for the low-voltage winding means the transformer provides a three-wire connection with 120 V mid-tap voltage and 240 V full-winding voltage. A specification of 480Y/277 V for the low voltage winding means the winding is permanently wye-connected with a fully insulated neutral available for a three-phase, four-wire service to deliver 480 V line-to-line and 277 V line-to-neutral.

Distribution substations consist of one or more step-down power transformers configured with switch gear, protective devices, and voltage regulation equipment for the purpose of supplying, controlling, switching, and protecting the primary feeder circuits. The voltage is stepped down for safety and flexibility of handling in congested consumer areas. Over-current protective devices open and interrupt current flow in order to protect people and equipment from fault current. Switches are used for control to interrupt or redirect power flow. Switches may be operated manually, automatically with PLC control, or remotely with supervisory control. Switches are usually rated to interrupt load current and may be either pad or pole mounted.

Power transformers are used to control and change voltage level. Power transformers equipped with tap-changing mechanisms can control secondary voltage over a typical range of plus or minus 10%.

Voltage regulators are autotransformers with tap-changing mechanisms that may be used throughout the system for voltage control. If the voltage at a remote point is to be controlled, then the regulator can be equipped with a line drop compensator that may be set to regulate the voltage at the remote point based upon local voltage and current measurements. Modern microprocessor-based controls enable regulators and line capacitors to work together to provide optimal voltage regulation.

112.2 System Divisions and Types

Distribution transformers separate the primary system from the secondary. Primary circuits transmit energy from the distribution substation to customer distribution transformers. Three-phase distribution lines that originate at the substation are referred to as primary feeders or primary circuits. Primary feeders are illustrated in [Figure 112.1](#). Secondary circuits transmit energy from the distribution transformer to the customer’s service entrance. Line-to-line voltages range from 208 to 600 V.

Radial distribution systems provide a single path of power flow from the substation to each individual customer. This is the least costly system to build and operate and thus the most widely used.

Primary networks contain at least one loop that generally may receive power from two distinct sources. This design results in better continuity of service. A primary network is more expensive than the radial system design because more protective devices, switches, and conductors are required.

Secondary networks are normally underground cable grids providing multiple paths of power flow to each customer. A secondary network generally covers a number of blocks in a downtown area. Power is supplied to the network at a number of points via network units, consisting of a network transformer in series with a network protector. A network protector is a circuit breaker connected between the secondary winding of the network transformer and the secondary network itself. When the network is

operating properly, energy flows into the network. The network protector opens when reverse energy flow is detected, such as may be caused by a fault in the primary system.

112.3 Electrical Analysis, Planning, and Design

The distribution system is planned, designed, constructed, and operated based on the results of electrical analysis. Generally, computer-aided analysis is used.

Line impedances are needed by most analysis applications. Distribution lines are electrically unbalanced due to loads, unequal distances between phases, dissimilar phase conductors, and single-phase or two-phase laterals. Currents flow in return paths due to the imbalance in the system. Three-phase, four-wire, multigrounded lines have two return paths — the neutral conductor and earth. Three-phase, multigrounded concentric neutral cable systems have four return paths. The most accurate modeling of distribution system impedance is based upon Carson's equations. With this approach a 5×5 impedance matrix is derived for a system with two return paths, and a 7×7 impedance matrix is derived for a system with four return paths. For analysis, these matrices are reduced to 3×3 matrices that relate phase voltage drops (i.e., ΔV_A , ΔV_B , ΔV_C) to phase currents (i.e., I_A , I_B , I_C) as indicated by

$$\begin{bmatrix} \Delta V_A \\ \Delta V_B \\ \Delta V_C \end{bmatrix} = \begin{bmatrix} Z_{AA} & Z_{AB} & Z_{AC} \\ Z_{BA} & Z_{BB} & Z_{BC} \\ Z_{CA} & Z_{CB} & Z_{CC} \end{bmatrix} \begin{bmatrix} I_A \\ I_B \\ I_C \end{bmatrix}$$

Load analysis forms the foundation of system analysis. Load characteristics are time varying and depend on many parameters, including connected consumer types and weather conditions. The load demand for a given customer or group of customers is the load averaged over an interval of time, say 15 min. The peak demand is the largest of all demands. The peak demand is of particular interest since it represents the load that the system must be designed to serve. Diversity relates to multiple loads having different time patterns of energy use. Due to diversity, the peak demand of a group of loads is less than the sum of the peak demands of the individual loads. For a group of loads,

$$\text{Diversity factor} = \frac{\text{Sum of individual load peaks}}{\text{Group peak}}$$

Loads may be modeled as either lumped parameter or distributed. Lumped parameter load models include constant power, constant impedance, constant current, voltage-dependent, and combinations thereof. Generally, equivalent lumped parameter load models are used to model distributed loads. Consider the line section of length L shown in [Figure 112.2\(a\)](#), with a uniformly distributed load current that varies along the length of the line as given by

$$i(x) = \frac{I_2 - I_1}{L}x + I_1$$

The total load current drawn by the line section is thus

$$I_L = I_2 - I_1$$

An equivalent lumped parameter model for the uniformly distributed current load is shown in [Figure 112.2\(b\)](#).

Metered load values are used for analysis when available. Otherwise, estimated loads are calculated using kWhr-to-Peak-KW conversion factors, daily load shapes, and diversity factor curves based on

FIGURE 112.2 (a) Line section model with distributed load current; (b) lumped parameter equivalent model.

customer class. These estimation parameters are derived from load research data gathered from a set of randomly selected test customers. A representative diversified load curve for a residential customer type is shown in [Figure 112.3](#), and a representative diversity factor curve for a residential customer type is shown in [Figure 112.4](#).

Load forecasting is concerned with determining load magnitudes during future years from customer growth projections. Short-range forecasts generally have time horizons of approximately five years, whereas long-range forecasts project to around 20 years.

Power flow analysis determines system voltages, currents, and power flows. Power flow results are checked to ensure that voltages fall within allowable limits, that equipment overloads do not exist, and that phase imbalances are within acceptable limits. For primary and secondary networks, power flow

FIGURE 112.3 Representative diversified load curve for a residential customer type.

FIGURE 112.4 Representative diversity factor curve for a residential customer type.

methods used in transmission system analysis are applied. For radially operated systems, the ladder method is used. The actual implementation of the ladder method may vary with the type of load models used. All ladder load flow methods assume the substation bus voltage is known. An algorithm for the ladder method consists of the following five steps:

1. **Step 1.** Assume a value for all node voltages throughout the circuit. Generally, assumed voltages are set equal to the substation voltage.
2. **Step 2.** At each load in the circuit, calculate the current from the known load value and assumed voltage.
3. **Step 3.** Starting at the ending nodes, sum load currents to obtain line section current estimates, performing summation until the substation is reached.
4. **Step 4.** Having estimates of all line section currents, start at the substation and calculate line section voltage drops and new estimates of node voltages.
5. **Step 5.** Compare new node voltages with estimates of previous iteration values. The algorithm has converged if the change in voltage is sufficiently small. If the algorithm has not converged, return to Step 2.

Dynamic load analysis includes such studies as motor-starting studies. Rapid changes in large loads can result in large currents, with a resultant drop in system voltage. If the dip in voltage is too large or too frequent, then other loads are adversely affected, such as in an annoying flicker of lights. This study generally employs a power flow calculation that is run at a number of points along the dynamic characteristic of the load.

Planning involves using load forecasting and other analysis calculations to evaluate voltage level, substation locations, feeder routes, transformer/conductor sizes, voltage/power factor control, and restoration operations. Decisions are based upon considerations of efficiency, reliability, peak demand, and life cycle cost.

Phase Balancing

Phase balancing is used to balance the current or power flows on the different phases of a line section. This results in improved efficiency and primary voltage level balance. The average current in the three phases is defined as

$$I_{\text{avg}} = \frac{I_A + I_B + I_C}{3}$$

The maximum deviation from I_{avg} is given by

$$\Delta I_{\text{dev}} = \text{maximum of } \left\{ \left| I_{\text{avg}} - I_A \right|, \left| I_{\text{avg}} - I_B \right|, \left| I_{\text{avg}} - I_C \right| \right\}$$

Phase imbalance is defined as

$$\text{Phase imbalance} = \frac{\Delta I_{\text{dev}}}{I_{\text{avg}}}$$

Fault Analysis

Fault analysis provides the basis for protection system design. Thus, in the model used to calculate fault currents, load currents are neglected. Sources of fault current are the substation bus, distributed resource generators, and large synchronous motors on the feeder or neighboring feeders. A variety of fault conditions are considered at each line section, including three-phase-to-ground, single-phase-to-ground, and separate phases contacting one another. In performing the calculations, both bolted (i.e., zero-impedance) faults and faults with impedance in the fault path are considered. Of interest are the maximum and minimum phase and return path fault currents, as well as the fault types that result in these currents.

At a multi-phase grounded node in a linear distribution system, post-fault voltages are related to pre-fault voltages and fault currents as given by

$$\mathbf{V}_f = \mathbf{V}_0 - \mathbf{Z}_{\text{th}} \mathbf{I} \quad (112.1)$$

where \mathbf{V}_f denotes phase voltages (voltages between phase A and ground, B and ground, and C and ground) of the node during the fault, \mathbf{V}_0 is the array of phase voltages before the fault occurs, \mathbf{I} is the array of fault currents that will flow out of the phases of the node during the fault, and \mathbf{Z}_{th} (a 3×3 matrix) represents the phase Thevenin matrix looking into the node.

Once \mathbf{Z}_{th} and pre-fault voltages at the node are available, \mathbf{V}_f can be written in terms of \mathbf{I} depending upon conditions imposed by the fault. Then Equation (112.1) can be solved for \mathbf{I} . The pre-fault system model represents the system behavior before the fault occurs. On the pre-fault model, a power flow calculation may be used to obtain the voltages \mathbf{V}_0 .

The post-fault model represents the system behavior during the fault. For fault calculations, the circuit model used is modified in several ways from the pre-fault model. Usually, load currents are neglected in the post-fault model, and instead superposition is used to add load currents obtained from the pre-fault power flow analysis to fault currents. For the fault calculations, the circuit model is assumed to be linear. Other changes for the post-fault circuit analysis include neglecting slow-acting control devices (such as substation transformer tap changers) that do not have time to react during the time of the fault; and inserting appropriate Thevenin equivalent source impedances, representing the Thevenin impedance seen by the distribution substation looking back into the transmission or subtransmission system. Using the post-fault circuit model assumptions, a power flow calculation using constant current injections at the fault point may be used to perform the fault calculations. This is the approach described here.

The calculation of \mathbf{Z}_{th} may be performed by inserting a small test load sequentially at every individual phase of the faulted node. Prior to any test load insertion, the phase voltages of the node are obtained from a power flow solution. Let these voltages be \mathbf{V}_i . After inserting a test load, the power flow is used again to obtain the current flowing into the test load and the voltages at all phases of the node. Ratios of changes in \mathbf{V}_i to the current drawn by the test load constitute the columns of \mathbf{Z}_{th} . For instance, if the test load is inserted between phase A and ground at grounded node N , the results calculated are the first column of \mathbf{Z}_{th} .

To elaborate, refer to [Figure 112.5](#) where a grounded node N is considered. Here, a general node at which any phase may exist is assumed. The power flow is run on the post-fault system model, and phase-to-neutral voltages at node N are obtained as V_{an} , V_{bn} , and V_{cn} for the phases A, B, and C, respectively

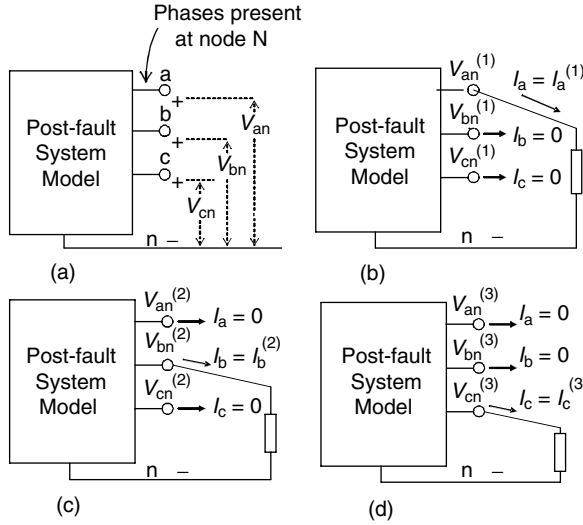

FIGURE 112.5 Constructing Z_{th} at a grounded node N . (a) Voltages before inserting any test load. (b) A test load being inserted between phase A and ground. (c) A test load being inserted between phase B and ground. (d) A test load being inserted between phase C and ground.

[Figure 112.5(a)]. The neutral n is regarded to be the same as ground. A test load will be inserted between A and n , B and n , and C and n sequentially [Figure 112.5(b) through Figure 112.5(d)]. During each load insertion, line currents and phase-to-neutral voltages may be obtained from a power flow calculation.

The elements z_{ij} of Z_{th} may be determined in the following manner:

$$z_{11} = \frac{V_{an} - V_{an}^{(1)}}{I_a^{(1)}}, \quad z_{21} = \frac{V_{bn} - V_{bn}^{(1)}}{I_a^{(1)}}, \quad z_{31} = \frac{V_{cn} - V_{cn}^{(1)}}{I_a^{(1)}}$$

$$z_{12} = \frac{V_{an} - V_{an}^{(2)}}{I_b^{(2)}}, \quad z_{22} = \frac{V_{bn} - V_{bn}^{(2)}}{I_b^{(2)}}, \quad z_{32} = \frac{V_{cn} - V_{cn}^{(2)}}{I_b^{(2)}}$$

$$z_{13} = \frac{V_{an} - V_{an}^{(3)}}{I_c^{(3)}}, \quad z_{23} = \frac{V_{bn} - V_{bn}^{(3)}}{I_c^{(3)}}, \quad z_{33} = \frac{V_{cn} - V_{cn}^{(3)}}{I_c^{(3)}}$$

Z_{th} represents the relationship between the voltage changes and the current changes at N . Suppose phase-to-neutral voltages at N before the fault are V_{an}^i , V_{bn}^i , and V_{cn}^i . Assume that a fault occurs at N and causes currents I_a , I_b and I_c to flow out of phases A, B, and C, respectively, resulting in phase-to-neutral voltages V_{an}^f , V_{bn}^f , and V_{cn}^f .

Then voltage changes at N are related to the currents drawn, via Z_{th} as

$$\begin{bmatrix} \Delta V_{an} \\ \Delta V_{bn} \\ \Delta V_{cn} \end{bmatrix} = \begin{bmatrix} z_{11} & z_{12} & z_{13} \\ z_{21} & z_{22} & z_{23} \\ z_{31} & z_{32} & z_{33} \end{bmatrix} \begin{bmatrix} I_a \\ I_b \\ I_c \end{bmatrix} \quad (112.2)$$

where $\Delta V_{kn} = V_{kn}^i - V_{kn}^f$ for $k = a, b, c$.

Equation (112.2) denotes a general case. Suppose node N is a double-phase location having phases A and B but no phase C. Then, all the elements in the third row and third column of Z_{th} are zero.

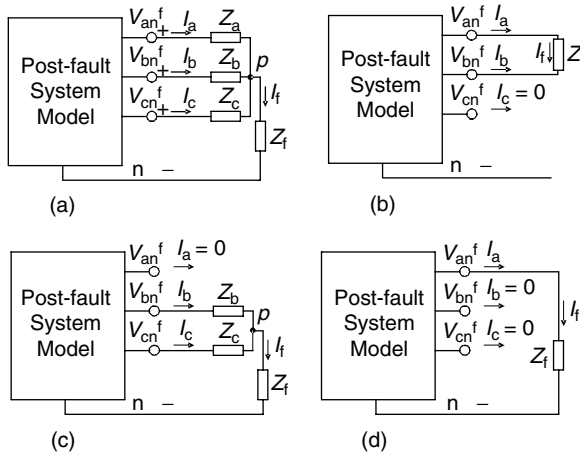

FIGURE 112.6 Various faults at a grounded node N . (a) Three-phase fault. (b) Phase-to-phase fault. (c) Double-phase-to-ground fault. (d) Single-phase-to-ground fault.

Various fault cases at N are shown in Figure 112.6. A general case of a three-phase-to-ground fault at N is represented in Figure 112.6(a). Here, each phase has its own fault impedance (Z_a , Z_b , and Z_c for phases A, B, and C, respectively) to the common point p . Z_f is the impedance between p and n . Consider solving for a three-phase-to-ground fault. Let V_{kn}^i and V_{kn}^f denote pre-fault and post-fault phase-to-ground voltages of phase k , respectively. Then the boundary conditions are:

$$I_f = I_a + I_b + I_c, \quad (112.3)$$

$$\Delta V_{an} = V_{an}^i - V_{an}^f = V_{an}^i - (I_a Z_a + I_f Z_f), \quad (112.4)$$

$$\Delta V_{bn} = V_{bn}^i - V_{bn}^f = V_{bn}^i - (I_b Z_b + I_f Z_f), \quad (112.5)$$

$$\Delta V_{cn} = V_{cn}^i - V_{cn}^f = V_{cn}^i - (I_c Z_c + I_f Z_f). \quad (112.6)$$

First using Equation (112.3) in Equation (112.4), Equation (112.5), and Equation (112.6), then substituting Equation (112.4), Equation (112.5), and Equation (112.6) into Equation (112.2) gives the fault currents as

$$\begin{bmatrix} I_a \\ I_b \\ I_c \end{bmatrix} = \begin{bmatrix} z_{11} + Z_a + Z_f & z_{12} + Z_f & z_{13} + Z_f \\ z_{21} + Z_f & z_{22} + Z_b + Z_f & z_{23} + Z_f \\ z_{31} + Z_f & z_{32} + Z_f & z_{33} + Z_c + Z_f \end{bmatrix}^{-1} \begin{bmatrix} V_{an}^i \\ V_{bn}^i \\ V_{cn}^i \end{bmatrix}$$

Any fault event imposes a set of boundary conditions. Initial voltages (pre-fault voltages) can be readily calculated from the power flow. The final voltages are expressed under the boundary conditions in terms of the fault currents and fault impedances. Then, Equation (112.2) is solved for fault currents. Using this approach, fault currents for cases b through d shown in Figure 112.6 may be evaluated. For an ungrounded node, the phase-to-phase voltages instead of phase-to-neutral voltages are employed.

Protection and Coordination

Over-current protection is the most common protection applied to the distribution system. With over-current protection, the protective device trips when a large current is detected. The time to trip is a function of the magnitude of the fault current. The larger the fault current is, the quicker the operation. Various types of equipment are used. A circuit breaker is a switch designed to interrupt fault current, the operation of which is controlled by relays. An over-current relay, upon detecting fault current, sends a signal to the breaker to open. A recloser is a switch that opens and then recloses a number of times before finally locking open. A fuse is a device with a fusible member, referred to as a fuse link, which in the presence of an over current melts, thus opening up the circuit.

Breakers may be connected to reclosing relays, which may be programmed for a number of opening and reclosing cycles. With a recloser or a reclosing breaker, if the fault is momentary, then the power interruption is also momentary. If the fault is permanent, then after a specified number of attempts at reclosing the device locks open. Breakers are generally more expensive than comparable reclosers. Breakers are used to provide more sophisticated protection, which is available via choice of relays. Fuses are generally used in the protection of laterals.

Protective equipment sizing and other characteristics are determined from the results of fault analysis. Moving away from the substation in a radial circuit, both load current and available fault current decrease. Protective devices are selected based on this current grading. Protective devices are also selected to have different trip-delay times for the same fault current. With this time grading, protective devices are coordinated to work together such that the device closest to a permanent fault clears the fault. Thus reclosers can be coordinated to protect load-side fuses from damage due to momentary faults.

Reliability Analysis

Reliability analysis involves determining indices that relate to continuity of service to the customer. Reliability is a function of tree conditions, lightning incidence, equipment failure rates, equipment repair times, and circuit design. The reliability of a circuit generally varies from point to point due to protection system design, placement of switches, and availability of alternative feeds. Many indices are used in evaluating system reliability. Common ones include system average interruption frequency index (SAIFI), system average interruption duration index (SAIDI), customer average interruption frequency index (CAIFI), and customer average interruption duration index (CAIDI) as defined by

$$\text{SAIFI} = \frac{\text{Total number of customer interruptions}}{\text{Total number of customers served}}$$

$$\text{SAIDI} = \frac{\text{Sum of customer interruption durations}}{\text{Total number of customers}}$$

$$\text{CAIFI} = \frac{\text{Total number of customer interruptions}}{\text{Total number of customers affected}}$$

$$\text{CAIDI} = \frac{\text{Sum of customer interruption durations}}{\text{Total number of customers affected}}$$

112.4 System Control

Voltage control is required for proper operation of customer equipment. For instance, in the U.S., “voltage range A” for single-phase residential users specifies that the voltage may vary at the service entrance from 114/228 V to 126/252 V. Regulators, tap-changing under load transformers, and switched capacitor banks are used in voltage control.

Power factor control is used to improve system efficiency. Due to the typical load being inductive, power factor control is generally achieved with fixed and/or switched capacitor banks.

Power flow control is achieved with switching operations. Such switching operations are referred to as system reconfiguration. Reconfiguration may be used to balance a load among interconnected distribution substations. Such switching operations reduce losses while maintaining proper system voltage.

Load control may be achieved with voltage control and also by remotely operated switches that disconnect load from the system. Generally, load characteristics are such that if the voltage magnitude is reduced, then the power drawn by the load will decrease for some period of time. Load control with remotely operated switches is also referred to as load management.

Effective system control is essential to provide adequate power quality. Power quality may be defined as the absence of service interruptions, voltage dips and sags, and voltage spikes and surges. Proper control of system voltage is more critical now than ever before because many microprocessor-based controls and adjustable speed drives have voltage tolerances less than 10%.

112.5 Operations

The operations function includes system maintenance, construction, and service restoration. Maintenance, such as trimming trees to prevent contact with overhead lines, is important to ensure a safe and reliable system. Interruptions may be classified as momentary or permanent. A momentary interruption is one that disappears very quickly — for instance, a recloser operation due to a fault from a tree limb briefly touching an overhead conductor. Power restoration operations are required to repair damage caused by permanent interruptions.

While damaged equipment is being repaired, power restoration operations often involve reconfiguration in order to restore power to interrupted areas. With reconfiguration, power flow calculations may be required to ensure that equipment overloads are not created from the switching operations.

Defining Terms

Current return path — The path that current follows from the load back to the distribution substation.

This path may consist of either a conductor (referred to as the neutral) or earth, or the parallel combination of a neutral conductor and the earth.

Fault — A conductor or equipment failure or unintended contact between conductors or between conductors and grounded objects. If not interrupted quickly, fault current can severely damage conductors and equipment.

Phase — Relates to the relative angular displacement of the three sinusoidally varying voltages produced by the three windings of a generator. For instance, if phase A voltage is $120\angle 0^\circ$ V, phase B voltage $120\angle -120^\circ$ V, and phase C voltage $120\angle 120^\circ$ V, the phase rotation is referred to as ABC. Sections of the system corresponding to the phase rotation of the voltage carried are commonly referred to as phase A, B, or C.

Tap-changing mechanism — A control device that varies the voltage transformation ratio between the primary and secondary sides of a transformer. The taps may only be changed by discrete amounts, say 0.625%.

Many electromagnetic compatibility problems are caused by low immunity to emissions and poor facility and data wiring and grounding which further affect equipment performance. Besides, radiated and conducted emissions generated by a piece of equipment may also affect that equipment's own performance. To avoid problems, electromagnetic interference (EMI) control measures must be incorporated into the initial circuit design. Grounding, shielding, and filtering are some of the important factors that must be considered during the initial design of electronic circuits.

The purpose of this chapter is to give engineers and facility engineers who are unfamiliar with EMI-related problems insights and information necessary to improve equipment compatibility. The goal here is not to duplicate information currently available, but rather to collect information in a single location and then supplement it to provide adequate information and procedures to applications personnel in effectively limiting the spurious emissions given off by electronics and ensuring that electronic equipment is not adversely affected by such emissions.

113.1 Analyzing and Solving Problems Associated with Electromagnetic Interference

What Is Electromagnetic Interference?

Electromagnetic interference (EMI) is any natural or manmade electrical or electromagnetic energy that results in unintentional and undesirable equipment responses. Electromagnetic energy travels in the form of emissions, either conducted or radiated.

Conducted emissions are generated inside electrical or electronic equipment and may be transmitted outward through the equipment's data input or output lines, its control leads, or its power conductors. Conducted emissions may cause an EMI problem between equipment that generates useful emissions and other equipment with low immunity to those same emissions.

Radiated emissions are radio-frequency electromagnetic energy that travels through the air. Radiated emissions are also generated by electrical or electronic equipment and may be emitted from power and data cables that are poorly shielded or unshielded, leaky equipment apertures, equipment housings that are inadequately shielded, or equipment antennae that may or may not be operating normally.

Current trends in the electronics industry (such as increases in the quantity of electronic equipment, reliance on electronic devices in critical applications, higher clock frequencies of computing devices, higher power levels, lower sensitivities, increased packaging densities, use of plastics, etc.) will tend to create more EMI problems. Whether conducted or radiated, emissions include three properties: amplitude, frequency, and waveform. EMI can occur in equipment with low immunity to emissions when any or all of these properties vary from normal, for example, emissions that are too high in amplitude, are too low or too high in frequency, or whose waveforms are distorted. EMI can also occur when these properties are within normal operating parameters, usually resulting from equipment's low immunity to emissions. Examples of intentional and unintentional conducted and radiated emissions are illustrated in [Table 113.1](#).

Causes of EMI

EMI is generally common-mode (CM) noise, which is induced onto a signal with respect to a reference ground. The noise is coupled to ground from the power cables through the capacitance between the power cable and ground. [Figure 113.1](#) demonstrates this principle.

The capacitance between the cable and ground increases as the length of cable increases. Therefore, short lengths of cable have a low risk of common-mode noise. As the length of cable increases, the risk of common-mode noise increases and the need for EMI solutions rises.

As shown in [Figure 113.2](#), the common-mode ground current $I_{a0} = C_{1-g} dv/dt$. This characteristic of common-mode current makes the adjustable-speed drive a prime source of common-mode noise because of its abrupt voltage transitions on the drive output terminal. The conducted noise will be created as the individual pulses on the drive output couple with the ground conductor. Some common symptoms of EMI-related problems are:

- Unexplained drive trips with no correlation with voltage disturbances.
- Malfunctions of barcode/vision systems, ultrasonic sensors, and weighing and temperature sensors.
- Intermittent data errors in drive-control interfaces such as encoder feedback, I/O, and 0-10-V analog out.
- Interference with TV, AM radio, and radio-controlled devices.

Radiated emissions from many types of electronic equipment, including ASDs, lighting systems, broadcast communication equipment, and medical equipment, have been shown to cause electromagnetic interference with other types of sensitive electronic equipment. [Figure 113.1](#) shows how conducted and radiated emissions propagated through the electromagnetic environment may interfere with sensitive electronic medical equipment that is microprocessor based.

TABLE 113.1 Examples of Intentional and Unintentional Conducted and Radiated Emissions

| Examples of Conducted Emission Waveform or Electromagnetic Disturbance | Description | Radiated Emission Waveform or Electromagnetic Disturbance | Description |
|---|---|--|---|
|  Nominal 60 Hz Line Voltage | No electrical noise, or conducted emissions, are present on ideal noise-free nominal voltage. |  Amplitude Modulated (AM) Radiated Emissions | AM radio broadcast towers and some high-frequency medical equipment generate useful AM radiated emissions ranging from 535 kHz to 1605 kHz |
|  Conducted Emissions = 2 to 20 kHz Nominal Voltage with Continuous Conducted Emissions | Power-line carriers, which are often continuous emissions superimposed upon nominal voltage, carry useful information to other devices on the building wiring, such as automatic clock systems. |  Frequency Modulated (FM) Radiated Emissions Broadcast Transmission | FM radio broadcast towers generate useful FM radiated emissions ranging from 88 MHz to 108 MHz |
|  Conducted Emissions = 120 kHz Nominal Voltage with Pulsed Conducted Emissions | Power-line carriers may also be pulsed, or short bursts of conducted emissions to operate equipment, such as energy management systems, transmitters and receivers on the building wiring system. |  Frequency Modulated (FM) Radiated Emissions (Wireless Communications Devices) | Land-mobile transmitter towers and analog wireless communications devices generate useful FM radiated emissions ranging from 1605 kHz to 459 MHz. |
|  Nominal Voltage with Continuous Electrical Noise | Switching electronic equipment, which may contain a switch-mode power supply, and rotating electrical machinery, may generate continuous unintentional electrical noise, or conducted emissions. |  Zero Carrier Television Broadcast Radiated Emissions | Television transmissions generate useful radiated emissions from 54 MHz to 890 MHz. |
|  Nominal Voltage with Pulsed Electrical Noise | The turning on and off of electrical loads and electronic equipment may generate unintentional conducted emissions. |  Analog Cellular Telephone Radiated Emissions | Analog cellular telephones generate a continuous type of useful radiated emissions ranging from 824 MHz to 893 MHz. |
| | |  Telemetry Signal Radiated Emissions with Undesired Radiated Interference | Radiated emissions from telemetry transmitters may become distorted by undesired emissions from nearby sources of other radiated emissions. |
| | |  Normal High-Energy Radiated Emissions from High-Frequency Medical Equipment | High-frequency medical equipment such as electrosurgical units (ESU) generate useful radiated emissions that are used to perform medical procedures during surgery. |
| | |  Electrostatic Discharges (ESDs) Generate Radiated Emissions | ESD events may generate unwanted radiated emissions from the electromagnetic fields that collapse around the discharge of current from one surface to another. |

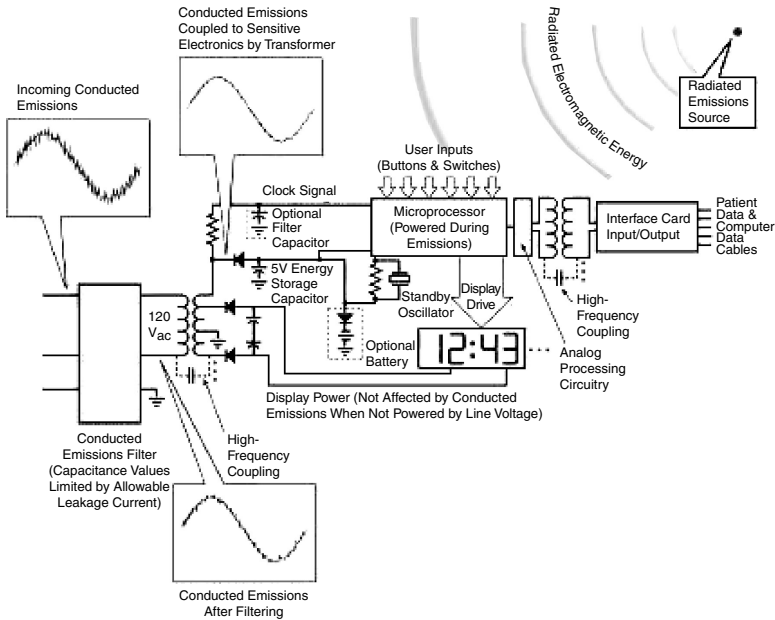

FIGURE 113.1 Capacitive-coupling from phase-to-ground conductor.

FIGURE 113.2 Examples of conducted and radiated emissions interfering with equipment.

Ungrounded shields or floating shields can act like an antenna to unwanted radiated emissions. In the case of a shielded cable, a cable connector also helps to connect the cable shield to the equipment enclosure electromagnetically. Connectors are used to mechanically secure a cable to a piece of equipment. The pieces of a connector must fit together properly and securely to ensure the electromagnetic integrity of the connector. Particular attention must be paid to how the pieces fit together during connector installation. Improperly fitted or loose connector joints can cause electromagnetic leaks in the connector, which can allow unwanted radiated electromagnetic energy from the electromagnetic environment to penetrate the cable system.

Solutions to EMI Problems

Methods to mitigate EMI in an industrial facility could include proper grounding and shielding of sensitive equipment, attenuating emissions at the source, capturing and returning emissions to the source, etc.

FIGURE 113.3 Use of a shielded/armor cable to reduce EMI.

Proper Grounding and Shielding of Sensitive Equipment

The practice of using unshielded phase conductors in a cable tray from an ASD to a motor could introduce common-mode noise into the system. The use of a shielded-armor power cable from a drive to a motor will provide a path for the common-mode noise to return to the source. Figure 113.3 demonstrates this concept.

Signal shields reduce external coupling but may introduce EMI if the shield is connected to a noisy ground potential. The standard practice is to ground the shield at the source side of the cable. If the standard practice does not eliminate the EMI, it becomes necessary to do whatever it takes to fix the problem, including grounding on both ends, grounding on the other end, or not grounding at all.

The path of common-mode emissions can be diverted from sensitive equipment by separating control and signal cables from high-voltage wires. It is also best if the power conductors include a ground wire and are placed in a conduit. The conduit should be bonded to an ASD cabinet, the motor junction box, and the ground wire should be connected to the cabinet ground bus and motor ground stud. The ground wire and conduit setup parasitic capacitive paths within the conduit and couple high dV/dt pulses and return them back to the source of emissions.

Often it is necessary to isolate the conduit coupling at the point of the motor to prevent the coupled emissions from traveling on the outer surface of the conduit. Insulated motor pairs and ground are recommended to prevent inadvertent grounding of the conduit where new ground loops may be established to radiate the noise. In this practice, it is critical to carry the safety ground within the conduit and ensure proper bonding at the motor ground stud to ensure NEC compliance. This practice is usually necessary where interference levels may be in the low frequency band, for example, 10 to 100 kHz.

Another often-recommended and important practice is to separate control and signal cables from power cables in cable trays. The practice of placing covers on a signal cable tray will further reduce the noise coupled to the signal cables from the power cables.

Attenuating Emissions at the Source

The best way to eliminate system emissions is to attenuate emissions at the source. The use of a common-mode choke (CMC) is one way to achieve this. A CMC is an inductor with phases A, B, and C conductors wound in the same direction through a common magnetic core. It provides high impedance and high inductance to any line-to-ground capacitive current emissions. Unlike a line reactor/inductor, a CMC does not affect the power-line circuit. This device is available from drive vendors. Figure 113.4 shows an example of a CMC application.

Capturing and Returning Emissions to the Source

Another method to reduce EMI is to capture emissions and return them to the source. This can be accomplished with an EMI filter. Figure 113.5 demonstrates the use of an EMI filter. This figure shows that the CM current I_{ao} will collect in the ground conductors and return to the drive through the EMI filter. The filter contains a large common-mode core inductance and individual phase capacitors that limit the high frequency ground return current to low levels in the main AC supply.

FIGURE 113.4 Application of a common-mode choke.

FIGURE 113.5 Application of EMI filter.

113.2 Grounding

With electrical power systems, there are at least two groups or classes of grounding:

1. System grounding
2. Equipment grounding

System grounding pertains to the manner in which a circuit conductor of a system is intentionally connected to earth, or to some conducting body that is effectively connected to earth or serves in place of earth. Equipment grounding is the process of bonding together, with equipment-grounding conductors, all conductive enclosures for conductors and equipment within each circuit. Article 250-50 of the NEC and other important standards require that at each building or structure served, metal underground water pipes, supplemental electrodes, metal frames of the building, and concrete-encased electrodes (rebar) be bonded together to form the grounding electrode system. This grounding practice establishes a zero-voltage reference for an electrical power distribution system. Fundamental design principles for system and equipment grounding and the basic factors that influence the selection of the type of system/equipment grounding are extensively covered in IEEE Color books, including IEEE Std. 141-1993, IEEE Std. 142-1991, IEEE Std. 446-1995, IEEE Std. 1100-1999, NFPA 70-1999 National Electric Code (NEC), and Federal Information Processing Standards (FIPS) 1994.

Note that the basic objectives for grounding circuits, cables, equipment, and systems are to prevent a shock hazard; to protect circuits and equipments; and to reduce EMI due to electromagnetic field, common ground impedance, or other forms of interference coupling. However, grounding is one of the least understood and most significant factors in many EMI problems. Most equipment manufacturers will provide details on grounding of their equipment and may often violate NEC and other important standards. The EMI part of the problem is emphasized in the subsequent sections.

Characteristics of Ground Conductors

Ideally, a ground conductor should provide a zero-impedance path to all signals for which it serves as a reference. If this were the situation, signal currents from different circuits would return to their respective sources without creating unwanted coupling between circuits. Many interference problems occur because

FIGURE 113.6 Idealized equipment grounding.

FIGURE 113.7 Typical impedance versus frequency behavior of a grounding conductor.

designers treat the ground as ideal and fail to give proper attention to the actual characteristics of the ground conductor.

A commonly encountered situation is that of a ground conductor running along in the proximity of a ground plane as illustrated in Figure 113.6. The ground conductor and ground plane may be represented as a short-circuited transmission line. At low frequencies the resistance of the ground conductor will predominate. At higher frequencies the series inductance and the shunt capacitance to ground will become significant, and the ground conductor will exhibit alternating parallel and series resonance as illustrated in Figure 113.7. To provide a low impedance to ground, it is necessary to keep the length of the grounding conductor short relative to wavelength (i.e., less than 1/20 of the wavelength).

Ground voltage equalization of voltage differences between parts of an automated data processing (ADP) grounding system is accomplished in parts when the equipment-grounding conductors are connected to the grounding point of a single power supply. However, if the equipment grounding conductors are long, it is difficult to achieve a constant potential throughout the grounding system, particularly for high frequency noise. Supplemental conductors, low-inductance ground plates, and grounding and bonding of raised floor pedestals may be necessary. Detailed discussions and standard practices and procedures are extensively covered in IEEE Color books, including IEEE Std. 142-1991 and IEEE Std. 1100-1999.

Ground-Related EMI Coupling

Ground-related EMI involves one of two basic coupling mechanisms. The first mechanism results from circuits sharing the ground with other circuits. Figure 113.8 illustrates EMI coupling between culprit and

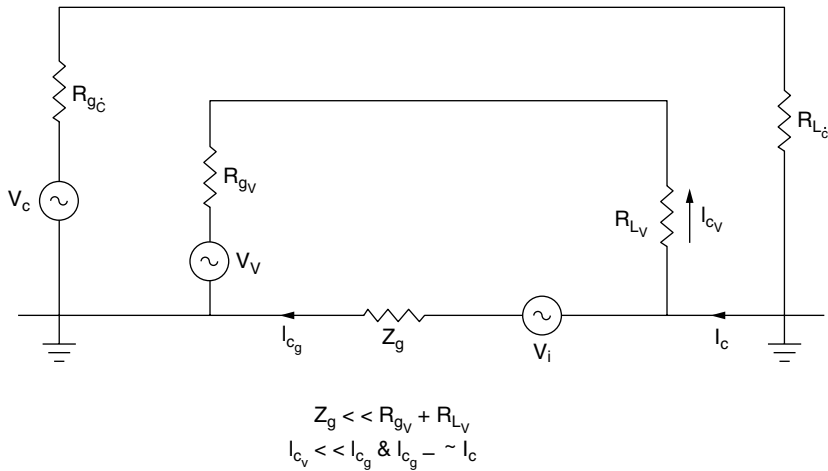

FIGURE 113.8 Common-ground impedance coupling between circuits.

victim circuits via the common-ground impedance. In this case, the interference current (I_{c_g}) flowing through the common-ground impedance (Z_g) will produce an interfering signal voltage (V_i) in the victim circuit. This effect can be reduced by minimizing or eliminating the common-ground impedance.

The second EMI coupling mechanism involving ground is a radiated mechanism whereby the ground loop, as shown in Figure 113.9, acts as a receiving or transmitting antenna. Ground loops are probably the most common cause of interference in network systems and also the most common problem with multi-port devices in general. For this EMI coupling mechanism the induced EMI voltage (for the susceptibility case) or the emitted EMI field (for the emission case) is a function of the EMI driving function (field strength, voltage, or current), the geometry and dimensions of the ground loop, and the frequency of the EMI signal.

Common wisdom on electromagnetic compatibility recommends that radiated effects can be minimized by routing conductors as close as possible to ground and minimizing the ground-loop area. Even though theory holds up that closely routing conductors next to a ground plane will reduce the effects of coupling, however, where building steel and in particular in cases of lightning where large currents may flow, the coupling will still occur. The coupling effect applies to stray common-mode currents also. The primary factor is that in practical installations, ideal placement of the conductor next to the surface of the ground plane is difficult. Examples of this may be the upgrade of existing plant operation to incorporate multiple remote PLC systems communicating to a central control room. These cable runs are seldom able to achieve the ideal installation.

Figure 113.10 uses linear scales to emphasize the very rapid rise of induced voltage near a conductor and the small additional gain after a few meters. However, if “close to” were interpreted by an installer as a few centimeters, all the expected benefits from the “close” installation would be lost — in other words, it is not very effective to attempt minimizing induced voltages by casual routing of unshielded

FIGURE 113.9 Common-mode radiations into and from ground loops.

FIGURE 113.10 Voltage induced by the field into the loop.

cables “near” the ground planes. From Figure 113.10 it can be clearly seen that when a cable is just a few centimeters above the ground plane, the cable will still have significant amounts of induced noise.

Grounding Configurations

Typical electronic equipment may have a number of different types of functional signals as shown in Figure 113.11. To mitigate interference due to common-ground impedance coupling, as many separate grounds as possible should be used.

The grounding scheme for a collection of circuits within equipment can assume any one of several configurations. Each of these configurations tends to be optimum under certain conditions and may contribute to EMI problems under other conditions. In general, the ground configurations are a floating ground, a single-point ground, a multiple-point ground, or some hybrid combination. The determination to use single-point grounding or multiple-point grounding typically depends on the frequency range of interest. Analog circuits with signal frequencies up to 300 kHz may be candidates for single-point grounding. Digital circuits with signal frequencies in the MHz range should utilize multiple-point grounding.

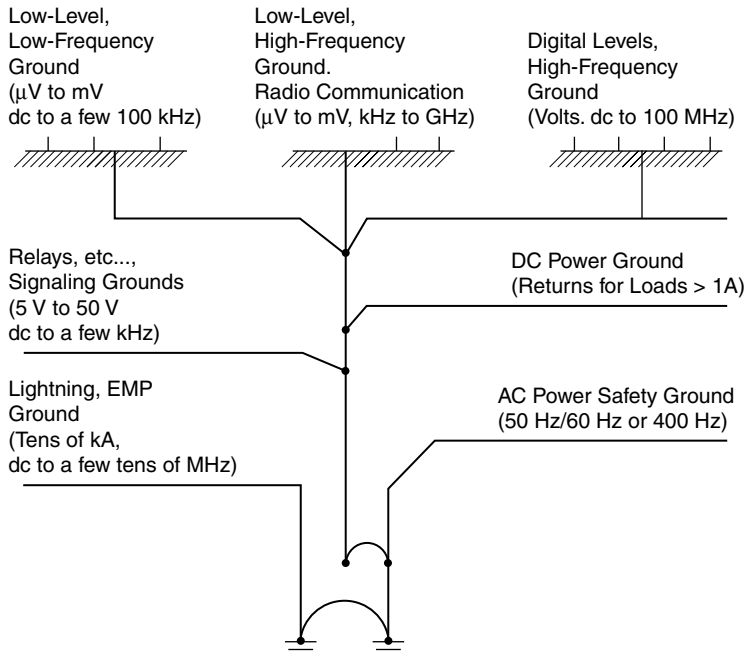

FIGURE 113.11 Grounding hierarchy.

FIGURE 113.12 Floating signal ground.

A floating ground configuration is illustrated in Figure 113.12. The signal ground is electrically isolated from the equipment ground and other conductive objects. Hence, equipment noise currents present in the equipment and power ground will not be conductively coupled to the signal circuits.

The effectiveness of floating ground configurations depends upon their true isolation from other nearby conductors; that is, to be effective, floating ground systems must really float. It is often difficult to achieve and maintain an effective floating system. A floating ground configuration is most practical if only a few circuits are involved and power is supplied from either batteries or DC-to-DC converters.

A single-point ground configuration is illustrated in Figure 113.13. An important advantage of the single-point configuration is that it helps control conductively coupled interference. As illustrated in Figure 113.13, EMI currents or voltages in the equipment ground are not conductively coupled into the signal circuits via the signal ground. Therefore, the single-point signal ground network minimizes the effects of any EMI currents that may be flowing in the equipment ground.

The multiple-point ground illustrated in Figure 113.14 is the third configuration frequently used for signal grounding. With this configuration, circuits have multiple connections to ground. Thus, in equipment, numerous parallel paths exist between any two points in the multiple-point ground network. Multipoint grounding is more economical and practical for printed circuits and integrated circuits.

FIGURE 113.13 Single-point signal ground.

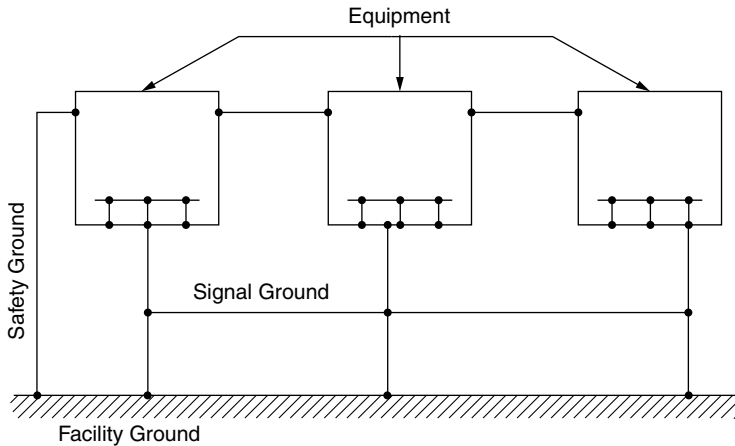

FIGURE 113.14 Multiple-point ground configuration.

Interconnection of these components through wafer risers, mother boards, and so forth should use a hybrid grounding approach in which single-point grounding is used to avoid low-frequency ground loops and/or common-ground impedance coupling; multipoint grounding is used otherwise.

Summary of Grounding Considerations

It should be noted that both the conducted and radiated EMI coupling mechanisms identified earlier involve a “ground loop.” It is important to recognize that ground loop EMI problems can exist without a physical connection to ground. In particular, at RF frequencies, capacitance-to-ground can create a ground loop condition even though circuits or equipments are floated with respect to ground.

A properly designed ground configuration is one of the most important engineering elements in protecting against the effects of EMI. The ground configuration should provide effective isolation between power, digital, high-level analog, and low-level analog signals. In designing the ground it is essential to consider the circuit, signal characteristics, equipment, cost, maintenance, and so forth. In general, either floating or single-point grounding is optimum for low-frequency situations, and multiple-point grounding is optimum for high-frequency situations. In many practical applications, a hybrid ground approach is employed to achieve the single-point configuration for low frequencies and the multiple-point configuration for high frequencies.

113.3 Shielding

Shielding is one of the most effective methods for controlling radiated EMI effects at the component, circuit, equipment, subsystem, and system levels. Good EMC design reduces EMI signals to a level where they do not cause problems within the equipment or with any other equipment.

Shielding effectiveness is a measure of how well a shield blocks radiated emissions. Reducing the level of radiated emissions incident upon the equipment requires selecting the proper shielding material (see [Figure 113.15](#)), and correct installation and maintenance to ensure the integrity of the shield.

Radiated Electromagnetic Waves

The performance of shields is a function of the characteristics of the incident electromagnetic fields. All electromagnetic waves consist of two oscillating fields that operate at right angles to each other. One of these fields is the electric (E) field, whose strength is measured in volts per meter. Perpendicular to the E field is the magnetic (H) field, whose strength is measured in amps per meter. H fields usually are generated by high current, low voltage, low impedance circuits. In contrast, E fields are produced by

FIGURE 113.15 A variety of shields can be used to solve EMI problems.

devices that have high voltage, but relatively low current and high impedance. The ratio of E field to H field is called the wave impedance. The H and E fields vary in relative magnitude according to the distance of the wave from the generating source and the nature of the source itself.

The material selected for the shield depends upon characteristics of the source of the radiated emissions and the reflective and absorbent properties of the shielding material (see [Figure 113.16](#)). These include the impedance of the electromagnetic fields of the source creating the emissions, which depends on the distance from the emissions source to the malfunctioning equipment. In most cases, this distance (referred to as the “far-field”) is such that the emissions are primarily due to electric fields resulting in field impedance that is constant and can be easily approximated. If the equipment is relatively close to the source of emissions, the impedance will be lower where the equipment is referred to as being in the “near-field,” and where the magnetic field component must be considered. Before a shielding material can be selected, one must determine whether the affected equipment is in the “near-” or “far-field.”

In the “far-field,” a moderately good conductor may be used to shield against radiated emissions from electric fields. For emissions above about 1 MHz, the conductivity of the material, which is partially based on its thickness, does not have a significant effect on the material’s ability to block electric fields. The primary dependence is on conductivity, which is the material’s ability to carry electrons from the field and thus, provide a low impedance path to ground for the radiated emissions. However, at distances closer to the source of the emissions, more attention must be placed on selecting the shielding material.

FIGURE 113.16 Diagram of a shielding material absorbing and reflecting emission.

FIGURE 113.17 Shielding of plane waves.

Unlike the mitigation of electric fields in the “far-field,” which only requires the shield to be reflective, equipment in the “near-field,” which may be in an area containing both electric and magnetic-field components, requires a material that will reflect and absorb electromagnetic energy. Therefore, shielding considerations in the near-field region of an EMI source may be significantly different from shielding considerations in the far-field region.

Shielding Theory

If a metallic barrier is placed in the path of an electromagnetic field as illustrated in Figure 113.17, only a portion of the electromagnetic field may be transmitted through the barrier. Several effects may occur when the incident wave encounters the barrier. First, a portion of the incident wave may be reflected by the barrier. Second, the portion of the incident wave that is not reflected will penetrate the barrier interface and may experience absorption loss while traversing the barrier. Third, additional reflection may occur at the second barrier interface, where the electromagnetic field exits the barrier. Usually, this second reflection is insignificant relative to the other effects that occur, and it may be neglected.

The shielding effectiveness of the barrier may be defined in terms of the ratio of the impinging field intensity to the exiting field intensity. For high-impedance electromagnetic fields or plane waves, the shielding effectiveness is given by

$$SE_{dB} = 20 \log \left(\frac{E_1}{E_2} \right) \quad (113.1)$$

where E_1 is the impinging field intensity in volts per meter and E_2 is the exiting field intensity in volts per meter. For low-impedance magnetic fields, the shielding effectiveness is defined in terms of the ratio of the magnetic field strengths.

The total shielding effectiveness of a barrier results from the combined effects of reflection loss and absorption loss. Thus, the shielding effectiveness, S , in dB is given by

$$S_{dB} = R_{dB} + A_{dB} + B_{dB} \quad (113.2)$$

where R_{dB} is the reflection loss, A_{dB} is the absorption loss, and B_{dB} is the internal reflection loss. Characteristics of the reflection and absorption loss are discussed in the following sections.

Reflection Loss

When an electromagnetic wave encounters a barrier, a portion of the wave may be reflected. The reflection occurs as a result of a mismatch between the wave impedance and the barrier impedance. The resulting reflection loss, R , is given by

$$\begin{aligned}
 R_{\text{dB}} &= 20 \log_{10} \frac{(K+1)^2}{4K}, & K &= \frac{Z_w}{Z_b} \\
 &= 20 \log_{10} \left(\frac{Z_w}{4Z_b} \right), & K &\geq 10
 \end{aligned}
 \tag{113.3}$$

where Z_w is the wave impedance = E/H , and Z_b is the barrier impedance.

Absorption Loss

When an electromagnetic wave encounters a barrier, a portion of the wave penetrates the barrier. As the wave traverses the barrier, the wave may be reduced as a result of the absorption loss that occurs in the barrier. This absorption loss, A , is independent of the wave impedance and may be expressed as follows:

$$A_{\text{dB}} = 8.68t / \delta = 131t \sqrt{f_{\text{MHz}} \mu_r \sigma_r} \tag{113.4}$$

where t is the thickness in mm, f_{MHz} is the frequency in MHz, μ_r is the permeability relative to copper, and σ_r is the conductivity relative to copper.

Shielding Material Characterization

The ability of a material to absorb radiated emissions depends on the frequency of the source, and the conductivity, permeability, and thickness of the shielding material. An increase in any of these variables will increase absorption. However, the variables of concern when selecting a material to absorb emissions in the “near-field” are the ones that vary widely among available materials. These are permeability, which is the extent to which a material can be magnetized, and thickness. Thus, to mitigate against low-frequency magnetic fields in the “near-field” such as those originating from power distribution equipment such as transformers from some medical equipment utilizing 60-hertz power and from electrical appliances, a material of the proper thickness such as iron, which can be magnetized and provide a path for the magnetic field emissions, is required. A screened or solid shield made of copper or other material to attenuate electric fields, some type of steel composite or other material to attenuate magnetic fields, or a combination of both may be installed around equipment or inside the walls of the room where equipment is used.

The total shielding effectiveness resulting from the combined effects of reflection and absorption loss are plotted in [Figure 113.18](#) for copper and iron materials having thicknesses of 0.025 mm and 0.8 mm, having electric and magnetic fields and plane-wave sources, and having source-to-barrier distances of 2.54 cm and 1 m.

As shown in [Figure 113.18](#), good shielding efficiency for plane waves or electric (high-impedance) fields is obtained by using materials of high conductivity, such as copper and aluminum. However, low-frequency magnetic fields are more difficult to shield because both the reflection and absorption loss of nonmagnetic materials, such as aluminum, may be insignificant. Consequently, to shield against low-frequency magnetic fields, it may be necessary to use magnetic materials.

Conductive Coatings

Conductive coatings applied to nonconductive materials such as plastics will provide some degree of EMI shielding. The principal techniques for metalizing plastic are the following:

- Conductive paints
- Plating (electrolytic)
- Electroless plating

FIGURE 113.18 Total shielding effectiveness.

- Flame spray
- Arc spray
- Ion (plasma torch) spray
- Vacuum deposition

Because the typical conductive coatings provide only a thin film of conductive material, the shielding results from reflection losses that are determined by the ratio of the wave impedance to the conductive barrier impedance. The surface resistance (in ohms per square) will determine shielding effectiveness. Figure 113.19 shows comparative data for shielding effectiveness for various conductive coatings. The most severe situation (i.e., a low-impedance magnetic field source) has been assumed.

Aperture Leakages

Various shielding materials are capable of providing a high degree of shielding effectiveness under somewhat idealized conditions. However, when these materials are used to construct a shielded housing, the resulting enclosure will typically have holes and seams that may severely compromise the overall shielding effectiveness.

Figure 113.20 shows a rectangular aperture in a metal (or metalized) panel. A vertically polarized incident electric field will induce currents in the surface of the conductive panel. If the aperture dimensions are much less than a half wavelength of the incident electric field, the aperture leakage will be small. On the other hand, as the aperture dimensions approach a half wavelength, the aperture leakage will be significant. An aperture with dimensions equal to or greater than a half wavelength will provide almost no shielding (i.e., the incident field will propagate through the aperture with very little loss). In general, the shielding effectiveness of a conductive panel with an aperture may be approximated by the following equation:

$$SE_{dB} \cong 100 - 20 \log L_{mm} \times F_{MHz} + 20 \log \left(1 + \ln \frac{L}{S} \right) \quad (113.5)$$

FIGURE 113.19 Shielding of conductive coatings. (By standard 30 cm distance test. Near field attenuation is given against the H field.) For paints, thickness is typically 2 mil = 0.05 mm.

FIGURE 113.20 Slot and aperture leakage.

To maintain shielding integrity for an equipment enclosure, it may be necessary to provide EMI protection for the apertures.

Summary of Shielding Considerations

Shielding can provide an effective means of controlling radiated EMI effects. To ensure that shielding effectiveness requirements are met, it is necessary to:

- Select a material that is capable of providing the required shielding
- Minimize the size of openings to control aperture leakages
- Subdivide large openings into a number of smaller ones
- Protect leaky apertures (e.g., cover with wire screen)
- Use EMI gaskets on leaky seams
- Filter conductors at points where they enter or exit a shielded compartment

113.4 Using Shielded Isolation Transformers to Improve Equipment Compatibility

Some EMI problems can be solved with appropriate power-conditioning devices that contain EMI filtering and shielding. For EMI problem-solving purposes, a shielded isolation transformer can be used to reduce emissions common to both power and neutral conductors induced by “ground loops” or multiple-current paths in the grounding system, for which in many cases a source cannot be identified. Subsequent sections provide an overview of this technology and their effectiveness to reduce EMI problems. More realistic methods of measurements for shielding and attenuation performance of isolation transformers are also discussed.

Shielded Isolation Transformers

Shielding isolation transformers are not true “power conditioning” devices but rather low frequency “noise rejectors” that provide good common-mode noise isolation. The main characteristic that distinguishes an isolation transformer (IT) from a general-purpose dry-type transformer (GPT) is the introduction of a grounded electrostatic shield made from an aluminum or copper sheet, called a Faraday shield, between the primary and secondary windings (as shown in Figure 113.21). The electrostatic shield is wrapped and insulated on its edges to prevent a short circuit in the loop around the core. As shown in Figure 113.21, the shield is then connected to ground, which establishes two new capacitances that link the primary and secondary windings to the static shield, as shown in Figure 113.21.

By grounding the shield, the original distributed capacitances, C_p and C_s , are now referenced to ground. Inter-winding capacitance, marked as C_w in the figure, is the primary path for noise. The grounded electrostatic shield effectively reduces C_w by a factor of 10 to 100 and increases the total capacitance between line and neutral on the primary and secondary. The reputed reduction of high-frequency common-mode noise resulting from the electrostatic shield ranges from 20 to 60 dB, depending on the material used to make the shield. If an isolation transformer is required to reduce high-level conducted emissions, some are available with a “super-isolation” type electrostatic shield, which further decouples the primary and secondary windings.

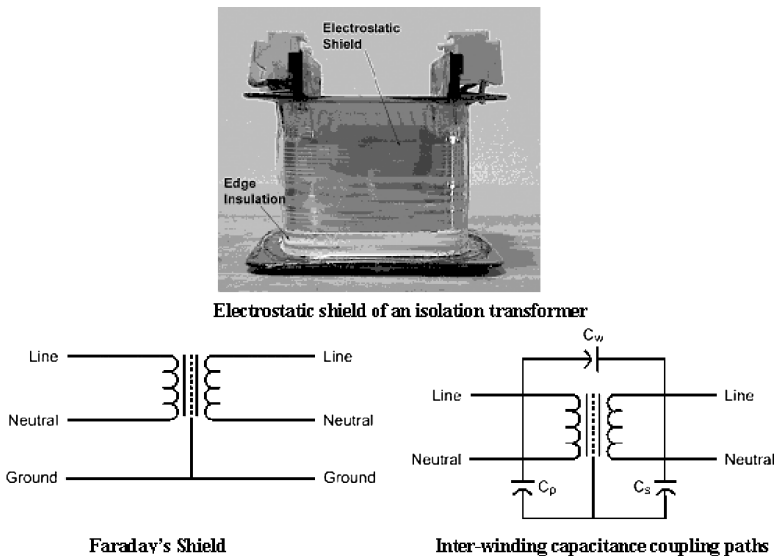

FIGURE 113.21 Primary to secondary EMI coupling in a shielded isolation transformer.

FIGURE 113.22 Capacitance-coupling paths for properly bonded GPT (model shown here has a static shield).

FIGURE 113.23 Test setup for CM noise measurement using insertion-loss method (IT shown in the test circuit).

It is noteworthy to mention here that although ITs are known for superior CM isolation, GPTs may provide enough noise attenuation without the expensive electrostatic-shield design. In most cases, simply establishing a neutral-to-ground bond on the secondary of a transformer will reduce common-mode noise caused by the capacitances between the transformer windings. Figure 113.22 shows the capacitance-coupling paths resulting from a neutral-to-ground bond on the secondary of a GPT (compare to Figure 113.21).

Common-Mode Noise Measurements (Single Phase)

Presently, there is no recognized standard for measuring the noise-attenuation performance of transformers. The transformer-manufacturing industry has adopted methods similar to those described in the test procedure in MIL-Std-T27E, *Transformers and Inductors (Audio Power and High Power Pulses)*, which was designed to measure the performance of an electrostatic shield used in an IT. The transformer industry may use a no-power test and select a bypass capacitor placed on the output to achieve and describe better attenuation performance during the test. The audio industry, however, uses balanced networks on the input and output to perform the common-mode attenuation measurements. In both cases, measurements of greater than 100 dB attenuation can be made, resulting in an overestimated attenuation performance. Another method similar to MIL-Std-T27E is known as MIL-Std-220A, *Method of Insertion Loss Measurement*, which is similar to the method used by the audio industry. This method, shown in Figure 113.23, is used for measuring the performance of radio-frequency interference (RFI) filters, also resulting in an overestimated attenuation performance.

A more realistic method of measuring noise attenuation is the current-injection-probe (CIP) method, shown in Figure 113.24. Tests were performed from 10 kHz to 100 kHz to eliminate radiated coupling between the primary and secondary of the transformer. This method is more accurate than the insertion-loss method.

Results of CM Noise Measurements (Single Phase)

Figure 113.25 illustrates the noise-attenuation performance of a GPT, a GPT with a static shield, and low-leakage IT using the common-mode CIP method. Tests were performed up to 100 kHz. These results demonstrate that the attenuation performance of the isolation transformer is about 22 dB better than the general-purpose transformer. However, the GPT with a static shield attenuated common-mode noise nearly as well as the isolation transformer.

Measurements performed using the insertion-loss method can result in attenuation greater than 100 dB at 50 and 60 Hz, resulting in an overestimated attenuation performance. However, most transformer specifications do not reveal that attenuation performance decreases as the frequency increases. When tested using the insertion-loss test, the transformers experienced an even greater frequency-dependent attenuation performance. One can see that attenuation greater than 100 dB decreases quickly as the frequency increases. Figure 113.26 shows measurements from a MIL-Std-220A insertion-loss test for a GPT, a shielded GPT, and a medical-grade low-leakage IT.

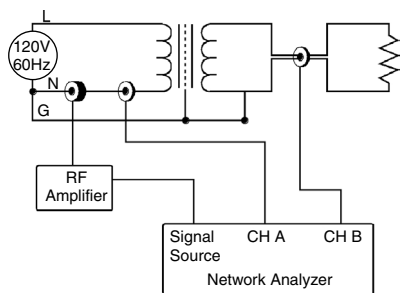

FIGURE 113.24 Test setup for common-mode noise measurement using the CIP method (IT shown in the test circuit).

FIGURE 113.25 Attenuation of common-mode noise for three different transformers using the CIP method.

FIGURE 113.26 Attenuation of common-mode noise for three different transformers using the insertion-loss method.

The difference in performance between the CIP and insertion-loss test methods occurs for two reasons. The primary reason is that not enough energy is present to excite the core in the insertion-loss method. The difference between the impedance of the source and the load, which also affects the performance but to a lesser degree, is another difference between the test methods.

Insufficient excitation of the core will cause the mutual flux to be nonuniformly distributed within the core. This results in poor inductive coupling between the windings, which yields an overestimate of attenuation performance. The inter-winding and core-to-winding capacitances continue to provide capacitive coupling between the windings, which provides for some attenuation. However, once the mutual flux in the core has been uniformly established — as it is in the CIP method — then coupling between the windings at higher frequencies improves. This results in a magnetic path, which allows the transfer of the higher-frequency components and a lower (and more realistic) attenuation performance.

Transverse-Mode Noise Measurements (Single Phase)

Transverse-mode (TM) noise, also known as across-the-line or line-to-line noise, is less likely to upset end-use equipment than common-mode noise is. TM noise is measured from line to line or line to neutral. This noise passes through an IT without appreciable attenuation and is not affected by the electrostatic shielding of the transformer for frequencies up to 100 kHz (see [Figure 113.27](#)). In most cases, end-use equipment is usually designed to handle this type of noise.

Standard electronic power supplies used in end-use equipment are designed to filter conducted emissions, to meet limits defined in EMI conducted-emissions standards that are promulgated, for example,

FIGURE 113.27 Illustration of a typical noise attenuation.

FIGURE 113.28 Test setup for TM noise measurement using the insertion-loss method (IT shown in the test circuit).

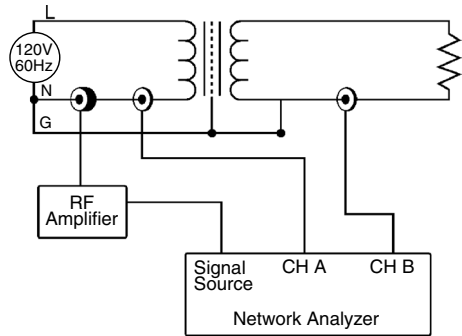

FIGURE 113.29 Test setup for CM/TM noise measurement using the CIP method (IT shown in the test circuit).

by the U.S. Federal Communication Commission (FCC) and the Electrotechnical Commission (IEC). Normally, the basic construction or design of the transformer will reduce TM noise somewhat at frequencies above 1 MHz.

Figure 113.28 illustrates the transverse-mode insertion-loss test setup used to measure TM noise coupling. Figure 113.29 shows common/transverse-mode CIP test setup.

Results of Transverse-Mode Noise Measurements (Single Phase)

Test results indicate little difference in the performance of shielded and nonshielded transformers when the transformer is grounded correctly, as shown in Figure 113.30 and Figure 113.31. One can see here almost zero attenuation in this mode up to about 100 kHz. These test results provide additional evidence and support for the statement, “Grounding the secondary alone in most cases will reduce common-mode noise.” A transformer by design will attenuate most high-frequency noise components because of the simple reactive drop associated with inductors. However, as shown in Figure 113.27, the significant noise attenuation (greater than 20 dB, times 10 reduction) for most transformers does not begin until about 100 kHz using the MIL-Std-220A measurement technique.

Three-Phase Isolation Transformer Shielding and Attenuation Performance

Just as in the case of single-phase isolation transformers, traditional evaluation techniques for shielding performance for three-phase isolation transformers are not well documented or standardized. Most manufacturers have adopted the same methods for balanced and unbalanced insertion loss tests to determine attenuation. As may be seen in Figure 113.32, it is very apparent no significant gain in signal rejection occurs at lower frequencies. By using single or double shields, there is relatively small difference

FIGURE 113.30 Attenuation of transverse-mode noise for three different transformers using the insertion-loss method.

FIGURE 113.31 Attenuation of transverse-mode noise for three different transformers using the CIP method.

in increased performance. Hence, choosing one or more shields may only be based on a performance-driven specification, where the winning method may only differ by less than 0.01%, for example, 1.4:1 (3 dB) when compared to the overall shielding ratios of 10,000:1 (60 dB) and 10,000:1 (80 dB).

From the experience of measuring actual attenuation performance of power line filters, the method of measurement by using RF current injection was chosen and adapted to gain an understanding of performance for three-phase isolation transformers under-load in a laboratory environment. These data may not be competitive in the market against MIL-Std-220A curves, but the yield data may be used by a customer who wishes to know a relative performance ability. These data may now be used to promote a new competitive environment and to ensure that the customer understands the actual attenuation performance versus shielding effectiveness of certain materials and construction techniques. An example of a specification is shown in Table 113.2 below.

For transformers of normal construction such as standard E-cores, it is already apparent that this is not a realistic specification even in nonloaded test systems and particularly in the traverse mode, where standard transformers will function up to several kHz with very little loss. Standard loss of such a transformer is designed in the normal construction of a four to one reduction from the delta to the Y side and has a factor of -12dB in the operating region of the transformer when converting from 480 to 120V, as seen in Figure 113.33.

FIGURE 113.32 Common-mode shielding performances under no load conditions.

TABLE 113.2 Performance Specifications

| Mode | Frequency Range (kHz) | Attenuation (dB) |
|------------|-----------------------|------------------|
| Common | 0 to 1.5 | -120 |
| Common | 1.5 to 10 | -90 |
| Common | 10 to 100 | -65 |
| Transverse | 1.5 to 10 | -52 |
| Transverse | 10 to 1000 | -30 |

FIGURE 113.33 Transverse mode three-phase isolation under load shielding performance.

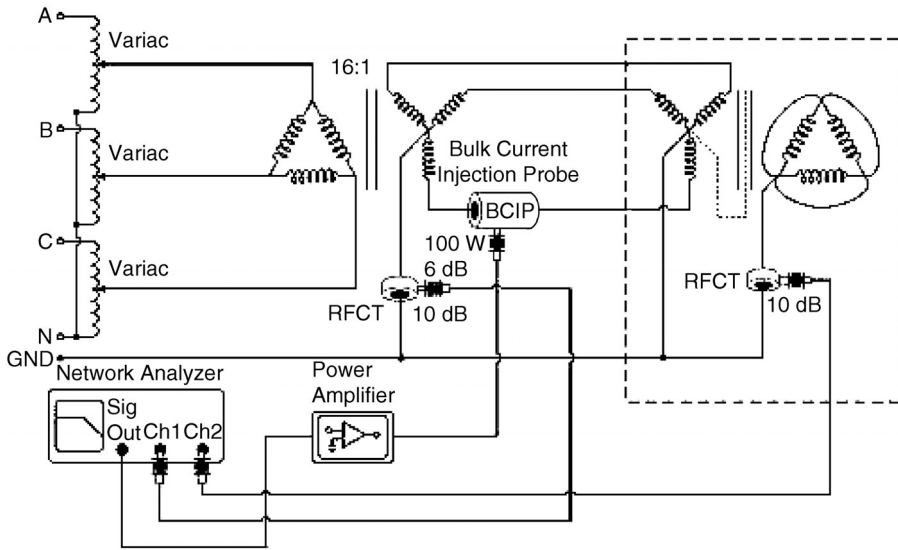

FIGURE 113.34 Common mode current injection.

When testing large three-phase transformers, it is difficult to supply large currents. Therefore, elaborate setups must be established in order to load the transformer for delta or wye configuration testing. Figure 113.34 represents the setup requirements, where the delta side is shorted and then the Y side is loaded by a 16:1 transformer to limit the power frequency current during the test. By energizing the core, we have established that the magnetic path that must be considered in attenuation performance of the transformer; one cannot just depend upon the traditional shielding effectiveness measurement.

One can see that the transformer is more than capable of transferring the signal well past 100 kHz before achieving any significant loss or gain in the MHz region. The most practical method of achieving the specifications shown in Table 113.2 is the use of three-phase filters constructed within the transformer. Some manufacturers may add such filtering inside the case of the transformer. Also, a special class of transformer known as CVTs may exhibit more than satisfactory attenuation results.

FIGURE 113.35 Common mode three-phase isolation transformer shielding performance under load.

FIGURE 113.36 A variety of filters can be used to solve EMI problems.

113.5 Using Filtering Technologies to Improve Equipment Compatibility

Many commercial and industrial electrical environments contain equipment that is sensitive to radio-frequency (RF) interference. Theft detectors, digital sensors, and medical-telemetry systems have all been known to malfunction in the presence of RF interference. To prevent RF signals from entering a facility via the power lines, a variety of filters (as shown in Figure 113.36), installed between sensitive loads and the power source, can be used to block unwanted emissions from sensitive electronic equipment. A screened or solid shield made of copper to attenuate electric fields or some type of steel composite to attenuate magnetic fields may be installed around equipment or in the room where equipment is used. If properly designed and installed, it can protect the equipment from electromagnetic interference. In some situations, both filters and a shield may be needed at an installation site.

Line filters prevent electrical noise from traveling into sensitive electronic equipment from the building wiring system by blocking higher-frequency noise that has been shown to cause EMI problems but passing 60 Hz power. They also eliminate noise generated by the protected equipment from feeding back into the building wiring system. As shown in Figure 113.37, a power-line filter passes frequencies in its pass

FIGURE 113.37 Attenuation plot for an ideal power-line filter.

band (including the frequency of the power source, either 60 or 50 Hz) but blocks frequencies in its stop band (including the frequencies of RF interference).

The attenuation plot in Figure 113.37 is entirely conceptual; the *in situ* performance of a power-line filter will certainly fail to meet this ideal and may even fail to meet the performance predicted by the manufacturer's specifications. Therefore, power-line filters are routinely tested to determine their actual performance in the field. One of the parameters of filter performance is *insertion loss*, which is the difference between the level of an interference signal without and with a filter in the circuit.

Harmonic filters trap harmonic currents, which are low-frequency conducted emissions. They range in size from small units for plug-connected loads to high-power units that are hard-wired to electrical distribution panels. These filters are selected based on the predominant harmonic currents to be blocked.

The subsequent sections provide an overview of the current standard being used to measure the insertion loss of a power-line filter. The existing standard has inherent shortcomings and needs substantial modifications. IEEE Standard for Method of Tests for Filter Performance, P1560 Working Group, is an effort towards improving the testing methods of measuring insertion loss. An overview of the testing method recommended by P1560 Working Group is also provided.

An Overview of the Current Standard

The main standard currently used to measure the insertion loss of a power-line filter is MIL-STD-220, *Method of Insertion Loss Measurement*. This standard is used to measure the attenuation performance of a filter that is connected to a 50-ohm power source and a 50-ohm load, which is called "matched impedance." The standard was originally developed in 1952 to measure the insertion loss of filters used to mitigate radio interference in mobile communication systems. Since 1952, MIL-STD-220 has been widely used to create general performance specifications for all types of filters. The problem arises from the application of MIL-STD-220 to determine the insertion loss of a power-line filter used with an unmatched source and load. In the real world, power line filters must operate under a wide range of impedances (see Schlicke 1976), as well as a wide range of load types.

Unfortunately, MIL-STD-220A has become the industry norm, largely because of the lack of a viable alternative. The problems associated with the test methods defined in MIL-STD-220A have been known since it was first used. In fact, the standard itself warns users about its limitations. Nevertheless, this standard has been referenced in other standards and applied in thousands of applications throughout the military and commercial industries to characterize power-line filters.

Although MIL-STD-220A was revised in 2000 to MIL-STD-220B (some describe this revision as a facelift), its test methods are virtually unchanged. MIL-STD-220B describes itself as a quality-control standard. The standard itself emphasizes that its test methods are not intended to predict actual performance of filters that are used in mismatched-impedance situations. Yet, people continue to use this standard to predict the behavior of filters in the field.

Many other standards have also been developed since the creation of MIL-STD-220A. Two examples of standards used to measure power-line filters are SAE ARP4244 – 1998, *Recommended Insertion Loss Test Methods for EMI Power Line Filters*, and C.I.S.P.R. 17 1981, *Methods of Measurement of the Suppression Characteristics of Passive Radio Interference Filters and Suppression Components*. The authors of these standards have attempted to correct the problems associated with using MIL-STD-220A. At best, these standards address the issues pertinent to the requirements for a particular organization or application but do not directly address the root of the problem — test methods incorrectly defined for actual applications with mismatched-impedance conditions. The next section describes the typical test setup used for MIL-STD-220B standard.

Limitations of MIL-STD-220B

Frequency Range

If testing adheres to the 100-kHz minimum frequency of MIL-STD-220B, then some significant filter behaviors may be missed. For example, Figure 113.38 shows the effect of inductor saturation and

FIGURE 113.38 Effect of inductor saturation under DC current loading.

resonance on filter attenuation for frequencies below 100 kHz. Resonance may develop when a filter is loaded. The peaks in the attenuation indicate this. Also, note that the cutoff frequency shifts to the right as the current through the filter increases as a result of inductor saturation. Testing at a minimum of 100 kHz would obscure this behavior.

Inductor Saturation

A buffer network, according to MIL-STD-220B, is used to isolate the test equipment to prevent short-circuiting the direct current (DC) source under loaded conditions. Not only is the frequency range of a typical buffer network insufficient for accurate predictions of field performance, a buffer network poses yet another problem in measurement accuracy. As shown in Figure 113.39, a buffer network, when placed in a test circuit, adds additional LC elements to the already complicated network of the filter under test. This is an extreme analogy to Heisenberg’s Uncertainty Principle, wherein the introduction of a measuring device introduces an uncertainty in the measured value. With the addition of these LC elements, it is difficult to ascertain the effects that the additional elements will have on the overall filter-attenuation measurement being performed, unless one compensates for the insertion loss of the buffer network for the filter parameters.

Inaccuracy of 220B Measurements

Matched-impedance testing under no-load conditions should not be used to predict the performance of filters used in an unmatched-impedance environment. Unmatched impedance causes an unbalancing of the filter network, which can result in less-than-expected attenuation of the stop band or, in some cases, random resonance or even an amplification of the pass band.

Another problem with determining the performance of a filter under loaded conditions using the MIL-STD-220B method is that it is best suited for evaluating inductor saturation and traditionally uses

FIGURE 113.39 Buffer network and filter arrangement demonstrating additive effect of additional LC networks.

FIGURE 113.40 Effect of inductor saturation under DC current load using strictly RF current injection.

only DC current to do so. When the inductor becomes saturated, it loses most of its inductive properties. This effect varies according to core construction and the core material chosen. The loss of inductance due to saturation alters the attenuation properties of the filter at frequencies below 100 kHz. As shown in Figure 113.38, the cutoff frequency increases as the core approaches saturation. In addition, the gains from 2 to 7 kHz vary as a function of filter load. These filter characteristics may not be detected using MIL-STD-220B.

Although the application of current through buffer networks seems like a reasonable way to predict the attenuation performance of a powered filter, it still does not account for realistic source and load impedances. More often than not, when a filter is tested with a load, the load is usually resistive. Fifty years ago, using a purely resistive load in a filter test may have been an acceptable method because most building wiring systems powered linear (passive) loads, such as motors. Today, however, silicon technologies permeate the electrical environments where power-line filters are used. For example, motors are rarely connected directly to the power source. Instead, they are controlled by motor drives, which are power-electronic, nonlinear loads.

Millions of end-use devices now use nonlinear power supplies. According to Briggs (1994), problems with applying power-line filters to these nonlinear loads are often not fully realized until the filter has failed, either in expected performance or in a catastrophic event, such as the failure of capacitors inside the filter. Figure 113.40 illustrates the dynamic difference of filter performance under linear and nonlinear loading using a method called “RF current-injection,” which can be found in MIL-STD-461. This standard is used to determine the susceptibility of equipment to conducted RF interference by injecting RF currents into the cables and harnesses of the equipment.

IEEE P1560: A Step Forward

To address the shortcomings of MIL-STD-220B, IEEE P1560 Working Group is working towards a new standard. The main objectives of the working group are:

- To develop alternative methods for characterizing the performance of power-line filters that account for real-world situations.
- To assemble the accepted and proven test methods into a single standard for the frequency range of 100 Hz to 10 GHz.

The latest draft, IEEE P1560 D/1.3 (March 5, 2003) is now available for review. The draft specifies no-load and loaded test methods, which are extended down to 100 Hz, as opposed to MIL-STD-220B, which extends down to only 100 kHz for the loaded test and 150 kHz for the loaded method using standardized buffer networks. The draft discourages the use of buffer networks and line-impedance stabilization networks (LISNs) for measurements below 100 kHz and proposes techniques using RF

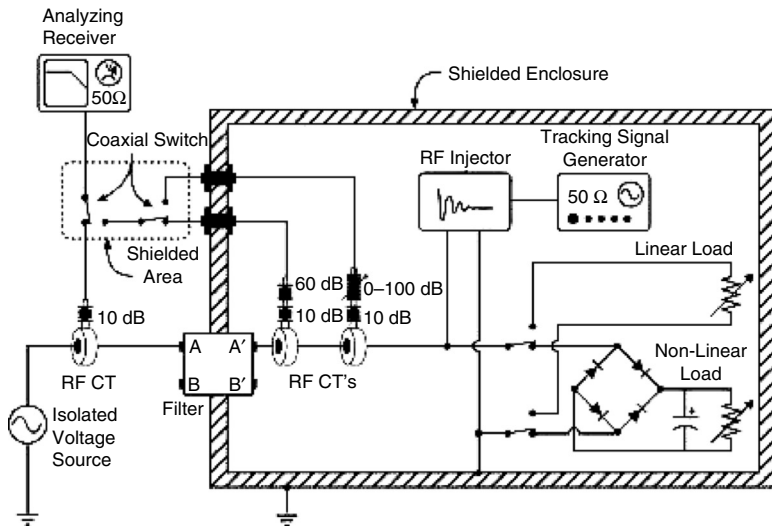

FIGURE 113.41 Typical common mode test setup: 100 Hz to 100 kHz.

current injection probes to be utilized from 100 Hz to 100 kHz. The test setup for common mode tests is shown in Figure 113.41.

Defining Terms

Ground — Any reference conductor that is used for a common return.

Near-field/far-field transition distance — For electrically small radiators (i.e., dimensions \ll wavelength), the near-field/far-field transition occurs at a distance equal to approximately one sixth of a wavelength from the radiating source.

Plane wave — Far-field electromagnetic wave with an impedance of 377 ohms in air.

Reference — Some object whose potential (often 0 volts with respect to earth or a power supply) is the one to which analog and logic circuits, equipments, and systems can be related or benchmarked

Return — The low (reference) voltage side of a wire pair (e.g., neutral), outer jacket of a coax, or conductor providing a path for intentional current to get back to the source.

Wavelength — The distance corresponding to a period for the electromagnetic wave spatial variation.
Wavelength (meters) = $300/\text{frequency (MHz)}$.

Electromagnetics (EM) is that branch of physics or electrical engineering in which the interactions between charges at rest and in motion are examined. It entails the analysis, synthesis, physical interpretation, and application of electric and magnetic fields. EM theory is indispensable to the design and operation of many practical devices. EM principles find applications in diverse areas such as microwaves, antennas, electric machines, bioelectromagnetics, plasmas, fiber optics, satellite communication, electromagnetic compatibility, radar meteorology, and remote sensing.

The foundational basis of electromagnetic theory was established in 1873 by James Clerk Maxwell, who for the first time unified observations of Michael Faraday, Karl Friedrich Gauss, and Andre-Marie Ampere. In this chapter, we present Maxwell's equations in time-domain and frequency-domain and the constitutive equations. SI units are assumed throughout.

114.1 Maxwell's Equations

At the macroscopic level, electric and magnetic phenomena are described by Maxwell's equation. Maxwell's work was based on a large body of theoretical and empirical works of others such as Gauss, Ampere, and Faraday. In differential form, Maxwell's equations are given by

$$\nabla \times \mathbf{E} = -\frac{\partial \mathbf{B}}{\partial t} \quad (\text{Faraday's law}) \quad (114.1)$$

$$\nabla \times \mathbf{H} = \mathbf{J} + \frac{\partial \mathbf{D}}{\partial t} \quad (\text{Ampere's law}) \quad (114.2)$$

$$\nabla \cdot \mathbf{D} = \rho_v \quad (\text{Gauss's law}) \quad (114.3)$$

$$\nabla \cdot \mathbf{B} = 0 \quad (\text{Gauss's law}) \quad (114.4)$$

where \mathbf{E} , \mathbf{H} , \mathbf{D} , \mathbf{B} , \mathbf{J} , and ρ_v are real functions of space and time. \mathbf{E} is electric field intensity (volts/meter), \mathbf{H} is the magnetic field intensity (amperes/meter), \mathbf{D} is the electric flux density (coulombs/square meter),

\mathbf{B} is the magnetic flux density (webers/square meter), \mathbf{J} is the conduction current density (amperes/square meter), and ρ_v is the electric field charge density (coulombs/cubic meter). The differential form of Maxwell's equations as in Equation (114.1) to Equation (114.4) is the most widely used representation to solve boundary-value electromagnetic problems. Although the equations are simply a set of coupled, partial differential equations, they are sufficient to understand the full range of electromagnetic phenomena.

Maxwell's equations contain an important relationship between charge and current. Taking the divergence of both sides of Equation (114.2) and applying the vector identity $\nabla \cdot (\nabla \times \mathbf{A}) = 0$ yields

$$\nabla(\nabla \times \mathbf{H}) = \nabla \mathbf{J} + \nabla \frac{\partial \mathbf{D}}{\partial t} = 0 \quad (114.5)$$

Introducing (114.3) leads to

$$\nabla \mathbf{J} + \frac{\partial \rho_v}{\partial t} = 0 \quad (114.6)$$

which is the continuity equation expressing the conservation of charge and current.

Another equation associated with Maxwell's equation is the Lorentz force law, which relates the electromagnetic fields to measurable forces. If a charge q moves in an electric field \mathbf{E} and magnetic field \mathbf{B} at a velocity \mathbf{v} , the force on the charge is given by Lorentz force law:

$$\mathbf{F} = q(\mathbf{E} + \mathbf{v} \times \mathbf{B}) \quad (114.7)$$

When the charge is not discrete, Lorentz force law becomes

$$\mathbf{F} = \rho_v \mathbf{E} + \mathbf{J} \times \mathbf{B} \quad (114.8)$$

The integral form of Maxwell's equations can be obtained from the differential form by applying divergence and Stokes's theorems to Equation (114.1) to Equation (114.4). They are derived as

$$\oint_L \mathbf{E} \cdot d\mathbf{l} = -\frac{\partial}{\partial t} \iint_S \mathbf{B} \cdot d\mathbf{S} \quad (\text{Faraday's law}) \quad (114.9)$$

$$\oint_L \mathbf{H} \cdot d\mathbf{l} = \iint_S \mathbf{J} \cdot d\mathbf{S} + \frac{\partial}{\partial t} \iint_S \mathbf{D} \cdot d\mathbf{S} \quad (\text{Ampere's law}) \quad (114.10)$$

$$\iint_S \mathbf{D} \cdot d\mathbf{S} = \iint_V \rho_v dv \quad (\text{Gauss's law}) \quad (114.11)$$

$$\iint_S \mathbf{B} \cdot d\mathbf{S} = 0 \quad (\text{Gauss's law}) \quad (114.12)$$

The integral form of Maxwell's equations depicts the underlying physical laws, whereas the differential form is used more frequently in solving problems.

114.2 Constitutive Relations

Maxwell's equations contain more variables than equations. To solve an EM problem using Maxwell's equations therefore requires some additional set of relations between the field quantities \mathbf{E} , \mathbf{H} , and \mathbf{D} , \mathbf{B} .

Thus, we need the constitutive relations to supplement Maxwell's equation. For an isotropic medium, the constitutive relations are

$$D = \epsilon E \quad (114.13)$$

$$B = \mu H \quad (114.14)$$

$$J = \sigma E \quad (114.15)$$

where ϵ , μ , and σ are, respectively, the permittivity, the permeability, and the conductivity of the medium. In electromagnetics, a homogeneous and isotropic region with no sources in it is called *free space*. For free space,

$$\epsilon_o = 8.85 \times 10^{-12} \text{ (F/m)} \quad (114.16)$$

$$\mu_o = 4\pi \times 10^{-7} \text{ (H/m)} \quad (114.17)$$

$$\sigma = 0 \text{ (S/m)} \quad (114.18)$$

Equation (114.11) to Equation (114.13) are regarded as the *constitutive relations*, while ϵ , μ , and σ are known as the *constitutive parameters*. The constitutive parameters are often used to characterize the properties of a material. For example, a dielectric material is said to be linear if $D = \epsilon E$ applies and if ϵ does not change with the applied \mathbf{E} field; it is homogeneous if ϵ does not change from point to point; and it is isotropic if ϵ does not change with direction. A material is said to be dispersive if its constitutive parameters are functions of frequency.

For anisotropic media, the constitutive relations become

$$\bar{D} = \bar{\epsilon} \cdot \bar{E} \quad (114.19)$$

$$\bar{B} = \bar{\mu} \cdot \bar{H} \quad (114.20)$$

where $\bar{\epsilon}$ and $\bar{\mu}$ are permittivity and permeability tensors, respectively. In this case, the vector field \mathbf{D} is no longer parallel to \mathbf{E} and the vector field \mathbf{B} is no longer parallel to \mathbf{H} . For example, in the Cartesian coordinate system, Equation (114.19) becomes

$$\begin{bmatrix} D_x \\ D_y \\ D_z \end{bmatrix} = \begin{bmatrix} \epsilon_{xx} & \epsilon_{xy} & \epsilon_{xz} \\ \epsilon_{yx} & \epsilon_{yy} & \epsilon_{yz} \\ \epsilon_{zx} & \epsilon_{zy} & \epsilon_{zz} \end{bmatrix} \begin{bmatrix} E_x \\ E_y \\ E_z \end{bmatrix} \quad (114.21)$$

For crystals,

$$\bar{\epsilon} = \begin{bmatrix} \epsilon_x & 0 & 0 \\ 0 & \epsilon_y & 0 \\ 0 & 0 & \epsilon_z \end{bmatrix} \quad (114.22)$$

indicating that crystals are described by symmetric permittivity tensor.

FIGURE 114.1 Boundary condition at the interface between two media.

114.3 Boundary Conditions

Along the interface where the media involved exhibit discontinuity in electrical properties or sources exist along the interface, the field vectors themselves are discontinuous, and their behavior across the interface is governed by the boundary conditions. In fact, the solution of Maxwell's equation is not complete until the boundary conditions are imposed. However, Maxwell's equations in integral form can be used to obtain the boundary conditions at the interface between two media. A sufficient set of boundary conditions is

$$n \times (H_2 - H_1) = J_s \quad (114.23)$$

$$(E_2 - E_1) \cdot n = M_s \quad (114.24)$$

where \mathbf{n} is unit normal directed from medium 1 (with $\epsilon_1, \mu_1, \sigma_1$) to medium 2 (with $\epsilon_2, \mu_2, \sigma_2$) as shown in Figure 114.1. J_s and M_s are, respectively, the electric and magnetic surface currents. Equation (114.23) and Equation (114.24) can be written in terms of the tangential components of the fields as

$$H_{2t} = H_{1t} + J_s \quad (114.25)$$

$$E_{2t} = E_{1t} + M_s \quad (114.26)$$

If one medium is a perfect conductor, the boundary conditions in Equation (114.25) and Equation (114.26) become

$$H_t = J_s \quad (114.27)$$

$$E_t = 0 \quad (114.28)$$

A boundary on which Equation (114.28) is valid is known as electric wall since the tangential components of E are "shorted out" and must vanish at the surface of the conductor. Dual to this is the magnetic wall, which is a boundary on which H vanishes. For this case,

$$H_t = 0 \quad (114.29)$$

$$E_t = M_s \quad (114.30)$$

Finally, when dealing with problems that have one or more infinite boundaries, it is required that at an infinite distance from the source, the fields must be vanishingly small.

114.4 Power and Energy

Energy can be transported from one point to another by means of EM waves. (This is the case in wireless communication systems.) The rate of such energy transportation can be obtained from Maxwell's equations. Dotted both sides of Equation (114.2) with \mathbf{E} and replacing \mathbf{J} by $\sigma\mathbf{E}$ leads to

$$E(\nabla \cdot \mathbf{H}) = \sigma E^2 + E\epsilon \frac{\partial E}{\partial t} \quad (114.31)$$

Using the vector identity

$$\nabla(\mathbf{A} \times \mathbf{B}) = \mathbf{B}(\nabla \cdot \mathbf{A}) - \mathbf{A}(\nabla \cdot \mathbf{B}) \quad (114.32)$$

gives

$$H(\nabla \cdot \mathbf{E}) + \nabla(\mathbf{H} \times \mathbf{E}) = \sigma E^2 + \frac{1}{2}\epsilon \frac{\partial E^2}{\partial t} \quad (114.33)$$

From Equation (114.1) and Equation (114.14),

$$H(\nabla \cdot \mathbf{X}\mathbf{E}) = H\left(-\mu \frac{\partial H}{\partial t}\right) = -\frac{\mu}{2} \frac{\partial H^2}{\partial t} \quad (114.34)$$

Substituting Equation (114.34) into Equation (114.33),

$$\nabla(\mathbf{E} \times \mathbf{H}) = -\frac{1}{2}\epsilon \frac{\partial E^2}{\partial t} - \frac{1}{2}\mu \frac{\partial H^2}{\partial t} - \sigma E^2 \quad (114.35)$$

Taking the volume integral of both sides and applying the divergence theorem to the left-hand side yields

$$\oint_S (\mathbf{E} \times \mathbf{H}) \cdot d\mathbf{S} = -\frac{\partial}{\partial t} \int_v \left[\frac{1}{2}\epsilon E^2 + \frac{1}{2}\mu H^2 \right] dv - \int_v \sigma E^2 dv \quad (114.36)$$

↓
↓
↓

 Total power leaving the volume Rate of decrease in energy stored in EM fields Ohmic power loss

where volume v is bounded by the closed surface S . This expresses a conservation of power or Poynting's theorem. The first term on the right-hand side is interpreted as the rate of decrease in energy stored in the electric and magnetic fields. The second term is the power dissipated due to a conducting medium ($\sigma \neq 0$). The quantity $\mathbf{E} \times \mathbf{H}$ on the left-hand side of Equation (114.36) is known as the Poynting vector \mathbf{P}

$$\mathbf{P} = \mathbf{E} \times \mathbf{H} \quad (114.37)$$

\mathbf{P} is the flow of power flux per unit area. It represents the power flux density and its unit is watts/m².

114.5 Vector and Scalar Potentials

It is sometimes convenient in electromagnetics to introduce a vector magnetic potential from which both electric and magnetic fields may be derived. This reduces the number of equations to be solved. We define this potential (one of several possible potentials) in terms of the magnetic flux density:

$$\nabla \times \mathbf{A} = \mathbf{B} \quad (114.38)$$

But $\nabla \times \mathbf{E} = -\partial \mathbf{B} / \partial t$ so that

$$\nabla \times \left(\mathbf{E} + \frac{\partial \mathbf{A}}{\partial t} \right) = 0 \quad (114.39)$$

Since the curl of the gradient of any scalar field is zero, the bracket term in Equation (114.39) can be replaced by the gradient of a scalar potential V .

$$\mathbf{E} + \frac{\partial \mathbf{A}}{\partial t} = -\nabla V$$

or

$$\mathbf{E} = -\nabla V - \frac{\partial \mathbf{A}}{\partial t} \quad (114.40)$$

From Equation (114.38) and Equation (114.40), we can determine the vector fields \mathbf{B} and \mathbf{E} provided the potentials \mathbf{A} and V are known. By taking the divergence of Equation (114.40) and introducing Equation (114.3), we have

$$\nabla \cdot \mathbf{E} = \frac{\rho_v}{\epsilon} = -\nabla^2 V - \frac{\partial}{\partial t} (\nabla \cdot \mathbf{A})$$

or

$$\nabla^2 V + \frac{\partial}{\partial t} (\nabla \cdot \mathbf{A}) = -\frac{\rho_v}{\epsilon} \quad (114.41)$$

Taking the curl of Equation (114.38) and incorporating Equation (114.2) and Equation (114.40) results in

$$\nabla \times \nabla \times \mathbf{A} = \mu \mathbf{J} - \mu \epsilon \nabla \left(\frac{\partial V}{\partial t} \right) - \mu \epsilon \frac{\partial^2 \mathbf{A}}{\partial t^2} \quad (114.42)$$

Applying the vector identity

$$\nabla \times \nabla \times \mathbf{A} = \nabla (\nabla \cdot \mathbf{A}) - \nabla^2 \mathbf{A} \quad (114.43)$$

leads to

$$\nabla^2 \mathbf{A} - \nabla (\nabla \cdot \mathbf{A}) = -\mu \mathbf{J} + \mu \epsilon \nabla \left(\frac{\partial V}{\partial t} \right) + \mu \epsilon \frac{\partial^2 \mathbf{A}}{\partial t^2} \quad (114.44)$$

A vector field is uniquely defined when its curl and divergence are specified. The curl of \mathbf{A} has been specified in Equation (114.38). We may choose the divergence of \mathbf{A} as

$$\nabla \cdot \mathbf{A} = -\mu \epsilon \frac{\partial V}{\partial t} \quad (114.45)$$

This choice relates \mathbf{A} and V , and it is called the *Lorentz condition*. By imposing this condition, Equation (114.41) and Equation (114.44) become

$$\nabla^2 V - \mu\epsilon \frac{\partial^2 V}{\partial t^2} = -\frac{\rho_v}{\epsilon} \quad (114.46)$$

and

$$\nabla^2 A - \mu\epsilon \frac{\partial^2 A}{\partial t^2} = -\mu J \quad (114.47)$$

which are wave equations. Once Equation (114.46) and Equation (114.47) are solved, the fields \mathbf{E} and \mathbf{B} are obtained from Equation (114.38) and Equation (114.40). The magnetic vector potential \mathbf{A} does not have the physical significance of the scalar potential V and is solely a mathematical convenience in determining EM fields.

114.6 Time-Harmonic Fields

In many practical applications involving EM fields, the time variations are of sinusoidal form and are referred to as time-harmonic. Also, it is expedient to first understand the behavior of monochromatic waves (which have only a single frequency) and from them construct any other waveform using Fourier analysis. For time-harmonic fields, the time variation can be represented by $e^{j\omega t}$. Hence, for time-harmonic field \mathbf{A} ,

$$A(x, y, z, t) = \text{Re} \left[A_s(x, y, z) e^{j\omega t} \right] \quad (114.48)$$

where \mathbf{A}_s is the phasor form of \mathbf{A} and is only a function of position in space (x, y, z) . \mathbf{A} in Equation (114.48) stands for EM fields \mathbf{E} , \mathbf{H} , \mathbf{B} , or \mathbf{D} . We notice from Equation (114.48) that the differential and integral operations respectively yield

$$\frac{\partial A}{\partial t} \rightarrow j\omega A_s \quad (114.49)$$

$$\int A \partial t \rightarrow \frac{A_s}{j\omega} \quad (114.50)$$

Thus, for time-harmonic fields, Maxwell's equations can be written in simpler forms, as shown in Table 114.1. Also, Maxwell's equations are easier to solve for time-harmonic fields. For time-harmonic fields,

TABLE 114.1 Time-Harmonic Maxwell's Equations

| Differential Form | Integral Form |
|---|--|
| $\nabla D_s = \rho_{vs}$ | $\oint D_s \cdot dS = \int \rho_{vs} dv$ |
| $\nabla B_s = 0$ | $\oint B_s \cdot dS = 0$ |
| $\nabla \times E_s = -j\omega B_s$ | $\oint E_s \cdot dl = -j\omega \int B_s \cdot dS$ |
| $\nabla \times H_s = J_s + j\omega D_s$ | $\oint H_s \cdot dl = \int (J_s + j\omega D_s) \cdot dS$ |

the boundary conditions are not independent of each other. If, for example, the tangential components of the E and H fields satisfy the boundary conditions, the normal components of the same fields automatically satisfy their appropriate boundary conditions.

We can also show that for time-harmonic fields, the time-average Poynting vector is

$$P_{ave} = \frac{1}{T} \int_0^T ExH \partial t = \frac{1}{2} \text{Re} [E_s x H_s^*] \quad (114.51)$$

where the asterisk (*) denotes complex conjugate.

114.7 Wave Equations

Consider a linear, isotropic, homogeneous, lossless dielectric medium ($\sigma = 0$) that is charge free ($\rho_v = 0$). Assuming and suppressing the time factor $e^{j\omega t}$, Maxwell's equations (see Table 114.1) become

$$\nabla E_s = 0 \quad (114.52)$$

$$\nabla H_s = 0 \quad (114.53)$$

$$\nabla x E_s = -j\omega \mu H_s \quad (114.54)$$

$$\nabla x H_s = j\omega \epsilon E_s \quad (114.55)$$

Taking the curl of both sides of (114.54) gives

$$\nabla x \nabla x E_s = -j\omega \mu \nabla x H_s \quad (114.56)$$

Applying the vector identity in Equation (114.43) to the left-hand side of Equation (114.56) and invoking Equation (114.52) and Equation (114.55), we get

$$\nabla^2 E_s + \omega^2 \mu \epsilon E_s = 0 \quad (114.57)$$

Using separation of variables, we find that the solution to Equation (114.57) is plane waves. The simplest solution for the electric field E_s is

$$E_s = E_o \cos(kz - \omega t) a_x \quad (114.58)$$

where $k = \omega \sqrt{\mu \epsilon}$ and ω is the angular frequency of the wave. The EM wave is polarized along the x-direction, propagates in the +z-direction, travels at the speed

$$u = \frac{1}{\sqrt{\mu \epsilon}} \quad (114.59)$$

and has a wave impedance

$$\eta = \sqrt{\frac{\mu}{\epsilon}} \quad (114.60)$$

The wave repeats itself at a regular interval. The frequency f is defined as

$$f = \frac{\omega}{2\pi} \quad (114.61)$$

The EM waves obey all other usual wave phenomena of reflection and refraction when incident on interfaces between two different media.

115.1 The Ideal Op Amp

115.2 Feedback Circuit Analysis

115.3 Input and Output Impedances

115.4 Practical Limitations and Considerations

The operational amplifier (op amp) is one of the most versatile building blocks for analog circuit design. The earliest op amps were constructed of discrete devices — first vacuum tubes and later transistors. Today, an op amp is constructed of numerous transistors along with a few resistors and capacitors, all fabricated on a single piece of silicon. Parts are sold with one, two, or four op amps in a small integrated circuit package.

Op amps are popular because they are small, versatile, easy to use, and inexpensive. Despite their low cost, modern op amps offer superb performance. An op amp provides high voltage gain, high input impedance, and low output impedance. Many op amps are commercially available, and they differ in specifications such as input noise, bandwidth, gain, offset voltage, output swing, and supply voltage.

Op amps are used as high-gain amplifiers in negative feedback circuits. An advantage of such circuits is that design and analysis is relatively simple, with the overall gain depending only on external passive components that provide the feedback around the op amp. In the following sections, analysis and design of op-amp feedback circuits are covered.

115.1 The Ideal Op Amp

The schematic symbol for an op amp is shown in [Figure 115.1\(a\)](#). The op amp has two inputs, v_+ and v_- , and a single output. The voltages v_+ , v_- , and v_{OUT} are measured with respect to ground. The op amp amplifies the voltage difference $v_+ - v_-$ to produce the output voltage v_{OUT} . A simple model for the op amp that is valid when the op amp is operating in its linear high-gain region is shown in [Figure 115.1\(b\)](#). The model consists of an input impedance Z_i , output impedance Z_o , and voltage gain a . Here, the voltage difference $v_+ - v_-$ is called v_E . If Z_i , Z_o , and a are known, this model can be used to analyze an op-amp circuit if the op amp is biased in the linear region, which is usually the case when the op amp is in a negative feedback loop. A typical op amp has large Z_i , small Z_o , and large a . As a result, the op-amp model is often further simplified by setting $Z_i = \infty$ and $Z_o = 0$, as shown in [Figure 115.1\(c\)](#).

For an example of an op-amp feedback circuit, consider the inverting gain amplifier shown in [Figure 115.2](#). Using the model of [Figure 115.1\(c\)](#) in [Figure 115.2](#), the gain can be found by summing currents at the v_- input of the op amp. Since the current into the op amp is zero (due to $Z_i = \infty$), $i_1 = i_2$; therefore,

$$\frac{v_{\text{IN}} - (-v_E)}{R_1} = i_1 = i_2 = \frac{-v_E - v_{\text{OUT}}}{R_2} \quad (115.1)$$

(a)

(b)

(c)

FIGURE 115.1 (a) The schematic symbol for an op amp. (b) A simple three-element model for the op amp. (c) The model in (b) simplified further by setting $Z_i = \infty$ and $Z_o = 0$.

Using the relationship $v_E = v_{OUT}/a$, Equation (115.1) yields

$$\frac{v_{OUT}}{v_{IN}} = -\frac{R_2}{R_1} \frac{1}{1 + (R_1 + R_2)/aR_1} \quad (115.2)$$

Assuming that the op-amp gain is very large ($a \rightarrow \infty$), Equation (115.2) becomes

$$\frac{v_{OUT}}{v_{IN}} = -\frac{R_2}{R_1} \quad (115.3)$$

The gain depends on the ratio of resistors and is independent of the op-amp parameters.

The above analysis can be made easier by assuming that the op amp is ideal ($Z_i = \infty$, $Z_o = 0$, and $a = \infty$) before beginning the analysis. This **ideal op-amp model** greatly simplifies analysis and gives results that are surprisingly accurate. The assumption $Z_i = \infty$ ensures that the currents flowing into the op-amp input terminals are zero. With $Z_o = 0$, the controlled source directly controls the output, giving $v_{OUT} = av_E$. The final assumption $a = \infty$ leads to $v_E = v_{OUT}/a = 0$ if v_{OUT} is bounded, which is typically true in negative feedback circuits. The condition $v_E = 0$ is referred to as a *virtual short circuit* because the op-amp input voltages are equal ($v_+ = v_-$), even though these inputs are not actually connected together. Negative feedback forces v_E to be equal to zero.

To demonstrate the advantage of the ideal op-amp model, consider the circuit in [Figure 115.3](#). If the op amp is ideal, $v_+ = v_-$, and therefore $v_- = v_{IN}$ as a result of the virtual short circuit. Since no current flows into the op-amp input, the currents i_3 flowing through resistor R_3 and i_4 through R_4 must be equal:

$$\frac{0 - v_{IN}}{R_3} = i_3 = i_4 = \frac{v_{IN} - v_{OUT}}{R_4} \quad (115.4)$$

The resulting gain is positive, or noninverting, and is given by

FIGURE 115.2 An inverting gain amplifier.

FIGURE 115.3 A noninverting gain amplifier.

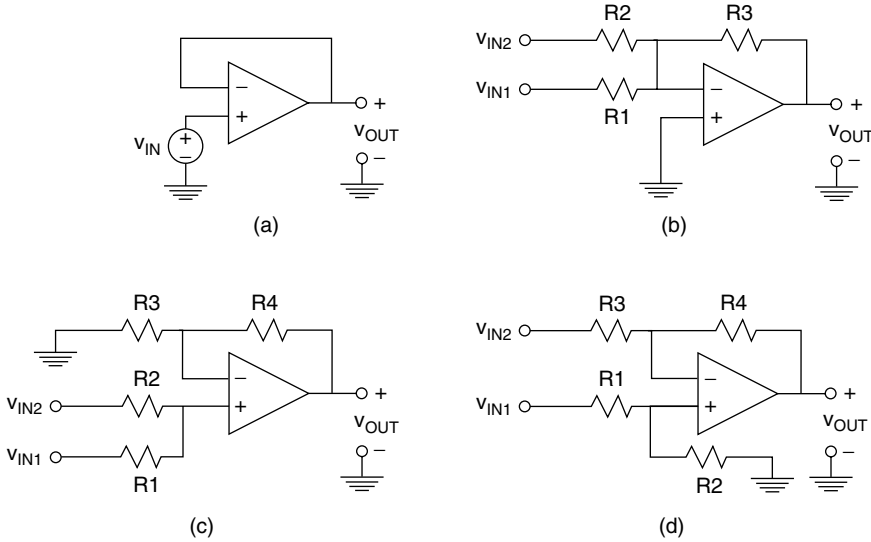

FIGURE 115.4 (a) A voltage buffer, $v_{OUT} = v_{IN}$. (b) A two-input inverting gain amplifier, $v_{OUT} = - (R_3/R_1)v_{IN1} - (R_3/R_2)v_{IN2}$. (c) A two-input noninverting stage, $v_{OUT} = \{ [R_2/(R_1 + R_2)]v_{IN1} + [R_1/(R_1 + R_2)]v_{IN2} \} (R_3 + R_4)/R_3$; (d) a differencing amplifier, $v_{OUT} = - (R_4/R_3)v_{IN2} + [R_2/(R_1 + R_2)] [(R_3 + R_4)/(R_3)]v_{IN1}$.

$$\frac{v_{OUT}}{v_{IN}} = 1 + \frac{R_4}{R_3} \quad (115.5)$$

This example demonstrates how the ideal op-amp model can be used to quickly analyze op-amp feedback circuits.

A number of interesting op-amp feedback circuits are shown in Figure 115.4. The corresponding expressions for v_{OUT} are given in the caption for Figure 115.4, assuming an ideal op amp. The simplest circuit is the voltage buffer of Figure 115.4(a), which has a voltage gain of 1. The circuits in Figure 115.4(b–d) have multiple inputs. Figure 115.4(b) is an inverting, summing amplifier if $R_1 = R_2$. Figure 115.4(c) is a noninverting, summing amplifier if $R_1 = R_2$. If $R_1/R_2 = R_3/R_4$ in Figure 115.4(d), this circuit is a differencing amplifier with

$$v_{OUT} = \frac{R_4}{R_3} (v_{IN1} - v_{IN2}) \quad (115.6)$$

Op amps can be used to construct filters for signal conditioning. If R_1 in Figure 115.2 is replaced by a capacitor C_1 , the circuit becomes a differentiator and its input and output are related by either of the following:

FIGURE 115.5 A one-pole, one-zero filter.

$$v_{\text{OUT}}(t) = -R_2 C_1 \frac{dv_{\text{IN}}(t)}{dt} \quad (115.7a)$$

$$V_{\text{OUT}}(s) = -sR_2 C_1 V_{\text{IN}}(s) \quad (115.7b)$$

where s is the Laplace operator and $V(s)$ is the Laplace transform of $v(t)$.

Again, starting with Figure 115.2, if R_2 is replaced by a capacitor C_2 , the circuit becomes an integrator. Its input and output are related by either of the following:

$$v_{\text{OUT}}(t) = -\frac{1}{R_1 C_2} \int_0^t v_{\text{IN}}(\tau) d\tau \quad (115.8a)$$

$$V_{\text{OUT}}(s) = -\frac{V_{\text{IN}}(s)}{sR_1 C_2} \quad (115.8b)$$

Here, $v_{\text{OUT}}(t=0) = 0$ is assumed. Since there is no DC feedback from the op-amp output to its input through capacitor C_2 , an integrator will only work properly when used in an application that provides DC feedback around the integrator for biasing. Integrators are often used inside feedback loops to construct filters or control loops.

Figure 115.5 is a one-pole, one-zero filter with transfer function

$$\frac{V_{\text{OUT}}(s)}{V_{\text{IN}}(s)} = -\frac{R_2}{R_1} \frac{1 + sR_1 C_1}{1 + sR_2 C_2} \quad (115.9)$$

Higher-order filters can be constructed using op amps [Jung, 1986].

115.2 Feedback Circuit Analysis

The goal of every op-amp feedback circuit is an input/output relationship that is independent of the op amp itself. An exact formula for the closed-loop gain A of an op-amp feedback circuit (e.g., Figure 115.2) is given by Rosenstark [1986]:

$$A = \frac{v_{\text{OUT}}}{v_{\text{IN}}} = A_{\infty} \frac{RR}{1 + RR} + \frac{d}{1 + RR} \quad (115.10)$$

Here, A_{∞} is the gain when the op-amp gain $a = \infty$. The term $d = v_{\text{OUT}}/v_{\text{IN}}|_{a=0}$ accounts for feed-forward directly from input to output; typically, d is zero or close to zero. RR is the return ratio for the controlled

FIGURE 115.6 Figure 115.2 modified to allow calculation of the return ratio.

source a . From Equation (115.10), it can be seen that gain A approaches the ideal value A_∞ as RR approaches infinity. The return ratio for the controlled source a can be found by (1) setting all independent sources to zero, (2) breaking the connection between the controlled source a and the rest of the circuit, (3) driving the circuit at the break with a voltage source with value v_t , and (4) finding the resulting voltage v_r across the dependent source. Then $RR = -v_r/v_t$. For negative feedback, RR is positive. Ideally, RR is large so that the gain A is close to A_∞ .

For example, consider Figure 115.2. Using the op-amp model of Figure 115.1(c), the return ratio for the dependent source a can be found using Figure 115.6, and the result is

$$RR = -\frac{v_r}{v_t} = a \frac{R_1}{R_1 + R_2} \quad (115.11)$$

With this model, d is zero, since setting a equal to 0 forces v_{OUT} equal to 0. Therefore, Equation (115.10) simplifies to

$$A = \frac{v_{OUT}}{v_{IN}} = A_\infty \frac{RR}{1 + RR} \quad (115.12)$$

The RR in Equation (115.11) can be used in Equation (115.10) to determine A at DC or as a function of frequency if $a(s)$ is known. Information on $a(s = j\omega)$ is usually provided graphically on a data sheet.

Since op-amp circuits use feedback, stability is a concern. In circuits with passive feedback and load elements, the terms A_∞ , RR , and d in Equation (115.10) are stable (all poles are in the left half of the s plane). Therefore, stability of the closed-loop transfer function $A(s)$ is determined by the location of the zeroes of $[1 + RR(s)]$, which are poles of $A(s)$. The location of the zeroes of $[1 + RR(s)]$ can be determined by examining the phase and gain margins of RR [Rosenstark, 1986]. The phase margin is $180^\circ - [\text{the phase of } RR(s = j\omega_U)]$, where ω_U is the frequency where the magnitude of RR is unity. The **gain margin** is $-20 \log_{10} |RR(s = j\omega_{180})|$, where ω_{180} is the frequency where the phase of RR is -180° . The phase and gain margins are positive for a stable circuit. Using an accurate frequency-dependent model for the op amp, or using the frequency response plot of $a(s = j\omega)$ on the data sheet, the gain and phase margins can be found. Roughly, $A(s = j\omega) = A_\infty$ for frequencies below ω_U , and $A(s = j\omega)$ will deviate from A_∞ at frequencies near and above ω_U .

Most op amps are designed to be unity-gain stable — that is, they are stable when connected as a buffer [see Figure 115.4(a)]. In that configuration, $RR(s) = a(s)Z_i/(Z_i + Z_o) \approx a(s)$ (the approximation follows from $|Z_o| \ll |Z_i|$).

115.3 Input and Output Impedances

The input impedance of an op-amp circuit can be found by applying a test voltage source across the input port and measuring the current that flows into the port. The applied voltage divided by the resulting current is the input impedance. (When computing the output impedance, the input source(s) must be

TABLE 115.1 Typical Op-Amp Specifications

| Part # | a at DC | $R_i = Z_i$ (DC) | $R_o = Z_o$ (DC) | Output Swing | $ V_{OS} $ | I_B | Bandwidth for $A_{\infty} = 1$ | Slew Rate |
|---------|------------------|---------------------|---------------------|-----------------|------------|--------|-----------------------------------|----------------|
| OP-07 | $5 \cdot 10^5$ | 60 M Ω | 60 Ω | ± 14 V | 30 μ V | 1.8 nA | 0.6 MHz | 0.3 V/ μ s |
| LF411 | $2 \cdot 10^5$ | 10^{12} Ω | 40 Ω | ± 13.5 V | 0.8 mV | 50 pA | 4 MHz | 15 V/ μ s |
| OP-177F | $1.2 \cdot 10^7$ | 45 M Ω | 60 Ω | ± 12.5 V | 10 μ V | 1.2 nA | 0.6 MHz | 0.3 V/ μ s |

Note: Supply voltage = ± 15 V; temperature = 25°C .

set to zero and then the same procedure is carried out on the output port.) Using the model in Figure 115.1(b), the input impedance for the voltage buffer in Figure 115.4(a) can be found by following these steps, and the result is

$$Z_{in}(\text{with feedback}) = (Z_i + Z_o) \cdot \left(1 + a \frac{Z_i}{Z_o + Z_i} \right) \approx aZ_i \quad (115.13)$$

where the approximation is valid since $|Z_o| \ll |Z_i|$ and $a \gg 1$. The negative feedback increases the input impedance from Z_i to aZ_i . For the OP-07 op amp (see Table 115.1), $Z_i = 60 \text{ M}\Omega$ and $a = 500\,000$ at DC, giving a remarkably large $Z_{in}(\text{with feedback}) = 3 \cdot 10^{13} \Omega$ at DC. Calculation of the output impedance in Figure 115.4(a) gives

$$Z_{out}(\text{with feedback}) = \frac{Z_i \parallel Z_o}{1 + a(Z_i)/(Z_o + Z_i)} \approx \frac{Z_o}{a} \quad (115.14)$$

where $x \parallel y = xy/(x + y)$, and $Z_i \parallel Z_o \approx Z_o$ because $|Z_o| \ll |Z_i|$. The feedback reduces the output impedance. Again, using values for the OP-07, $Z_{out}(\text{with feedback}) = 0.1 \text{ m}\Omega$ at DC.

In some cases, the ideal op-amp model can be used to quickly determine the input impedance. For example, the input resistance in Figure 115.2 is approximately R_1 because feedback forces v_- to be close to 0. The output impedance of an ideal op-amp circuit is zero because $Z_o = 0$. The actual value can be found by using the model in Figure 115.1(b) and carrying out the computation described earlier.

115.4 Practical Limitations and Considerations

The ideal op-amp model is easy to use, but practical limitations are not included in this simple model. Specifications for a few popular op amps are given in Table 115.1 [Analog Devices, 1992; National Semiconductor, 1993]. The LF411 uses field-effect input transistors to give extremely high-input resistance and low-input bias current. The input bias current I_B is the DC current that flows into the op-amp inputs; this is bias current required by the input transistors in the op amp. (This current is not included in the simple models of Figure 115.1, and it cannot be computed using Z_i .)

The output voltage swing over which the linear model is valid is limited by the power supply voltage(s) and the op-amp architecture. The peak output current is limited by internal bias currents and/or protection circuitry. The output slew rate, which is the maximum slope of the output signal before distortion occurs, is limited by op-amp internal currents and capacitances. The common-mode input voltage range is the range of the common-mode (or average) input voltage, which is $(v_+ + v_-)/2$, for which the linear op-amp model is valid. In Figure 115.2, it is important that ground be within this range since $(v_+ + v_-)/2 \approx 0$ in this circuit. In Figure 115.3, v_{IN} must stay in the common-mode input range since $(v_+ + v_-)/2 \approx v_{IN}$.

The **input offset voltage** V_{OS} is the DC op-amp input voltage that causes v_{OUT} to equal 0 V DC. The offset voltage varies from part to part; it is dependent on imbalances within the op amp. The input offset voltage can be included in the op-amp model, as shown in Figure 115.7. When this model is used in Figure 115.2, for example, the output voltage depends on the input voltage and the offset voltage:

FIGURE 115.7 The op-amp model of Figure 115.1(c) with the addition of the input offset voltage V_{OS} .

$$v_{OUT} = -\frac{R_2}{R_1} v_{IN} + \left(1 + \frac{R_2}{R_1}\right) V_{OS} \quad (115.15)$$

For high gain ($R_2 \gg R_1$), the amplification of V_{OS} can cause problems, in which case a capacitor can be added in series with R_1 . This eliminates the amplification of V_{OS} , but it also causes the DC gain from v_{IN} to v_{OUT} to be zero.

These parameters and many more are specified on the data sheet and are incorporated into an op-amp macro model, which is an interconnection of circuit elements that model the linear and nonlinear behavior of the op amp. Most companies provide macro models for their op amps that can be used in a circuit simulation program such as SPICE.

Defining Terms

Ideal op-amp model — Has $Z_i = \infty$, $Z_o = 0$, and $a = \infty$, which leads to $v_E = v_+ - v_- = 0$ (the virtual-short-circuit condition).

Input offset voltage — The op-amp DC input voltage, $v_+ - v_-$, that causes v_{OUT} to equal 0 V DC.

Phase margin — $180^\circ - [\text{the phase of } RR(s = j\omega_U)]$, where ω_U is the frequency where the magnitude of RR is unity (i.e., $|RR(s = j\omega_U)| = 1$). Phase margin is measured in degrees.

Gain margin — Is $-20 \log_{10} |RR(s = j\omega_{180})|$, where ω_{180} is the frequency where the phase of RR is -180° (i.e., phase of $RR(s = j\omega_{180}) = -180^\circ$). Gain margin is measured in decibels. Since RR is some factor times $a(s)$ [e.g., see Equation (115.11)], plots of the magnitude and phase of RR versus frequency can be generated from plots of $a(s = j\omega)$. The gain and phase margins can be found from magnitude and phase plots of $RR(s = j\omega)$.

SPICE — A computer program that can simulate circuits with linear and nonlinear elements. Many versions of SPICE are available.

Active RC filters arose out of the need for filters that are compatible with modern integrated circuit (IC) technology. Attempts to implement passive RLC filters in IC technology have largely failed due to difficulties in implementing inductors using IC technology. Circuit theorists, however, have shown that adding an active device (e.g., an operational amplifier) to resistors and capacitors makes it possible to implement any filter function that can be implemented using passive components (i.e., passive R, L, C filters). Since operational amplifiers (op amps), resistors, and capacitors are all compatible with modern IC technology, active RC filters are very attractive.

While the primary motivation for active RC filters comes from the desire to implement filter circuits in IC technology, there are additional advantages over passive RLC filters:

- Op amps, resistors, and capacitors perform much more closely to their ideal characteristics than inductors, which typically exhibit large parasitic resistances and significant nonlinearities.
- Passive RLC filters are not able to take advantage of the component tracking and very accurate matching of component ratios available in IC technologies. (Note: Filter characteristics depend on ratios of element values rather than the absolute value of the components.)
- Passive RLC filters cannot realize power gain, only attenuation.

In their infancy, active filters often suffered from a tendency to oscillate. Early work in active filters eliminated these problems but led to filters with high sensitivity to component values. Finally, in the 1970s, active filters emerged that clearly outperformed passive filters in cost, power consumption, ease of tuning, sensitivity, and flexibility. While IC technology allows for active filters that take full advantage of the new active RC filter design techniques, even active RC filters designed with discrete components will perform as well as, if not better than, their passive counterparts.

116.1 History of Active Filters

The first practical circuits for active RC filters emerged during World War II and were documented much later in a classic paper by Sallen and Key [1955]. With the advent of IC technology in the early 1960s, active filter research flourished with the emphasis on obtaining stable filters [Mitra, 1971]. During the early 1970s, research focused on reducing the sensitivity of active filters to their component values [Schaumann et al., 1976]. By the end of the 1970s, active filters had been developed that were better than passive filters in virtually every aspect [Bowron and Stephenson, 1979; Ghausi and Laker, 1981; Schaumann et al., 1990; Tsividis and Voorman, 1993]. Unfortunately, most active filter handbooks and books that concentrate on the practical design of active filters have used the old Sallen and Key approach to active filter design. In this chapter we briefly discuss op-amp-based active RC filter design techniques. (Note: In VLSI applications transconductance-based active filters offer an excellent alternative, which we not discuss [Tsividis and Voorman, 1993].) Then we introduce a table-based design procedure for one of the modern op-amp techniques that yields active RC filters as good as or better than passive RLC filters.

116.2 Active Filter Design Techniques

In this section we define three categories of active RC filter design using very different approaches. Within each category, we briefly describe several of the specific methods available.

Cascaded Biquads

The simplest and most popular active RC filter design techniques are based on a cascade of second-order (biquadratic or biquad) sections. The numerator and denominator of the filter function $H(s)$ (expressed in terms of the complex frequency variable s) are factored into second-order factors (plus one first-order, in the case of an odd-order filter). Second-order transfer functions are then formed by combining appropriate numerator terms with each second-order denominator term such that the product of the second-order transfer functions is equal to the original $H(s)$. (Note: In the case of odd-order filters, there will also be one first-order section.) Active RC biquad circuits are then used to implement each second-order section. In the case of odd-order filters, a separate first-order RC section may be added or the real pole can be combined with one of the second-order sections to form a third-order section. The different cascade methods are defined based on which biquad circuits are used and whether the ordering of the biquads is considered as part of the design procedure.

The advantages of the cascade design lie in the ease of design and the fact that the biquads are isolated and thus can be separately tuned during the manufacturing process. The disadvantage of the cascade design also derives from the isolated sections, as it allows only for feedback around individual second-order stages without overall feedback around the entire filter structure. Thus the cascade of second-order sections is essentially operated open loop.

Cascade of Sallen and Key Filters

This approach is the basis for most active RC filter handbooks and many practical texts on active RC filter design. The resulting filters have the advantage of being canonical (i.e., having the fewest possible components — two resistors, two capacitors, and one op amp per second-order stage). The performance of these filters is generally acceptable but is not as good as passive RLC filters. The primary disadvantage of this approach lies in the fact that it is not possible to use matched op amps to compensate for the nonideal properties of the operational amplifier, since the sections only use one op amp. A complete description of the design of a cascade of Sallen and Key filters can be found in Williams [1975]. Williams also describes a slightly improved design using state-variable-based second-order sections. However, one should use optimum biquads rather than state-variable biquads since the optimum biquads have the same number or fewer components and outperform the state-variable filters.

Cascade of Optimum Biquads

Optimum biquads require at least two active elements in order to make use of matched op amps to reduce the effects of the nonideal properties of the active elements. Optimum two-op-amp biquad circuits are based on the gyrator circuits introduced by Antoniou [1967] and modified by Hamilton and Sedra [1971]. The design of these circuits is covered later in this chapter.

Ordered Cascade of Optimum Biquads

In order to obtain the best performance possible using the cascade technique, it is not sufficient to use optimum biquads. The second-order sections must also be ordered in an optimum fashion. In this chapter we show how to design using the optimum biquads, but we do not go into the details of ordering the biquads. For those who need the ultimate in performance, an excellent discussion of ordering is provided in chapter 10 of Sedra and Brackett [1978].

Simulation of LC Ladders

This approach was originally designed simply to take advantage of the vast reservoir of knowledge on passive LC ladder filter circuit design in the design of active filters. The simplest approach uses a gyrator [Antoniou, 1967] and a capacitor to simulate an inductor and replaces the inductors in the passive RLC ladder with this simulation (chapter 11 of Sedra and Brackett [1978]). More sophisticated techniques simulate the voltage and current equations of the passive RLC ladder (chapter 12 of Sedra and Brackett [1978]) or the scattering parameters [Haritantis et al., 1976]. The latter techniques have resulted in the best filter circuits ever constructed.

At first it may seem that simulating passive RLC filters would at best yield filters equal to, but not better than, passive filters. However, the poor quality of passive inductors coupled with the ability of active RC filters to be constructed in IC technology, where very accurate ratios of components can be obtained, gives a huge advantage to active RC filters compared with passive RLC filters. Even for filters realized with discrete components (i.e., not using IC technology), the advantage of not using an inductor and the use of dual matched op amps yields circuits superior to those available with passive RLC filters.

Component Simulation of LC Ladders

The primary attraction of this technique is the ease of design. You simply replace the inductors in a passive RLC filter obtained from any passive RLC design handbook [Hansell, 1969; Zverev, 1967] with active RC simulated inductors. Unfortunately, the floating inductors (inductors which do not have one terminal grounded) required for most passive RLC filters are one of the poorer-performing active RC components. However, modifications of this approach using *frequency-dependent negative resistors* (FDNRs) proposed by Bruton et al. [1972] have largely eliminated these problems. For details on the component simulation of LC ladders, see chapter 11 of Sedra and Brackett [1978].

Operational Simulation of LC Ladders

In this approach active RC components are used as an *analog computer* to simulate the differential equations of Kirchhoff's current and voltage laws at each node in a passive RLC circuit. This approach has resulted in some of the best filter circuits ever designed. For details, see chapter 12 of Sedra and Brackett [1978] (see also [Ghausi and Laker, 1981; Schaumann et al., 1990]).

Wave Analog Filters

This approach is similar in concept to the operational simulation of RLC ladders except that scattering matrices of the passive RLC filter are simulated rather than Kirchhoff's current and voltage laws. This approach has become very popular in Europe, yielding filters every bit as good as those designed using the operational simulation of RLC ladders. For details see either Schaumann et al. [1990] or Haritantis et al. [1976].

Coupled Biquads

The *coupled biquad* approach uses the same optimum biquads that we use in the cascade approach later in this chapter, but provides feedback around the biquad sections. The advantage of this approach is that this additional feedback makes it possible to obtain filter performance equivalent to the filters realized by simulating RLC ladders, but using the modular, easily tuned biquad sections. However, the coupling of the biquads makes it much more difficult to tune the structure than in the case of cascaded biquads. For an excellent discussion of the coupled biquad design approach, see chapter 5 of Ghausi and Laker [1981] (see also chapter 10 of Sedra and Brackett [1978] and chapter 5 of Schaumann et al. [1990]).

Current Feedback Active Filters

All of the filters we have considered to this point were based upon the use of voltage feedback operational amplifiers. Recently a number of authors have praised the virtues of current-feedback operational amplifiers in active filter circuits [Becvar et al., 2000; Chiu et al., 1996; Chong and Smith, 1986; Roberts and Sedra, 1989; Toumazou and Lidgley, 1990]. As with most technologies, current-feedback active filters provide some improvements over voltage feedback active filters, but also show some disadvantages. National Semiconductor provides a series of application notes that pretty much set the record straight [Buck, 1992; Brandenburg, 1998; National Semiconductor, 1993; Potson, 1988]. In particular the article by Brandenburg [1998] provides a very good comparison of the two technologies. She concludes that for most applications the two technologies are equivalent. However, current-feedback does offer independence between the gain and bandwidth that results in faster slew rates and lower distortion at the expense of restrictions on the value of the feedback resistors when compared to voltage-feedback circuits. On the other hand, voltage feedback offers lower noise, better DC performance, and freedom of selection of feedback resistance that is not available in current-feedback circuits. In this chapter we shall only discuss voltage-feedback circuits, but it should be noted that most of the voltage-feedback circuits have analogies in current-feedback and therefore it is easy to substitute current-feedback into the circuits discussed in this chapter [Brandenburg, 1998].

116.3 Filter Specifications and Approximations

Low-pass filters are specified by four parameters: (1) α_p , the passband ripple; (2) ω_p , the passband frequency; (3) α_s , the stopband attenuation; and (4) ω_s , the stopband frequency. Figure 116.1 illustrates these parameters. A filter meeting these specifications must have $|H(s)|$ lie between 0 dB and α_p from DC to frequency ω_p , and below α_s for frequencies above ω_s . For passive filters and odd-order active filters, α_p is always negative. For active even-order filters, α_p is positive and these filters exhibit power gain. Note that the gain for all active filter designs is normalized to 0 dB at DC (normalization is different for even-order passive filters). In practice, active RC filters are capable of providing an overall gain K , which multiplies the system function $H(s)$ with the effect of scaling the vertical axis in Figure 116.1.

The specifications of Figure 116.1 are only half the story, however. In addition to the magnitude characteristics, filters have group delay characteristics related to the phase response of the filter. Figure 116.2 shows a typical group delay specification where (1) τ_0 is the nominal group delay, (2) $\Delta\tau$ is the passband group delay tolerance, and (3) ω_g is the frequency at which the group delay has decayed to 50% of τ_0 . Unfortunately, magnitude characteristics cannot be specified independent of group delay characteristics. Thus designers must make a choice between which set of specifications they wish to implement and must settle for whatever they get with the other specifications. Filter approximations are specific techniques for achieving one or the other set of specifications. Each approximation offers a different compromise between meeting the magnitude specification and meeting the group delay specification.

Filters can be classified into two broad classes: (1) all-pole filters and (2) filters with finite zeros. Figure 116.3 shows the basic asymptotic response for all-pole filters in the left column and the basic asymptotic response for filters with finite zeros in the right column. In each column the response of the three basic

FIGURE 116.1 Magnitude specifications for a low-pass filter.

FIGURE 116.2 Delay specifications for a low-pass filter.

filters, low-pass, high-pass, and band-pass, are shown. A fourth filter type, called a notch filter or band-elimination filter, is not shown because this type of filter exhibits an asymptotic response that is 0 dB at all frequencies, with a notch (area of high attenuation) around the corner frequency ω_c . Most filter design procedures concentrate on designing low-pass filters and use standard transformations to convert these low-pass filters to high-pass, band-pass, or notch filters. (A good explanation of how to do this can be found in chapter 6 of Sedra and Brackett [1978].)

All passive RLC and active RC filters, regardless of the filter approximation or the method of implementation, have the same asymptotes for the some-order filter (*order* refers to the number of effective reactive elements — inductors and capacitors in a passive RLC filter, and capacitors in an active RC filter). The various filter approximations that we are about to introduce primarily affect how the filter performs in the transition band between frequencies ω_p and ω_s . In general, the wider the transition band, the better the group delay performance, but at the expense of significant deviation from the asymptotic response in the transition band. Note that the corner frequency ω_c is an important parameter for all-

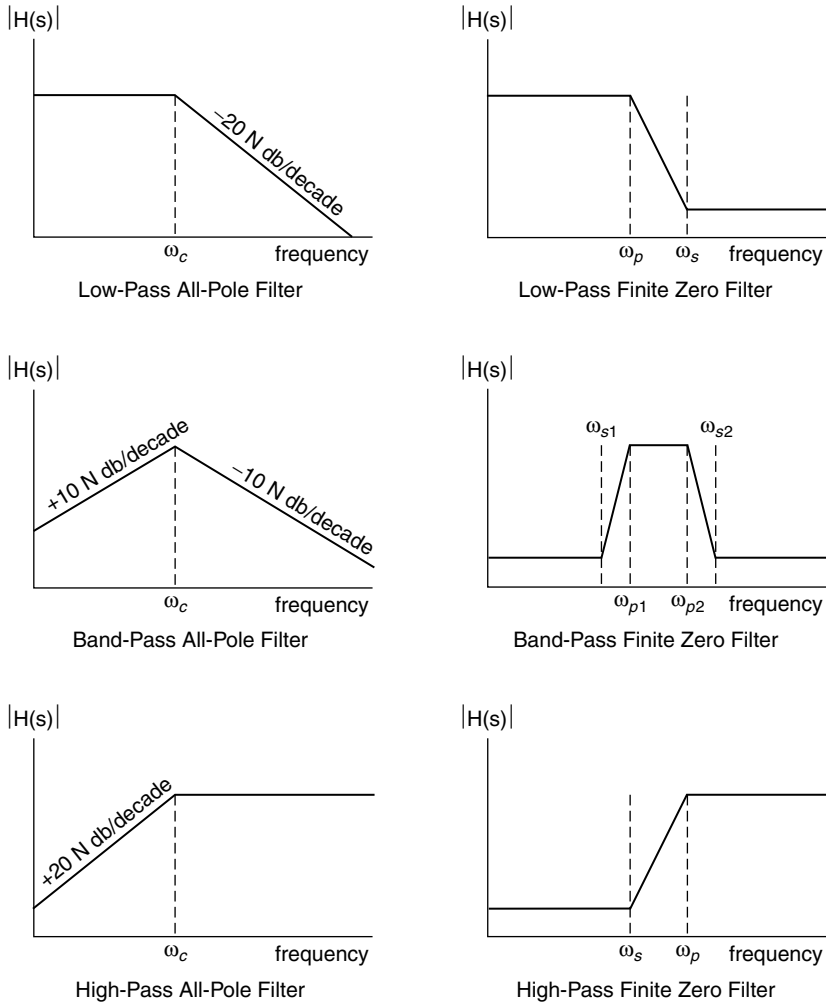

FIGURE 116.3 Asymptotic response of filters.

pole filters because the asymptotic response is defined by this corner frequency along with the order of the filter N and the filter gain K .

Bessel–Thompson Filters

The focus of the Bessel–Thompson filters is on meeting the group delay specification. The group delay is fixed at τ_0 for DC, and as many derivatives of the group delay function as possible are set to zero at DC. This yields what is called a *maximally flat* delay response. Mathematically it can be shown that this will obtain the closest possible match to the ideal “brick wall” delay response without any delay in excess of the prescribed group delay τ_0 . These filters were originally developed by Thompson and make use of Bessel functions — hence the name Bessel–Thompson filters. Bessel–Thompson filters exhibit the low-pass all-pole asymptotic response of Figure 116.3.

Although Bessel–Thompson filters offer the best possible group delay response, they do this at the expense of very poor magnitude response in the transition band. Furthermore, for a given order of filter, the transition band is much larger than for the other filter approximations. Other group delay approximations such as the equal-ripple group delay approximation provide only slightly better magnitude performance.

It is often very useful to calculate the required order of a Bessel–Thompson filter from the specifications for that filter. Since Bessel–Thompson filters are primarily dependent on the group delay specifications, the exact formula does not involve the standard magnitude specifications. However, the following approximate formula estimates the order of a Bessel–Thompson filter:

$$N \approx \frac{\alpha_s}{20 \log_{10}(\omega_s / \omega_c)} \quad (116.1)$$

with α_s in dB and ω_c and ω_s in radians (or hertz).

Butterworth Filters

Butterworth filters provide a maximally flat passband response for the magnitude of the transfer function at the expense of some peaking in the group delay response around the passband frequency ω_p . In most cases the large improvement in magnitude response compared with Bessel–Thompson filters more than compensates for the peaking of the group delay response. Butterworth filters exhibit the low-pass all-pole asymptotic response of [Figure 116.3](#) with exactly 3 dB of attenuation at the corner frequency ω_c . This is less droop (i.e., attenuation at the corner frequency) than Bessel–Thompson filters, but more than the other filter approximations we discuss.

It is often very useful to calculate the required order of a Butterworth filter from the specifications. The following formula gives this relationship:

$$N \geq \frac{\log_{10}(K_\alpha)}{\log_{10}(K_\omega)} \quad (116.2)$$

where

$$K_\alpha = \sqrt{\frac{10^{\alpha_s/10} - 1}{10^{\alpha_p/10} - 1}} \quad (116.3)$$

$$K_\omega = \omega_s / \omega_p \quad (116.4)$$

with α_p and α_s in dB and ω_p and ω_s in radians (or hertz).

Chebyshev Filters

Chebyshev filters provide an equal-ripple response in the passband (i.e., the magnitude of $H(s)$ oscillates or ripples between zero and α_p in the passband). Chebyshev filters are all-pole filters that can be shown to provide the narrowest transition band for a given filter order N of any of the all-pole filters. This narrow transition band, however, comes at the expense of significant and often unacceptable peaking and oscillation in the group delay response.

It is often very useful to calculate the required order of a Chebyshev filter from the specifications for that filter. The following formula gives this relationship:

$$N \geq \frac{\cosh^{-1}(K_\alpha)}{\cosh^{-1}(K_\omega)} \quad (116.5)$$

or

$$N \geq \frac{\log_{10} \left(K_{\alpha} + \sqrt{K_{\alpha}^2 - 1} \right)}{\log_{10} \left(K_{\omega} + \sqrt{K_{\omega}^2 - 1} \right)} \quad (116.6)$$

where K_{α} and K_{ω} are as defined in Equations (116.3) and (116.4), respectively.

Inverse Chebyshev Filters

Inverse Chebyshev filters provide the same maximally flat magnitude response of Butterworth filters, including the slight, but usually acceptable, peaking in the group delay response, with a transition band exactly the same as for the Chebyshev filters. However, the inverse Chebyshev filters exhibit the low-pass finite-zero asymptotic response of Figure 116.3 with equal ripple in the stopband.

It is often very useful to calculate the required order of an inverse Chebyshev filter from the specifications. Since the inverse Chebyshev filter has the same order as the Chebyshev filter, Equations (116.5) or (116.6) can also be used to calculate the order of inverse Chebyshev filters.

Elliptical–Cauer Filters

The elliptical–Cauer filters exhibit the low-pass finite-zero asymptotic response of Figure 116.3 with equal ripple in both the passband (like Chebyshev filters) and the stopband (like inverse Chebyshev filters). While the group delay of these filters is poor, like that of the Chebyshev filters, elliptical–Cauer filters can be shown to have the narrowest transition band of any of the filter approximations.

It is often very useful to calculate the required order of an elliptical–Cauer filter. The following formula gives this relationship:

$$N \geq \frac{CEI(1/K_{\omega})CEI\left(\sqrt{1-1/K_{\alpha}^2}\right)}{CEI(1/K_{\alpha})CEI\left(\sqrt{1-1/K_{\omega}^2}\right)} \quad (116.7)$$

where CEI is the *complete elliptic integral* function. (The CEI function is denoted by K or q in most textbooks, but we have chosen CEI so as not to confuse it with other filter parameters.) Although the CEI function is not typically provided on calculators or in computer mathematics libraries, computer programs are readily available for calculating the CEI function. (For example, MATLAB has the algorithm *ellipord* for calculating the order of both digital and analog elliptic filters. Also, Daniels [1974] contains a computer algorithm for calculating CEI , and Lindquist [1977] contains an approximate formula for N . K_{α} and K_{ω} are as defined in Equations (116.3) and (116.4), respectively.

116.4 Filter Design

Figure 116.4 represents a biquad circuit that can be used for low-pass all-pole filters, and Figure 116.5 shows a biquad that can be used for low-pass finite-zero filters. Both biquads exhibit optimum performance with regard to both passive and active sensitivities [Sedra and Brackett, 1978]. The element values for the circuit of Figure 116.4 are given by

$$R = Q \quad C = 1/\omega_0 \quad (116.8)$$

where ω_0 and Q are the normalized pole frequency and Q of the second-order filter section. Practical element values are obtained by impedance scaling to practical impedance levels (i.e., multiply each resistor by the desired impedance level and divide each capacitor by the desired impedance level) and frequency scaling to the desired ω_p (i.e., divide each capacitor by the desired frequency in radians per second or by

FIGURE 116.4 Biquad circuit for all-pole low-pass filters.

FIGURE 116.5 Biquad circuit for finite-zero low-pass filters.

2π times the desired frequency in hertz). Unlike most filter design tables, the tables with this chapter of the handbook are normalized to $\omega_p = 1$ rather than $\omega_c = 1$. This makes the tables somewhat longer but simplifies the use of the tables.

Figure 116.5 is used for the filters with finite zeros. The element values for the circuit of Figure 116.5 are given by

$$R_a = \frac{Q^2 \omega_n^2}{Q^2 \omega_n^2 + \omega_0^2} \quad R_b = \frac{Q \omega_n^2}{\omega_0^2} \quad R_c = \frac{\omega_n^2}{\omega_0^2} \quad (116.9)$$

$$R = Q \quad C = 1/\omega_0$$

where ω_0 and Q are the normalized resonant frequency and Q for the second-order filter section and ω_n is the normalized frequency of the finite zero. As for the all-pole filter section, our tables have been normalized to $\omega_p = 1$. Practical resistor and capacitor values are obtained by impedance scaling to the desired impedance level and frequency scaling to the desired ω_p .

In order to determine what the resonant frequencies, Q 's, and zero frequencies are for various types of filters, one may either use a computer program or a table. Many commercial computer programs are

available for this purpose and should be used if a significant number of filters are going to be designed. For the casual filter designer, public domain software is available, or the tables included with this chapter may be used. In what follows, we make use of the tables to develop a design example. (The programs *filter* [Wilamowski, 1994] and *ladder* [Koller and Wilamowski, 1994] can be obtained by anonymous FTP to *PLAINS.UWYO.EDU* in directory “electrical.” Copy files *FILTERxx.ZIP* and *LADDERyy.ZIP* — where *xx* and *yy* are the version numbers; currently *xx* = 35 and *yy* = 31 — in *binary* mode, as these are in “zip” format. You must use an “unzip” program to expand them.)

Low-Pass All-Pole Filter Design Example

Table 116.1 applies to the circuit of Figure 116.4 and is used for the design of the all-pole filters: Bessel–Thompson, Butterworth, and Chebyshev. Consider the design of an all-pole filter with the specifications

$$\alpha_p = 1 \text{ dB}, \quad \omega_p = 1 \text{ kHz}, \quad \alpha_s = 40 \text{ dB}, \quad \text{and} \quad \omega_s = 3 \text{ kHz}$$

Plugging these values into Equations (116.3) and (116.4), we obtain $K_\alpha = 197$ and $K_\omega = 3$. Using Equations (116.2) and (116.5), we see that the order of filter necessary to meet these specifications is $N_B = 5$ for a Butterworth filter and $N_C = 4$ for a Chebyshev filter. Note that these specifications are too restrictive to be met by a Bessel–Thompson filter. (From Table 116.1 we see that $\omega_c \approx 3$ for a sixth-order Bessel–Thompson filter and $\omega_c > 3$ for higher-order Bessel–Thompson filters. From Equation (116.1) for the order of a Bessel–Thompson filter, we see that $\omega_s = 3 > \omega_c$ to obtain a practical value for N .)

From Table 116.1 we obtain the following values for the Butterworth fifth-order and Chebyshev fourth-order filters that meet the specifications

Butterworth fifth-order ($\alpha_p = 1.00 \text{ dB}$):

| | | |
|---------|----------------|----------------|
| Stage 0 | $R_0 = 1.0000$ | $C_0 = 0.8736$ |
| Stage 1 | $R_1 = 0.6180$ | $C_1 = 0.8736$ |
| Stage 2 | $R_2 = 1.6180$ | $C_2 = 0.8736$ |

Chebyshev fourth-order ($\alpha_p = 1.00 \text{ dB}$):

| | | |
|---------|----------------|----------------|
| Stage 1 | $R_1 = 0.7845$ | $C_1 = 1.8919$ |
| Stage 2 | $R_2 = 3.5590$ | $C_2 = 1.0068$ |

To obtain practical values, we must denormalize by impedance scaling to a practical impedance level (we have chosen $10 \text{ k}\Omega$) and frequency scaling to $\omega_p = 1 \text{ kHz}$. Thus we multiply all resistors by 10^4 and divide all capacitors by 10^4 to impedance-scale, and we then divide all capacitors by $2\pi \times 10^3$ to frequency-scale. For active filter implementation, we recommend *metal film* resistors and *polystyrene* capacitors. *Mica* capacitors are slightly superior to polystyrene capacitors but have a more restricted range of values. *Polycarbonate* capacitors have a larger range of values but a poorer “retrace” property. *Mylar* capacitors provide large capacitance values in a small package, but at the expense of a much poorer temperature coefficient. The practical values for the resistors and the capacitors of our example after scaling are as follows:

Butterworth fifth-order ($\alpha_p = 1.00 \text{ dB}$):

| | | |
|---------|------------------------------|-------------------------|
| Stage 0 | $R_0 = 10.0 \text{ k}\Omega$ | $C_0 = 13.9 \text{ nF}$ |
| Stage 1 | $R_1 = 6.18 \text{ k}\Omega$ | $C_1 = 13.9 \text{ nF}$ |
| Stage 2 | $R_2 = 16.2 \text{ k}\Omega$ | $C_2 = 13.9 \text{ nF}$ |

Chebyshev fourth-order ($\alpha_p = 1.00$ dB):

Stage 1 $R_1 = 7.85$ k Ω $C_1 = 30.1$ nF

Stage 2 $R_2 = 35.6$ k Ω $C_2 = 16.0$ nF

Note: All resistors labeled 1 Ω in Figure 116.4 become 10 k Ω , and the two resistors labeled 2 Ω become 20 k Ω . These values are well suited for metal film resistors and polystyrene capacitors.

Low-Pass Finite-Zero Filter Design Example

Table 116.2 applies to the circuit of Figure 116.5 and is used for the design of the finite-zero filters: inverse Chebyshev and elliptical-Cauer. Consider the design of a finite-zero filter with the same specifications as in the first example:

$$\alpha_p = 1\text{dB}, \quad \omega_p = 1\text{ kHz}, \quad \alpha_s = 40\text{ dB}, \quad \text{and} \quad \omega_s = 3\text{ kHz}$$

Plugging these values into Equations (116.3) and (116.4), we obtain $K_\alpha = 197$ and $K_\omega = 3$. Using Equations (116.6) and (116.7), respectively, we see that the order of filter necessary to meet these specifications is

$N_{IC} = 4$ for an inverse Chebyshev filter and $N_{EC} = 3$ for an elliptical–Cauer filter. From [Table 116.2](#) we obtain the following values for the inverse Chebyshev fourth-order and elliptical–Cauer third-order filters that meet the specifications:

Inverse Chebyshev fourth-order ($\alpha_s = 40$ dB and $\alpha_p = 1.00$ dB):

| | | | |
|---------|----------------|---------------------|------------------------|
| Stage 1 | $Q_1 = 0.5540$ | $\omega_1 = 1.3074$ | $\omega_{n1} = 2.5312$ |
| Stage 2 | $Q_2 = 1.4780$ | $\omega_2 = 1.1832$ | $\omega_{n2} = 6.1109$ |

Elliptical–Cauer third-order ($\alpha_s = 40$ dB and $\alpha_p = 1.00$ dB):

| | | | |
|---------|----------------|---------------------|------------------------|
| Stage 0 | | $\omega_0 = 0.5237$ | |
| Stage 1 | $Q_1 = 2.2060$ | $\omega_1 = 1.0027$ | $\omega_{n1} = 2.7584$ |

With [Table 116.2](#), an extra step is required in order to find the normalized element values for the circuit of [Figure 116.5](#). We must use Equation (116.9) to find the element values for each stage from the values found in the table for $Q(Q_1, Q_2, \dots)$, $\omega_0(\omega_1, \omega_2, \dots)$, and $\omega_n(\omega_{n1}, \omega_{n2}, \dots)$. For odd-order filters, we must also add a first-order RC low-pass filter to the cascade with normalized values $R = 1.0$ and $C = \omega_0$. To obtain practical values, we then denormalize by impedance scaling to a practical impedance level (we have chosen 10 k Ω) and frequency scaling to $\omega_p = 1$ kHz. Thus we multiply all resistors by 10^4 and divide all capacitors by 10^4 to impedance-scale, and we then divide all capacitors by $2\pi \times 10^3$ to frequency-scale. The practical values for the resistors and the capacitors become:

Inverse Chebyshev fourth-order ($\alpha_p = 1.00$ dB):

| | | | |
|---------|-------------------------|-------------------------|-------------------------|
| Stage 1 | $R_a = 5.35$ k Ω | $R_b = 20.8$ k Ω | $R_c = 37.5$ k Ω |
| | $R = 5.54$ k Ω | $C = 12.2$ nF | |
| Stage 2 | $R_a = 9.83$ k Ω | $R_b = 394$ k Ω | $R_c = 267$ k Ω |
| | $R = 14.8$ k Ω | $C = 13.5$ nF | |

Elliptical–Cauer third-order ($\alpha_p = 1.00$ dB)

| | | | |
|---------|-------------------------|------------------------|-------------------------|
| Stage 0 | $R_0 = 10.0$ k Ω | $C_0 = 30.4$ nF | |
| Stage 1 | $R_a = 9.74$ k Ω | $R_b = 167$ k Ω | $R_c = 75.7$ k Ω |
| | $R = 22.1$ k Ω | $C = 15.9$ nF | |

Note: All resistors labeled 1 Ω in [Figure 116.5](#) become 10 k Ω .

Defining Terms

Active RC filter — A filter circuit that uses an active device (FET, transistor, op amp, transconductance amp, etc.) with resistors and capacitors without the need for inductors. Active RC filters are particularly suited for integrated circuit applications.

Bessel–Thompson filter — A mathematical approximation to an ideal filter in which the group delay of the transfer function in the frequency domain is maximally flat. Bessel–Thompson filters are optimum in the sense that they offer the least droop without overshoot in the group delay.

Biquad — A filter circuit that implements a second-order filter function. High-order filters are often built from a cascade of second-order blocks. Each of these second-order blocks is referred to as a biquad because in the s domain these filters are characterized by a quadratic function of s in both the numerator and denominator.

- Butterworth filter** — A mathematical approximation to an ideal filter in which the magnitude of the transfer function in the frequency domain is maximally flat. Butterworth filters are optimum in the sense that they provide the least droop without overshoot in the magnitude response.
- Cascade** — A circuit topology in which a series of simple circuits (often biquads) are connected with the output of the first to the input of the second, the output of the second to the input of the third, and so forth. Using this configuration, a complex filter can be constructed from a “cascade” of simpler circuits.
- Chebyshev filter** — A mathematical approximation to an ideal filter in which the magnitude of the transfer function has a series of ripples in the passband that are of equal amplitude. Chebyshev filters are optimum in the sense that they offer the sharpest transition band for a given filter order for an all-pole filter.
- Elliptical–Cauer filter** — A mathematical approximation of an ideal filter in which the magnitude of the transfer function has a series of ripples in both the passband and stopband that are of equal amplitude. Elliptical–Cauer filters are optimum in the sense that they provide the sharpest possible transition band for a given filter order.
- Filter circuit** — An electronic circuit that passes some frequencies and rejects others so as to separate signals according to their frequency content. Common filter type are low pass, band pass, and high pass, which refer to whether they pass low, middle, or high frequencies, respectively.
- Inverse Chebyshev filters** — A mathematical approximation to an ideal filter exhibiting a Butterworth magnitude response in the passband and an elliptical–Cauer magnitude response in the stopband.
- LC ladder filter circuits** — A planar circuit topology resembling a ladder in which the rungs of the ladder (referred to as the *parallel circuit elements*) consist of inductors or capacitors, one rail of the ladder is the ground plane, and the other rail (referred to as the *series circuit elements*) consists of a series connection of inductors and capacitors.
- Passband** — The frequencies for which a filter passes the signal from the input to the output without significant attenuation.
- Passive RLC filter** — A filter circuit that uses only passive devices, resistors, capacitors, inductors, and mutual inductors.
- Pole frequency (ω_0)** — A parameter of a biquad filter used along with Q to define the location of the complex second-order pole pair in the s domain. The pole frequency ω_0 is the distance of the second-order pole pair from the origin in the s plane. This frequency is approximately equal to the cutoff frequency for low-pass and high-pass filters and to the resonant frequency for band-pass filters (see Q).
- Q** — A parameter of a biquad circuit used along with ω_0 to define the location of the complex second-order pole pair in the s plane. The real part of the pole pair is located in the s plane at $\omega_0/2Q$. The two poles are at a distance ω_0 from the origin in the s plane.
- Stopband** — The frequencies for which a filter provides significant attenuation for signals between the input and output.
- Transition band** — The frequencies between a passband and stopband for which there are no filter specifications that must be met. Transition bands are necessary to allow for practical filter circuits, but it is desirable to keep transition bands as narrow as possible (i.e., a sharp transition band).

Transistors form the basis of all modern electronic devices and systems, including the integrated circuits used in systems ranging from radio and TVs to computers. Transistors are solid-state electron devices made out of a category of materials called *semiconductors*. The most widely used semiconductor for transistors, by far, is silicon, although gallium arsenide, which is a compound semiconductor, is used for some very-high-speed applications. We start off with a very brief discussion of semiconductors. Next is a short discussion of PN junctions and diodes, followed by a section on the three major types of transistors — the bipolar junction transistor (BJT), the junction field-effect transistor (JEET), and the metal-oxide silicon field-effect transistor (MOSFET).

117.1 Semiconductors

Semiconductors are a category of materials with an electrical conductivity that is intermediate between that of the good conductors and the insulators. The good conductors, which are all metals, have electrical resistivities down in the range of $10^{-6} \Omega \cdot \text{cm}$. The insulators have electrical resistivities that are up in the range of 10^6 to as much as about $10^{12} \Omega \cdot \text{cm}$. Semiconductors have resistivities that are generally in the range of 10^{-4} to $10^4 \Omega \cdot \text{cm}$. The resistivity of a semiconductor is strongly influenced by impurities, called *dopants*, which are purposely added to the material to change the electronic characteristics.

We will first consider the case of the pure, or intrinsic, semiconductor. As a result of the thermal energy present in the material, electrons can break loose from covalent bonds and become free electrons able to move through the solid and contribute to the electrical conductivity. The covalent bonds left behind have an electron vacancy called a *hole*. Electrons from neighboring covalent bonds can easily move into an adjacent bond with an electron vacancy, or hole, and thus the hole can move from one covalent bond to an adjacent bond. As this process continues, we can say that the hole is moving through the material. These holes act as if they have a positive charge equal in magnitude to the electron charge, and they can also contribute to the electrical conductivity. Thus, in a semiconductor there are two types of mobile electrical charge carriers that can contribute to the electrical conductivity: the free electrons and the holes. Since the electrons and holes are generated in equal numbers and recombine in equal numbers, the free electron and hole populations are equal.

FIGURE 117.1 PN junction.

FIGURE 117.2 Diode.

In the extrinsic or doped semiconductor, impurities are purposely added to modify the electronic characteristics. In the case of silicon, every silicon atom shares its four valence electrons with each of its four nearest neighbors in covalent bonds. If an impurity or dopant atom with a valency of five, such as phosphorus, is substituted for silicon, four of the five valence electrons of the dopant atom will be held in covalent bonds. The extra, or fifth, electron will not be in a covalent bond and is loosely held. At room temperature, almost all of these extra electrons will have broken loose from their parent atoms and become free electrons. These pentavalent dopants thus donate free electrons to the semiconductor and are called *donors*. These donated electrons upset the balance between the electron and hole populations, so there are now more electrons than holes. This is now called an *N-type semiconductor*, in which the electrons are the majority carriers and holes are the minority carriers. In an N-type semiconductor the free electron concentration is generally many orders of magnitude larger than the hole concentration.

If an impurity or dopant atom with a valency of three, such as boron, is substituted for silicon, three of the four valence electrons of the dopant atom will be held in covalent bonds. One of the covalent bonds will be missing an electron. An electron from a neighboring silicon-to-silicon covalent bond, however, can easily jump into this electron vacancy, thereby creating a vacancy, or hole, in the silicon-to-silicon covalent bond. These trivalent dopants thus accept free electrons, thereby generating holes, and are called *acceptors*. These additional holes upset the balance between the electron and hole populations, so there are now more holes than electrons. This is now called a *P-type semiconductor*, in which the holes are the majority carriers and the electrons are the minority carriers. In a P-type semiconductor the hole concentration is generally many orders of magnitude larger than the electron concentration.

Figure 117.1 shows a single crystal chip of silicon that is doped with acceptors to make it a P-type on one side and doped with donors to make it N-type on the other side. The transition between the two sides is called the *PN junction*. As a result of the concentration difference of the free electrons and holes there will be an initial flow of these charge carriers across the junction, which will result in the N-type side attaining a net positive charge with respect to the P-type side. This results in the formation of an electric potential “hill” or barrier at the junction. Under equilibrium conditions the height of this potential hill, called the *contact potential*, is such that the flow of the majority carrier holes from the P-type side up the hill to the N-type side is reduced to the extent that it becomes equal to the flow of the minority carrier holes from the N-type side down the hill to the P-type side. Similarly, the flow of the majority carrier free electrons from the N-type side is reduced to the extent that it becomes equal to the flow of the minority carrier electrons from the P-type side. Thus, the net current flow across the junction under equilibrium conditions is zero.

In Figure 117.2 the silicon chip is connected as a diode, or two-terminal electrode device. The situation in which a bias voltage is applied is shown. In Figure 117.2(a) the bias voltage is a forward bias, which produces a reduction in the height of the potential hill at the junction. This allows for a large increase in the flow of electrons and holes across the junction. As the forward bias voltage increases, the forward current will increase at approximately an exponential rate and can become very large.

In Figure 117.2(b) the bias voltage is a reverse bias, which produces an increase in the height of the potential hill at the junction. This essentially chokes off the flow of (1) electrons from the N-type side to the P-type side, and (2) holes from the P-type side to the N-type side. The only thing left is the very small trickle of electrons from the P-type side and holes from the N-type side. Thus, the reverse current of the diode will be very small.

FIGURE 117.3 Diode symbol.

FIGURE 117.4 Current versus voltage curve.

In Figure 117.3 the circuit schematic symbol for the diode is shown, and in Figure 117.4 a graph of the current versus voltage curve for the diode is presented. The P-type side of the diode is called the *anode*, and the N-type side is the cathode of the diode. The forward current of diodes can be very large — in the case of large power diodes, up into the range of 10 to 100 A. The reverse current is generally very small, often down in the low nanoampere or even picoampere range.

The diode is basically a one-way voltage-controlled current switch. It allows current to flow in the forward direction when a forward bias voltage is applied, but when a reverse bias is applied the current flow becomes extremely small. Diodes are used extensively in electronic circuits. Applications include rectifiers to convert AC to DC, wave shaping circuits, peak detectors, DC level shifting circuits, and signal transmission gates. Diodes are also used for the demodulation of amplitude-modulated (AM) signals.

117.2 Bipolar Junction Transistors

A basic diagram of the bipolar junction transistor, or BJT, is shown in Figure 117.5. Whereas the diode has one PN junction, the BJT has two PN junctions. The three regions of the BJT are the emitter, base, and collector. The middle, or base, region is very thin, generally less than 1 micrometer wide. This middle electrode, or base, can be considered as the control electrode that controls the current flow through the device between emitter and collector. A small voltage applied to the base (i.e., between base and emitter) can produce a large change in the current flow through the BJT.

BJTs are often used for the amplification of electrical signals. In these applications the emitter-base PN junction is turned “on” (forward biased) and the collector-base PN junction is “off” (reverse biased). For the NPN BJT shown in Figure 117.5, the emitter will emit electrons into the base region. Since the P-type base region is so very thin, most of these electrons will survive the trip across the base and reach the collector-base junction. When the electrons reach the collector-base junction they will “roll downhill” into the collector and thus be collected by the collector to become the collector current, I_C . The emitter and collector currents will be approximately equal, so $I_C \cong I_E$. There will be a small base current, I_B , resulting from the emission of holes from the base across the emitter-base junction into the emitter. There will also be a small component of the base current due to the recombination of electrons and holes in the base. The ratio of collector current to base current, given by the parameter β or h_{FE} , is $\beta = I_C / I_B$, which will be very large, generally up in the range of 50 to 300 for most BJTs.

In Figure 117.6(a) the circuit schematic symbol for the NPN transistor is shown, and in Figure 117.6(b) the corresponding symbol for the PNP transistor is given. The basic operation of the PNP transistor is similar to that of the NPN, except for a reversal of the polarity of the algebraic signs of all DC currents and voltages.

FIGURE 117.5 Bipolar junction transistor.

FIGURE 117.6 BJT schematic symbols.

FIGURE 117.7 BJT amplifier.

FIGURE 117.8 The BJT as a two-port device.

In Figure 117.7 the operation of a BJT as an amplifier is shown. When the BJT is operated as an amplifier the emitter-base PN junction is turned “on” (forward biased) and the collector-base PN junction is “off” (reverse biased). An AC input voltage applied between base and emitter, $v_{in} = v_{be}$, can produce an AC component, i_c , of the collector current. Since i_c flows through a load resistor, R_L , an AC voltage, $v_o = v_{ce} = -i_c \cdot R_L$, will be produced at the collector. The AC small-signal voltage gain is $A_V = v_o / v_{in} = v_{ce} / v_{be}$.

The collector current, I_C , of a BJT when operated as an amplifier is related to the base-to-emitter voltage, V_{BE} , by the exponential relationship $I_C = I_{CO} \cdot \exp(V_{BE} / V_T)$, where I_{CO} is a constant and $V_T =$ thermal voltage $= 25$ mV. The rate of change of I_C with respect to V_{BE} is given by the transfer conductance, $g_m = dI_C / dV_{BE} = I_C / V_T$. If the net load driven by the collector of the transistor is R_L , the AC small-signal voltage gain is $A_V = v_{ce} / v_{be} = -g_m \cdot R_L$. The negative sign indicates that the output voltage will be an amplified but inverted replica of the input signal. If, for example, the transistor is biased at a DC collector current level of $I_C = 1$ mA and drives a net load of $R_L = 10$ k Ω , then $g_m = I_C / V_T = 1$ mA / 25 mV $= 40$ mS, and $A_V = v_{ce} / v_{be} = -g_m \cdot R_L = -40$ mS $\cdot 10$ k $\Omega = -400$. Thus, we see that the voltage gain of a single BJT amplifier stage can be very large, often up in the range of 100 or more.

The BJT is a three-electrode or *triode* electron device. When connected in a circuit it is usually operated as a two-port, or two-terminal pair device, as shown in Figure 117.8. Therefore, one of the three electrodes of the BJT must be common to both the input and output ports. Thus, there are three basic BJT configurations: common-emitter (CE), common-base (CB), and common-collector (CC). The most often-used configuration, especially for amplifiers, is the common-emitter (CE), although the other two configurations are used in some applications.

The BJT is often used as a switching device, especially in digital circuits, and in high-power applications. When used as a switching device, the transistor is switched between the *cutoff region*, in which both junctions are off, and the *saturation region*, in which both junctions are on. In the cutoff region the collector current is reduced to a very small value, down in the low nanoampere range, so the transistor looks essentially like an open circuit. In the saturation region the voltage drop between collector and emitter becomes very small, usually less than 0.1 volts, and the transistor looks like a very small resistance.

117.3 Junction Field-Effect Transistors

A *junction field-effect transistor* (JFET) is a type of transistor in which the current flow through the device between the drain and source electrodes is controlled by the voltage applied to the gate electrode. A simple physical model of the JFET is shown in Figure 117.9. In this JFET an N-type conducting channel exists between drain and source. The gate is a heavily doped P-type region (designated as P⁺) that surrounds the N-type channel. The gate-to-channel PN junction is normally kept reverse biased. As the reverse bias voltage between gate and channel increases, the depletion region width increases, as shown in Figure 117.10. The depletion region extends mostly into the N-type channel because of the heavy doping on the P⁺ side. The depletion region is depleted of mobile charge carriers and thus cannot contribute to the conduction of current between drain and source. Thus, as the gate voltage increases, the cross-sectional area of the N-type channel available for current flow decreases. This reduces the current flow between drain and source. As the gate voltage increases, the channel gets further constricted and the current flow gets smaller. Finally when the depletion regions meet in the middle of the channel, as shown in Figure 117.11, the channel is pinched off in its entirety, all of the way between the source

FIGURE 117.9 JFET model.

FIGURE 117.10 JFET with increased gate voltage.

and the drain. At this point the current flow between drain and source is reduced to essentially zero. This voltage is called the *pinch-off voltage*, V_p . The pinch-off voltage is also represented as $V_{GS}(\text{off})$, as being the gate-to-source voltage that turns the drain-to-source current, I_{DS} , off.

We have been considering here an N-channel JFET. The complementary device is the P-channel JFET, which has a heavily doped N-type (N^+) gate region surrounding a P-type channel. The operation of a P-channel JFET is the same as for an N-channel device, except the algebraic signs of all DC voltages and currents are reversed.

FIGURE 117.11 JFET with pinched-off channel.

We have been considering the case for V_{DS} small compared to the pinch-off voltage, such that the channel is essentially uniform from drain to source, as shown in Figure 117.12(a). Now let us see what happens as V_{DS} increases. As an example, let us consider an N-channel JFET with a pinch-off voltage of $V_p = -4$ V. We will see what happens for the case of $V_{GS} = 0$ as V_{DS} increases. In Figure 117.12(a) the situation is shown for the case of $V_{DS} = 0$ in which the JFET is fully on and there is a uniform channel from source to drain. This is a point A on the I_{DS} versus V_{DS} curve of Figure 117.13. The drain-to-source conductance is at its maximum value of g_{ds} (on), and the drain-to-source resistance is correspondingly at its minimum value of r_{ds} (on). Now let us consider the case of $V_{DS} = +1$ V, as shown in Figure 117.12(b). The gate-to-channel bias voltage at the source end is still $V_{GS} = 0$. The gate-to-channel bias voltage at the drain end is $V_{GD} = V_{GS} - V_{DS} = -1$ V, so the depletion region will be wider at the drain end of the channel than at the source end. The channel will thus be narrower at the drain end than at the source end and this will result in a decrease in the channel conductance, g_{ds} , and correspondingly, an increase in the channel resistance, r_{ds} . So the slope of I_{DS} versus V_{DS} curve that corresponds to the channel conductance will be smaller at $V_{DS} = 1$ V than it was at $V_{DS} = 0$, as shown at point B on the I_{DS} versus V_{DS} curve of Figure 117.13.

In Figure 117.12(c) the situation for $V_{DS} = +2$ V is shown. The gate-to-channel bias voltage at the source end is still $V_{GS} = 0$, but the gate-to-channel bias voltage at the drain end is now $V_{GD} = V_{GS} - V_{DS} = -2$ V, so the depletion region will now be substantially wider at the drain end of the channel than at

FIGURE 117.12 N-type channel.

FIGURE 117.13 I_{DS} versus V_{DS} curve.

FIGURE 117.14 JFET drain characteristics.

the source end. This leads to a further constriction of the channel at the drain end and this will again result in a decrease in the channel conductance, g_{ds} , and correspondingly, as increase in the channel resistance, r_{ds} . So, the slope of the I_{DS} versus V_{DS} curve will be smaller at $V_{DS} = 2$ V than it was at $V_{DS} = 1$ V, as shown at point C on the I_{DS} versus V_{DS} curve of Figure 117.13.

In Figure 117.12(d) the situation for $V_{DS} = +3$ V is shown, and this corresponds to point D on the I_{DS} versus V_{DS} curve of Figure 117.13.

When $V_{DS} = +4$ V, the gate-to-channel bias voltage will be $V_{GD} = V_{GS} - V_{DS} = 0 - 4$ V = -4 V = V_p . As a result the channel is now pinched off at the drain end, but it is still wide open at the source end since $V_{GS} = 0$, as shown in Figure 117.12(e). It is very important to note that the channel is pinched off just for a very short distance at the drain end, so that the drain-to-source current, I_{DS} , can still continue to flow. This is not at all the same situation as for the case of $V_{GS} = V_p$ wherein the channel is pinched off in its entirety, all of the way from source to drain. When this happens, it is like having a big block of insulator the entire distance between source and drain, and I_{DS} is reduced to essentially zero. The situation for $V_{DS} = +4$ V = $-V_p$ is shown at point E on the I_{DS} versus V_{DS} curve of Figure 117.13.

For $V_{DS} > +4$ V, the current essentially saturates and does not increase much with further increases in V_{DS} . As V_{DS} increases above $+4$ V, the pinched-off region at the drain end of the channel gets wider, which increases r_{ds} . This increase in r_{ds} essentially counterbalances the increase in V_{DS} such that I_D does not increase much. This region of the I_{DS} versus V_{DS} curve, in which the channel is pinched off at the drain end, is called the *active region* and is also known as the *saturated region*. It is called the active region because when the JFET is to be used as an amplifier it should be biased and operated in this region. The saturated value of drain current up in the active region for the case of $V_{GS} = 0$ is called I_{DSS} . Since there is not really a true saturation of current in the active region, I_{DSS} is usually specified at some value of V_{DS} . For most JFETs, the values of I_{DSS} fall in the range of 1 to 30 mA. In the current specification, I_{DSS} , the third subscript "S" refers to I_{DS} under the condition of the gate *shorted* to the source.

The region below the active region where $V_{DS} < +4$ V = $-V_p$ has several names. It is called the *nonsaturated region*, the *triode region*, and the *ohmic region*. The term *triode region* apparently originates from the similarity of the shape of the curves to that of the vacuum tube triode. The term *ohmic region* is due to the variation of I_{DS} with V_{DS} as in Ohm's law, although this variation is nonlinear except for the region where V_{DS} is small compared to the pinch-off voltage, where I_{DS} will have an approximately linear variation with V_{DS} .

The upper limit of the active region is marked by the onset of the breakdown of the gate-to-channel PN junction. This will occur at the drain end at a voltage designated as BV_{DG} , or BV_{DS} , since $V_{GS} = 0$. Breakdown voltages are generally in the 30 to 150 V range for most JFETs.

So far we have looked at the I_{DS} versus V_{DS} curve only for the case of $V_{GS} = 0$. In Figure 117.14 a family of curves I_{DS} versus V_{DS} for various constant values of V_{GS} is presented. These are called the *drain characteristics*, also known as the output characteristics, since the output side of the JFET is usually the drain side. In the active region where I_{DS} is relatively independent of V_{DS} , there is a simple approximate equation relating I_{DS} to V_{GS} . This is the "square law" transfer equation as given by $I_{DS} = I_{DSS} [1 - (V_{GS}/V_p)]^2$. In Figure 117.15 a graph of the I_{DS} versus V_{GS} *transfer characteristics* for the JFET is presented. When $V_{GS} = 0$, $I_{DS} = I_{DSS}$ as expected, and as $V_{GS} \rightarrow V_p$, $I_{DS} \rightarrow 0$. The lower boundary of the active region is controlled by the condition that the channel be pinched off at the drain end. To meet this condition the basic requirement is that the gate-to-channel bias voltage at the drain end of the channel, V_{GD} , be greater
