common inheritance of an ancestral chromosomal fragment, or *haplotype*, among affected individuals. (A haplotype denotes the collective genotype of a number of closely linked DNA markers or loci on a chromosome.) This approach can be viewed as a linkage test in one enormous family. Because the family is so big, with numerous generations and thus numerous recombinations of chromosomal fragments, the chromosomal region implicated by a positive finding—the region left unrecombined, or intact—is much smaller than the region implicated by linkage.

The chromosomal distance across which linkage disequilibrium can be detected in a European population ranges from a few thousand to 100,000 bases, with an average of about 22,000 bases (Gabriel et al., 2002). The distance is smaller for African populations. These regions, called *haplotype blocks*, are roughly 1,000-fold smaller than the typical size of a linkage region (Roberts et al., 1999). These short distances have been an obstacle to the use of linkage disequilibrium mapping because they necessitate large numbers of very tightly spaced DNA markers to detect association with a disease gene. Only since the turn of the century have large numbers of SNPs become available, allowing for the conduct of very dense marker studies. A number of projects are currently using SNPs to narrow the localization of a linkage region, although no study employing this method in a general bipolar population, as opposed to a population isolate, has yet been published. It is thought that 300,000 or more SNPs would be required to conduct a genomewide association study in a genetically mixed population (Gabriel et al., 2002). Studies that would test 500,000 SNPs in a large bipolar sample are currently being planned.

Population Isolates

Linkage disequilibrium studies have been published for a population isolate. Such populations are thought to be more genetically homogeneous than ethnically mixed populations; moreover, linkage disequilibrium may exist over a larger chromosomal region in these isolates than in a mixed population, potentially facilitating detection. Population isolates that have been studied in relation to bipolar disorder include the Amish, Ashkenazi Jews, the population of the Central Valley of Costa Rica, inhabitants of eastern Finland, and families from the Saguenay-Lac-St-Jean region in Quebec. A genome scan on the Costa Rican sample yielded several strong linkage findings, including one on 18p11.3. SNP genotyping across the region yielded a strong association with markers in a 19,000-base region that contains just two genes, with the most strongly implicated gene being *CLUL1*, clusterin-like 1 (retinal), for which the function is not known (McInnes et al., 2001). Another study from the same group included a genomewide linkage disequilibrium scan using 1,186 microsatellite markers on 109

unrelated Costa Rican BP-I subjects. This study found evidence for increased sharing of an ancestral chromosomal fragment among ill subjects on 8p23.1, suggesting the possibility of a susceptibility gene in this region (Ophoff et al., 2002).

There are caveats to the population isolate strategy. The necessary homogeneity may exist only if the isolate has a particular history, that is, a small number of unrelated founders (10–100) and slow population growth during the early generations following the initial bottleneck. Some populations currently regarded as isolates may not meet these criteria (Wright et al., 1999). Further, the age and frequency of the sought-after disease mutation affect the ability to detect linkage disequilibrium with neighboring markers. In particular, if the disease mutation is significantly older than the marker mutation, little or no association may be detected even when the physical distance between the two is small (Chakravarti, 1999). If gene variants leading to susceptibility to bipolar disorder are common variants, they probably developed a very long time ago. Because of their age, they are likely to have been scrambled by the many recombinations that have occurred during the numerous meioses between then and now. In this setting, linkage disequilibrium between the marker and the disease allele may not exist over any greater distance in an isolate than in the general population.

CONSIDERATION OF ALTERNATIVE GENETIC MECHANISMS

Earlier we discussed alternative phenotypic definition as a potential means of achieving greater genetic homogeneity in a bipolar sample. Another promising route to gene discovery involves considering alternative genetic mechanisms that underlie disease. Whereas previously we focused on “rethinking the phenotype,” we now turn to “rethinking the genotype.” Clinical observations of the patterns of illness and inheritance in families can provide important clues to the underlying genetic mechanism.

Anticipation and Trinucleotide Repeats

The phenomenon of *anticipation*, in which successive generations of afflicted individuals suffer from an earlier and more severe form of the disease, implicates a unique pathogenetic mechanism. Anticipation has been observed in a number of neurologic and neuropsychiatric diseases, including myotonic dystrophy, fragile X syndrome, and Huntington’s disease—all caused by genes with trinucleotide repeat sequences that expand in successive generations. In 34 Johns Hopkins families, evidence for anticipation in bipolar disorder was observed (McInnis et al., 1993). Anticipation in bipolar illness was also seen in Swedish families, Japanese families,

and a Romanian sample, in which it was restricted to subjects inheriting the disorder from the paternal side (Nylander et al., 1994; Grigoriu-Serbanescu et al., 1997; Ohara et al., 1998a). In a Canadian bipolar sample, evidence for anticipation was also found, although the authors suggested that a censoring bias may have been partially responsible for this result (Merette et al., 2000). This bias is due to having apparently normal subjects in the younger generation who might eventually develop the disorder, though their potentially later age at onset is not evident at the time of the study. Other potential biases can also influence analyses of anticipation (Goossens et al., 2001). Anticipation studies of bipolar disorder have attempted to control for these biases, but the possibility of false positive findings cannot be ruled out.

In support of the clinical findings, a few reports have suggested that expanded trinucleotide repeat sequences may exist in bipolar disorder; however, the majority of studies have been negative in this regard (see Table 13–7 for trinucleotide repeat–containing genes that have been tested for association with bipolar disorder; see Goossens et al., 2001, for further references). Although the anticipation and trinucleotide repeat hypothesis has not yet yielded strong candidate bipolar genes, the possibility remains that types of repeats not yet carefully examined may play a role in the etiology of bipolar disorder.

Parent-of-Origin Effect

Among 34 Johns Hopkins pedigrees, an excess of maternal transmission of bipolar disorder was observed, a finding consistent with those of a number of prior studies (summarized by McMahon et al., 1995). Some subsequent findings (Lin and Bale, 1997), though not all (Kato et al., 1996b), have been consistent with this observation. One study found that the rate of the disorder among the offspring of affected fathers was significantly higher than that among those with affected mothers (Kornberg et al., 2000).

If there is a clinical parent-of-origin effect, there are a number of possible explanations. In some cases, bipolar disorder could be inherited through mitochondrial genes. In other cases, the illness could be accounted for by an imprinted gene, for which alleles are expressed differentially based on the gender of the transmitting parent. Other possibilities include X-linkage; the psychosocial consequences of being reared by an affected mother; and intrauterine maternal factors, such as differential susceptibility to infectious agents. It is also possible that ascertainment bias accounts for the clinical parent-of-origin findings. The first two possibilities are discussed below.

Mitochondrial Inheritance

The *mitochondria* are organelles within cells; they have their own unique genome, composed of 16,569 nucleotides

coding for 37 genes. The inheritance of this genome is strictly maternal. Thus mitochondrial inheritance would be a good explanation for maternal inheritance of disease. McMahon and colleagues (2000) examined the mitochondrial genome in a Johns Hopkins bipolar sample and found no evidence of an association between any SNPs examined and the illness. One group has, however, reported modest evidence of an association between two mitochondrial SNPs and bipolar disorder (Kato et al., 2000, 2001), while another group found evidence for a nonspecific weak effect of mitochondrial gene variants on the disorder (Kirk et al., 1999).

Genomic Imprinting

When heritable differences in gene expression between individuals exist and are not accounted for by variation in the DNA sequence, epigenetic factors are said to be involved. One important epigenetic mechanism is *genomic imprinting*—the parent-of-origin-specific silencing of one allele of a given gene with a corresponding parent-of-origin-specific expression of the other allele. Imprinting has been demonstrated for about 25 genes to date (Morison and Reeve, 1998), and imprinted genes have been implicated in such diseases as Angelman syndrome, Prader-Willi syndrome, and Beckwith-Weidemann syndrome. Although imprinted genes are thought to play an important role in growth, they can also be involved in maternal behavior (Li et al., 1999a) and in social behavior (Skuse et al., 1997). Mouse studies of the developing brain employing genetically engineered mice with predominantly maternal or predominantly paternal genomes have indicated that maternal genes play a disproportionate role in the development of the cortex, while paternal genes play a disproportionate role in hypothalamic development (Keverne et al., 1996).

Two bipolar genome scans have examined parent-of-origin-specific linkage. Reporting on the Bonn sample, Cichon and colleagues (2001) identified two regions—2p21–24 and 2q31–32—that showed suggestive evidence for linkage when only maternal transmission was examined, and two regions—14q32 and 16q21–23—that showed suggestive linkage when only paternal regions were examined (Cichon et al., 2001). Of interest, the 14q32 linkage region is immediately adjacent to a known imprinted gene, *DLK1*. Because imprinting is thought to occur in clusters, there may be other imprinted genes in the region. McInnis and colleagues (2003), examining the Johns Hopkins sample, found two regions—1q42 and 13q12—that showed linkage with maternally transmitted alleles and one region—18q21–22—that showed linkage with paternally transmitted alleles (McInnis et al., 2003). The 13q12 region contains *5-HT_{2A}*, reported to be imprinted in fibroblasts (Kato et al., 1996a) and in brain tissue from some subjects but not others (Bunzel

et al., 1998). One association study of *5-HT_{2A}* examined whether parent-of-origin-specific association could be detected in bipolar subjects; results were negative (Murphy et al., 2001).

Earlier studies of chromosome 18 in the Johns Hopkins sample found that linkage to chromosome 18q21–22 came predominantly from paternally inherited alleles. A subsequent study, focusing on a phenotypically defined subgroup of families (see the earlier section on alternative phenotypic definition), obtained a nonparametric LOD score of 4.67 for paternally transmitted alleles (which rose to 5.42 in a more recent analysis [Schulze et al., 2003]) and near zero for maternally transmitted alleles. This result suggested the possibility that an imprinted gene in the region could account for the linkage in the 18q22 region. Of note, one imprinted gene, *TCEL2*, has been reported on 18q12, although that is the only identified imprinted human gene to date on chromosome 18.

Two association studies have found parent-of-origin-specific evidence for association with bipolar disorder: one study of *DDC*, which codes for dopa-decarboxylase (Borglum et al., 2003), and one study of *DRD4* (Muglia et al., 2002). Both genes are biologically plausible candidates, and both lie adjacent to known imprinted genes. A study assessing imprinting of *DRD4*, however, found evidence for normal, nonimprinted expression of the gene.

A more complex scenario of brain region-specific, developmental stage-specific, or alternative transcript-specific imprinting cannot be ruled out at present. An example of brain region-specific imprinting is the *UBE3A* gene, which is thought to cause Angelman syndrome. In a mouse model, this gene was expressed in an imprinted fashion in Purkinje cells, hippocampal neurons, and mitral cells of the olfactory bulb, but not clearly imprinted in other brain regions (Albrecht et al., 1997). *Transcripts* are expressed genes, encoded as messenger RNA. A single gene may give rise to several different, or alternative, transcripts, as a result of cutting and pasting (*splicing*) of the exons that form the gene. One striking example of alternative transcript-specific imprinting is the *GNAS* gene. It is expressed normally with one transcript, only from the maternal copy with another transcript, and only from the paternal copy with still another transcript (Hayward et al., 1998).

TOWARD THE PROMISED LAND: GENE EXPRESSION AND PATHOGENESIS

In this section we review work that moves the argument for the involvement of a gene in manic-depressive illness beyond the realm of statistical association and into the realm of neurobiology. Establishing causal relationships between gene variants and disease depends first on being able to show that

the susceptibility variant alters the structure or function of the messenger RNA and/or protein product. Establishing causality also depends on demonstrating a relationship between a susceptibility variant and other intermediate features of disease pathology or disease phenotype, such as neuronal structure and function, brain structure and function, and intermediate neuropsychological variables. Figure 13–7 illustrates the many intervening levels that come between genotype and phenotype. The discussion that follows focuses on studies of gene expression in the bipolar subgroup of manic-depressive illness and on the few studies that have examined candidate gene variants in relation to intermediate phenotypes. These studies have been carried out in brain samples and in white blood cell samples from bipolar patients, as well as in experimental cell lines and in mouse models.

Expression in the Brain

Gene expression studies ideally employ brain tissue from patients. For obvious reasons, these must be postmortem tissues. Several collections of such brains exist, including

the collections of the Stanley Medical Research Institute and the Harvard Brain Tissue Resource Center. The Stanley collection has been widely distributed, and many investigators have studied changes in gene expression levels in the 50 bipolar brains available. A challenge in these studies lies in the selection of the brain area to study. Investigators would like to choose the area with known pathology in bipolar disorder, though this cannot yet be done with certainty (see Chapter 15). Studies have focused on the prefrontal and frontal cortex, the amygdala, and the hippocampus as the most likely candidate brain regions (see Table 13–8).

In studies focusing on the role of one or a few specific genes in bipolar disorder, decreased levels of the following messenger RNAs were found: prodynorphin in the amygdaloid complex, GAD65 and complexin I and II in the hippocampus, and Ca²⁺/calmodulin-dependent protein kinase II and neuropeptide Y in the prefrontal cortex (see Table 13–8).

Four published studies employed broad approaches that can be used to measure changes in many gene transcripts

Figure 13–7. Genetic to pathogenic pathway to manic-depressive illness. Many levels of pathogenesis intervene between genetic etiology and the syndrome of manic-depressive illness. Study of the relationship between a potential susceptibility gene variant and manic-depressive illness requires examination of the impact of the variant on a number of these disease components. An interaction of environmental factors with gene expression or function, or protein expression or function, is also possible. (Source: Adapted from McHugh and Slavney, 1998.)

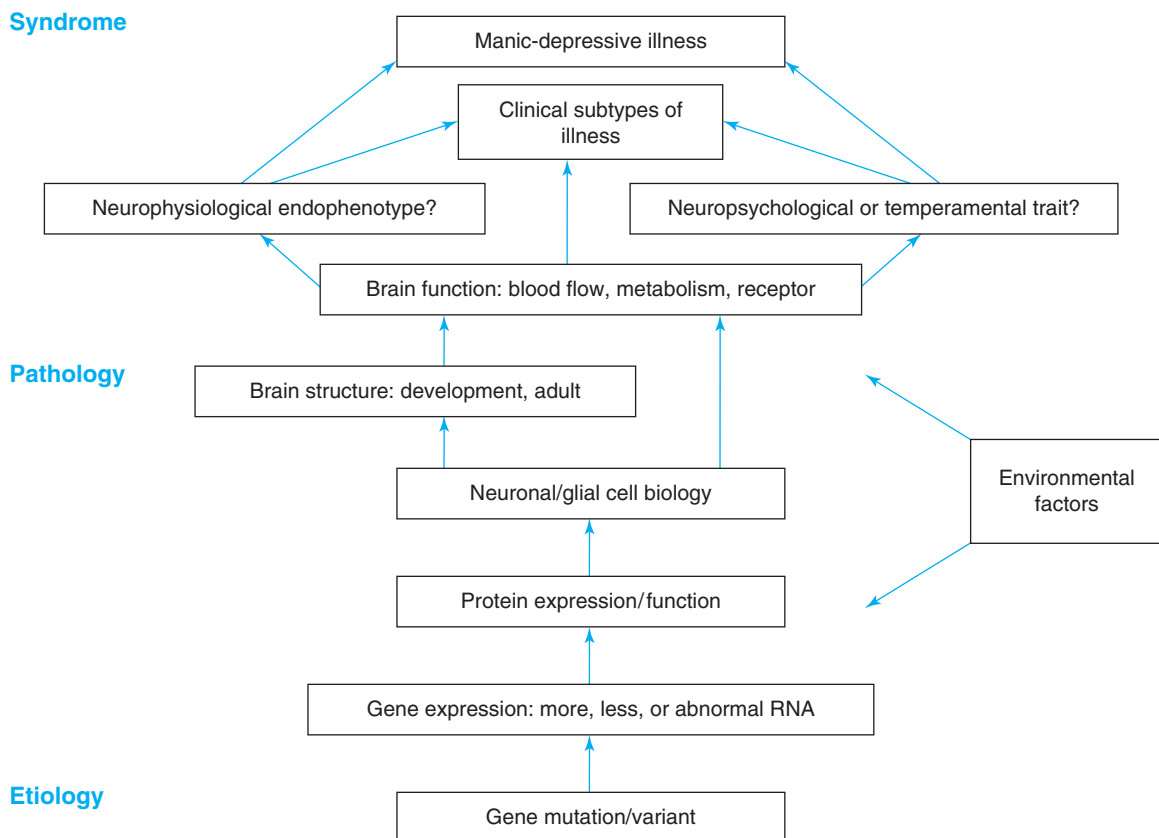

TABLE 13–8. Gene Expression Studies of Bipolar Brain Samples

Study	Sample Size ^a	Gene	Change	Brain Region
<i>Findings in Bipolar Samples Only</i>				
Young et al., 1996	20	G protein α (s)	No change	Frontal, temporal, occipital
Caberlotto et al., 1999	30 (Stanley)	Neuropeptide Y	Decreased	Prefrontal
Eastwood et al., 2000	30 (Stanley)	Complexin I and II	Decreased	Hippocampus
Sun et al., 2001	34 (Stanley)	Serotonin transporter and NF- κ B	Increased	Frontal
Bezchlibnyk et al., 2001	30 (Stanley)	TGF- β 1	Decreased	Frontal
		CASP8	Increased	
		TOB	Increased	
Heckers et al., 2002	30 (Harvard)	GAD65	Decreased	Hippocampus
		GAD67	No change	
Xing et al., 2002	30 (Stanley)	CaMKII	Decreased	Prefrontal
Hurd, 2002	29 (Stanley)	Prodynorphin	Decreased ^b	Amygdaloid complex
Woo et al., 2004	34 (Harvard)	GRIN2A	No change	Anterior cingulate
Konradi et al., 2004	19 (Harvard)	43 genes, including 18 mitochondrial, GAD67, and somatostatin	Decreased	Hippocampus
Iwamoto et al., 2004	26 (Stanley)	53 genes, including LIM1 and HSPF1	Increased and decreased	Prefrontal
Iwamoto et al., 2005	70 (Stanley ^{2c})	27 genes	Increased for 23 of 27	Prefrontal
<i>Findings in Bipolar Samples Also Found in Schizophrenia Samples in Same Study</i>				
Guidotti et al., 2000	30 (Stanley)	RELN and GAD67	Decreased ^d	Prefrontal and cerebellum
Vawter et al., 2002	19	Synapsin Ia, IIa, IIIa	Decreased	Hippocampus
Mimmack et al., 2002	30 (Stanley)	APOL2	Increased	Prefrontal
Koh et al., 2003	30 (Stanley)	Neuronal calcium sensor-1	Increased	Dorsolateral prefrontal
Tkachev et al., 2003	30 (Stanley)	8 oligodendrocyte- and myelin-related genes	Decreased	Prefrontal
Iwamoto et al., 2004	26 (Stanley)	9 genes, including serotonin receptor 2C	Decreased	Prefrontal

^bDecrease also found in major depression brain sample in the same study.

^cThis sample, though from the Stanley Medical Research Institute, differs from those in the other studies.

^dDecrease found in psychotic bipolar samples.

simultaneously without regard to prior hypotheses about the gene's biological role. One used a technique called *serial analysis of gene expression* (SAGE), while the other used a microarray approach. SAGE generates short sequence tags for many of the transcripts present in a tissue sample and identifies them by comparison with the public gene sequence database. Three studies employed *microarrays*, which use large numbers of short sequences from genes as bait to detect matching transcripts from tissue samples. The totality of the expressed genes, or *transcripts*, is sometimes referred to as the *transcriptome* (by analogy with the word *genome*). The SAGE and microarray methods have the potential to be transcriptome-wide, to assess all transcripts at once, though at present their coverage is more limited.

The SAGE study, conducted by Sun and colleagues (2001), covered 1,856 sequence tags, although some of these may have come from the same transcript, so that this figure represents some smaller number of transcripts. This study yielded evidence that two transcripts—for the serotonin transporter gene and for the NF- κ B transcription factor—were significantly overexpressed in the frontal cortex of 19 bipolar subjects as compared with 15 controls. Essentially the same sample was used in a second study, conducted by Bezchlibnyk and colleagues (2001), which employed the microarray approach and examined the same brain region, the frontal cortex. However, the results of the two studies do not coincide. Instead, the microarray study, which assessed 1,200 genes simultaneously, found decreased levels of transforming growth factor beta 1 (TGF- β 1) and increased levels of caspase-8 precursor (CASP8) and transducer of erbB2 (TOB).

Another microarray study assessed 12,558 genes, using hippocampal tissue from the Harvard Brain Tissue Resource (Konradi et al., 2004). In this study, the expression of 43 genes was found to be decreased in bipolar disorder; 18 of these genes coded for mitochondrial proteins. Expression of GAD67 and somatostatin were decreased as well. A third microarray study assessed about 12,000 genes using prefrontal cortex (Iwamoto et al., 2004). The investigators found altered expression of 53 genes in bipolar disorder, 7 of which overlapped with schizophrenia and 8 with major depressive disorder. The study focused on two genes, *HSPF1* and *LIM*, whose expression was also altered in lymphoblastoid cells from bipolar subjects. This same group conducted an expression study of 676 mitochondria-related genes (Iwamoto et al., 2005). They found a global decrease in expression of these genes in the prefrontal cortex of bipolar subjects, but they also found evidence that the decrease was correlated with both sample pH and medication use. When these factors were accounted for, there were 27 genes with altered expression, 23 of which showed up-regulation.

Other studies, like that of Iwamoto and colleagues (2005) noted above, have found changes in expression levels of genes in both bipolar and schizophrenic samples. One of these studies found a reduction in eight oligodendrocyte- and myelin-related genes in both bipolar and schizophrenic subjects (Tkachev et al., 2003). Two of these genes—*OLIG2* on 21q22.11 and *SOX10* on 22q13.1—are in bipolar disorder linkage regions; another, *ERBB3*, is particularly interesting functionally as it codes for the receptor of neuregulin 1, a gene strongly implicated in schizophrenia.

In subjects with both disorders, the expression levels of the genes coding for neuronal calcium sensor-1 (Koh et al., 2003) and apolipoprotein L2 (Mimmack et al., 2002) were found to be increased in the prefrontal cortex, and the expression levels for synapsin IIa and IIIa were decreased (the expression levels for synapsin Ia were decreased only in the bipolar brains) (Vawter et al., 2002). Expression levels of RELN, coding for the reelin protein, and GAD67, coding for a form of glutamate decarboxylase, were decreased in the brains of subjects with psychotic bipolar disorder and with schizophrenia when prefrontal cortex and cerebellum were assayed (Guidotti et al., 2000). The decrease in RELN expression appears to be mediated through an epigenetic change known as *hypermethylation* in the promoter region of the gene. The addition of a methyl group to the C nucleotide residing in this region may result in reduced binding of transcription factors (which facilitate gene expression), leading in turn to decreased expression of the gene. In a mouse model of reelin expression, investigators found that when mice were injected with methionine, an amino acid that provides methyl groups, the mice showed a decrease in reelin expression; further, they displayed poorer performance on a test of prepulse inhibition, which is thought to be a neurophysiological endophenotype for schizophrenia (Tremolizzo et al., 2002).

Studies of gene expression in the bipolar brain face a number of important difficulties. One is simply the limited access to tissues. Although samples are available, the number of samples remains small, limiting the power to detect modest changes. Second, the quality of the available tissue varies, as samples undergo varying postmortem delay prior to autopsy and varying pH due to differences in the agonal period prior to death—both of which affect RNA quality (Johnston et al., 1997). Third, samples studied typically come from patients who have been treated with psychiatric medications, which may themselves alter gene expression. Fourth, there may be microbrain region-specific expression alterations that are not readily detected or replicated in gross samples. Finally, although transcriptome-wide approaches hold great promise, the technology is still evolving, so that aspects of data analysis, reliability, and validity remain to be fully resolved.

Expression in White Blood Cells

Studies using lymphoblast cells or granulocytes from patients have the great advantage that these samples are much more readily obtainable than brain tissue. A recent study demonstrates the value of using lymphoblastoid cell lines to examine variation in gene expression levels. Cheung and colleagues (2003) examined expression levels in lymphoblastoid cells from normal individuals, including some sibling pairs and some MZ twin pairs. They found that for some genes, expression levels varied significantly among the subjects. For five genes that were intensively studied, the variance among individuals was 3–11 times greater in unrelated individuals than among MZ twins, and the variance among sibling pairs was 2–5 times greater than among these twins. These results suggest that heritable factors that vary among individuals contribute to differences in levels of gene expression.

Although studies have indicated that functional abnormalities exist in the lymphocytes of bipolar patients, there have been few efforts to examine gene expression. The major weakness of this approach to studying bipolar disorder is that it is not clear that expression in these white blood cells mirrors expression in neurons, as control of expression may be tissue- and cell type-specific.

On the other hand, some abnormalities that have been detected in lymphocytes appear to mirror changes detected in postmortem brain tissue from bipolar subjects. For example, low inositol levels have been found in the frontal cortex of patients, as well as in lymphocytes (Shimon et al., 1997; Belmaker et al., 2002). A crucial component of the inositol pathway is inositol monophosphatase (IMPase). A report examining IMPase activity in drug-free bipolar patients using quantitative reverse transcription-polymerase chain reaction (RT-PCR) on lymphocytes found an approximately two-thirds reduction in IMPase-relative messenger RNA levels compared with control subjects (Nemanov et al., 1999). Yoon and colleagues (2001) found decreased IMPA2 messenger RNA levels in lymphoblastoid cell lines from BP-I patients, though only in males with decreased basal levels of intracellular calcium. Inositol system genes have been considered leading candidates for involvement in bipolar etiology because of this system's central involvement in response to mood-stabilizing medications (Williams et al., 2002). One study examined messenger RNA levels of three G protein alpha subunits and of phosphatidylinositol-3 kinase (PI-3K) regulatory subunit p85 in the granulocytes of bipolar patients compared with controls. One of the G protein alpha subunits, alpha(s), was markedly increased in bipolar patients; this increase was observed in both lithium-treated and unmedicated patients.

Testing Gene- and Allele-Specific Function

Functional studies of the impact of an allele associated with bipolar disorder can be performed using cell culture. A copy of the gene containing the candidate allele can be inserted (transfected) into cells in culture. These cells can then be compared with control cells. Gene expression in these cells can be measured, as can relevant consequences of gene function, such as binding capacity for a receptor. For example, the serotonin transporter promoter polymorphism was studied in this way. Lymphoblast cell lines were transfected with genes encoding the long variant and genes encoding the short variant. The transcriptional activity of the long variant was found to be twice that of the short variant (Lesch et al., 1996). The observation that this variant is functionally significant has helped make the serotonin transporter promoter polymorphism the object of intense study.

Another example of the use of cell culture to study candidate gene function comes from a report on the gene *DISC-1*. To understand why *DISC-1* is a candidate gene for manic-depressive illness requires a brief digression to discuss a method called *cytogenetics*. Cytogenetics is the third method—linkage and linkage disequilibrium being the other two—that can provide evidence for particular genes as positional candidates. This approach involves detecting chromosomal aberrations in families with manic-depressive illness and determining whether the aberration travels with the illness across generations. A chromosomal aberration, referred to as a *balanced translocation*, between chromosomes 1 and 11 has been reported, in which a portion of each chromosome has broken off and joined onto the broken end of the other. This phenomenon can be tolerated, except to the extent that the breakpoints result in the disruption of genes. In a large family containing 87 members, 37 were found to carry the translocation, including 7 individuals with schizophrenia, 1 with bipolar disorder, and 10 with recurrent major depression. The breakpoint on chromosome 1 has been found to disrupt two genes—*DISC-1* and *DISC-2*. Researchers have shown that the *DISC-1* protein normally associates with another protein, NUDEL, which is associated with cortical development and is linked to *LIS-1*, the disease gene for a form of lissencephaly, a disorder of cortical development. The abnormal form of *DISC-1*, the form predicted to occur in individuals with the translocation, failed to bind NUDEL. Neuronal cells were transfected with either normal or abnormal *DISC-1* genes. While neuronal outgrowth was normal in the normal *DISC-1* cells, it was reduced in the abnormal *DISC-1* cells (Ozeki et al., 2003). These results support the potential involvement of *DISC-1* in the etiology of recurrent affective illness, and schizophrenia.

An even more powerful approach to the study of gene function is to create mouse models for the gene under study. A variety of approaches exist for genetically altering the mouse. The *knockout* approach allows for the creation of a mouse lacking one or both copies of the gene. Tissue-specific knockout methods allow even more narrowly defined gene effects to be examined. In the conditional knockout, the mouse carries the gene, but investigators can turn it off at will. Transgenic approaches allow for the introduction of extra copies of normal genes or copies of altered genes. The *knockin* approach allows for the simultaneous knockout of the normal gene and transgenic insertion of an altered version of the gene. With these mouse models, gene effects in the brain and on behavior can be studied. For example, a mouse model of Huntington's disease was created using a transgenic *huntingtin* gene, which was altered to carry the disease mutation (abnormal variant) and was under conditional control using a tetracycline-responsive system. The mouse exhibited Huntington's disease-like motor symptoms because of the action of the mutant gene. When the investigators administered tetracycline to the mice and thus turned off the mutant gene, the symptoms abated (Yamamoto et al., 2000). These methods have not yet been applied to the study of bipolar disorder, though they have been applied to depression.

The glucocorticoid receptor (GR) has been much studied in mouse models of depression and anxiety. The following lines of mice have been generated: those with disrupted *GR* alleles; those with nervous system-specific knockout of *GR*; transgenic mice with increased *GR* expression; transgenic mice that express an antisense RNA, which results in decreased *GR* expression by binding to and neutralizing the normal *GR* RNA; and knockin mice, in which the normal gene is knocked out while abnormal *GR* genes are introduced and then expressed (Gass et al., 2001). Behaviors thought to model depression—such as performance on the Porsolt forced swim test, the tail suspension test, or the learned helplessness paradigm—can be measured in these genetically altered mice as a way of gauging the impact of the gene, and these behaviors may have relevance for manic-depressive illness. Attempts at creating animal models of depression with these mice have yielded mixed results, however. Behaviorally, none of these mouse lines has consistently exhibited depression-like impairment. The transgenic line with decreased *GR* expression did, however, show an enhanced stress-associated adrenocorticotrophic hormone (ACTH) response, which was normalized by antidepressant medication treatment. This finding suggests that the endocrinological component of depression might be partially modeled in this mouse line (Montkowski et al., 1995).

Other genes studied in this way include *BDNF* and the serotonin transporter gene. A line of mice carrying a

knockout of one of two *BDNF* alleles was developed and studied for depressive-like behaviors. The knockout mice generally did not show significant differences from wild mice in their propensity to these behaviors; thus they may not constitute a model for depression (MacQueen et al., 2001). A serotonin transporter gene knockout mouse line has also been developed. When investigators studied this knockout using two genetically disparate mouse lines, they found that in one line, the knockout mice showed decreased immobility on the tail suspension test, whereas in the other, the knockout mice did not differ on this test. The former group showed a reaction consistent with an antidepressant-like effect, which would be expected because these mice had an increased extracellular level of serotonin, but the other group did not. It is possible that the behavioral difference was mediated by an interaction of the serotonin transporter gene with other, as yet unknown, genes that vary between the two mouse lines (Holmes et al., 2002).

Although no genetically engineered mouse models for mania exist, one team of investigators suggested using rats administered amphetamine for such a model (Niculescu et al., 2000). They argued that the euphoric and stimulated state that results in humans who ingest this drug is reminiscent of mania, and the hyperactive state that results in rats may be a reasonable proxy. The researchers gave rats amphetamines and then a day later sacrificed them and extracted RNA from their amygdala and prefrontal cortex. The expression levels of 8,000 genes were assessed simultaneously in these samples by means of a microarray. The investigators were particularly interested in the altered expression of genes having human homologues that mapped to regions of prior linkage interest in bipolar disorder and schizophrenia. They found altered expression of eight genes that met this criterion, one of which—*GRK3* (G-protein receptor kinase 3)—was expressed 14-fold more in the prefrontal cortex of the amphetamine-treated rats than in that of the control samples. The human homologue maps to chromosome 22q11, where the same investigators had suggestive evidence for linkage with bipolar disorder.

Reports are beginning to emerge from studies examining aspects of allele-specific functions of genes in the human brain. For example, the serotonin transporter promoter region polymorphism was assessed in relation to amygdala activation in a functional magnetic resonance imaging paradigm. Subjects carrying a short variant of the polymorphism had greater amygdala activation in response to fearful stimuli compared with those having only the long variant. This result was consistent with a prior observation of greater anxiety associated with carrying the short allele (Hariri et al., 2002).

FROM GENE TO BEDSIDE: PHARMACOGENETICS AND GENETIC COUNSELING

Pharmacogenetics

Pharmacogenetics is a field that first developed in the 1950s with clinical observations of inherited differences in drug effects. In the early 1960s, a few studies of familial correlation in response to antidepressants were published. One such study found that of 41 pairs of relatives treated with the antidepressant imipramine, 38 had a concordant response: both responded in 34 pairs, neither responded in 4 pairs, and one responded in 3 pairs (Angst, 1961, 1964, cited in Pare and Mack, 1971). A second study, by Pare and colleagues (1962), found that in 8 relative pairs, there was concordance for 6 of 6 pairs of tricyclic antidepressant trials and for 6 of 6 pairs of MAOI antidepressant trials. Pare and Mack (1971) later reported concordance in 10 of 12 new pairs of related patients treated with antidepressants from the same class, making the total 22 of 24 (92 percent) for the Pare et al. and Pare and Mack studies. By contrast, analysis of relatives' responses to antidepressants of different classes from the two studies revealed concordance in just 7 of 18 pairs (39 percent) (Pare and Mack, 1971).

The first study to report on familial correlation in lithium response involved just six children of lithium-responsive relatives. The two children in the study who had bipolar disorder both had clear responses to lithium (McKnew et al., 1981). In the only sizable study of familiarity of lithium response, 24 bipolar relatives of lithium responders were assessed, along with 40 lithium-treated patients from an outpatient clinic. The prevalence of unequivocal response among the relatives was 67 percent, compared with a response rate of 35 percent in the comparison clinic group (Grof et al., 2002).

More recent studies have analyzed the relationship of allelic variation in biological candidate genes to drug response. At least nine studies have examined lithium response in bipolar disorder in this way. Negative findings have been reported for the dopamine type 2, 3, and 4 receptors; for the serotonin type 1A, 2A, and 2C receptors; and for the GABAA- α 1, INPP1, and PLC- γ 1 genes (Serretti et al., 2002c). A study of the tryptophan hydroxylase gene found a worse lithium response for those with the A/A variant of the gene, though this difference was only marginally significant (Serretti et al., 1999b). One published study of the serotonin transporter gene found a significantly worse response in subjects carrying two copies of the short allele in the promoter region polymorphism (Serretti et al., 2001). Another study found that people carrying a particular version of a variant within their mitochondrial DNA had a better response to lithium than those without this version (Washizuka et al., 2003).

At least 14 studies have examined antidepressant response in relation to gene variants. The serotonin transporter gene promoter region variant has been studied most extensively because the selective serotonin reuptake inhibitor (SSRI) antidepressants are known to work through the protein product of this gene (and because the variant is functionally significant). Eight of eleven published studies have suggested a better response to SSRIs in patients with long alleles and a slower or worse response in subjects with short alleles. Of interest, one study included a group treated with nortriptyline as well as one treated with paroxetine. Those with the long allele in that study did not respond as quickly to nortriptyline as they did to paroxetine (Pollock et al., 2000), a result suggesting the possibility of an SSRI-specific effect. The findings of three studies, however, were not consistent with those of the other eight, showing a better response to SSRIs for carriers of the short allele or no association (see Table 13–9). It may be significant that two of the three negative studies involved Asian populations, while seven of the eight positive studies involved populations of European ancestry. The short and long alleles have been shown to be composed of subtypes, and these subtypes have been found to vary between Japanese and Caucasian populations (Nakamura et al., 2000). Given that one study in a Chinese sample was positive for the long variant, however, this explanation may be incomplete. Further uncertainty stems from the observation by Mundo and colleagues (2001a) that bipolar patients who had experienced antidepressant-induced mania were more likely to carry the short allele than those who did not have this response to antidepressants. The authors hypothesized that the short allele may be associated with an exaggerated response to antidepressants, which is difficult to reconcile with the findings noted above.

A number of other gene variants have been studied in relation to antidepressant response. Variants of the tryptophan hydroxylase gene were found to be associated with slower or poorer response to SSRIs in two studies (Serretti et al., 2001; Peters et al., 2004), while variants of the serotonin 2A receptor and of the G-protein beta-3 gene were associated with response to mixed antidepressants in one study each. A variant of the norepinephrine transporter gene was associated with response to milnacipran, a serotonin and norepinephrine reuptake inhibitor, in a small sample (Yoshida et al., 2004). No association with antidepressant response was found in studies of the dopamine 2 and 4 receptors or of the MAOA gene.

Genetic Counseling

Studies of the familial aggregation of manic-depressive illness (especially the bipolar form) have provided valuable data that can be used by clinicians to help educate concerned

TABLE 13–9. Studies of the Association of the Serotonin Transporter Gene Promoter Region Variant with Response to Selective Serotonin Reuptake Inhibitor (SSRI) Antidepressants

Study	Sample Size	Medication	Result
Positive			
Smeraldi et al., 1998	99	Fluvoxamine	L allele associated with better response, $p=0.017$
Zanardi et al., 2000	64	Paroxetine	L allele associated with more favorable and faster response, $p<.0001$
Pollock et al., 2000	95	Paroxetine	L/L genotype associated with more rapid response, $p=.028$
Zanardi, 2001	155	Fluvoxamine	L allele associated with better response, $p=.002$
Yu et al., 2002	121	Fluoxetine	L/L allele carriers had better response, $p=.013$
Rausch et al., 2002	51	Fluoxetine	L allele associated with better response, $p<.03$
Serretti et al., 2004	220	Fluvoxamine or paroxetine	L allele associated with better response, $p=.034$
Murphy et al., 2004	255	Paroxetine	L/L genotype associated with better response, $p=.04$
Negative			
Kim et al., 2000	120	Fluoxetine/paroxetine	S/S genotype associated with better response, $p=.007$
Yoshida et al., 2002	66	Fluvoxamine	S allele associated with better response, $p=.01$
Peters et al., 2004	96	Fluoxetine	No association reported

Source: Based on Serretti et al., 2002a.

patients who wonder what vulnerabilities they may be passing on to their children. Particularly when they are considering conceiving a child, patients often ask clinicians for information and sometimes advice concerning their plans. On the one hand, some patients may be unaware of the increased likelihood that their children will develop manic-depressive illness (see the above section on family studies). On the other hand, some people have exaggerated fears about the risk of illness. One of the authors of this text counseled a healthy woman who was considering having her first child. She was concerned because her brother-in-law had bipolar disorder, and she feared that her child might develop it as well. When she was informed that the risk for developing bipolar disorder in a second-degree relative was just 2–3 percent, she felt more at ease.

Although risk data from genetic epidemiology are of some value in providing a sense of the magnitude of risk for developing bipolar or recurrent unipolar disorder, it is also important to bear in mind that enormous variation in the rates of illness among family members will be evident in any collection of pedigrees. This observation illustrates an important weakness of counseling based on averages. Genetic counseling for such illnesses as cystic fibrosis, Huntington's disease, and Tay-Sachs disease is based on a genetic assay that can yield a fairly precise prediction of risk. In contrast, because the genes for bipolar disorder remain

largely unidentified and unstudied in terms of risk, counselors and clinicians do not yet have available the kind of data that would allow for more exact predictions.

Additional complexities affect the potential benefits of genetic counseling: manic-depressive illness is for the most part not a fatal condition; there are several available treatments, and there is good reason to believe that many patients can lead full and meaningful lives with treatment; and the risk data that exist do not distinguish between those in whom the illness would be severe and those who would respond well to standard treatments. What is quite predictable in a family at high risk seeking counseling is that the delay in recognition and diagnosis of manic-depressive illness in all affected children will likely be brief compared with the usual decade-long delay encountered by those with the bipolar form of the illness. There are many reasons to believe that much morbidity can be prevented by such early diagnosis.

Our practice has been to ask common clinical psychiatric questions as well as standard family-history questions of couples seeking counseling. For example: "Why do you want a child now as opposed to at some other time? What are your plans for child care?" And for a mother with bipolar disorder: "What are the risks and plans if a postpartum (puerperal) depression or mania ensues?" These standard clinical questions usually lead to the most fruitful discussions of the prospective parents' expectations. A sensible determination

of the wisdom of proceeding with childbearing can often be made in the current era in which precise DNA tests are lacking.

Couples who come for counseling reveal scenarios both common and worrisome. Some have difficult marriages and want a child to bring them closer together. Other couples present a situation in which the prospective mother had bipolar disorder. In one instance she was also the prime breadwinner in the family, and had a brittle illness in which pregnancy and changes of medication had led to severe relapses. The couple had not formulated a plan for what they would do if the mother became ill before, during, or after childbirth. On the other hand, very (financially and emotionally) secure couples express worries about modest risks of illness. In some cases, the parent's illness is under excellent control with simple monotherapies. These couples often have not fully considered the pragmatic aspects of their prospective child's potential functional level. When asking such couples about their concerns, one might ask: "Well, what if he or she turns out exactly like you (the ill parent)?" When the answer is "OK, I think that would be wonderful," the question of risk levels can become moot again.

Three studies have attempted to assess how genetic counseling might proceed in the future. These studies examined the attitudes of patients and their families toward genetic testing for bipolar genes, should such tests become available. One study found that the overwhelming majority of patients and spouses said they would take advantage of genetic tests for bipolar disorder if such tests were to become available, primarily to ensure that they would obtain treatment to prevent episodes of illness. A majority of respondents said they would "definitely not" abort a fetus that carried a bipolar gene, and a majority agreed that the knowledge that one of them carried such a gene would not have deterred them from marriage or childbearing (Trippitelli et al., 1998). The results of another study were similar: the vast majority of respondents supported genetic testing for adults and children, but 70 percent did not support prenatal testing as a means of deciding whether abortion would be indicated (Jones et al., 2002).

Smith and colleagues (1996), however, painted a more complex picture. In their study of members of a bipolar support group, medical students, and psychiatry residents, a clear majority of respondents said they would have their children tested for a bipolar gene if prophylactic treatment were available, though interest was more mixed in the absence of such treatment. The proportion of subjects who said they would choose termination of pregnancy depended on both the likelihood and the severity of illness indicated by a positive test. With a 25 percent likelihood of illness or a

mild course of illness, fewer than 10 percent preferred termination, whereas with a 100 percent chance of illness or a severe course, the proportion who said they would terminate was much higher—40–55 percent and 70–85 percent, respectively.

LOOKING TO THE FUTURE

Research Directions

From Linkage to Association

Linkage studies, the workhorse of research in bipolar genetics since the late 1980s, will move from center stage as association studies assume a greater role. The chromosomal regions implicated by bipolar linkage studies will be studied using large case–control and trio (case–parents) samples. This shift is occurring because linkage studies can identify the general chromosomal localization of a gene, but only association can truly pinpoint the location of the disease gene and, even more specifically, the location of the particular variant within the gene that is responsible for disease susceptibility. By analogy, think of searching for a needle in 23 enormous haystacks. Linkage is analogous to figuring out which haystack and which general area of that haystack holds the needle. Once that has been accomplished, a more fine-grained approach is needed to sort through the pieces of straw. Association is that fine-grained method.

Association Methods and Strategies

The feasibility of performing association studies is advancing rapidly as SNP genotyping methodologies become faster, more accurate, and less expensive. Several good methodologies exist, though no single one has yet emerged as the definitive best option. The number of SNPs available on Web-based databases is in the millions already and still growing. Further, biotechnology companies have genotyping assays prepared for SNPs within tens of thousands of genes, making these studies even more readily available to researchers.

The recent discovery that haplotype blocks exist in the genome across broad populations has led to the proposal that association could be performed more cost-effectively using these blocks than was previously thought possible. Most individuals might share one of just four or five variants of a given block. Thus characterizing the variation across most individuals for the block to determine which haplotype they have might require genotyping 15–20 SNPs rather than all 200 or so that would be predicted to exist in the block. This proposal rests on the assumption of the common disease–common variant hypothesis, under which the common haplotype blocks would likely harbor the common alleles that predispose some people to

manic-depressive illness. An alternative position holds that testing gene-related SNPs is much more efficient. This approach would require genotyping only one-tenth as many SNPs, and those tested would stand a far greater chance of being the functionally relevant variants. This approach would also allow for the possibility of detecting lower-frequency disease alleles (Botstein and Risch, 2003).

Power

Very large samples are now being gathered for bipolar studies. The NIMH Bipolar Disorder Collaborative study has already ascertained and assessed a linkage sample of 644 families with 921 affected sibling pairs. The collaborative is currently in the process of acquiring a sample of 5,000 cases for association studies, including, potentially, studies that would assay 500,000 SNPs simultaneously across the genome (whole-genome association). Very large samples have the power to detect the modest gene effects likely to play a role in susceptibility to bipolar disorder. Large samples also provide sufficient power to employ new analytical techniques that can test for interactions between genes.

Genetic Homogeneity

Use of phenotypic subtypes and endophenotypes may allow linkage and association to be performed on more genetically homogeneous subgroups within bipolar disorder. This capability would prevent the dilution of individual gene effects that occurs when all bipolar subjects are considered jointly if multiple genes are contributing to the broad phenotype. Potential examples of relevant subgroups are BP-II, BP-I with psychotic features, bipolar disorder with comorbid panic disorder, BP-I with an early age at onset, and lithium-responsive bipolar disorder. More work is needed to define genetically meaningful clinical subtypes and to determine familial endophenotypic measures. Conversely, genetic findings may help clarify the validity of potential subtypes. For example, we may come to better understand how early-onset recurrent major depression differs from less recurrent severe forms of depression; such understanding could allow us to differentiate the genetics of recurrence or cyclicity from that of polarity. Population isolates may also be of use in limiting genetic heterogeneity.

Gene Expression and Pathogenesis

Findings of statistical association between a gene variant and manic-depressive illness will need to be complemented by functional studies of the relevant gene and its potentially pathogenic alleles. Given its greater homogeneity relative to the very broad category of recurrent unipolar as defined by DSM-IV, the bipolar subgroup provides the most fruitful phenotype for such studies. For example, postmortem brain samples from bipolar subjects will be

a valuable resource for testing gene expression levels. Brain tissue is, of course, not available on subjects who are studied for linkage and association, but lymphoblastoid cell lines are. Although these cells express only about one-half of all genes, and potential tissue-specific regulation of gene expression may limit their usefulness, the existence of such cell lines in the very bipolar subjects who show association could provide investigators with a useful means of studying the expression of some candidate genes.

In the best-case scenario, a smoking-gun genetic lesion will be found that is clearly and obviously an etiologic factor in bipolar disorder. Such a lesion might be a nonsense mutation leading to a truncated and entirely dysfunctional protein product. This hypothesis would be most persuasive if the mutation occurred in a large percentage of cases and in no subjects who were not cases. If, in addition, the gene coded for a protein that had a known role in neurotransmission or neuronal migration, the case for an etiologic role would be exceedingly strong. An example of this situation is the Duchenne's muscular dystrophy gene, where the majority of mutations result in truncation of the dystrophin protein. Similarly, researchers studying Crohn's disease found a gene, *NOD2*, with a truncating mutation in some cases (Ogura et al., 2001). This gene codes for a protein involved in the immune response to bacterial lipopolysaccharides, a process previously implicated in the disease.

Perhaps more likely is that assembly of the smoking gun will be required. We are likely to find variations in genes that have subtle effects, such as the substitution of one amino acid for another, or the increased or decreased level of expression of the gene and, hence, the protein product. These variations may occur more often than expected in patients, though they may also occur in nonpatients. We will need to see multiple replications, and these may have to occur in large samples for the small effects to be detectable. A potential complication here is that a given genetic variation may be clearly associated with disease in one population, but may be rare and thus only minimally associated with disease in another population. The finding of an association between calpain-10 and non-insulin-dependent diabetes in Mexican Americans illustrates the difficulties involved in demonstrating a cause-effect relationship between a gene of small effect and disease (Horikawa et al., 2000). Studies of association in other ethnic populations have not been obviously supportive, with a negative association being reported in Japanese subjects (Horikawa et al., 2003) and four nonsignificant results in Europeans (see Rasmussen et al., 2002). When the four European samples were pooled, however, a significant result with an odds ratio for the risk haplotype of 1.62 was obtained.

Ultimately, determination of the relationship between a gene and bipolar illness will require studies that go beyond

DNA to look at gene expression (RNA), the protein product, and pathogenesis as well. It may be possible to study genotype–endophenotype correlations. If a gene is involved in bipolar illness, it should be possible to demonstrate the effect the disease allele has on, for example, P300 deficits and white-matter hyperintensities. Given the likelihood of relatively modest effects for bipolar susceptibility alleles, a conclusive case for the involvement of an implicated gene may require demonstration of a pathogenic pathway.

Gene–Environment Interactions

Once bipolar genes have been discovered, researchers will want to know whether the illness occurs more often when people carrying the susceptibility allele are exposed to particular factors or experiences. A number of environmental exposures that have been suggested as causative factors in manic-depressive illness, whether bipolar or recurrent depressive, such as loss of a parent at an early age or obstetrical complications, could be assessed to determine whether they increase the risk of illness in conjunction with the risk genotype. For example, the interaction between the short variant of the serotonin transporter promoter polymorphism and stressful life events may play a role in the predisposition to major depressive episodes (Caspi et al., 2003).

Future Prospects for Patients

Pharmacogenetics

Pharmacogenetic studies could provide the first exciting clinical benefits to come from genetic investigations of manic-depressive illness. If the illness is genetically heterogeneous, some of its genetic forms could predict response to one treatment, such as lithium, while other forms could predict response to another treatment, such as carbamazepine, valproate, or lamotrigine. For treating nonrecurrent depression, there may be some genetic vulnerabilities associated with good SSRI response, and other genetic vulnerabilities associated with a better response to norenergic medications such as bupropion or desipramine. These findings could allow clinicians to optimize the use of already-effective medications by choosing the drug most likely to work for a given patient with a particular genetic profile.

Rational Drug Development

Fundamental benefit will come from an improved understanding of the pathophysiology of manic-depressive illness in both its bipolar and recurrent unipolar forms. Finding a gene will lead to an examination of the functions of its protein product in the neuron. This examination could lead in turn to the elucidation of a cascade of neuronal events at work in the disorder. Understanding of

these basic processes would guide the search for treatments of bipolar and/or recurrent unipolar disorder, and could illuminate the mechanisms and functions of mood regulation generally. The gene product or another protein with which the gene product interacts could be a target for conventional pharmacology, such as receptor blockade or inactivation of an enzyme. Alternatively, the gene product could be cloned and introduced, as has been done with blood clotting factor VIII (for hemophilia A) and growth hormone (for growth hormone deficiency).

Gene Therapy

Even variations on gene therapy, where the aim is to modify gene function directly, could be conceived. The gene itself could be directly targeted by gene augmentation therapy if loss of function of a gene were the problem, with extra copies of the normal gene being introduced. Alternatively, targeted inhibition of gene expression could be employed if there were a novel gene product or inappropriate expression of a gene; this could be accomplished using antisense therapeutics, whereby gene-specific antisense sequences block the effects of a given susceptibility gene. The desirability of such an intervention is less than clear when a “susceptibility” gene rather than a “causative” gene is at issue, however, because a susceptibility gene may have important positive as well as negative effects (see the section below on pitfalls).

Diagnosis

There are currently no laboratory methods for diagnosing bipolar or recurrent unipolar disorder; rather, these diagnoses rest solely on clinical data. Identification of a causative gene could clarify the diagnostic process by providing physical evidence of the disorder (though see the discussion of pitfalls for a cautionary note). Presymptomatic diagnosis may also become possible and could lead to preventive treatments. Greater precision in prognosis may come from genotype–phenotype correlations, whereby particular symptom clusters and natural course are found to be associated with specific gene variants. This could be especially helpful in sharpening the definitions within the broad category of “recurrent unipolar,” which in DSM-IV can range from two episodes in a lifetime to highly cyclic cases with as many lifetime episodes as are typically seen in untreated bipolar disorder.

Prevention

The role of life events and other environmental factors in the causation of bipolar or early-onset recurrent unipolar disorder may be defined more clearly by epidemiologic studies when groups homogeneous for the presence of a bipolar or recurrent unipolar susceptibility gene can be ascertained.

Preventive efforts targeted at reducing these factors in vulnerable individuals would logically follow. This has been done most effectively for phenylketonuria, a rare genetic disease in which failure to metabolize dietary phenylalanine leads to severe mental retardation. This devastating outcome is now largely prevented through identification of newborns with the mutation and the implementation of a phenylalanine-restricted (and tyrosine-supplemented) diet.

Stigma

Finding a gene for manic-depressive illness would accelerate efforts at destigmatizing the condition by establishing it even more firmly as a disease rather than a frightening mystery or a weakness of character. It may also be possible to define a relationship between disease-promoting gene variants and adaptive psychological functions, such as creativity (Jamison, 1993), which would further destigmatize the disorder by illuminating positive aspects of the genetic endowment.

Pitfalls

Though the promise of genetics is great, expectations have far outpaced actual progress in the minds of some. Study participants sometimes ask when they will get back their results because of the mistaken belief that genetic testing for manic-depressive illness (especially bipolar disorder) is already available. Not only is such testing currently unavailable, but it is also not clear that a useful genetic test will emerge even when a bipolar gene is found. Because risk alleles for the disorder may elevate risk only to a relatively small degree, they may prove to be of questionable predictive value. The *APOE4* allele of the *APOE* gene, which confers increased risk for Alzheimer's disease, provides an illustrative example. The risk of Alzheimer's across the population is 9 percent. Having a copy of the *APOE4* allele increases the lifetime risk to 17 percent. It is difficult to know whether this information would be useful to people. Indeed, experts have generally recommended against performing diagnostic genetic tests for this gene (Liddell et al., 2001). On the other hand, a study of three susceptibility genes for deep venous thrombosis showed that, while having a single disease gene variant increased the disease risk to only a minor degree, having disease variants in all three genes led to an eight-fold increase in risk (Yang et al., 2003). Similarly with bipolar disorder, diagnostic and predictive testing may become valuable after several disease genes have been identified.

Another area of concern is the possibility of unintended consequences of obtaining genetic information about manic-depressive illness. At the beginning of this chapter, the misuse of genetics in the form of the eugenics movement, and eventually in the form of the mass murder of

mental patients, was described. This history suggests the need to think carefully about what people will do with the knowledge generated by genetic studies. One major concern is whether parents would choose to abort fetuses known to carry, for example, bipolar susceptibility genes. Might there be a price to pay for this kind of intervention? What if Abraham Lincoln or Winston Churchill, both of whom had mood disorders, had never been born?

The temptation may also arise to modify germ cells to purge the germ line of susceptibility alleles. The technical danger here stems from uncertainty about the biological results of such manipulations. For example, while the celebrated cloning of Dolly the sheep and other mammals appeared initially to be a great success, these efforts were subsequently plagued by the development of an overgrowth syndrome in many of the cloned animals (Young et al., 1998). Similarly, there is some evidence that in vitro fertilization procedures used by infertile couples may increase the risk of altered gene programming that can lead to disease (DeBaun et al., 2003).

Beyond biological concerns regarding germ-line manipulation, there are ethical concerns. As Billings and colleagues (1999, p. 1874) noted:

Choices about . . . programmes for enhancement would . . . reflect prejudices, socioeconomic and political inequalities, and even current fashion. . . [G]ermline intervention would intentionally subject later generations to modifications undertaken on the basis of existing values and conditions. The chance that 'desirable' manipulations might later be viewed as disastrous makes germline enhancement 'therapies' unacceptable.

While we can envision a time when we may have a comprehensive understanding of manic-depressive illness genes, their interactions, their role in the brain, and their role in behavior, as well as a full understanding of the technical requirements for adroitly manipulating the germ line, that time is a very long way off.

CONCLUSIONS

Genetic Epidemiology of Manic-Depressive Illness

For the bipolar subgroup, the risk of illness in a first-degree relative of an ill person is roughly 10 times the risk in a random person. The risk of having the illness if an identical twin has it is about 63 percent. The calculated heritability for bipolar disorder from twin studies is about .78. For major depression, the risk to first-degree relatives of depressed probands is about three times higher than the overall population risk. The risk in identical twins of depressed probands is about 34 percent, and the calculated

heritability is also about 34 percent. These numbers are higher when probands with the highly recurrent forms of depression are examined. There have been fewer adoption studies of manic-depressive illness; the studies that have been done modestly support a genetic contribution to the illness. Taken together, the data indicate a strong genetic component to susceptibility to bipolar disorder and a less strong, though still significant, genetic component to susceptibility to major depression, especially the more recurrent forms. Modeling of disease transmission through family studies has suggested that bipolar disorder is most likely caused by at least three interacting susceptibility genes, and maybe more. Furthermore, family and twin studies clearly demonstrate a genetic relationship between bipolar disorder and major depression.

Advances in Understanding the Human Genome

About 20,000 genes exist in the human genome. The information they contain is spelled out in a nucleotide alphabet made up of four letters—the nucleotides G, C, A, and T. There are about 3 billion of these nucleotides spread over 23 chromosomes, and most of the sequence does not vary among people throughout the world. There is some variability, however, and it is in this occasional variability that potential differences in susceptibility to manic-depressive illness may be found. The capacity to investigate genes has benefited enormously from advances in genetic technology and information. Microsatellite markers have made possible highly informative linkage studies aimed at identifying chromosomal regions where disease genes might lie. The Human Genome Project has provided a wonderfully detailed roadmap of the genome, allowing those investigating manic-depressive illness to select genes to study from chromosomal regions of interest, and to choose SNPs to study from candidate genes or candidate regions.

The Linkage Method

The linkage method has been the major focus of genetic investigation of bipolar disorder since the mid-1980s. As of this writing, however, attempts to localize bipolar genes through linkage have had only limited success, as the findings obtained have not converged as consistently as might be hoped on one or a small number of chromosomal regions. The most likely reasons for this are that bipolar illness is a genetically complex disorder, meaning a number of different genes confer susceptibility to the disorder; that these genes may each individually confer only a modest increase in the risk of illness; and that differing combinations of susceptibility genes may cause disease in differing groups of people. Though the pace of progress has been slower than expected, the 20 or so genome scans of bipolar illness conducted to date have yielded some strong linkage

signals, some of which have been identified in a number of studies. The more promising linkage regions—including 4p16, 4q35, 6q22, 8q24, 12q24, 13q31–33, 16p12, 18p11–q12, 18q22–23, 21q22, and 22q11–13—are worthy of further study to clarify whether they do, in fact, harbor bipolar genes. The lack of definitive success in discovering bipolar genes has prompted some investigators to consider other approaches to the problem, including redefining the phenotype (such as focusing first on highly recurrent mood disorders and only secondarily on polarity) and rethinking potential genetic mechanisms that may underlie the disease.

Alternative Phenotypic Definition

Use of alternative methods of phenotypic definition may help define more genetically homogeneous groups of manic-depressive and bipolar subjects. Familial aggregation and linkage data exist for bipolar disorder to support the utility of subtyping by the presence of psychotic symptoms, of comorbid panic disorder, and of BP-II in families. Similar support exists for using age at onset as a phenotypic variable and for selecting families on the basis of lithium-responsive probands. Familial aggregation has been demonstrated for bipolar disorder with comorbid anxiety disorders and comorbid ADHD, but no correlation with linkage evidence has been reported. Little evidence exists at present for familial aggregation of cognitive impairments or temperamental vulnerabilities in bipolar disorder. Finally, the biological variables, or endophenotypes, of white-matter hyperintensities and abnormal P300 evoked potential have been found to be familial in individual pedigrees.

The Association Method

Association studies can be used for two different purposes. The first is to test directly whether a gene variant may be implicated in illness. Studies of this kind have until recently focused on monoamine system genes. Studies of genes encoding the serotonin transporter, the monoamine oxidase type A enzyme, the catechol-O-methyltransferase enzyme, and the type 2 and type 4 dopamine receptors have yielded some weakly positive, along with some negative findings. Small effects for variants of these genes in bipolar disorder are a possibility. More recently, an association has been found for three other genes—one coding for BDNF and two overlapping genes of unknown function, called *G72* and *G30*. The BDNF finding is promising, particularly because of biological evidence for the role of BDNF in depression and in antidepressant response, but cannot be viewed as conclusive because the effect is small, and replication has not been consistent. The *G72/G30* finding is notable for reproducing an association first seen with schizophrenia, for showing positive findings across

six bipolar samples, and for being the only replicated positional candidate finding in bipolar studies. The second use of association studies is for the narrowing of linkage regions through linkage disequilibrium mapping. This approach was taken using a population isolate with linkage to 18p11.3, and the result was to narrow the region of interest to 19,000 bases, a stretch containing just two genes.

Alternative Genetic Mechanisms

Exploration of alternative genetic mechanisms of disease may aid in the process of gene discovery. Clinical observations have suggested some of these mechanisms. Anticipation, or worsening severity of illness in successive generations, has been observed, suggesting the trinucleotide repeat hypothesis, though subsequent clinical studies have not consistently confirmed the initial clinical observation. An excess of clinically defined maternal transmission of bipolar disorder has also been observed, indicating mitochondrial inheritance or genomic imprinting, though again, subsequent clinical studies have not consistently replicated the initial observation.

Of the genetic avenues pursued to date in the study of bipolar disorder, the trinucleotide repeat hypothesis and the mitochondrial inheritance hypothesis have been studied extensively but have not yielded bipolar genes to date, although work continues in these areas. The genomic imprinting hypothesis has generated some interesting leads that are currently being pursued. These include modest evidence of parent-of-origin-specific linkage on chromosomes 1q, 2p, 2q, 13q, 14q, 16q, and 18q, as well as modest evidence for parent-of-origin-specific association with bipolar disorder for the dopamine receptor type 4 gene and the dopamine decarboxylase gene, both of which lie near known imprinted genes.

Gene Expression and Pathogenesis

Proving that a gene—or more specifically a particular gene variant, an allele—is causally related to manic-depressive illness will require more than simply demonstrating a statistical association between the allele and the disease; an important piece of evidence would be the demonstration that the allele causes meaningful alteration in the structure or expression level of messenger RNA. A number of genes have been shown to have abnormal expression levels in the prefrontal cortex, hippocampus, or amygdala of bipolar subjects, though none of these findings have yet been replicated. Allelic variation, however, has not yet been shown to correlate with any of these changes. Studies in lymphoblastoid cell lines from the general population show inherited variation in the expression of a number of genes, but few studies of gene expression in white blood cells derived from bipolar subjects have been done.

Candidate genes and candidate allelic variants can be studied in cell culture and in genetically engineered mice. Cell culture has been employed to demonstrate that the serotonin transporter gene promoter polymorphism differentially affects transcriptional activity. No genetically engineered mice provide a clear animal model for depression or bipolar disorder at present. BDNF heterozygous knockout mice did not show depressive-like behavior. Serotonin transporter knockout mice did show depressive-like behavior when the mice derived from one genetic background, but not when they derived from a second background. Transgenic mice with decreased glucocorticoid receptor expression showed endocrine abnormalities of the kind seen in depression, and these abnormalities were reversible with antidepressant administration, but the mice did not show depressive-like behavior.

Ultimate proof of a causal relationship between a gene variant and manic-depressive illness will depend on investigations that go beyond the study of nucleic acids. Changes in structure and/or function will need to be shown in the protein product of the putative disease gene. Further, the proposed disease allele should result in observable changes in aspects of biochemical pathway processes, in neuronal and/or glial function, in brain region structure or function, and in intermediate phenotype measures. Again, study of the promoter region polymorphism of the serotonin transporter gene provides an example of this kind of study. The short variant was shown to be associated with greater amygdala activation in response to fearful stimuli in a functional magnetic resonance imaging study.

Pharmacogenetics and Genetic Counseling

There is modest evidence suggesting that response to antidepressants and to lithium may be inherited traits. This finding implies that when a choice of medications must be made for patients with new-onset mood disorders, selecting one that has worked for a family member may be a sensible practice. While the familiarity of lithium response suggests that genetic variation is responsible for differences in the drug's effectiveness, no particular gene has yet been clearly associated with these differences. A number of studies have suggested that the long promoter variant of the serotonin transporter gene may confer a greater likelihood or speed of response to SSRIs than the short promoter variant, though this result cannot yet be considered definitive.

Genetic counseling is a feature of current clinical practice. It should be informed by results of family studies, which suggest that on average, the risk to children of those with manic-depressive illness is elevated to a modest degree. There are no genetic tests available at present to provide precise estimates of the risk to children in specific

cases. Should such tests become available, they are likely to be used in particular to aid in early diagnosis. Even without these tests, the attention paid by ill parents to the possibility of illness in their children can help ensure prompt diagnosis and treatment, which may stave off more substantial morbidity.

Looking to the Future

While linkage studies of major depression are just getting under way, work in bipolar genetics is moving toward association studies designed to narrow the localization of disease genes and to test gene variants for a role in bipolar disorder. These studies rely on a rapidly developing set of technologies for the detection, screening, and analysis of SNPs. The ongoing recruitment of large numbers of patients and families is creating study samples with the power to enable detection of relatively small gene effects and examination of the interactions between genes. The discovery of susceptibility genes will also be enhanced by approaches that decrease genetic heterogeneity, such as the study of phenotypic subtypes and endophenotypes. It is possible that the first genes for bipolar disorder have already been discovered, though ultimately proving that a particular gene plays an etiologic role in the illness will require studies that extend beyond DNA to demonstration of the gene's role in a pathogenic pathway.

The discovery of bipolar genes (and ultimately those associated with recurrent unipolar depression) will open the door to a number of potential benefits to patients. An intangible benefit may be the reduced stigma that would result from demonstrating that manic-depressive illness has a physical basis. Moreover, pharmacogenetics could allow clinicians to optimize their choice of medications based on a patient's genetic profile. The discovery of biochemical pathways of disease could lead to the development of novel medications. Gene therapy, in which unhelpful alleles are turned off or helpful ones turned on, might even become possible. Genetic testing could become a possibility as well for purposes of diagnosis, prognosis, prevention, or early intervention.

Despite these reasons for optimism about the future of genetic medicine in manic-depressive illness, there are also grounds for caution and pitfalls of which to be aware. Because of the possibility that alleles for the illness or any of its subgroups will have only small effects, the use of each individually in genetic testing may be limited. Even if the tests were useful, it is not clear that employing them in prenatal testing would ultimately be desirable. Though some people might be tempted to eliminate susceptibility alleles for manic-depressive illness from germ-line cells, this kind of manipulation is fraught with technical hazards and ethical dangers.

NOTES

1. Only studies that employed direct interviews of the majority of relatives are included here.
2. The 12 studies are those in the bipolar and BP-I sections of Table 13–2, with the exception of Heun and Maier because that study used the same sample as Maier et al.
3. This calculation incorporates data from both the bipolar proband studies and the BP-I proband studies. Heun and Maier is not counted since the subjects in this study are accounted for by the Maier et al. study.
4. One criticism of twin studies is that the equal-environment assumption is not necessarily true; rather, MZ twins are more likely to seek out similar environments or be treated more similarly by people in the environment than are DZ twins. The validity of the assumption has been tested in several ways. For example, some studies have refuted this criticism (Kendler et al., 1993c; Hetttema et al., 1995; Xian et al., 2000) by failing to find differences in phenotypic similarity for psychiatric disorders based on perceived versus actual zygosity. A more direct approach to the question is that taken by Lytton and colleagues (1977), who observed young twins and their parents. They found that parents did respond more similarly to MZ than to DZ twins, but that this difference was in reaction to the behavior exhibited by the twins.
5. Only studies that employed direct interviews of the majority of relatives are included here.
6. Another important aspect of heritability is that it is not expected to be a constant figure, but to be population and environment dependent. Kendler (2001) summarized 10 studies of behavioral traits that demonstrate changing heritability over time. For example, Heath and colleagues (1985) showed that in Norway, heritability of educational attainment was about 40 percent for men born before World War II and about 70 percent for men born after. This result is thought to be due to increased equality of educational opportunity after the war, leading to a more merit-based system in which the innate potential of individuals could be expressed more fully (Heath et al., 1985).
7. As of this writing, the best-known of these websites are those of the National Center for Biotechnology Information (NCBI) (<http://www.ncbi.nlm.nih.gov/>), the University of California at Santa Cruz (UCSC) (<http://www.genome.ucsc.edu/>), and Celera (proprietary).
8. An earlier study, from an Icelandic and English group, was the first to use repeat-length polymorphisms to test linkage in manic-depressive illness, employing markers derived from larger repeats, called *minisatellites* (Hodgkinson et al., 1987a).
9. A well-known example of the problems inherent in the approach is the case of the chromosome 11p linkage finding by Egeland and colleagues (1987), who originally reported an impressive LOD score of 4.08 at a DNA marker in a single large Amish family from southeastern Pennsylvania. However, restudy of the same family provided evidence against the linkage, with the LOD score dropping to -9.31 . In the later reanalysis, additional subjects were included, and the diagnosis of some of the original subjects changed from unaffected to affected (Kelsoe et al., 1989). This reevaluation led to recognition of several pitfalls in the traditional linkage methods, including the precariousness of using unaffected

- family members in an analysis, and contributed to a shift toward a different analytic approach.
10. Reich et al., 1969; Mendlewicz et al., 1972, 1979, 1980; Baron et al., 1987, 1993.
 11. The complex phenotype of nonsyndromic hearing loss—deafness without nonauditory symptoms—provides a dramatic example of genetic heterogeneity: 12 different genes have been identified that each can cause the disorder independently, with more likely to follow (Griffith and Friedman, 1999).
 12. This appears to be the case, for example, with Hirschsprung's disease; in this case, the gene *EDNRB*, encoding a G protein-coupled receptor, and the gene *RET*, encoding a receptor tyrosine kinase, may interact to contribute to disease susceptibility (Carrasquillo et al., 2002).
 13. Suicide in people with manic-depressive illness has been studied as an alternative phenotype, and a genetic component to suicidal behavior has been established. This work is described in Chapter 9.
 14. Kendler et al., 1985, 1986, 1993a,b.
 15. DeLisi et al., 1987; Sham et al., 1994, 1996; Kendler et al., 1997.
 16. Both the LOD score noted here and the subsequent score described by Schulze and colleagues (2003) are nonparametric and paternal allele-specific. The latter refers to an LOD score calculated only on the basis of alleles inherited from fathers, omitting the alleles that come from mothers. (See the discussion below of genomic imprinting.)
 17. In one additional positive study, the variant was not specified (Vincent et al., 1999).
 18. Esterling et al., 1998; Kirov et al., 1999c; Mundo et al., 2000; Mynett-Johnson et al., 2000; Serretti et al., 2002a.
 19. Bocchetta et al., 1999; Kirov et al., 1999c; Mynett-Johnson et al., 2000; Dimitrova et al., 2002.

The madness results from an aberrant biochemical process. . . . With all of this upheaval in the brain tissues, the alternating drenching and deprivation, it is no wonder that the mind begins to feel aggrieved, stricken, and the muddled thought processes register the distress of an organ in convulsion.

—William Styron (1990, p. 47)

Attempts to comprehend the brain's role in mania and depression—a quest the ancients could undertake only in rhetorical flight—began in earnest as clinically effective mood-altering drugs began to appear in the late 1950s and early 1960s. The psychopharmacological revolution fortuitously coincided with the arrival of new techniques that made it possible to characterize neurotransmitter function in the central nervous system. Over the next three decades, clinical studies attempted to uncover the biological factors mediating the pathophysiology of manic-depressive illness through a variety of biochemical strategies. Studies were, by and large, designed to detect relative excess or deficiency associated with pathological states; not surprisingly, progress in unraveling the unique neurobiology of recurrent mood disorders was slow using such strategies in isolation.

The last decade of the twentieth century marked the start of a truly remarkable period for biomedical research. The “molecular medicine revolution” has brought to bear the power of sophisticated cellular and molecular biologic methodologies to tackle many of society's most devastating illnesses. The rate of progress has been exciting indeed, and hundreds of G protein-coupled receptors and more than a dozen G proteins and effectors have been identified and characterized at the molecular and cellular levels. As a result, it has become possible to study a variety of human diseases caused by abnormalities in cell-to-cell communication; these studies are offering unique insights into the physiologic and pathophysiologic functioning of many cellular transmembrane signaling pathways.

Psychiatry, like much of the rest of medicine, has entered a new and exciting age resulting from the rapid advances in and the promise of molecular and cellular biology as well as

neuroimaging (discussed in Chapter 15; Cowan et al., 2002). Although we have yet to identify the specific abnormal genes or proteins associated with manic-depressive illness, there have been major advances in our understanding of the illness, particularly in the bipolar subgroup and in the mechanisms of action of the most effective treatments. These advances have generated considerable excitement among the clinical neuroscience community and are reshaping views about the neurobiological underpinnings of the disorder. It is our firm belief that the impact of molecular and cellular biology—which has been felt throughout clinical medicine—will have major repercussions for understanding the fundamental pathophysiology of bipolar and recurrent unipolar disorders and that we will see the development of markedly improved treatments for these devastating illnesses.

In this chapter, we begin by discussing some fundamental, unique facets of manic-depressive illness that have made a true understanding of its core pathophysiology so challenging. We then trace the evolution of the models that have guided biochemical and pharmacological studies, with emphasis on bipolar disorder. Next we review findings of the literature on the potential involvement of several major neurotransmitter and neuropeptide systems. We then turn to an area that has witnessed the greatest advances in biomedical science in recent years—the molecular and cellular mechanisms underlying long-term neuroplasticity and gene expression. Finally, we attempt to synthesize the findings from molecular, cellular, biochemical, systems, circuitry, neuroimaging, postmortem, and behavioral studies to propose an integrated model.

As is the case throughout this volume, we focus primarily on the bipolar subgroup of manic-depressive illness. Where recurrent unipolar disorder (especially the highly

recurrent forms) is salient, however, it is included in the discussion. We also note when data for unipolar depression (unfortunately all too often broadly defined without respect to recurrence) may shed light on the underlying pathophysiology of manic-depressive illness or highly recurrent unipolar depression.

The approach taken in this chapter reflects the explosion of information since we published the first edition of this volume:

- Our emphasis in the chapter is on findings of the literature on bipolar disorder. To supplement this discussion, we provide additional information on the Web site for this volume: (1) a summary of older but important biological findings in manic-depressive illness that have not been extensively pursued in recent years for reasons that are not always clear (these investigations include electrolytes, sodium, magnesium, and calcium; membrane transport studies including red blood cells/plasma lithium ratio, Na/K ATPase studies, and red blood cell cation transport); (2) investigations of neurotransmitter-related enzymes, including monoamine oxidase (MAO), catechol-O-methyltransferase (COMT), and dopamine- β -hydroxylase (DBH); and (3) additional discussion of biological correlates of the switch process, focusing on the hypothalamic–pituitary–adrenal and hypothalamic–pituitary–thyroid axes, the serotonergic, dopaminergic, and noradrenergic systems, and related neuropeptides. Additional details on various other topics in this chapter are provided on the accompanying Web site as well.
- We present a considerable amount of material in table form; in general, when we extensively covered a topic in the first edition of this volume (e.g., biogenic amines), we present a summary table of the major findings that have stood the test of time, as well as a table of findings from more recent studies.
- When discussing the effects of medication on various biochemical pathways, we focus in general (with notable exceptions) on the well-established mood stabilizers—lithium, carbamazepine, and valproate.

THE UNIQUE NEUROBIOLOGY OF RECURRENT MOOD DISORDERS (ESPECIALLY BIPOLAR): CONSTRAINTS FOR CLINICAL STUDIES

It is likely that in individuals with manic-depressive illness, perhaps especially in its bipolar form, altered expression of critical proteins ensuing from a series of interacting susceptibility genes predisposes to a dysregulation of signaling in regions of the brain, resulting in a periodic loss of homeostasis and clinical manifestation of affective symptomatology—that is, mania and/or depression (Goodwin

and Ghaemi, 1998; Manji and Lenox, 1999; Payne et al., 2002). Thus the biological processes underlying the risk for mood cycling may even be quite distinct from the biology driving the clinical symptoms of mania or depression per se (Goodwin and Ghaemi, 1998). In this regard, it should be noted that there is increasing evidence for a shared genetic risk for both bipolar and recurrent unipolar disorders (see Chapter 13), suggesting that the underlying pathophysiological processes predisposing to recurrent mood disturbance may share common features. Furthermore, the clinical picture and system response are the result of a complex, dynamic interaction between the dysregulated signaling systems and activation of existing physiological feedback mechanisms designed to compensate for extreme changes. In this manner, the constellation of symptoms—including not only mood but also autonomic, endocrine, sleep/wake, and circadian activity determinants—reflects both the stage and progression of illness and unique individual characteristics conferring heterogeneity in clinical presentation and diagnosis.

In light of this complexity and the dynamic properties of the system, we would expect research strategies examining biochemical and endocrine variables to be subject to a high degree of inherent variability, using not just cross-sectional analyses among patients but even longitudinal designs over time within individual patients. Furthermore, the use of peripheral sources and postmortem brain to address biochemical and neuroendocrine activity within the brains of patients introduces another set of variables inherent in the experimental design, most often placing significant constraints on the interpretation of data. Additionally, when patient groups cannot be matched for comparison on a particular variable, the appropriate statistic may be an analysis of covariance, used to control for the influence of confounding variables. These characteristics may be associated (confounding) or not (independent) with the phenomenon under study (e.g., the observed outcome of an illness after a specific intervention), thereby making a simple analysis of variance problematic. Even age matching can introduce distortions. For example, in age-matched unipolar and bipolar depressed patients, the latter group's earlier age of onset means their average duration of illness will have been longer, and this parameter should be evaluated independently despite the general homogeneity of the population (Goodwin et al., 1978).

We should also keep in mind that a true understanding of the pathophysiology of manic-depressive illness in either its bipolar or highly recurrent unipolar form, must address its neurobiology at different physiological levels—molecular, cellular, systems, and behavioral (see Fig. 14–1); unfortunately, most studies to date have examined these levels in isolation.

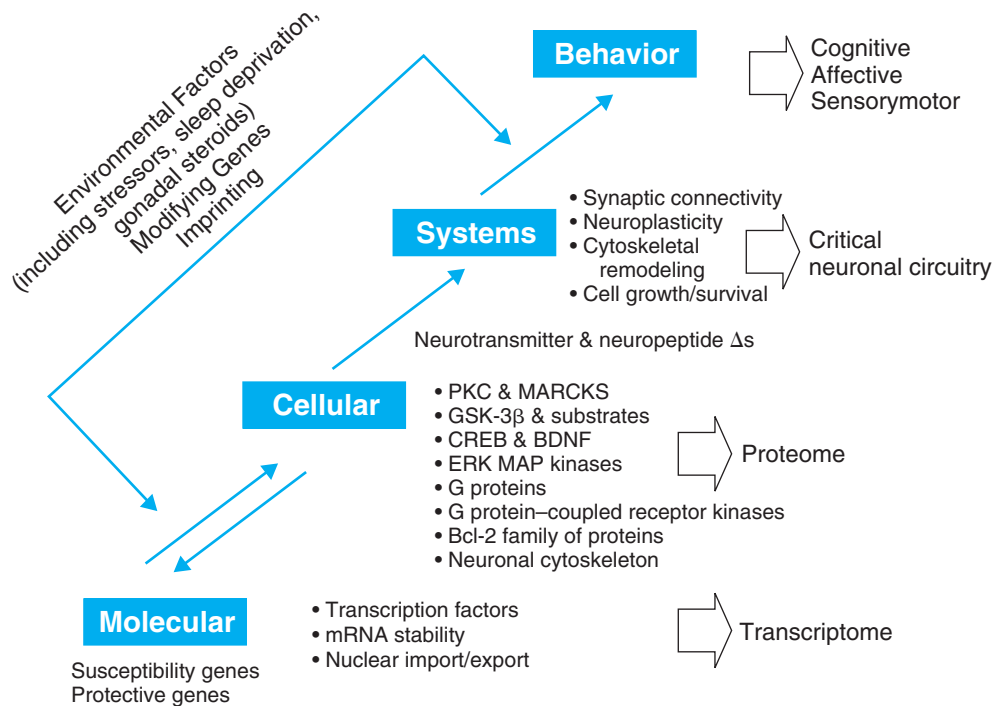

Figure 14-1. For a complete understanding of the pathophysiology of bipolar disorder, its neurobiology must be addressed at different physiologic levels (i.e., molecular, cellular, systems, and behavioral levels). Bcl-2 = B-cell leukemia/lymphoma; BDNF = brain-derived neurotrophic factor; CREB = cAMP response element binding protein; ERK = extracellular receptor-coupled kinase; GSK-3 = glycogen synthase kinase-3; MAP kinase = mitogen-activated protein kinase; MARCKS = myristoylated alanine-rich C kinase substrate; PKC = protein kinase C; proteome = the population of cellular protein species and their expression level; transcriptome = the population of cellular messenger RNA species and their expression level. (Source: Manji and Lenox, 2000a. Reprinted with permission from Elsevier.)

As discussed in Chapter 13, it is clear that manic-depressive illness arises from the interaction of multiple susceptibility (and likely risk) genes. These genes (and the proteins for which they code) are undoubtedly related much more closely to specific biochemical processes and thus specific symptoms than to “bipolar disorder or recurrent depression” as defined by the *Diagnostic and Statistical Manual*, 4th edition (DSM-IV) (Manji et al., 2003a).

One strategy that may have considerable utility in elucidating the complex neurobiology of the bipolar form of the illness is an endophenotype-based approach (Lenox et al., 2002; Gottesman and Gould, 2003; Manji et al., 2003a; Hasler et al., 2006). Such an approach may allow for the enrichment of study populations based on pathophysiological considerations, and may ultimately lead to a greater understanding of the illness. It is our strong belief that conceptualizing the disorder through an endophenotypic approach will also enable a more biologically relevant classification of patients along dimensional properties of the disorder, rather than the traditional categorical classifications imposed by our diagnostic manuals and reimbursement systems.

Additional major problems in the interpretation of biological data are associated with the diagnostic specificity of

patient populations and the lack of comparability of patient states across studies even in those who truly have the same diagnosis. Are they studied at the same point in their recurrent illness? Are the effects “primary” to the illness, or do they represent the individual’s compensatory adaptations to the illness? How long have patients been drug-free? It is now clear, for instance, that withdrawal from the high therapeutic doses of antidepressants currently employed produces biochemical changes that persist for at least 3 and up to 8 weeks following discontinuation. For more than a decade, the bulk of psychiatric patients available for biochemical studies have been those recently or currently on medication at the beginning of an investigation. None of the studies reported here, for example, specify a minimum withdrawal over 3 weeks, and most involve only a 1- to 2-week drug-free period. Indeed, as we discuss later, it is quite likely that medication has major effects on brain structure as well, calling into question many of the volumetric brain imaging studies conducted without regard to medication status. Indeed, there are only a few studies in which a parameter is followed longitudinally over different states in one or two untreated subjects. From a research point of view, such studies are particularly valuable,

BOX 14–1. The Pathophysiology of Manic-Depressive Illness: Constraints for Experimental Design

- Complex disease with diagnostic heterogeneity
- Episodic nature of symptoms and distinct symptom clusters
- The biology underlying recurrence and cyclicity may be distinct from that responsible for specific symptom clusters
- Disease progression dictates changes over the course of the illness
- Dynamic interaction between compensatory and adaptive changes in brain and primary neurobiology of the disorder
- Effect of treatment and treatment withdrawal on measures
- Potential circadian rhythm abnormalities suggest that single time-point studies may be inadequate
- Relative inaccessibility of target organ and dependence on peripheral models
- Lack of suitable animal models
- Characterization of “mood” as a quantitative trait (QTL analysis) has not yet been accomplished

Source: Bachmann et al., 2005.

although they clearly must be generalized with caution since investigated patients are those able and willing to tolerate prolonged periods without drugs, and therefore may be atypical.

Our task becomes even more daunting when one considers the possibility that a major component of the pathophysiology of bipolar disorder (and perhaps also the more highly recurrent forms of unipolar depression) may stem from discordant biological rhythms, ranging from ultradian to infradian, that ultimately drive the periodic recurrent nature of the disorder. Not only do data collected at different times of the day (or seasons) lack comparability, but a free-running rhythm can produce epiphenomena that may be misinterpreted as correlates of the mood cycle. These problems are of more than passing interest, since rhythm disturbances have been hypothesized to be central to the pathophysiology of the illness (see Chapter 16).

In summary, constraints on experimental design in the study of recurrent mood disorders include the diagnostic heterogeneity of a complex disease; the biology underlying recurrence and cyclicity (which may be distinct from that responsible for specific symptom clusters); and potential circadian rhythm abnormalities. Thus simple time-point studies may be inadequate. Another constraint for research on bipolar disorder is posed by the lack of suitable animal models for use in biochemical and pharmacological studies. The evolution of such models is the subject of the next section. For additional constraints on experimental design, see Box 14–1.

ANIMAL MODELS OF MOOD DISORDERS

The need to use caution in applying animal models to complex neuropsychiatric disorders has been well described (McKinney, 2001; Weiss and Post, 1994). It is unlikely we will ever develop rodent models that display the full range of validity criteria. Modeling in animals is a valuable tool for exploring the underlying pathologies of human diseases and developing better therapies. Yet, modeling psychopathology is more difficult than modeling other somatic diseases, primarily because of three major considerations (Einat et al., 2002a; Nestler et al., 2002a):

- The diagnosis of psychiatric disorders is based on evaluation of diverse symptoms rather than on specific, objective measures.
- There are no fully validated biological markers for psychiatric disorders.
- Many features of major psychiatric illnesses can be totally observed only in humans, in whom the cortical mantle has evolved to a much greater extent than in other species.

Despite these limitations, however, animal models have been used for many years as the basis for experimental efforts to reproduce in nonhuman species the essential features of human disorders (Suomi, 1982; McKinney, 1988). Animal models of psychiatric disorders can also be defined operationally as unusual behavioral states in animals that are specifically reversed by the same pharmacological treatments that reverse symptoms of the human disorder (Petty and Sherman, 1981). An homologous animal model for a human mental disorder ideally should be simple, reproducible, and similarly quantifiable, compared to the human disorder in these paradigms: symptoms, postulated etiology, mediating mechanisms, and treatment responses.

In considering an animal model of depression or of any other illness seen in humans, it is critical to be clear on the validity criteria of that model (McKinney, 2001). The best animal model of a disease is theory driven (McKinney, 2001; Einat et al., 2002b, 2003a; Nestler et al., 2002a). An animal model of depression, for example, is expected to replicate the etiological factors and many of the symptoms associated with depression in humans. A related approach is to model a disease mechanism in a laboratory animal and recreate particular features of the disorder. Both approaches have been used recently with considerable success in creating animal models for several neurological conditions (e.g., Huntington’s disease, familial Alzheimer’s and Parkinson’s diseases) in which the underlying genetic abnormalities are known.

An alternative approach is to reproduce in animals particular symptoms of mood disorders. Integrated in the concepts of face and construct and predictive validity, these

models can then be used to study the biological mechanisms underlying those symptoms and to develop new treatments that alleviate the symptoms. The main limitation of these models is that they may poorly reflect mechanisms involved in the human situation. Thus the biological basis of the animal symptoms may be different from that of human symptoms, and drugs that treat the former may not treat the latter. Another approach is to simply develop models that can be used to screen for new treatments. Such models may not have face validity for the human disease, but this does not matter as long as the models have predictive value for identifying new treatment agents. Several such screening tests are available, as outlined below, but the value of these tests in identifying treatments with novel mechanisms of action will remain unknown until such treatments are identified (Einat et al., 2002b; Nestler et al., 2002b).

Models of Depression

It should be noted at the outset that, while many of the depression models do show construct, face, or predictive validity for depression, none model recurrence. The only paradigms that model recurrence, at least to some extent, are the kindling models discussed later and circadian/ultradian rhythm models discussed in Chapter 16.

The Primate Separation Paradigm

In its earliest version, the primate separation paradigm consisted of rearing monkeys from birth either in total isolation, completely deprived of social contact with other animals, or in wire cages with only visual and auditory contact permitted. Animals reared in either environment for the first 6 to 12 months of life, then tested socially with other animals, spend most of their time manifesting a despair syndrome: huddled alone in a corner, rocking, clasping themselves, and refraining from play or social encounters with peers (McKinney, 1988). Subchronic treatment with tricyclic antidepressants, such as imipramine, can significantly reduce elements of this despair syndrome, such as huddling (Suomi et al., 1978). Certain elements of the syndrome have been reversed by other categories of drugs, including a neuroleptic (chlorpromazine) and an anxiolytic (diazepam) (McKinney et al., 1973; Noble et al., 1976). In a few studies, even electroconvulsive therapy (ECT) has been shown to reverse this depressive-like behavior (McKinney, 1986). Endogenous neurochemical changes noted during the separation period include reduced cerebrospinal fluid levels of norepinephrine, which were shown to be reversed by antidepressant treatment (Kraemer et al., 1984).

Although some of the observed behaviors are roughly analogous to major depression in humans, the fact remains that the onset of depressive illness typically occurs in adulthood. These infant monkeys are probably displaying a

response more analogous to the “anaclitic depression” observed by Spitz (1946) among newborn human infants suffering from maternal deprivation. Aware of these limitations, some investigators of primates have attempted to model depression using juvenile monkeys separated from their peer groups (Kraemer et al., 1984). Of course, one of the fundamental realities of depressive illness is that it clusters in genetically predisposed individuals. Thus, the observation of considerable individual variability in the development of despair behavior among rhesus monkeys is of special importance and has prompted cross-fostering studies, which are beginning to tease apart environmental and genetic factors in individual vulnerability to separation (Mineka and Suomi, 1978; McKinney, 1988).

Several rodent models involving manipulation of early life environment have also been used, including prenatal stress, early postnatal handling, and maternal separation (Meaney et al., 1994; Caldji et al., 2000; Ladd et al., 2000). Environmental enrichment has been used as a reciprocal stimulus. In some of these models, early life stress produces neuroendocrine and behavioral changes in rats and mice that persist into adulthood. For example, animals subjected to early stress show a hyperactive hypothalamic–pituitary–adrenal (HPA) axis, as indicated by elevated corticotropin-releasing factor (CRF) and glucocorticoid levels in response to stress. They also exhibit increased locomotor responses to novelty and, in some studies, greater vulnerability to learned helplessness (see below) and drug self-administration.

Overall, separation models of depression are generally good in terms of their replicability, and have been used successfully with a variety of species, from rodent to non-human primate. In addition, many of the resulting abnormalities can be reversed by antidepressant treatment, although negative reports have also appeared.

The Learned Helplessness Model of Depression

The learned helplessness model is based on exposing animals to uncontrollable, aversive stressors (Seligman and Maier, 1967). Variations of the original paradigm include inescapable tailshock or footshock, which is varied and random, and behavioral despair, as evidenced in a test involving swimming to exhaustion. The former produces a more naturalistic situation, whereas the latter is essentially a version of learned helplessness.

Rats subjected to various forms of stress, such as shock or forced swimming, are subsequently unable to acquire and perform a simple escape task. The effect lasts up to 1 week after the inescapable stress (Weiss et al., 1984). The interpretation is that any behavioral or other difference found between groups can be attributable to the psychological variable of control over shock termination. Animals that have

acquired learned helplessness show several neurovegetative changes that are reminiscent of depression, such as rapid eye movement (REM) sleep alterations, reduced body weight, diminished sexual behavior, and elevated CRF and corticosterone levels. Repeated dosing with antidepressants, as well as repeated electroconvulsive seizures (the animal model of ECT), reduces the latency to escape and decreases the number of animals that show learned helplessness (Willner, 1984; Hitzemann, 2000).

The attractiveness of the learned helplessness model is that it is based on a plausible theory linking cognitive function to visceral sequelae. On the other hand, these models suffer from some of the same limitations as the separation models:

- Compared with the relatively low frequency of clinical depression in the populations studied, the behavior is produced in a substantially larger proportion of the individual animals tested.
- The animals require a considerable amount of stress, and severe stress does not uniformly play a critical role in the onset of major depressive episodes in humans. In recurrent mood disorders, stress may be more important to the onset of the initial episode than to subsequent episodes. Thus, the extent to which learned helplessness is a superior model for post-traumatic stress disorder and other conditions in which stress is a clear etiological factor remains unknown.
- These syndromes generally can be reversed rather quickly by restoring the animal to a normal environment. This is certainly not the case in major depressive illness.
- Controversy has centered on whether the effects of learned helplessness are truly cognitive or simply products of stress-induced inactivity.
- As noted above, while these models have utility in reproducing some facets of the depressive syndrome, they do very little to address the recurrent nature of manic-depressive illness.

Forced Swim Test

The forced swim test, also known as the Porsolt test, is the most widely used animal model in depression research, more specifically as a screen for antidepressant treatments (Borsini and Meli, 1988; Lucki, 1997; Porsolt, 2000). The test involves placing a rat or mouse in a tank filled with water and measuring the amount of time the animal is immobile. Acute or short-term treatment with most antidepressants increases the latency to immobility and decreases the period of immobility, and in most cases this occurs at drug doses that are not activating on their own. Although this test is used mainly as an empirical test, one interpretation is that antidepressants may increase active coping responses to

swim stress. A variant of the forced swim test, used in mice, is the tail suspension test. Here, mice are suspended by their tails, and the time it takes each animal to become immobile (to hang passively upside down) is measured. Acute administration of most antidepressants decreases immobility.

The major advantage of the forced swim test (or tail suspension test) is its relatively high throughput and ease of use. However, there are also disadvantages. Antidepressants decrease immobility in the test animals even after single doses, despite the fact that the clinical effects of these agents require administration for several weeks at least. Thus, the test is sensitive to the immediate effects of these agents and may not be capturing per se the true mood-elevating changes produced by these medications in the brain.

Chronic Mild Stress

Several tests related to learned helplessness and based on exposure of animals to uncontrollable stress have been used in rats. In general, it has been much more difficult to establish equivalent tests in mice.

In the chronic mild stress paradigm, rodents are exposed to a variety of relatively mild stresses (isolation housing, disruption of light–dark cycles, brief food or water deprivation, tilting of home cages) intermittently for relatively prolonged periods of time (e.g., several weeks). Another stress-based model is social defeat. Here, an animal is exposed repeatedly to an aggressive and dominant animal. In some laboratories, no physical contact is involved, while in others the defeated animals experience mild physical duress.

The advantage of these tests is that they have greater face validity than many other tests because they involve more naturalistic stresses. Stressed animals are reported to exhibit “anhedonia” as inferred from a reduction in sucrose drinking, as well as a variety of cardiovascular or neuroendocrine sequelae, which are reported to be reversed by longer-term antidepressant treatment in some studies. The major disadvantage of the chronic stress models is their poor reproducibility. Both the behavioral abnormalities produced by chronic stress and the palliative effects of antidepressants in these paradigms have been difficult to replicate across laboratories, which has reduced their general application.

Models of Bipolar Disorder

An ideal model for bipolar disorder should include spontaneous and progressive behavior that oscillates between increased and decreased manifestations of the model behavior and that may be similar to a human behavior phenotypic to mania or depression (face validity). The model behavior should also be normalized by chronic, but not acute, treatment with mood stabilizers such as lithium and several anticonvulsant drugs, but react in the manic-like direction to treatment with antidepressants (predictive validity).

Additionally, a well-validated model should be based on one of the mechanistic theories of the disease.

The progressive and cycling nature of the disease presents a unique difficulty in any attempts to model it. Indeed, most models tend to focus on one pole of the disorder, either mania or depression, whereas a number of models employ other examples of oscillatory physiology or behavior even if they do not overtly resemble any symptoms of bipolar disorder.

Hyperactivity Models

Because models for major depression are relatively available, there have been more attempts to develop valid animal models for the manic state that is a unique feature of bipolar disorder. Since hyperactivity is one of the simpler behaviors to detect, monitor, and quantify, a number of models for mania have focused on this aspect of the disorder. Some of these models are reviewed by Einat and colleagues (2000, 2002b) and are briefly described here.

Baseline Locomotor Activity

Locomotor activity in a novel environment is affected by many factors, such as the time of day, environmental stimuli, and the history of the animal. The effects of mood stabilizers on spontaneous activity are equivocal, but more effects have been reported for chronic lithium use (Lerer et al., 1984; Berggren, 1985) than for acute treatment with this drug (Ushijama et al., 1986). Interestingly, a clearer reduction in basal activity following lithium treatment has been observed during the dark phase (when rodents are more active), which suggests that the drug may suppress only high levels of activity (similar to the manic state) without affecting low baseline activity levels (Lerer et al., 1984; Kofman and Belmaker, 1990).

Psychostimulant-Induced Hyperactivity

Acute treatment with appropriate doses of psychostimulants can produce a range of mania-like behaviors, including hyperactivity, heightened sensory awareness, alertness, insomnia, and changes in sleep patterns (Gessa et al., 1995; Einat et al., 2000). The hyperactivity induced by psychostimulants can be easily detected (Antoniou et al., 1998) and is sensitive to lithium treatment¹ and possibly to anticonvulsant mood stabilizers (Kuruvilla and Uretsky, 1981; Maitre et al., 1984; Maj et al., 1985). Yet the sensitivity of this model to mood stabilizers is not universal; rather, it is dependent on the mode of administration or the specific type of activity measured (see Einat et al., 2000, 2002a).

Sleep Deprivation

Sleep deprivation has a rapid therapeutic effect in both unipolar and bipolar depression (see Post et al., 1987; Szuba

et al., 1994; Barbini et al., 1998; see also Chapters 16 and 19), which can be maintained by treatment with lithium or antidepressant drugs (Szuba et al., 1994). At the same time, sleep deprivation can induce manic episodes in euthymic bipolar patients and has been suggested as a final common pathway in the genesis of mania (Wehr et al., 1987).

With the clinical phenomenon in mind, Gessa and colleagues attempted to examine the effects of sleep deprivation in animals. In their studies, they demonstrated that rats exposed to 72 hours of sleep deprivation exhibit a variety of behaviors that have face validity for modeling a manic episode. These behaviors include insomnia (for about 30 minutes, after rats are permitted to sleep), hyperactivity, irritability (Albert et al., 1970; Fratta et al., 1987; Gessa et al., 1995), aggressive behavior (Hicks et al., 1979), and hypersexuality (Morden et al., 1968). Furthermore, Gessa and colleagues (1995) demonstrated that lithium treatment alleviates the insomnia and hyperactivity elements of the behavior, thereby adding predictive validity to the face validity of the proposed model.

Gessa and colleagues (1995) suggest that sleep deprivation in the rat may be a valid model for mania and that this model can offer new directions for the study of the pathological mechanism of the disorder. They attempted to study the brain mechanisms underlying these manic-like behaviors. Their findings indicate that treatment with the dopaminergic D₂ antagonist haloperidol or with the dopamine D₁ receptor antagonist SCH 23390 significantly reduces the sleep latency (time to the onset of sleep after sleep deprivation) in the model (Fratta et al., 1987), whereas treatment with the dopamine D₁ agonist SKF 38393 prolongs the period of insomnia (Gessa et al., 1995). Interestingly, the dopamine D₂/D₃ agonist quinpirole produces a biphasic effect in small doses, possibly acting presynaptically (Eilam and Szechtman, 1990) to reduce sleep latency, whereas at higher doses, acting postsynaptically, it was shown to prolong sleep latency (Gessa et al., 1995). Furthermore, naloxone (an opioid antagonist) reduces sleep latency, whereas morphine, beta-endorphin, and [D-Ala₂, D-Leu₅] enkephalin prolong the period of insomnia (Fratta et al., 1987). Neurochemical studies of this model demonstrated that sleep deprivation induces only small effects related to adrenergic or serotonergic receptors (Siegel and Rogawski, 1988) but has stronger effects on the dopaminergic (DeMontis et al., 1990) and opioid (Fadda et al., 1991, 1992) systems in the brain (Gessa et al., 1995).

Recent molecular and cellular biology studies have renewed interest in sleep deprivation as a possible model. Thus there is now incontrovertible evidence that the expression of selected critical genes varies dramatically during sleep and waking events, a variation that likely plays a major role in regulating various long-term neuroplastic

events. Messenger ribonucleic acid (mRNA) differential display, microarray, and biochemical studies have shown that short-term sleep deprivation (short-term sleep deprivation has no clear definition regarding number of hours) is associated with a rapid increase in various plasticity-related genes. Notably, these are precisely the plasticity-related molecules whose expression is increased by chronic antidepressant treatment.

In an extension of the gene expression studies, Cirelli and colleagues (Cirelli and Tononi, 2000; Cirelli et al., 2002) hypothesize that a key factor responsible for the induction of the plasticity genes may be the level of activity of the neuromodulatory noradrenergic and serotonergic systems. Both of these systems project diffusely to most of the brain, where they regulate gene expression, and are quiescent only during REM sleep (Cirelli et al., 2002). Thus sleep deprivation may be capable of rapidly activating “antidepressant/mania-inducing” genes (Payne et al., 2002), and despite the technical difficulties inherent in establishing this model, it is clearly worthy of further study.

Sensitization and Kindling

Most longitudinal studies of the course of manic-depressive illness indicate that recurrences are not simply random. Rather they show, on average, that its course presents a pattern of increasing frequency over time, a phenomenon most extensively studied in the bipolar subgroup (see Chapter 4). Post and colleagues (Post and Kopanda, 1976; Post et al., 1984d,e; Post and Weiss, 1989) have focused on two intriguing animal models that attempt to account for this tendency of episodes to accelerate: behavioral sensitization and electrophysiological kindling. These models are of considerable interest, even though they do not provide full homologies for other aspects of the illness.

Behavioral Sensitization to Psychostimulants. Repeated, intermittent administration of many psychostimulants results in a gradual increase in behavioral response termed *reverse tolerance* or *sensitization* (e.g., Robinson and Becker, 1986; Stewart and Badiani, 1993; Einat et al., 1996). This clearly progressive phenomenon, used in the past to model psychosis (see Robinson and Becker, 1986), has frequently been proposed and used as a model for the development of bipolar illness, since the development of sensitized behavior is similar to the progression of manic episodes, with a gradual increase in severity and progressively more rapid onset (Post et al., 1981, 1982). This model offers not only face validity but also some construct validity, considering the involvement of the dopaminergic system in manic psychosis (e.g., Jimerson et al., 1982; Carli et al., 1997). Moreover, cocaine mimics several of the pharmacological effects of stress, and one of the proposed models for bipolar

disorder suggests that the clinical course of the disorder is exacerbated by psychosocial stressors that interact with effector genes and immediate early genes (Post and Weiss, 1996).

Intriguingly, recent studies have shown that cocaine sensitization and reward are under the influence of circadian genes and rhythm (see Chapter 16). Abarca and colleagues (2002) found that mPer1 and mPer2 mutant mice, as well as wild-type mice, exhibited an approximately five-fold increase in activity after an acute cocaine injection compared with controls, showing that there is no initial difference in sensitivity to acute cocaine administration in Per mutants. After repeated cocaine injections, however, wild-type mice exhibited a sensitized behavioral response that was absent in mPer1 knockout mice. By contrast, mPer2 mutant mice exhibited a hypersensitized response to cocaine (Abarca et al., 2002). Conditioned place preference experiments revealed similar behavioral reactions: mPer1 knockout mice showed a complete lack of cocaine reward, whereas mPer2 mutants showed a strong cocaine-induced place preference. Finally, in another set of experiments, these investigators tested C57/BL6J mice at different zeitgeber times and found that cocaine-induced behavioral sensitization and place preference are under the control of the circadian clock. These studies are highly complementary to those of Nikaido and colleagues (2001), who found that methamphetamine augmented the expression of mPer1 in the caudate-putamen. Together, these studies suggest that processes involved in some of the actions of psychostimulants that may be of particular relevance to bipolar disorder (sensitization and reward) are under the influence of circadian rhythms and modulated in a complex manner by clock genes.

Despite the many strengths of this model, it should be noted that its predictive (pharmacological) validity is equivocal. Some studies have found inhibition of the phenomenon by lithium (Post et al., 1984c), but others have not (Poncelet et al., 1987; Cappelliez and Moore, 1990). Moreover, in contrast with the kindling model (see below), carbamazepine treatment has not been found to have any clear-cut effects (Post et al., 1984c; Weiss et al., 1990). An additional problem with the model is the gradual transition in behaviors across injections of most psychostimulants, from hyperactivity that is easily monitored and quantified to locally oriented stereotypic movements that may be difficult to interpret (see Ellinwood et al., 1972; Kilbey and Ellinwood, 1977; Eilam and Szechtman, 1990).

Amygdala Kindling. The amygdala kindling model was the first major attempt to develop a model on the basis of its progressive nature rather than on a clear behavioral similarity with bipolar disorder. As a nonhomologous model

it should be emphasized that the model is not based on the notion that bipolar disorder is a seizure disorder, but reflects the progressive nature of the illness and has considerable heuristic value (see also Chapter 4). In kindling of the amygdala, for example, repeated once-daily stimulation for 1 second initially produces no observable behavioral or electrophysiological effects. Upon repetition, however, afterdischarges increase in frequency, duration, and complexity of waveform, and eventually the animal develops a full-blown major motor seizure in response to a stimulus that was previously below the threshold. If the stimulation is repeated frequently enough, the animal will eventually develop a spontaneous seizure disorder, in which seizures occur without any exogenous stimulation (e.g., Racine, 1978; for a review see Post and Weiss, 1997).

Because of the gradual intensification of the response and the ongoing transition from stressor vulnerability to autonomous episodes, Post and colleagues suggest that although the behavioral response is different from that observed during manic episodes (Weiss et al., 1995), kindling may be an appropriate model for bipolar disorder (Post and Ballenger, 1981; Post et al., 1984b; Post and Weiss, 1997). Support for the model comes from studies demonstrating reduced seizure response after pretreatment with lithium, anticonvulsant mood stabilizers,² or electroconvulsive shock (the animal model of ECT) (see Post et al., 1984b; Minabe et al., 1987, 1988). Moreover, in the course of treatment of amygdala-kindled animals with anticonvulsant drugs, the drugs show tolerance episodically with breakthroughs of seizures; this appearance of seizures during treatment may be similar to the periodic outbursts of bipolar episodes (Post and Weiss, 1996).

Interestingly, the kindling model was a key factor for the study of the anticonvulsant drug carbamazepine as an effective mood stabilizer (Post et al., 1984b; Post and Weiss, 1997). The model is also supported by some mechanistic findings (construct validity) as it induces changes in immediate early genes, gene expression, and synaptic structure that may be similar to changes in bipolar disorder (see Post and Weiss, 1997).

The kindling model therefore offers strong predictive validity, some face validity, and partial construct validity. Unfortunately, the model is quite complicated to induce and demands special equipment and conditions. These technical problems, combined with the theoretical difficulty of a clear dissimilarity between the observed behavior (seizures) and the behavioral manifestation of manic-depressive illness in patients, have led to less than enthusiastic acceptance of the model in recent years.

Nevertheless, it is important to point out that both the sensitization and kindling models, while not directly analogous to the behavioral or affective disturbances of

manic-depressive patients, have helped clarify the mechanisms underlying the accelerating longitudinal course of the illness, especially in its bipolar form. Thus when one reviews the parallels between the two models and bipolar disorder, the following features are notable:

- For each model, evidence exists for the predisposing effects of both genetic factors and early environmental stress.
- These models show threshold effects (mild alterations eventuating in full-blown episodes).
- Each model can show similarity of episodes through repeated occurrences.
- With each model, a maximum disturbance occurs earlier in the episode as the number of recurrences increases.
- In both models, early episodes may require precipitants, whereas later ones can occur spontaneously.
- With each model, repeated episodes of one phase may lead to emergence of the opposite phase.
- Younger animals appear to be more vulnerable to sensitization and kindling, a finding suggesting a parallel with the young age of onset of bipolar disorder.
- As we discuss later, a growing body of data has shown that both psychostimulant sensitization and kindling are associated with activation of the protein kinase C (PKC) signaling cascade, a pathway whose activity is inhibited by mood stabilizers.

Thus, these models serve to broaden the conceptual framework for linking clinical phenomenology to neurobiological mechanisms. The average pattern of cycle acceleration over time could reflect a mix of patients with a variety of patterns. Some might accelerate dramatically over time, whereas others might do so moderately or not at all. In patients having a dramatically shorter cycle with each episode, the form of the illness may be analogous to the pattern of increasingly rapid onset of hyperactivity and stereotypy following repeated administration of a psychomotor stimulant. The role of environmental stress in enhancing behavioral sensitization may resemble its postulated role in the onset of affective episodes. These findings may help integrate psychosocial and neurobiological perspectives. Specifically, if one postulates that a psychosocial stress can precipitate manic or depressive episodes, the sensitization and kindling models would suggest that, after a certain amount of repetition, the episodes will develop spontaneously (see Chapter 4). This chain of events fits the clinical histories of many patients with bipolar disorder, in which clear-cut psychosocial or physical stresses are associated with the onset of early episodes, but in time the episodes become more autonomous. By the time patients are seen in treatment settings, they may indeed have an autonomous illness.

As Post and Weiss (1989) point out, however, sensitization and kindling phenomena in animals do not yet represent precise models of human cyclic mood disorders. In addition to the respective time frames being quite different, the models imply a close similarity between stress-precipitated and pharmacological-induced events, a similarity that needs to be demonstrated experimentally.

Extreme Sensitization. An extension of the psychostimulant sensitization model was recently suggested by Antelman and colleagues (Antelman et al., 1995; Antelman and Caggiula, 1996; Caggiula et al., 1998), who demonstrated that when animals reach a level of extreme sensitization to cocaine, some of their behavioral and biochemical responses begin to oscillate. The oscillations can be detected in some measures—such as the efflux of striatal and nucleus accumbens dopamine, hippocampal serotonin, and plasma levels of corticosterone and glucose—and in one behavioral measure—shock-induced hypoalgesia. Moreover, both biochemical and behavioral oscillations are completely prevented by chronic lithium pretreatment, adding predictive validity to the model (Antelman et al., 1998).

The extreme sensitization model appears to have more similarities with bipolar disorder than is the case for other models because it incorporates features of progressive and oscillating responses. Moreover, a recent study demonstrates that the behavioral response can be conditioned (Kucinski et al., 1999); that is, the behavior can be influenced by the environment, just as a manic or depressive episode can be triggered or precipitated by the environment. However, the measures used in the model are far removed from changes observed in bipolar patients, whereas other measurable changes induced by extreme sensitization, such as hyperactivity and reward-related behaviors, that are more homologous with human behavior and appear to model mania do not show cyclicality. These latter behaviors are not easily normalized by mood stabilizers. Moreover, the cycling measures were normalized by lithium, but further validation will require additional studies testing the effects of other mood stabilizers as well as other psychiatric drugs. Still, the notion of a cycling phenomenon is important, and additional study of this model might be useful.

A different derivative of the psychostimulant-induced models focusing on the response to the direct D₂/D₃ agonist quinpirole has been studied. Unlike other dopamine agonists, quinpirole (in appropriate doses) induces a biphasic response over time, starting with hypolocomotion and developing into a hyperlocomotion state (Eilam and Szechtman, 1989). This biphasic response can have face validity as a model for the two states of bipolar disorder—depression and mania. To assess this possibility, researchers examined the effects of mood stabilizers on the biphasic response.

They found that treatment with lithium or valproate affected the hyperactivity but not the hypoactivity phase (Shalubina et al., 2002). Accordingly, this model has no advantage over the other psychostimulant-induced models.

Conclusions

If animal models are to realize their promise, they must incorporate certain cardinal features of recurrent mood disorders, especially the bipolar subgroup. The first is spontaneous, progressive behavior that oscillates between increased and decreased manifestations of the model behavior that is similar to the human phenotypic expression of mania or depression (face validity). The model behavior should also be normalized by chronic, but not acute, treatment with mood stabilizers such as lithium and several anticonvulsant drugs, but react in the manic-like direction to treatment with antidepressants, psychostimulants, and sleep deprivation (predictive validity). Finally, the models should involve both genetic vulnerability and cyclicality.

Ideal animal models for bipolar disorder are not available, but a variety of behaviors in animals may represent certain facets of the disease. Beyond the long-standing debate over the value of models that are not a comprehensive reflection of a disorder, or its underlying pathophysiology (Kilts, 2001; Machado-Vieira et al., 2004), it is accepted that partial models are helpful (McKinney 2001). Furthermore, there is a growing appreciation that bipolar disorder may represent a heterogeneous group of disorders that may be more amenable to study with an endophenotypic approach (Lenox et al. 2002; Hasler et al., 2006; discussed in greater detail later in this chapter). Accordingly, changes in behavior that are related to any facet of the depression–mania *continuum* may be relevant as models of these components of bipolar disorder. Behavioral tests for many such components are available and used in different contexts. Animals are tested for activity, response to drugs, hedonistic properties, resilience and despair, anxiety and risk-taking behaviors, judgment, sexual behavior, distractibility, sleep patterns, and more, all behaviors that may be relevant to bipolar disorder. Not all these models may be valid for components of bipolar disorder, and the process of validating models requires significant work (Willner, 1991; Einat et al., 2003a). However, experimentation done in different contexts may still help gain insight into possible mechanisms involved in bipolar disorder.

An increasing number of methodologies are now available that allow for the targeted manipulation of a specific gene (and protein) in a precise temporal and spatial (brain region–specific) manner. These evolving methodologies represent a new horizon for modeling the disorder, as it is now possible to attempt and create models that are hypothesis driven and have a sound theoretical base, rather

than being based on behavioral similarity. Moreover, the availability of new molecular techniques makes it possible to explore connections between specific molecules and behavior, as well as gene–environment interactions. These advances will undoubtedly allow for the creation of improved animal models of arguably one of the most complex human neuropsychiatric disorders.

MAJOR NEUROTRANSMITTER AND NEUROPEPTIDE SYSTEMS IN MANIC-DEPRESSIVE ILLNESS

The impetus for the study of the biogenic amines in patients with manic-depressive illness was provided largely by the discovery of effective pharmacologic treatments for depression and mania. These treatments led to the formulation of the so-called pharmacological bridge between depressive illness and neurotransmitter systems in the brain. Unfortunately, as a rule, the studies of neurotransmitters and neuropeptides in depressed patients have not separately analyzed those patients with the more recurrent forms, that is, those who are a part of the manic-depressive spectrum. An initial foundation for this pharmacological bridge was formed by the following observations:

- Reserpine—an antihypertensive later shown to deplete amine transmitters in rodents—is associated with an unexpectedly high incidence of depression.
- Effective antidepressant drugs increase intrasynaptic concentrations of serotonin and norepinephrine.
- Antihypertensives that deplete these monoamines sometimes precipitate depressive episodes in susceptible individuals.
- Psychostimulants and dopamine agonists are capable of triggering manic episodes in susceptible individuals.
- Cholinomimetics (e.g., intravenous physostigmine, a central cholinesterase inhibitor) briefly but dramatically reduce symptoms in manic patients and precipitate depression in euthymic bipolar patients maintained on lithium.

Even more striking pharmacological findings go beyond effects on a single episode of depression or mania to indicate the effects of drugs on the long-term course of manic-depressive illness, particularly the bipolar subgroup. As discussed in Chapter 19, antidepressants in general and tricyclics in particular may increase the frequency of cycles and worsen long-term outcome. Finally, the monoaminergic systems are extensively distributed throughout the network of limbic, striatal, and prefrontal cortical neuronal circuits thought to support the behavioral and visceral manifestations of mood disorders.

Given these compelling pharmacological data, it is not surprising that investigators have postulated that

dysregulation of the major monoaminergic systems may play a major role in the pathophysiology of manic-depressive illness. We now review biological studies related directly or indirectly to the hypotheses generated by various pharmacological bridges, addressing in turn the noradrenergic, dopaminergic, serotonergic, cholinergic, GABAergic, and glutamatergic systems, and finally neuroendocrine systems and neuropeptides.

The Noradrenergic System

The noradrenergic system was one of the first neurotransmitter systems examined in studying the pathophysiology of affective disorders. Early theories of depression postulated that an imbalance in the metabolism of norepinephrine (NE) was responsible for mood disorders (Bunney and Davis, 1965; Schildkraut, 1965). This postulate has been extensively investigated but has proven difficult to study experimentally, in part because of the formidable methodological difficulties involved in assessing central nervous system (CNS) noradrenergic function in humans. Here we briefly review, critically appraise, and integrate the research findings to date on NE in manic-depressive illness, with a focus on the bipolar subgroup. (See Figure 14–2 for a depiction of the regulatory processes involved in NE neurotransmission.)

Studies of Norepinephrine and MHPG in Plasma

The principal metabolite of NE, 3-methoxy-4-hydroxyphenylglycol (MHPG), has been extensively measured in cerebrospinal fluid (CSF), plasma, and urine. In earlier studies, MHPG was found to be elevated in CSF in patients with depression, mania, and schizoaffective disorder (Schildkraut, 1965). The 1980s saw a series of investigations of plasma NE, the majority of which revealed some degree of elevation, interpreted as evidence of increased peripheral sympathetic nervous system activity in patients with major depression.³ Several studies using radioenzymatic and radiotracer assay techniques also demonstrated elevated plasma NE concentrations under presumed resting conditions in patients with major depression, in particular unipolar patients fulfilling criteria for melancholia (Roy et al., 1985, 1987; Veith et al., 1985). In well-controlled studies, Rudorfer and colleagues (1985) found that supine plasma NE levels were significantly lower in bipolar patients than in either unipolar depressive patients or normal volunteers.

Going beyond the study of plasma NE levels under resting conditions, studies of the responsiveness of plasma NE to various provocative challenge tests provide evidence for dysregulation of the noradrenergic system in depression. Thus, using an orthostatic challenge paradigm, it was demonstrated that the increase in plasma NE is consistently greater in depressed unipolar or bipolar patients than in age- and

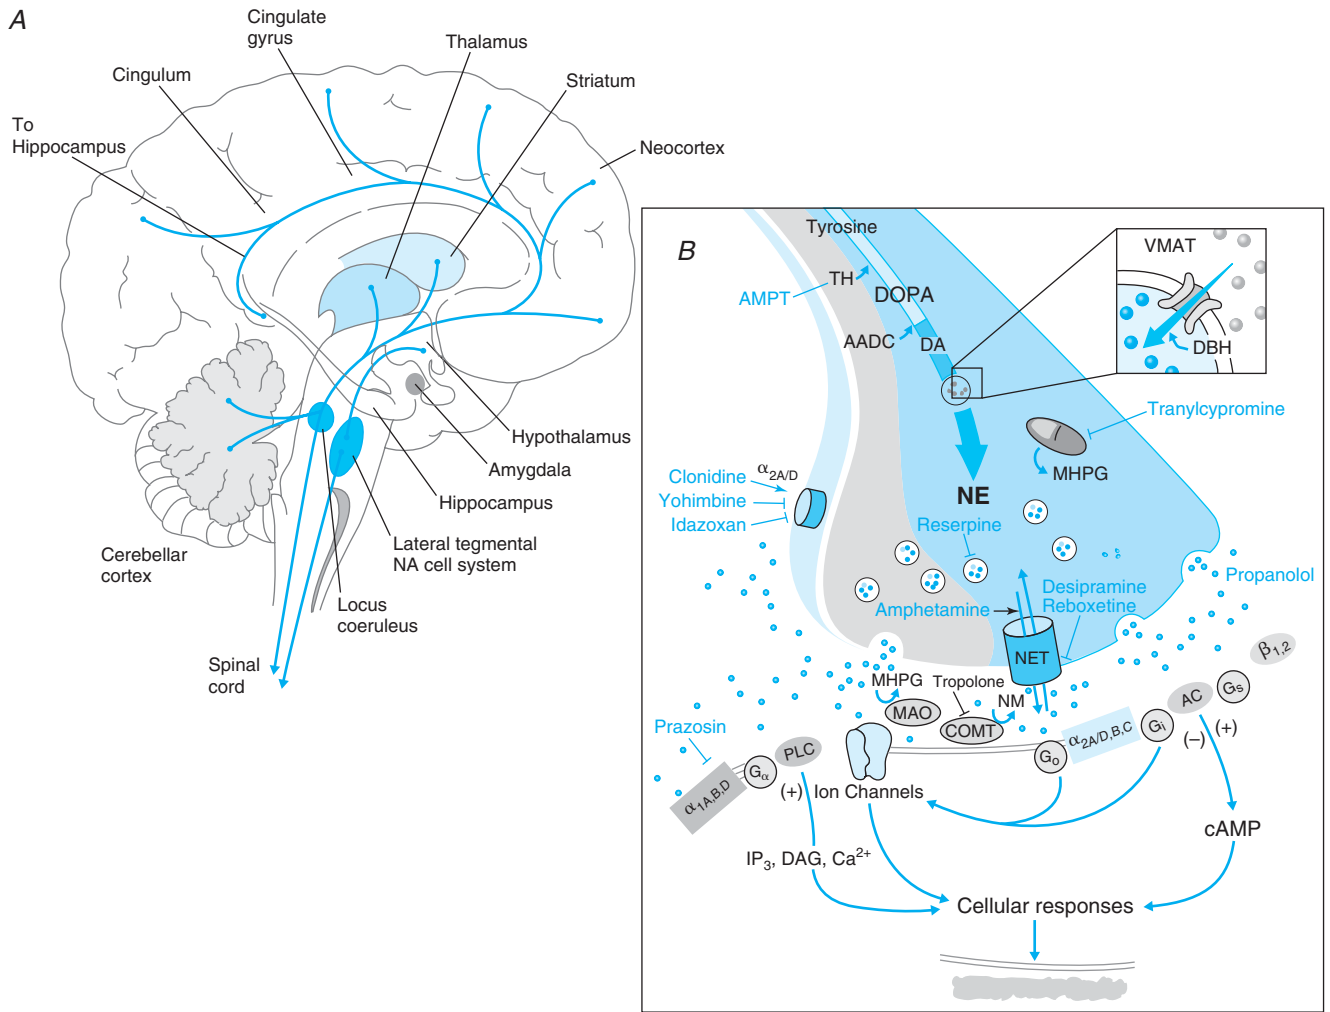

Figure 14–2. *A:* Gross anatomical relationships. *B:* The various regulatory processes involved in norepinephrine neurotransmission. The amino acid L-tyrosine is actively transported into presynaptic norepinephrine (NE) nerve terminals, where it is ultimately converted into NE. The rate-limiting step is conversion of L-tyrosine to L-dihydroxyphenylalanine (L-DOPA) by the enzyme tyrosine hydroxylase (TH). AMPT (α -methyl-para-tyrosine) is a competitive inhibitor of TH and has been used to assess the impact of reduced catecholaminergic function in clinical studies. Aromatic amino acid decarboxylase (AADC) converts DOPA to DA. DOPA then becomes decarboxylated by decarboxylase to form dopamine (DA). DA is then taken up from the cytoplasm into vesicles, by vesicular monoamine transporters (VMATs) and hydroxylated by DA β -hydroxylase (DBH) in the presence of O² and ascorbate to form NE. Normetanephrine (NM) is formed by the action of catechol-O-methyltransferase (COMT) on NE. NE can be further metabolized by monoamine oxidase (MAO) and aldehyde reductase to 3-methoxy-4-hydroxyphenylglycol (MHPG). Reserpine causes a depletion of NE in vesicles by interfering with uptake and storage mechanisms (depressive-like symptoms have been reported with this agent). Once released from the presynaptic terminal, NE can interact with a variety of presynaptic and postsynaptic receptors. Presynaptic regulation of NE neuron firing activity and release occurs through somatodendritic (not shown) and nerve terminal α_2 -adrenoceptors, respectively. Yohimbine potentiates NE neuronal firing and NE release by blocking these α_2 -adrenoceptors, thereby disinhibiting these neurons from a negative feedback influence. Conversely, clonidine attenuates NE neuron firing and release by activating these receptors. Idazoxan is a relatively selective α_2 -adrenoceptor antagonist primarily used for pharmacologic purposes. The binding of NE to G protein–coupled receptors, which are coupled to adenylyl cyclase (AC) and phospholipase C beta (PLC- β) produces a cascade of second messenger and cellular effects (see diagram). NE’s action is terminated in the synapse by rapidly being taken back into the presynaptic neuron through NE transporters (NET). Once inside the neuron it can either be repackaged into vesicles for reuse or it undergoes enzymatic degradation. The selective NE reuptake inhibitor and antidepressant reboxetine and older-generation tricyclic antidepressant desipramine are able to interfere with or block the reuptake of NE. Amphetamine is able to facilitate NE release by altering NET function. Note: Grey spheres = DA neurotransmitters; blue spheres = NE neurotransmitters. DAG = diacylglycerol; IP₃ = inositol (1,4,5) trisphosphate. (Source: Schatzberg and Nemeroff, 2004. Reprinted with permission from *The American Journal of Psychiatry*. gender-matched controls (Rudorfer et al., 1985). Depressed patients have been shown to produce an exaggerated release of NE in response to a variety of stressors, including orthostatic, cold pressor, and mental arithmetic stressors (Roy et al., 1985; Rubin et al., 1985; Veith et al., 1988).

Taken together, the studies of plasma NE provide strong evidence for dysregulation of peripheral release of NE in affective illness, with a difference in the pattern of dysregulation between unipolar and bipolar patients. Stated another way, bipolar patients appear to have reduced to average resting output of NE with a highly exaggerated NE response to standing, while unipolar patients (especially a subgroup of anxious, melancholic patients with dexamethasone non-suppression) have an average to elevated resting NE, with moderately exaggerated response to standing (and perhaps “stressors” in general) (Rudorfer et al., 1985; Potter and Manji, 1994). Whether these differences can be attributed to the difference in polarity or cyclicity cannot be known since the unipolar and bipolar groups were not matched for the frequency of recurrence.

As we reviewed in the first edition of this text, studies of plasma MHPG have yielded variable results and do not generally support the concept of a unipolar–bipolar distinction (Potter and Linnoila, 1989). Plasma MHPG in unipolar depressive patients tends to be similar to that of controls, albeit with greater variance (Siever and Uhde, 1984). Similar to the association with plasma NE, depressed dexamethasone-nonsuppressors have higher levels of plasma MHPG (Jimerson et al., 1983; Roy et al., 1986). Plasma MHPG levels tend to be lower in bipolar than in unipolar depressed patients (Siever, 1987; Goodwin and Jamison, 1990) and are higher in bipolar patients when manic than when depressed (Halaris, 1978; Jimerson et al., 1981; Maj et al., 1984) or euthymic (Maj et al., 1984).

Studies of Norepinephrine and MHPG in Cerebral Spinal Fluid

For some years, measures of NE and its metabolites in CSF were thought to directly reflect brain NE “activity.” This assumption is, however, problematic, since high correlations have been found between plasma and CSF NE and MHPG (Kopin, 1985; Goldstein et al., 1987). Pharmacological studies in dogs have revealed parallel changes in plasma and CSF NE following ganglion blockade, suggesting that sympathetic outflow may determine (at least in part) NE concentrations in both compartments (Goldstein et al., 1987). Plasma MHPG is the major source of CSF MHPG, which readily crosses the blood–brain barrier (Kopin, 1985). Given the high correlation between plasma and CSF MHPG observed in comparisons of high and low catecholamine output states, an equation has been derived to “correct” for the contribution of plasma MHPG to that of CSF (Kopin, 1985;

Goldstein et al., 1987). In the relatively narrow range of values observed in depressed patients and controls, however, such an equation is of questionable utility for identifying “brain MHPG” (Linnoila et al., 1986), and to date has not provided new insights in studies of depression.

Certain other methodological problems are unique to CSF measures. First, standards for obtaining spinal fluid, such as elapsed time between needle insertion and sample collection, have not been established. Therefore, subjects may not have the same degree of accommodation to the stress of the needle stick. Moreover, sampling at a single point in time may not reflect the biochemical process of depression or mania, but a state-dependent fluctuation from a recent external or internal stress.

CSF concentrations of NE have been reported to be elevated in depressed patients with an atypical presentation, higher scores for nurse-rated anxiety, and a longer duration of hospitalization (Post et al., 1984b). Earlier investigations showed that CSF NE is higher in mania than in depression (Post et al., 1978; Gerner et al., 1984). Moreover, in dysphoric mania, defined by the coexistence of high depression ratings, NE in CSF correlates modestly but significantly ($r \approx .5$) with ratings for dysphoria and anxiety but not with ratings for mania (Post et al., 1989). Post and colleagues suggest that CSF NE may be positively correlated with the degree of anxiety across a variety of psychopathologic syndromes, including depression, mania, and perhaps anxiety.

Reports suggest that CSF MHPG is lower in bipolar-I depressed patients than in unipolar patients, but as is the case for CSF NE, variables other than overall diagnosis may influence values (Potter et al., 1987). Thus, for instance, within a group of depressed patients, those with increased anxiety, agitation, somatization, and sleep disturbance were found to have significantly elevated levels of CSF MHPG (Redmond et al., 1986). CSF MHPG has been reported to be elevated in manic patients compared with controls (Post et al., 1984b; Redmond et al., 1986; Swann et al., 1986). In one study of mania, CSF MHPG concentration correlated with certain dysphoric elements of the manic syndrome—namely total manic severity and hostility (Swann et al., 1987). Moreover, this study found a significant reduction in CSF MHPG with lithium treatment, even when the treatment was unsuccessful.

Swann and colleagues have conducted the most comprehensive studies of catecholamine function in mania since publication of the first edition of this text. When they compared biogenic amines in mixed manic ($n=8$) and in pure and nonagitated bipolar depressed ($n=27$) inpatients, they found that MHPG was higher in CSF from mixed manic than that from agitated depressed patients (Swann et al., 1994). Moreover, patients in a mixed state had higher urinary excretion of NE and elevated output of NE relative to

its metabolites, suggesting that mixed manic patients combine certain biological abnormalities considered to be characteristic of both mania and depression.

More recently, the same group investigated relationships between performance on psychomotor tests of motor speed (reaction time and tapping speed) and visual tracking (trail making and dot placement) and catecholamine system function, including CSF or urinary concentrations of catecholamines or their metabolites (Swann et al., 1999). They found that both unipolar and bipolar depressed patients were impaired in motor speed, dexterity, and visual tracking, whereas manic and mixed patients did not differ from controls in these areas. Furthermore, increased catecholamine function correlated with slowing on all other measures for patients with bipolar disorder; relationships between catecholamines and psychomotor function were weaker in unipolar depressed subjects, and psychomotor function was related to severity of depression only in bipolar patients. These latter findings add to the data suggesting that catecholamine systems are associated with increased arousal and psychomotor impairment in patients with bipolar disorder (Goodwin and Ghaemi, 1998).

Taken together, findings from CSF studies of NE and its metabolite MHPG suggest that NE output is higher in mania than in depression and that there may be relatively higher values in unipolar than in bipolar depression. Relative elevation within patient groups may, in turn, be related to anxiety or the overall severity of the condition. As noted previously, it is possible that the CSF findings reflect events occurring in the sympathetic nervous system as much as those occurring in the brain. It is therefore not surprising that the pattern of findings is similar in CSF and plasma. Nevertheless, in some studies, CSF NE or MHPG was found to be correlated with dysphoric elements of the manic syndrome, while urinary measures tended to be associated with euphoric components (Swann et al., 1986; Post et al., 1989), suggesting that studies examining multiple measures and components of the noradrenergic system allow for the most meaningful interpretations.

Studies of Postmortem Brain

Numerous postmortem studies have investigated the role of monoaminergic functioning in major depressive disorder and suicide. Yet there has been a dearth of studies examining the status of monoamine transmitters in autopsy specimens from subjects specifically with bipolar disorder. A study by Young and colleagues (1994c) found that NE turnover (MHPG/NE ratio) was markedly elevated in autopsied frontal, temporal, and occipital cortex of individuals with an antemortem diagnosis of bipolar disorder. In comparison, serotonin (also known as 5-hydroxytryptamine [5-HT]) and dopamine (DA) turnover (5-hydroxy-indoleacetic acid

[5-HIAA]/5-HT and homovanillic acid [HVA]/DA, respectively) were found to be significantly reduced in temporal and occipital cortex, respectively. In an intriguing preliminary study, Baumann and colleagues (1999a) investigated a possible unipolar–bipolar dichotomy by performing a morphological comparison of the locus coeruleus (LC) obtained postmortem. They found that bipolar patients ($n=6$) had significantly more neurons on both sides of the LC as a whole than did patients with unipolar depression ($n=6$). Furthermore, topographical analysis revealed that this difference was restricted to the rostral two-thirds and the dorsal portion of the LC, in which bipolar patients showed at least a trend to higher neuron numbers than those of unipolar patients or controls. However, as is characteristic of most unipolar–bipolar comparisons, the two groups were not matched for frequency of recurrence, so that one cannot know whether the differences reflect a difference in polarity or cyclicity.

Studies of Norepinephrine and Its Metabolites in Urine

Since the catecholamine hypothesis of affective disorders was proposed, attempts to characterize the output of the noradrenergic system in depressed patients have focused on measurements of MHPG in urine more than any other single parameter (Potter et al., 1987; Filser et al., 1988). These studies were fueled (at least to some extent) by early data interpretations suggesting that about 50 percent of MHPG in urine was derived from the CNS. However, subsequent work indicated that MHPG readily crosses the blood–brain barrier to the CSF; earlier estimates of the CNS contribution to urinary MHPG have thus been revised to approximately one-third their original values (see Kopin, 1985).

The conclusions in the literature vary, but some authors emphasize that there is (albeit modestly) decreased 24-hour urinary excretion of MHPG in depressed patients compared with that of controls. Also with regard to urinary excretion of MHPG, unipolar depressed patients are more heterogeneous than bipolar-I patients (Maas, 1972). When one examines the studies more closely, it appears that the reduced excretion of MHPG is accounted for exclusively by bipolar patients—although a more recent study, in which subsequent patients in the same center were examined, does not replicate this finding, perhaps suggesting a change in the patient population over time (Grossman and Potter, 1999). Moreover, reduced urinary MHPG may be present only in bipolar-I and not in bipolar-II patients (Mussettola et al., 1984; Schatzberg et al., 1989), with MHPG levels in the former group being similar to those of patients with unipolar depression (Schatzberg et al., 1989). Patients with unipolar depression generally have greater urinary MHPG concentrations than those of bipolar-I patients. Average urinary MHPG is not reduced in unipolar

populations taken as a whole; rather, there may be a subgroup of such patients who have elevated MHPG compared with that of controls and bipolar subjects (Schatzberg et al., 1982). Furthermore, pretreatment levels of urinary MHPG have correlated with improvement in manic syndrome scores (Swann et al., 1999). Consistent with an overall activation of the noradrenergic system during mania, manic patients also exhibit significantly increased urinary concentrations of NE compared with those of depressed patients or control subjects (Swann et al., 1987).

Low levels of urinary MHPG in depressed patients have been reported to approach normal values with clinical improvement, thus this measure may be state-dependent (Pickar et al., 1978). Similarly, longitudinal studies of bipolar patients suggest increased MHPG excretion in manic compared with depressed states (Post et al., 1984b; Potter et al., 1987). It has also been noted that manic patients responding to lithium have decreased MHPG and increased NE excretion relative to the total excretion of NE and its metabolites, a finding suggesting that lithium response is associated with an alteration of catecholamine metabolism pathways (Swann et al., 1987). Overall, however, urinary MHPG by itself has not proven to be a sufficiently robust and consistent measure to warrant general acceptance as a useful tool in diagnosis or in prediction of treatment response (Davis and Bresnahan, 1987).

Subsequent investigators have attempted to go beyond the “too little or too much” hypotheses of affective disorders. One approach has been to measure the 24-hour concentrations of urinary catecholamines and their metabolites in an effort to identify possible abnormalities in the relative activity of NE metabolic pathways in depression and mania. Since all major metabolites are measured, 24-hour urinary measures of NE and its metabolites can account for differences among individuals in the relative metabolism of NE, as well as its turnover (amount formed and excreted per 24 hours at steady state) (Manji and Lenox, 1994, 1998).

Consistent with the findings of elevated basal and/or stress-induced plasma NE, several investigators have observed elevated urinary excretion of NE and its major extraneuronal metabolite, normetanephrine (NMN), in depressed patients (Roy et al., 1985, 1986, 1988; Maas et al., 1987; Davis et al., 1988). Moreover, this finding appears more impressive when the excretion of NE and NMN in depressed patients is examined relative to total NE excretion. Thus in the study by Maas and colleagues (1987), a modest increase in total urinary catecholamine excretion (16 percent) was accompanied by marked increases in urinary NE (57 percent) and NMN (42 percent) in depressed patients. These results suggest a shift toward extraneuronal metabolic pathways and are consistent with findings suggesting increased NE release and “spillover” in depression.

More recently, Grossman and Potter (1999) compared the urinary excretion of NE, NMN, MHPG, and vanillylmandelic acid (VMA) in age- and gender-matched unipolar and bipolar depressed patients with that of healthy volunteers hospitalized in an inpatient unit at the National Institute of Mental Health (NIMH). Only depressed subjects with a minimum 4-week drug-free period were included. Total turnover (NE + NMN + MHPG + VMA) was reduced in these patients. In contrast with previous reports, MHPG concentration did not distinguish unipolar from bipolar depressed patients and was not significantly different from that in healthy volunteers. A construct of the average fractional extraneuronal concentration of NE (NE + NMN/NE + NMN + MHPG + VMA) was significantly higher in unipolar and bipolar depressed patients than in healthy volunteers. These findings, which suggest that both unmedicated unipolar and bipolar depressed patients have a “hyperresponsive” noradrenergic system, provide a framework linking plasma and urinary findings. Interestingly, total turnover of NE (NE + NMN + MHPG + VMA) was significantly lower in both unipolar and bipolar depressed patients than in healthy volunteers, suggesting a reduction of tyrosine hydroxylase (TH) activity in sympathetic neurons; these findings are noteworthy in view of lithium's effects on TH (see below).

The relationship between sympathoadrenal and HPA axis activity has also been investigated in patients with unipolar depression. Some investigators (Schatzberg et al., 1989) but not all (Maes et al., 1987) have reported significant positive correlations between urinary cortisol and urinary MHPG concentrations in depressed patients. A similar positive correlation has been reported for plasma cortisol and epinephrine concentrations (Stokes et al., 1981). Previous studies examining the levels of CSF NE and CSF corticotropin-releasing hormone (CRH) receptor found normal, reduced, and increased levels (Nemeroff et al., 1984b; Roy et al., 1988; Potter and Manji, 1994; Geraciotti et al., 1997). Subsequently, Wong and colleagues (2000) found that around the clock, patients with melancholic depression had elevated levels of CSF NE and plasma cortisol, but not CSF CRH or plasma adrenocorticotrophic hormone (ACTH).

In summary, although the data suggest that measures of catecholamines in CSF, plasma, and urine have provided important information, these types of studies have fallen into disuse over recent years. Rather, there has been a steady shift toward the use of less invasive, *in vivo*, high-resolution methods (functional magnetic resonance imaging [MRI], positron emission tomography [PET], and single photon emission computed tomography [SPECT]). Yet while some progress has been made in visualizing specific molecules, such as receptors and transporter sites, these brain imaging

modalities do not yet permit detailed examination of brain biochemistry.

Clinical Studies of Adrenergic Receptors

The future development of selective receptor ligands for PET studies may eventually permit the direct assessment of CNS adrenergic receptors in humans. To date, studies of NE receptors in affective disorders have been limited to indirect research strategies. Two strategies are most commonly used: (1) characterization of receptor number and function in readily accessible blood elements, and (2) pharmacological challenge strategies whereby alterations in biochemical, neuroendocrine, cardiovascular, or behavioral parameters in response to various receptor agonists and/or antagonists are measured.

Receptors on Blood Cells. Because of the accessibility of platelets and lymphocytes, both α_2 and β_2 adrenergic receptors have been studied extensively in affective disorders, and elaborate hypotheses about CNS adrenergic receptor dysfunction have been generated solely on the basis of such studies. There are several problems with the assumption that changes in adrenergic receptors on peripheral cells reflect similar alterations in the CNS.⁴ This caveat notwithstanding, we now turn to a discussion of adrenergic receptors in manic-depressive illness.

α_2 -Adrenergic Receptors. Numerous studies have measured the binding of α_2 -agonist or -antagonist ligands to platelets obtained from patients with affective illness and normal individuals. Yet while human platelets and cerebral cortex contain homogeneous populations of the same α_{2A} receptors (Bylund et al., 1988), radioligand studies across groups are confounded by numerous methodological problems, such as patient populations that vary in gender, age, frequency of recurrence, and current clinical state, as well as differing drug washout periods and assay techniques (see Piletz et al., 1986).

A review of 13 studies using yohimbine-alkaloid radioligands revealed no significant differences in the B_{MAX} of platelet α_2 -adrenergic receptors between depressed patients and controls (see Kafka and Paul, 1986; Piletz et al., 1986; Katona et al., 1987). Most studies using partial or full agonists, however, have observed increased B_{MAX} in the platelets of depressed patients compared with controls (Garcia-Sevilla and Fuster, 1986; Pandey et al., 1989; Garcia-Sevilla et al., 1990; Piletz et al., 1990). These results have frequently been interpreted as evidence for the α_2 hypersensitivity theory of depression (Garcia-Sevilla et al., 1986b, 1990; Piletz et al., 1990). Yet these studies have used the imidazoline compounds clonidine, para-aminoclonidine (PAC), and UK-14,304 as radioligands, and it is now known that these ligands also bind to imidazoline sites (Bousquet

and Feldman, 1987; Michel et al., 1990). In one of the few studies of bipolar disorder, bipolar depressed patients were found to show a trend toward a higher density of α_2 -adrenergic receptors (Karege et al., 1992). In this study, platelet α_2 receptor measures were related to plasma MHPG. Moreover, stress-induced desensitization of α_2 -adrenergic receptors in human platelets (Freedman et al., 1990), accompanied by significant increases in plasma catecholamines and subjective anxiety, suggests that the circulating environment may be the prime determinant of platelet α_2 numbers.

In general, direct study of CNS adrenergic receptors has been limited to comparison of receptor density and affinity in suicide victims (generally unipolar depressive patients) and "appropriate controls." Notwithstanding the numerous methodological pitfalls associated with the study of postmortem tissues (e.g., postmortem delay, cause of death, morbid and premorbid drug history), preliminary data indicate alterations in the density and/or affinity of β - and possibly α_2 -adrenergic receptors in depressed suicide victims. Similar to the findings observed in platelets, there are elevations in the binding of the imidazolinic " α_2 ligands," such as clonidine and UK-14,304 (Meana and Garcia-Sevilla, 1987). Whether these sites represent α_2 receptors or imidazoline sites remains to be established, however, although more recent data indicate that both classes of receptors and sites are elevated (Garcia-Sevilla et al., 1996).

β -Adrenergic Receptors. It is now well documented that different classes of antidepressants, when administered chronically, desensitize β -adrenergic receptors (Banerjee et al., 1977; Sulser 1978; Bergstrom and Kellar, 1979). Thus peripheral β receptors, if they indeed mirror changes in central β -adrenergic receptors, would clearly represent useful tools for defining the role of β -adrenergic receptors in depressive illness and in the effects of treatment. However, alterations in β -adrenergic receptor density in rat brain induced by antidepressants appear to be restricted to the β_1 subtype (Minneman et al., 1979), while human mononuclear leukocytes (MNLs) contain only the β_2 subtypes (Meurs et al., 1982).

Despite these caveats, several groups have investigated the density of β -adrenergic receptors in untransformed lymphocytes or leukocytes of untreated or treated mood disorder patients, with fairly inconsistent results. Some report a decrease in numbers of β -adrenergic receptors in depressed patients,⁵ whereas others describe an increase or no change in comparison with healthy volunteers.⁶

In contrast to the inconsistent results of binding studies described above, most studies measuring MNL β -adrenergic receptor-stimulated adenylyl cyclase (AC) activity have found decreased responsiveness in depressed

patients compared with that in healthy volunteers.⁷ The consistently observed decrease in leukocyte β -adrenergic receptor function in depression could reflect an inherited abnormality of the β -adrenergic receptor/(Gs)/AC complex, as suggested by the findings of a study by Wright and colleagues (1984) using Epstein-Barr virus (EBV)-transformed lymphocytes from manic-depressive patients and controls. However, these findings need to be replicated and a number of additional confounding factors considered (Werstiuik et al., 1990; Manji et al., 1997a).

In another study, Kay and colleagues (1993, 1994) examined β -adrenergic receptor binding and AC activity in lymphoblast cell lines established from 12 patients with bipolar disorder and 10 unrelated healthy controls. The use of immortalized lymphoblasts offers the theoretical advantage of being able to grow the cells for several months away from the potentially confounding effects of circulating factors (catecholamines, hormones, drugs); thus the cells are presumed to reflect closely the individual's genetic contribution to the receptor system in question. It should be noted, however, that the immortalized cells are not "normal," and display a markedly altered β -receptor density relative to fresh, circulating lymphocytes. Nevertheless, unless the immortalization process affects the patients' lymphocytes differently from those of the controls, the model can be used to provide useful information. In Kay and colleagues' study, no significant differences were found in [¹²⁵I] iodocyanopindolol binding affinity or capacity or in β -adrenergic receptor agonist-stimulated cyclic adenosine monophosphate (cAMP) response. As expected, incubation of lymphoblasts with a β -adrenergic receptor for 24 hours prior to assay reduced both the number of receptors and adenylyl cyclase activity. There was significantly less receptor downregulation in cells of bipolar patients, suggesting that agonist downregulation of receptor number may be less efficient than in control cells. Although these results are clearly quite preliminary, they are intriguing because the inability to downregulate receptors in the face of excessive stimulation has been postulated as representing a fundamental defect in bipolar disorder.

Initial measurements of these β -adrenergic receptors in postmortem brain tissue from mood disorder patients (\pm individuals who committed suicide) have yielded mixed results. Biegon and Israeli (1988) reported a significant, 50 percent increase in β -adrenergic receptor density in prefrontal cortical homogenates in postmortem brain tissue of suicide victims. They noted that the increased binding was selective, appearing in some cortical regions but not in basal ganglia or white matter areas. Mann and colleagues also found increased β -adrenergic receptor density in the postmortem brain tissue of suicide victims (Arango et al., 1990; Mann et al., 1986). However, Crow and colleagues

(1984) demonstrated decreased density of hippocampal β -adrenergic receptor in the postmortem brain tissue of depressed patients who had been hospitalized. In this latter group, previous antidepressant treatment may have induced β -adrenergic receptor downregulation.

Pharmacological Challenge Strategies

Pharmacological challenge paradigms, which employ agents known to stimulate receptor sites directly or indirectly, have been used extensively to test pathophysiological hypotheses about noradrenergic dysfunction in affective illness (Siever, 1987). The α_2 -adrenergic agonist clonidine (which may also exert effects at imidazoline sites; see above) has been administered to depressed patients, and the responses of plasma MHPG, blood pressure, heart rate, sedation, growth hormone (GH), and cortisol have been measured. Clonidine-induced decreases in plasma MHPG have been found to be somewhat more marked (Siever et al., 1984) or unchanged (Charney et al., 1983) when using oral or intravenous (IV) clonidine, respectively. Similarly, the plasma MHPG response to yohimbine (an α_2 -adrenergic antagonist) is unchanged in depressed patients (Heninger et al., 1988). Price and colleagues (1986) reported that the cortisol response to yohimbine was significantly greater in depressed patients than in controls despite similar MHPG responses between groups. Clonidine-induced decreases in blood pressure and increases in sedation have been found to be not significantly different in depressed patients compared with normal controls (Checkley et al., 1981; Charney et al., 1982). Similarly, responses of cortisol and ACTH to acute clonidine administration in depressed patients vary, with levels increased, decreased, or unchanged (Siever, 1987).

In contrast, a series of studies has consistently shown a significantly reduced GH response to clonidine (presumably mediated by postsynaptic hypothalamic α_2 -adrenergic receptors) in depressed patients.⁸ These findings generally have been interpreted as evidence for subsensitive central postsynaptic α_2 -adrenergic receptors in depression, perhaps secondary to elevations in NE.

A much smaller number of studies have investigated the GH response to adrenergic challenge in bipolar disorder. Ansseau and colleagues (1987) investigated the GH response to clonidine in seven manic patients who had been medication-free for 3 months, age- and gender-matched to seven inpatients with major depression and seven with minor depression inpatients who had been drug-free for at least 2 weeks. Both the manic patients and those with major depression showed a blunting of the GH response relative to patients with minor depression. Additionally, Dinan and colleagues (1991) reported a significant blunting of the desipramine-induced GH release in medication-free

manic patients ($n=7$) compared with controls. Finally, in a longitudinal study of a single 64-year-old rapidly cycling patient, Gann and colleagues (1993) reported that GH secretion after clonidine stimulation was blunted on depressed and hypomanic days. It is now clear, however, that this response is not specific to depression and mania, since a blunted GH response to clonidine has been reported in patients with panic disorder (Charney and Heninger, 1986; Uhde et al., 1986; Nutt, 1989), generalized anxiety symptoms, and obsessive-compulsive disorder (Siever et al., 1983). Thus, a blunted α_2 -adrenergic response may be observed in any condition characterized by tonic or episodic abnormally elevated central NE.

Catecholamine Depletion Challenges

Additional evidence for noradrenergic dysfunction in the pathophysiology of depression comes from studies that use α -methylparatyrosine (AMPT) to deplete central NE stores (Miller et al., 1996). In these studies, administration of AMPT to depressed patients who had been successfully treated with desipramine or mazindol (both of which are NE uptake inhibitors) resulted in a rapid return of depressive symptoms. Interestingly, administration of AMPT to depressed patients did not worsen the core symptoms of depression but did cause worsening of some neurovegetative symptoms, in particular anergia and tiredness. Even more interesting is a study that investigated the effects of AMPT on lithium-treated, euthymic bipolar patients (Anand et al., 1999). Intriguingly, the authors did not observe any mood-lowering effects of AMPT, but did observe a “rebound hypomania” in a significant percentage of the patients. Although preliminary, these results are compatible with the notion of a dysregulated signaling system in which the compensatory adaptation to catecholamine depletion results in an “overshoot” due to impaired homeostatic mechanisms. We come back to this study in our discussion of dopamine below.

Lithium and the Noradrenergic System

In view of the long-standing interest in the role(s) of the noradrenergic system in manic-depressive illness, it is not surprising that extensive research has been conducted on lithium's effects on that system. Overall, lithium's effects on NE appear to be temporally and brain region-specific.⁹

Use of both acute and chronic lithium has been reported to increase (Schildkraut et al., 1966, 1969) or not to change (Ho et al., 1970; Ahluwalia and Singhal, 1980) the turnover of NE in some but not all regions of the brain. As is the case with the other neurotransmitters (see below), effects of lithium on NE receptor binding in studies in rodent brain have generally been inconclusive (Treiser and Kellar, 1979;

Maggi and Enna, 1980; Schultz et al., 1981). However, significant effects have been consistently observed on β AR-mediated cAMP accumulation, with lithium inhibiting the response both in vivo and in vitro (discussed in detail below). Lithium is unable to block antidepressant-induced β -adrenergic receptor downregulation (Rosenblatt et al., 1979) and in fact produces a greater subsensitivity (cAMP response) (Mork et al., 1990), but it does prevent reserpine or (6-OHDA)-induced β AR supersensitivity (Pert et al., 1978; Treiser and Kellar, 1979; Hermoni et al., 1980).

Additional data from preclinical and clinical studies suggest that lithium treatment results in subsensitive α_2 receptors.¹⁰ In preclinical studies, long-term lithium was found to attenuate α_2 -adrenergic-mediated behavioral effects (G. Goodwin et al., 1986a; Smith, 1988) and presynaptic α_2 inhibition of NE release (Moises et al., 1986), while enhancing (K^+)-evoked NE release (Ebstein et al., 1983). While lithium has been reported to reduce high-affinity platelet [³H] clonidine binding (Wood and Coppen, 1983; Garcia-Sevilla et al., 1986b; Pandey et al., 1989), compatible with a functional “uncoupling” of the receptor from the G protein (Kim and Neubig, 1987; Neubig et al., 1988), interpretation of these data is confounded by the coexistence of the imidazole binding site discovered later.

In clinical investigations, both increases and decreases in plasma and urinary NE metabolite levels have been reported after lithium treatment.¹¹ Lithium has been reported to reduce excretion of NE and metabolites in manic patients while increasing excretion in depressed patients, associated with higher plasma NE concentrations in some cases.¹² As discussed earlier, however, there is evidence that urinary excretion of MHPG is low during bipolar depression and elevated during mania/hypomania.¹³ In part, these inconsistencies may be related to the inability to control adequately for state-dependent changes in affective states, with associated changes in activity level, arousal, and sympathetic outflow. Subsequent studies have demonstrated that 2 weeks of lithium administration in normal subjects results in increases in urinary NE and NMN, fractional NE release, and a trend toward significantly increased plasma NE, suggesting an enhanced neuronal release of NE (Manji et al., 1991a). These data are compatible with similar observation of increased levels of plasma dihydroxyphenylglycol (DHPG), a major extraneuronal NE metabolite (Poirier-Littre et al., 1993), raising the possibility that lithium may regulate (TH) (discussed later).

Thus current evidence supports lithium's action in facilitating the release of NE, possibly through effects on the presynaptic α_2 “autoreceptor” and through upregulation of TH, while concurrently reducing the β -adrenergic-stimulated AC response. This action may contribute to lithium's attenuation of the euphorogenic effects of amphetamine.

Carbamazepine and the Noradrenergic System

Carbamazepine's effects on noradrenergic metabolism are complex, including decreases in NE turnover (Maitre et al., 1984), weak reuptake blockade (Purdy et al., 1977), and, contrary to the action of most other putative antidepressant substances, upregulation rather than downregulation of β_2 adrenergic receptors following chronic administration (G. Chen et al., unpublished results). Similar to antidepressants and lithium, however, carbamazepine decreases β_2 adrenergic receptor-stimulated AC activity, an effect due largely to direct inhibition of the catalytic subunit of AC (Chen et al., 1996b). Parenthetically, this effect could account for carbamazepine's atypical antidepressant properties in some patients, including those who are unresponsive to more traditional tricyclic and related compounds.

Carbamazepine's effects on noradrenergic metabolism are nonetheless intriguing from several perspectives. For one thing, determining which actions of carbamazepine are important to its antimanic effects, including its ability to decrease stimulated-induced release of NE as well as inhibit NE turnover, remains an open issue (Waldmeier et al., 1984; Post et al., 1985). It is of considerable interest that while noradrenergic tone is necessary to carbamazepine's anticonvulsant effects in some models (Quattrone and Samanin, 1977; Quattrone et al., 1978; Crunelli et al., 1979), it is unnecessary in others (Quattrone et al., 1981). The α_2 -adrenergic agonist clonidine blocks the anticonvulsant effects of carbamazepine on electroconvulsive shock (the animal model of ECT) (Crunelli et al., 1979; Fischer and Muller, 1988), while the α_2 -adrenergic agonist yohimbine blocks carbamazepine's effects on amygdala-kindled seizures (Weiss et al., 1993). Thus it is clear that even when a putative biochemical effect of the drug is linked to its mechanism of action in one type of seizure or psychiatric syndrome, this may not be the case for all the subcategories and subtypes of that syndrome. However, Post and colleagues (1985) found no changes in plasma or CSF NE or MHPG with carbamazepine treatment in affectively ill patients.

Valproate and the Noradrenergic System

Few studies have directly investigated the effects of valproate on the NE system. Khaitan and colleagues (1994) found that chronic (21 days of treatment in rats with valproate) did not significantly alter the density of β_2 adrenergic receptors in rat cortex. By contrast, Chen and colleagues (1996a) found that chronic (6-day) incubation of C6 glioma cells with valproate (.5 mM) resulted in a 33 percent reduction in B_{MAX} and a marked and selective 41 percent reduction in β_1 without having any significant effects on β_2 . Chronic (6-day) incubation of C6 cells with

valproate (.5 mM) also was found to markedly attenuate isoproterenol-stimulated cAMP production in intact cells at a rate of approximately 50 percent.

In a more recent study, Sands and colleagues (2000) examined changes in mRNA expression for TH, the NE transporter (NET), and the α_{2A} autoreceptor in rat LC after treatment with valproate. TH mRNA increased slightly (16 percent) following acute treatment, and more so after chronic valproate treatment (26 percent), while neither NET nor α_{2A} mRNA expression changed. Further, chronic valproate treatment attenuated the elevation in TH mRNA expression induced in the LC in response to acute restraint. This result is quite consistent with those of Manji and colleagues (unpublished observations). They investigated the effects of chronic valproate on TH protein levels and found that chronic administration of valproate increased TH protein levels in human neuroblastoma cells in vitro and in rat frontal cortex and hippocampus ex vivo.

The Noradrenergic System in Manic-Depressive Illness: Summary

Considerable evidence suggests that depressed patients excrete disproportionately greater amounts of NE and its major extraneuronal metabolite, NMN, relative to total catecholamine synthesis compared with controls. This is particularly true of melancholic unipolar depressed subjects, but more recent data suggest that under adequately controlled (>4 weeks) study, drug-free bipolar depressed subjects may exhibit a similar dysregulation of the noradrenergic system. At least with regard to mania, the original catecholamine hypothesis has withstood the test of time, with increased noradrenergic function consistently observed in mania, although this finding may ultimately reflect a secondary effect. The intriguing recent findings that CSF and urinary NE measures may be associated with the dysphoric and euphoric components of the manic syndrome, respectively, deserve further investigation and suggest that something other than mania per se may be producing the changes. Findings of increased fractional urinary output of NE and NMN and of an exaggerated rise in plasma NE upon orthostatic challenge in depressed unipolar and bipolar patients are compatible with findings of increased "leakiness" of presynaptic NE terminals (Esler 1982; Veith et al., 1985). Boxes 14-2 and 14-3 summarize overall major findings and findings of newer studies supporting the involvement of the noradrenergic system in the pathophysiology and treatment of bipolar disorder and recurrent unipolar depression.

The Dopaminergic System

It is perhaps surprising that the role of the dopaminergic system in the pathophysiology of manic-depressive illness

BOX 14–2. A Summary of Major Findings Supporting Involvement of the Noradrenergic System in the Pathophysiology and Treatment of Bipolar Disorder and Recurrent Unipolar Disorder

- CSF, urinary NE, and MHPG: Mania > depression in BP; UPd > BPd
- Plasma NE: Basal levels: BPd < N < UPd (for UPd, especially melancholic, DST+ve)
- Plasma NE: Upon challenge: BPd > UPd > N
- CSF NE: Correlated with dysphoric symptoms and severity in bipolar patients
- Effects of AMPT: Reversal of antidepressant effects in unipolar patients, but “rebound hypomania” in lithium-treated bipolar patients
- Blunted growth hormone response to α_2 agonists and increases in platelet α_2 binding density (most studies in recurrent UP, but likely to occur in both BP and UP)
- Antidepressant efficacy of agents whose biochemical effects include increasing NE
- Agents that increase NE release or block reuptake are capable of triggering mania
- Effective antidepressant treatments generally reduce NE turnover (even those whose primary biochemical target is not the NE system)
- Antidepressant and lithium reduce β adrenergic receptor density and/or function (cAMP formation) in limbic and limbic-related areas of rat brain

α -methyl paratyrosine; BPd = bipolar depressed; CSF = cerebrospinal fluid; DST+ve = dexamethasone nonsuppressors; MHPG = 3-methoxy-4-hydroxyphenylglycol; N = normal; NE = norepinephrine; UP = unipolar patients; UPd = unipolar depressed.

has not received greater study, since it represents a prime candidate on a number of theoretical grounds. For example, the opposite motoric changes seen in the bipolar subgroup are perhaps the most defining characteristics of the illness, ranging from near catatonic immobility to the profound hyperactivity of manic states. Similarly, loss of motivation is one of the central features of depression, while anhedonia and “hyperhedonic states” are among the most defining characteristics of bipolar depression and mania, respectively. In this context, it is noteworthy that the mid-brain dopaminergic system is known to play critical roles in regulating not only motoric activity but also motivational and reward circuits. It is clear that motivation and motor function are closely linked, and that motivational variables can influence motor output both qualitatively and quantitatively. Furthermore, there is considerable evidence that the mesolimbic dopaminergic pathway plays a crucial role in the selection and orchestration of goal-directed behaviors, particularly those elicited by incentive stimuli.

CSF Homovanillic Acid Levels

It should be noted that of the three monoamine neurotransmitters evaluated most extensively in preclinical studies, two—serotonin and DA—have been studied in depressed patients almost exclusively in terms of concentrations of their respective metabolites, 5-HIAA and HVA (the major DA metabolite), in CSF. Under carefully controlled conditions, the neurotransmitter metabolites will, in part, reflect relative differences in the output and metabolism of DA and serotonin in those brain regions that contribute the most to CSF concentrations. In humans, however, the relative contributions of different brain areas are not well understood. Moreover, it is really not possible to study the responsiveness of 5-HT and DA neuronal systems with a single-point measure of transmitter metabolite in CSF; at most, longer-term changes can be reflected in CSF studies. Thus, CSF studies of 5-HIAA and HVA in untreated depressed patients can identify some relative differences but cannot directly address the source of any alteration, even to the extent of distinguishing changes of output from those of metabolism and/or elimination.

When considering actual studies, it is also important to recognize that limitations of assay methodology make it difficult to be confident about many earlier studies. The technique of performing two lumbar punctures within a few days of each other, before and after the administration of probenecid to block the active acid transport of 5-HIAA and HVA out of CSF, was an ingenious approach to obtaining an estimate of 5-HT and DA function and release (that is, the amount of accumulation of 5-HIAA and HVA between the period of probenecid administration and the lumbar tap). Such probenecid-induced accumulations sometimes revealed group differences not seen when so-called baseline measures were used (Goodwin et al., 1973). Findings of lower levels of DA metabolite, HVA in CSF, and increased peripheral prolactin levels under both basal and challenge conditions in depressed patients indicated hypofunction of DA in the brain (Willner, 1995; Nicholas et al., 1998).

The strongest finding from clinical studies implicating DA in depression is reduced HVA in CSF; indeed, this is one of the most consistent biochemical findings in depression (Goodwin and Sack, 1974; Asberg et al., 1984; Manji et al., 1995b). There is also evidence for a decreased rate of CSF HVA accumulation in subgroups of depressed patients, including those with marked psychomotor retardation compared with patients with agitation. (Willner, 1983). Furthermore, low levels of HVA may be associated with cognitive impairment in both depressed patients and patients suffering from Parkinson’s disease (Wolfe et al., 1990).

BOX 14-3. Newer Studies Supporting Involvement of the Noradrenergic System in the Pathophysiology and Treatment of Manic-Depressive Illness (Primarily Bipolar)

Genetic Studies

- COMT low-activity allele (MET 158; COMTL) reported to be a risk factor to BPD (Li et al., 1997; Rotondo et al., 2002)
- COMT low-activity allele showed a tendency to be transmitted among female BPD probands (Mynett-Johnson et al., 1998)
- Increased presence of COMT LL (low-activity allele) in BPD ultrarapid cycling (Kirov et al., 1998; Papolos et al., 1998)
- Apparent association between COMT 158val (low-activity allele) in velocardiofacial syndrome and ultrarapid cycling (Lachman et al., 1996)
- Tyrosine hydroxylase gene variant subjects (TH*2/2) have lower depressive scores in mood disorder patients (Serretti et al., 1998)
- Decrease in depressive symptoms in mood disorder patients when tyrosine hydroxylase (TH) *2/2 gene is present (Serretti et al., 1998)
- Weak association between TH gene with BPD (Perez de Castro et al., 1995)
- Dopa decarboxylase gene reported to be a minor susceptibility gene for BPD (odds ratio 1.48 patients vs. control) (Borglum et al., 1999)

Norepinephrine and its Metabolites

<p>Clinical</p> <p>α_2-AR</p>	<ul style="list-style-type: none"> • Valproate reduces β-adrenergic receptor density and/or function (cAMP formation) in C6 glioma cells; in vivo data not available (Chen et al., 1996a) • Idaxozan, an α_2 antagonist, shown to have efficacy in treatment of BPD in small studies (Grossman and Potter, 1999) • Clonidine, an α_2 agonist, shown to have efficacy in treatment of acute mania in small studies (Bakchine et al., 1989; Kontaxakis et al., 1989; Diaciov and Tudorache, 1990; Tudorache and Diaciov 1991) 	<p>β-AR</p> <ul style="list-style-type: none"> • Increased α_2-adrenoreceptor sensitivity with CBZ in BPD (Dilsaver et al., 1993) • Increased (trend) density of α_2-adrenoreceptor in platelet in bipolar depressed patients (Karege et al., 1992) • Increased cortisol and GH in bipolar depression in single rapid-cycling case, normalized with valproate treatment (Juckel et al., 2000) • Decreased melatonin levels during light night in BP-I patients (β-adrenoreceptor mediated?) (Nurnberger et al., 2000)
---	---	---

AR = adrenoreceptor; BPD = bipolar disorder; BP-I = bipolar-I; CBZ = carbamazepine; COMT = catechol-O-methyltransferase; CSF = cerebrospinal fluid; DA = dopamine; GH = growth hormone; LC = locus coeruleus; MHPG = *s*-methoxy-4-hydroxyphenylglycol; NE = norepinephrine; NMN = normetanephrine; VMA = vanillylmandelic acid.

By contrast, levels of HVA in the CSF of manic patients have been found to be increased compared with controls in four studies and not significantly different in three studies. When manic patients are compared with depressed patients, the results are more consistent: five studies of bipolar depressed patients found higher HVA in mania, and one other yielded insufficient data to make this comparison. These studies confirm the evidence from older studies with mixed depressed groups.

The Dopaminergic System and the Switch Process

There is arguably the strongest pharmacological support for the dopaminergic system among all the neurotransmitter systems with regard to potential involvement in the switch process to hypomania/mania:

- The DA precursor L-dopa almost uniformly produces hypomania in bipolar patients (Goodwin et al., 1970; Murphy et al., 1971; Van Praag and Korf, 1975).
- Amphetamine, which promotes DA release and inhibits its uptake, can precipitate hypomania in bipolar patients and induce a hypomania-like state in normal people (Jacobs and Silverstone, 1986), but is generally not considered an antidepressant in unipolar patients (Goodwin and Sack, 1973).
- The direct DA agonists bromocriptine and piribedil appear to be effective antidepressants in some bipolar patients and capable of precipitating mania (Gerner et al., 1976; Silverstone, 1978, 1984). Interestingly, antidepressant response to piribedil has been associated with low pretreatment levels of HVA in CSF (Post et al., 1978).
- Neuroleptics that selectively block DA receptors (such as pimozide) are effective against severe mania.

Catecholamine Depletion Strategies

Earlier we described the work of Anand and colleagues (1999) who examined the effects of catecholamine depletion with AMPT in lithium-treated euthymic bipolar subjects. The rebound hypomania noted earlier was not associated with changes in iodobenzamide (IBZM) binding, suggesting that the “overshoot” was not mediated by enhanced “recovery-associated DA release.” Rather, the overshoot was most likely mediated by sensitized postsynaptic dopaminergic mechanisms (due to DA depletion) or noradrenergic mechanisms.

Most recently, McTavish and colleagues (2001) administered a tyrosine-free mixture that lowered both subjective and objective measures of the psychostimulant effects of methamphetamine, as well as manic scores. These preliminary findings suggest that tyrosine availability to the brain attenuates pathological increases in DA neurotransmission following methamphetamine administration and putatively in mania.

Neuroreceptor Imaging Studies of the Dopaminergic System

PET Studies. Compared with the number of studies in schizophrenia and depression, very few neurochemical studies of the dopaminergic system have been conducted in manic-depressive illness. One PET study with [¹¹C]-SCH23390 investigated D₁ binding in medication-free bipolar subjects. The authors found reduced binding potential in the frontal cortex in patients compared with normal controls, and no significant difference in striatum (Suhara et al., 1992). This study included a small sample (n=10) of euthymic, depressed, and manic patients. This

work needs to be extended to unipolar patients and replicated independently in bipolar individuals.

A PET study with N-[¹¹C]methylspiperone found increased binding potential (B_{\max}) for striatal D₂ receptors in psychotic bipolar patients compared with nonpsychotic bipolar patients and healthy individuals (Pearlson et al., 1995). Patients were neuroleptic-naïve or neuroleptic-free for at least 6 months. These findings are similar to those previously reported by this group for schizophrenia, and thus may be related to psychotic status.

In a subsequent study, the concentration of the vesicular monoamine transporter protein (VMAT₂) was quantified with (+)[¹¹C]dihydrotrabenazine (DTBZ) and PET (Zubieta et al., 2000). This study included 16 asymptomatic patients with bipolar-I disorder and a prior history of mania with psychosis (9 men and 7 women) and individually matched healthy subjects. VMAT₂ binding in the thalamus and ventral brain stem of the bipolar patients was found to be higher than that in the comparison subjects.

In a follow-up study, the same research group attempted to assess the diagnostic specificity of these findings by comparing VMAT₂ concentrations in euthymic bipolar-I patients (15), schizophrenic patients (12), and age-matched healthy volunteers (15) (Zubieta et al., 2001). It was found that VMAT₂ binding in the thalamus was higher in the bipolar-I patients than in the schizophrenic and control groups. The authors interpret the intriguing findings of increased VMAT₂ expression in euthymic bipolar-I patients as representing trait-related abnormalities in the concentration of monoaminergic synaptic terminals. However, chronic lithium treatment has recently been demonstrated to increase VMAT protein in rat FCx (the only region examined) (Zucker et al., 2001), raising the possibility that the PET human studies may have been confounded by treatment effects.

Most recently, Yatham and colleagues (2002) assessed presynaptic DA function in 13 neuroleptic- and mood stabilizer-naïve nonpsychotic first-episode manic patients by measuring [¹⁸F]6-fluoro-L-dopa ([¹⁸F]DOPA) uptake in the striatum by means of PET. No significant differences were found between [¹⁸F]DOPA uptake rate constants in the striatum in the manic patients and comparison subjects; however, treatment with valproate significantly reduced the [¹⁸F]DOPA uptake rate.

SPECT Studies. In major depression, SPECT studies performed using [¹²³I]-IBZM, a DA D₂ receptor ligand that is sensitive to endogenous DA concentrations, have found increased striatal DA D₂/D₃ receptor availability during the depressed phase, which could potentially be accounted for by a reduction of endogenous DA release (Drevets et al.,

2002). Two studies (D'Haenen and Bossuyt, 1994; Shah et al., 1997) found that patients with unipolar depression have increased striatal uptake of [¹²³I]-IBZM compared with controls. Ebert and Ebmeier (1996) found a nonsignificant trend toward increased [¹²³I]-IBZM binding in depressed patients versus controls, which became significant in a subgroup that displayed overt psychomotor retardation. Consistent with this latter observation, Shah and colleagues (1997) found that striatal [¹²³I]-IBZM binding correlated inversely with movement speed and verbal fluency measures, implying that the elevation of DA D₂/D₃ receptor availability correlated with psychomotor slowing in depression; however, interpretation of these data was confounded by the presence of drug effects (Drevets et al., 2002).

Anand and colleagues (1999, 2000b) have used SPECT to study dynamic changes in the DA synapse in response to pharmacological challenges with drugs such as amphetamine and AMPT that alter synaptic DA levels. The initial study included 13 patients with bipolar disorder (7 medication-free, 6 on mood stabilizer therapy) who at the time had been in a euthymic state for more than 4 weeks and 13 age- and gender-matched healthy controls. SPECT scans of the striatal D₂/D₃ receptor radiotracer [¹²³I]-IBZM were performed before and after an amphetamine challenge (.3 mg/kg IV). Reduction in striatal [¹²³I]-IBZM binding potential from the first scan to the second was used as an indirect measure of the amount of DA released. Bipolar patients and healthy subjects did not differ on baseline mood state and baseline striatal D₂ receptor binding. Amphetamine challenge led to a significantly greater behavioral response in bipolar patients than in healthy subjects. However, there was no significant difference between the two groups in striatal [¹²³I]-IBZM binding following amphetamine challenge. Thus, this study did not find evidence for increased striatal DA release in euthymic bipolar patients. Instead, these data are consistent with enhanced postsynaptic DA responsivity in bipolar patients (discussed later).

Enhancing Dopamine Function in the Treatment of Depression

Interestingly, monoamine oxidase inhibitors (MAOIs) represent the only pharmacological monotherapy that is reported to be effective in 50 percent or more of patients who fail to respond to the full range of tricyclic antidepressants. Nolen and colleagues (1988) reported on a controlled trial, indicating the superior efficacy of tranylcypromine (average dose of approximately 80 mg/day) in such patients. As reviewed in Chapter 19, tranylcypromine is superior to imipramine in chronic, mild unipolar depression (McGrath

et al., 1987) and in “anergic” bipolar depression (Himmelhoch et al., 1991; Thase et al., 1992), and phenelzine is superior in unipolar patients refractory to imipramine (McGrath et al., 1993). An open-label study of high-dose tranylcypromine (average 120 mg/day) in 14 unipolar patients with a clear history of nonresponse to at least two prior medication treatments yielded an impressive 50 percent “complete” response rate on the Hamilton Depression Rating Scale (HAM-D) (Amsterdam, 1991). The authors speculate that higher plasma concentrations of tranylcypromine enhance the drug’s sympathomimetic (amphetamine-like) activity. In other words, at higher doses, one may actually recruit a pharmacodynamic effect of the drug beyond MAO inhibition.

Identifying multiple specific effects in humans, however, is not simple. Studies with DA reuptake inhibitors such as nomifensine have shown clear antidepressant effects in major depression. Similarly, bromocriptine, a postsynaptic DA receptor agonist, has been reported to have efficacy comparable with that of standard tricyclic antidepressants (Silverstone, 1984) and to be useful in antidepressant-resistant depression (Inoue et al., 1996) and in relapses that occur with selective serotonin reuptake inhibitor (SSRI) treatment (McGrath et al., 1995).

In a small pilot study of depressed patients, Schaefer and colleagues (1996) found that 69 percent (9/13) of patients taking pramipexole (a D₂/D₃ agonist) had a greater than 30 percent reduction in (HAM-D) total scores relative to baseline scores. DeBattista and colleagues (2000) reported the successful augmentation of an SSRI when pramipexole was added in treatment-resistant major depression. In a retrospective chart review, Sporn and colleagues (2000) found that pramipexole (mean dose .70 mg/day) was effective in 50 percent (6/12) of subjects with bipolar depression and 40 percent (8/20) of subjects with unipolar depression. Lattanzi and colleagues (2002) reported that pramipexole in the dose range of .375–1.0 mg/day was effective in treatment-resistant depression (14 unipolar, 17 bipolar patients) when used adjunctively with other antidepressants. Pramipexole was also tested in a double-blind 8-week, placebo-controlled study involving 174 subjects with unipolar depression without psychotic features (Corrigan et al., 2000). In patients with bipolar depression, two double-blind, placebo-controlled trials found pramipexole to be superior to placebo in the treatment of depressive symptoms (Goldberg et al. 2004; Zarate et al. 2004b,c). In the bipolar II depression study (Zarate et al. 2004b,c), 21 patients treated with lithium or valproate were randomized to receive add-on pramipexole 1.7 ± .9 mg/day (n = 10) or placebo (n = 11) for 6 weeks. All subjects except for one in each group completed the study. At the endpoint, changes in both

Montgomery-Asberg Depression Rating Scale (MADRS) and 24-item HAM-D scores in the pramipexole group were significantly larger compared with those in the placebo group. Response rates were significantly higher among patients taking pramipexole than those taking placebo, 60 percent versus 9 percent.

In another study, the efficacy of pramipexole augmentation was assessed in patients who had treatment-resistant bipolar depression. Twenty-two patients (bipolar-I n = 15, bipolar-II n = 7) treated with lithium, divalproex, carbamazepine, lamotrigine, and/or topiramate at stable doses for a month, with HAM-D scores of ≥18, were randomized to receive pramipexole (1.7 ± 1.3 mg/day) or placebo for 6 weeks. The mean change from baseline in HAM-D scores was significantly greater in patients taking pramipexole than in those taking placebo. The proportion of responders was significantly higher in patients taking pramipexole, 67 percent versus 20 percent.

Lithium and the Dopaminergic System

The effect of lithium on DA synthesis and transmission has been investigated extensively in preclinical studies by directly determining changes in DA or HVA and indirectly examining lithium-induced changes in DA-linked behaviors (Bunney and Garland-Bunney, 1987). Lithium administration has also been found to cause a dose-dependent decrease in DA formation,¹⁴ which occurs at 25 percent lower doses in the striatum than in the limbic forebrain (Poitou and Bohuon, 1975; Segal et al., 1975; Laakso and Oja, 1979).

Based on the heuristic hypothesis that supersensitive DA receptors underlie the development of manic episodes, it has been postulated that lithium would prevent DA receptor supersensitivity (Bunney and Garland, 1983; Bunney and Garland-Bunney, 1987). In a series of studies, it was found that lithium prevented haloperidol-induced DA receptor upregulation (Rosenblatt et al., 1980; Verimer et al., 1980; Bunney and Garland, 1982) and supersensitivity to iontophoretically applied DA or IV apomorphine (Gallager et al., 1978). Indeed, lithium appears to be effective in blocking both the behavioral and biochemical manifestations of supersensitive DA receptors induced by receptor blockade.

A proposed site of action for lithium’s ability to block behavioral supersensitivity is the postsynaptic receptor and the prevention of haloperidol-induced increases in DA receptors. Despite significant functional evidence, however, DA receptor binding studies have remained inconclusive, suggesting a possible postreceptor site of lithium action, potentially related to receptor–effector coupling. Interestingly, a number of studies have reported a lack of effect if lithium is administered after the induction of DA super-

sensitivity (Klawans et al., 1977; Staunton et al., 1982a,b; Bloom et al., 1983), suggesting that in this model, lithium exerts its greatest effects prophylactically.

Among the numerous behavioral effects of lithium in animals, perhaps the best studied are those on stimulant-induced activity. Lithium's ability to antagonize increases in amphetamine-induced locomotor activity without having major effects on basal activity has gained much attention, in part because it tends to mimic the clinical situation in which lithium does not have major effects on "baseline" activity levels, but has a profound effect on the hyperactivity observed in manic states. It is also of interest that lithium has been reported to attenuate the euphoriant and motor-activating effects of oral amphetamine in depressed patients, although equivocal results have been observed upon methylphenidate challenge (Huey et al., 1981; Van Kammen et al., 1985).

Studies of DA and its metabolites in patients' CSF before and after lithium treatment have yielded conflicting results.¹⁵ A longitudinal study of one unipolar and seven bipolar women found that lithium reduced the levels of DA, DOPAC, and HVA in all the patients (Linnoila et al., 1983b), but the possible role of alterations in mood state and motor activity remained a confounding variable, as it does for all clinical investigations using this research strategy.

Overall, although the data from human investigations are sparse, lithium's postulated ability to reduce both pre- and postsynaptic aspects of DA transmission represents an attractive mechanism for its antimanic therapeutic action. Subsequent studies have investigated the effects of lithium on putative postreceptor components of dopaminergic signaling. Thus, lithium has been shown to potentiate the hyperactivity induced by intra-accumbens cholera toxin administration (which activates the stimulatory G proteins, G_s and G_{off}) (Kofman et al., 1998). Another study found that the G protein coupled to D₁ stimulation was upregulated after chronic lithium, presumably as a compensatory mechanism due to reduced DA throughput. Interestingly, chronic antidepressants have also been associated with enhanced D₁ signaling, suggesting that these compensatory effects of lithium may play a role in the "rebound" increase in manic episodes observed after abrupt lithium discontinuation (see Chapter 18).

Studies in the last few years have demonstrated that lithium at therapeutically relevant concentrations increases gene expression through the activator protein-1 (AP-1) transcription factor pathway in vitro (Yuan et al., 1998). Follow-up studies investigated the ability of lithium to increase the expression of endogenous genes known to be regulated by AP-1, in particular TH (Chen et al., 1998). Chronic lithium treatment resulted in significant increases in TH levels in rat frontal cortex, hippocampus, and striatum. Lithium

(1.0 mM) also increased TH levels in human SH-SY5Y neuroblastoma cells in vitro, indicating that the drug increases TH levels in both rodent and human tissues, likely through a direct cellular effect.

In subsequent studies, lithium's potential utility in a Parkinson's disease transplantation model was investigated. In this context, neurons derived from a human teratocarcinoma (hNT) were shown to survive and integrate within the host brain following transplantation and to provide functional recovery in animal models of stroke and Huntington's disease. To maximize the likelihood of success following transplantation (i.e., DA synthesis), researchers have recently investigated lithium's effects on TH expression in these derived neurons (Zigova et al., 1999). Therapeutically relevant doses of lithium chloride (1.0 mM) were found to increase the number of TH-positive neurons approximately six-fold (Zigova et al., 1999). In addition, the TH-positive hNT neuron mean soma profile area and neurite length were significantly larger than in controls by 60 and 70 percent, respectively. Moreover, even after withdrawal of lithium chloride on day 5, the number of TH-positive neurons in cultures remained significantly increased. These data suggest that hNT cells are indeed responsive to lithium exposure and may serve as a continual source of TH-expressing neurons in new therapeutic approaches to degenerative brain disease.

In additional follow-up work, researchers investigated the potential use of hNT neurons for transplantation into the substantia nigra (SN) and striatum of the rat model for Parkinson's disease (Baker et al., 2000). Twenty-seven rats were grafted with one of three hNT neuronal products—hNT neurons, hNT-DA neurons, or lithium chloride (LiCl)-pretreated hNT-DA neurons. Immunostaining for TH expression revealed no TH-immunoreactive (THir) neurons in any animals with hNT neuronal grafts. Interestingly, THir cells were observed in 43 percent of animals with hNT-DA neuronal grafts but in all the animals with LiCl-pretreated hNT-DA neuronal grafts.

Valproate and the Dopaminergic System

Few preclinical studies have examined the effects of valproate on the dopaminergic system after chronic administration, that is, in paradigms likely to reflect the biochemical effects of the drug most relevant for the treatment of bipolar disorder. Acute valproate administration has been demonstrated to increase or decrease HVA levels in caudate (Biggs et al., 1992; Vriend and Alexiuk, 1996), to increase HVA levels in brain stem and frontal cortex (Loscher and Honack, 1996), and to increase HVA levels in CSF of freely moving rats (MacMillan et al., 1987). Interestingly, Ichikawa and colleagues (2001) found that both carbamazepine and valproate increased extracellular DA levels in rat medial

prefrontal cortex, effects also seen with clozapine. Moreover, increased prefrontal DA was completely abolished by the selective 5-HT_{1A} receptor antagonist N-[2-[4-(2-methoxyphenyl)-1-piperazinyl]ethyl]-N-2-pyridinylcyclohexanecarboxamide (WAY100635, .05 mg/kg).

To elucidate possible mechanisms underlying the effects of carbamazepine and valproate on neurotransmitter exocytosis, the effects of these neuroleptic drugs and botulinum toxins (BoNTs) on basal, Ca²⁺- and K⁺-evoked release of DA and serotonin were determined by microdialysis in the hippocampus of freely moving rats (Murakami et al., 2001). Perfusion with low and high concentrations of carbamazepine and valproate increased and decreased basal DA release, respectively. On the basis of additional studies, these investigators postulated that carbamazepine and valproate affect both the enhancement of syntaxin-mediated monoamine release during the resting stage and the inhibition of synaptobrevin-mediated release during the depolarizing stage.

In animal behavioral studies, valproate was found to attenuate the acute locomotor effects of methylphenidate and, at higher doses, to block the development of sensitization to subsequent administration (Eckermann et al., 2001). Chronic valproate pretreatment also produced a borderline significant reduction in quinpirole-induced hyperactivity without effects on the hypoactive phase (Shalubina et al., 2002).

Carbamazepine and the Dopaminergic System

In Maitre and colleagues' (1984) review of the literature, they conclude that carbamazepine decreases DA turnover through unknown mechanisms. Later, Baptista and colleagues (1993) found that carbamazepine blocks cocaine-induced increases in DA overflow in the n. accumbens as measured by in vivo dialysis. This effect could account for the observation of Aigner and colleagues (1990) that carbamazepine inhibits cocaine intake in self-administration in the rhesus monkey, a process thought to be mediated by accumbens dopaminergic mechanisms.

The Dopaminergic System in Manic-Depressive Illness: Summary

Overall, indirect evidence for the involvement of recurrent mood disorder is provided by the involvement of that system in circuits known to regulate motivation, reward, and motoric activity, as well as pharmacological data demonstrating that dopaminergic agonists trigger hypomanic/manic episodes and that drugs that reduce dopaminergic throughput (including mood stabilizers and antipsychotics) are antimanic. However, there are fewer data suggesting *primary* dopaminergic abnormalities in manic-depressive illness. It is our contention that the

BOX 14-4. A Summary of Major Findings Supporting Involvement of the Dopaminergic System in the Pathophysiology and Treatment of Bipolar Disorder and Recurrent Unipolar Depression

- Reduced CSF HVA in depressed patients
- Blunted neuroendocrine and temperature responses to DA agonists
- Reduced internal jugular venoarterial HVA concentration gradients
- Antidepressant efficacy of agents whose biochemical effects include increasing intrasynaptic dopamine
- ECT consistently enhances DA function
- Depressogenic effects of AMPT and reserpine in susceptible individuals
- Medications that block D2 receptors have antimanic efficacy
- Lithium-treated euthymic bipolar patients show a rebound hypomania following AMPT
- Depression very common in Parkinson's disease
- Prominent anhedonia, amotivation, and psychomotor retardation in bipolar depression
- Critical role of DA in reward, motivation, and motoric circuits

CSF = cerebrospinal fluid; DA = dopamine; ECT = electroconvulsive therapy; HVA = homovanillic acid.

primary abnormality in manic-depressive illness, and perhaps especially in its bipolar form, is a compromised ability to regulate multiple signals (including those generated by the dopaminergic system). Indeed, supporting this contention are recent data suggesting that bipolar disorder may be associated with polymorphisms affecting the functioning of the G protein-coupled receptor kinase 3 (GRK-3).

The GRKs are a family of proteins whose cellular function is to turn off or dampen the signal when receptors are exposed to high levels of neurotransmitters. These proteins are involved in rapidly phosphorylating receptors that are overstimulated, thereby uncoupling the receptors from their second messenger systems. Thus, a faulty desensitization system due to a mutation in GRK is of considerable interest with respect to the pathophysiology of bipolar disorder, as it would result in overshooting in response to multiple neurotransmitter systems, thereby producing excessive excursions from the norm. These observations, if replicated, would suggest that bipolar disorder is associated with an abnormality of DA function, but is not due to defects in the dopaminergic system itself, rather in the machinery involved in dampening and fine-tuning dopaminergic signals. Boxes 14-4 and 14-5 summarize overall major findings and findings of newer studies supporting the involvement of the dopaminergic system in the pathophysiology and treatment of bipolar disorder and recurrent unipolar depression.

BOX 14-5. Newer Studies Supporting Involvement of the Dopaminergic System in the Pathophysiology and Treatment of Manic-Depressive Illness (Primarily Bipolar)

Genetic Studies

- Receptors**
- DA receptor D2 S311C variant associated with disorganization and delusion features in psychosis (Serretti et al., 2000)
 - Reduced novelty seeking in carriers of *DRD3* allele 1 in BPD (Staner et al., 1998)
 - D3 receptor (homozygous for the (2-2)Bal I polymorphism) reported to exhibit manic symptomatology in monopolar form (Chiaroni et al., 2000)
 - Increase in DA D3 receptor gene allele 1 reported in BPD families (Parsian et al., 1995)
 - Association between DA D4 receptor gene and mood disorders (Manki et al., 1996)
- Transporter**
- *DAT* (DA transporter) gene (single nucleotide polymorphism), linkage disequilibrium with BPD (Greenwood et al., 2001)
 - *DAT1* with a missense substitution inherited between a BPD father and his BPD son (Grunhage et al., 2000)
 - Linkage disequilibrium reported between *DAT1* gene and BPD (Waldman et al., 1997)
- Enzymes**
- Dopa decarboxylase gene reported to represent a minor susceptibility gene for BPD (odds ratio 1.48 patients. vs. control) (Borglum et al., 1999)
 - COMT low-activity allele showed a trend toward being transmitted among female BPD probands (Mynett-Johnson et al., 1998)
 - COMT low activity (MET 158; COMTL) reported to be a risk factor for BPD (Li et al., 1997; Rotondo et al., 2002)
 - Increased presence of COMT LL (low activity allele) in BPD ultrarapid cycling (Kirov et al., 1998; Papolos et al., 1998)
 - Apparent association between COMT 158val (low activity allele) in velocardiofacial syndrome and ultrarapid cycling (Lachman et al., 1996)
 - Decrease in depressive symptoms reported in mood disorder patients when tyrosine hydroxylase (TH) *2/2 gene is present (Serretti et al., 1998)
 - Weak association reported between *TH* gene and *DRD2* gene with BPD (Perez de Castro et al., 1995)
 - Mutation of *NURR1* in BPD, single case (*NURR1*-deficient animals fail to develop mesencephalic DA neurons) (Buervenich et al., 2000)

Other Observations

- Reduced frontal cortex D1 receptor binding (PET) reported in medication-free BPD (Suhara et al., 1992)
- Increased D2 receptor B_{max} reported in psychotic BPD (Pearlson et al., 1995)
- Increased levels of immunoglobulin G with affinity for DA reported in CSF of psychotic patients (12 of 20 were BPD) (Bergquist et al., 1993)
- Increased urinary DA reported to predict manic mood in one rapid-cycling patient (Joyce et al., 1995)
- Increase of episodic parkinsonism, before onset of depression, that disappeared during mania, in 3 cases of rapid-cycling patients (Scappa et al., 1993). Consistent with hypo- and hyperdopaminergic DA functioning in bipolar depression and mania, respectively
- Higher vesicular monoamine transporter (VMAT2) binding in the thalamus and ventral brain stem of bipolar patients than in controls. Unclear whether due to primary disease, lithium treatment, or a combination of these

Treatment Related

- Mood stabilizers**
- Reduction of platelet MAO activity and increase in dopamine β -hydroxylase activity with Li treatment in BPD (Sofuoglu et al., 1995)
 - Reduction in prolactin with long-term Li treatment in euthymic BPD (Basturk et al., 2001)
 - Increase in DA metabolism (increase in HVA) when Li is added to a neuroleptic in acute psychosis (Bowers et al., 1992)
 - Decrease in presynaptic DA after valproate in BP-I patients (Yatham et al., 2002)
 - Decrease by carbamazepine (and not by Li) of chronic imipramine-induced supersensitivity to locomotor response to quinpirole (D'Aquila et al., 2000, 2001) and decrease in quinpirole-induced biphasic locomotion (D2 D3 agonist) by anticonvulsants (Shaldubina et al., 2002)
 - Valproate treatment increases tyrosine hydroxylase mRNA in locus coeruleus (Sands et al., 2000)
 - Chronic lithium or valproate increases tyrosine hydroxylase protein levels in limbic and limbic-related areas of rat brain and human neuroblastoma cells (Chen et al., 2000)

BP = bipolar; BPD = bipolar disorder; BP-I = bipolar-I; COMT = catechol-O-methyltransferase; CSF = cerebrospinal fluid; DA = dopamine; HVA = homovanillic acid; Li = lithium; LiCl = lithium chloride; MAO = monoamine oxidase; TH = tyrosine hydroxylase.

The Serotonergic System

Interest in the role of the serotonergic system in mood disorders derived from a long-standing tradition of research into the role of this indoleamine in the therapeutic mechanisms of action of antidepressants and lithium. There is considerable evidence of abnormalities in the serotonergic neurotransmitter system in patients suffering from depression; however, the data for bipolar disorder are much less extensive, and for recurrent unipolar, data are virtually nonexistent (Meltzer and Lowy, 1987; Shiah and Yatham, 2000; Mahmood and Silverstone, 2001). The serotonergic dysfunction in the pathophysiology of depression has been reported to occur at many different levels, including precursor availability, neurotransmitter synthesis, storage, release, presynaptic autoreceptor function, neurotransmitter reuptake, metabolism, and postsynaptic neurotransmitter receptors.

Studies of Serotonin Metabolites in CSF

As we reviewed in the first edition of this text, earlier findings on 5-HIAA in CSF were in the direction of reductions in depressed patients, but with much less consistency than more recent findings, perhaps because of reliance on fluorometric assay. There was also a trend in those data toward lower 5-HIAA in bipolar than in unipolar patients. Investigators have been unable to demonstrate convincing evidence for group differences in the CSF levels of 5-HIAA (with or without probenecid) between unipolar and bipolar patients; there appears, however, to be a subgroup of patients

with low levels of 5-HIAA, which may be associated with certain illness characteristics (impulsivity, aggression, and suicide attempts [Van Pragg, 1982; Meltzer and Lowy, 1987; Virkkunen et al., 1989]). Findings of studies of baseline 5-HIAA in CSF of unmedicated depressed patients are inconsistent: the NIMH Collaborative Study reports increased 5-HIAA in depressed women (Koslow et al., 1983). In 83 patients with melancholia diagnosed and treated at the Karolinska Institute in Sweden, by contrast, 5-HIAA was found to be modestly but significantly reduced (Asberg et al., 1984). In the former study, there was a trend toward lower 5-HIAA in female bipolar than female unipolar patients; in the latter study, there were no unipolar-bipolar differences in this measure.

Studies of CSF 5-HIAA in manic patients have generally produced variable and inconsistent results (Goodwin and Ghaemi, 1998; Shiah and Yatham, 2000). Baseline CSF 5-HIAA levels in manic patients compared with nondepressed controls have been reported to be decreased in four studies, unchanged in nine studies, and increased in three studies; by contrast, most studies found no difference in the levels of CSF 5-HIAA between manic and depressed patients. Of four studies that examined CSF 5-HIAA accumulation following administration of probenecid in manic and depressive patients as well as controls, two found that both manic and depressed patients had diminished CSF 5-HIAA formation compared with that in controls, and one that manic patients had significantly lower CSF 5-HIAA accumulation than that in depressive patients and controls.

Mixed-State, Well-State, and Longitudinal Studies As discussed in Chapter 1, mixed states are now recognized as common, and it is likely that the biochemical studies already reviewed included such patients among subjects diagnosed as manic. To our knowledge, there has still been only one CSF study focused on mixed states—that of Tandon and colleagues (1988), who compared mixed bipolar patients with pure manic and unipolar depressive patients. Whereas both HVA and 5-HIAA were higher in the patients with pure mania than in those with depression, the mixed group could be biochemically divided into two subgroups whose metabolite levels resembled those of the pure manic and pure depressive groups, respectively. In addition, these authors compared their metabolite data with published normal control values obtained by the same method. They noted that all three groups had 5-HIAA levels significantly below normal, a finding they interpreted as consistent with the permissive hypothesis (discussed below).

In a few CSF amine metabolite studies, measurements were repeated after recovery in an attempt to assess the well state. In most studies of the well state, however, it is virtually impossible to tease drug effects apart from the recovered state itself. The study of spontaneous or ECT-induced recovery is one approach to this problem, but only preliminary data are available. Coppen and colleagues (1972), Ashcroft and colleagues (1973), and Van Praag and De Haan (1979) reported that their depressed patients with low levels of CSF 5-HIAA failed to normalize with recovery. Berrettini and colleagues (1985b), by contrast, found no difference in CSF 5-HIAA (and HVA) in recovered bipolar patients compared with healthy controls, although this study did not compare the well state with the illness phase in the same patients. The persistence of low 5-HIAA levels reported by Coppen and colleagues and by Van Praag and De Haan is of interest in light of the suggestion that CSF 5-HIAA is similar in both manic and depressive phases of the illness. Relevant to these questions are two small longitudinal studies of 5-HIAA (Asberg et al., 1973; Post et al., 1980a), which demonstrated reasonable stability of 5-HIAA levels over time. The issue of postrecovery metabolite data reemerges when we review drug effects.

To our knowledge, no group of bipolar patients has been studied with serial measurement of CSF metabolites through the depressive and manic phases. A few scattered cases of rapid-cycling patients have been presented, although it is not clear just how representative such patients are. Post and colleagues (1977) and Cutler and Post (1982) followed CSF amine metabolites through seven depressive phases and eight manic phases in three patients. Baseline and probenecid-induced accumulation of 5-HIAA were not significantly different during mania and depression, but NE levels were significantly higher in mania. Addi-

tional longitudinal studies are discussed in the next two sections.

In postmortem studies, low concentrations of 5-HT and its metabolite 5-HIAA have been reported in the brain stem of depressed patients who completed suicide (Traskman et al., 1981). In brains from nine subjects with a DSM-III-R diagnosis of bipolar disorder who died while depressed, a significant reduction in levels of 5-HIAA was found in frontal (–54 percent) and parietal cortex (–64 percent) (Young et al., 1994c).

Overall, however, findings on CSF and brain 5-HIAA tend to support the permissive hypothesis of Prange, which suggests that, in bipolar disorder, a background state independent deficit in central 5-HT function is associated with impaired buffering so that bidirectional changes in other systems (perhaps involving norepinephrine and/or dopamine) are “permitted” to occur and produce abnormal excursions in mood and behavior.

Platelet 5-HT Uptake

Rausch and colleagues (1986) measured 5-HT uptake in depressed patients, manic bipolar patients, and patients with other affective disorders and nonaffective psychiatric disorders using a randomized block factorial analysis of variance. They found that the depressed patients had significantly lower maximal velocity (V_{\max}) of serotonin uptake in comparison with matched controls, without a statistically significant difference in affinity (i.e., the tightness of binding of the transmitter to the reuptake site). No statistically significant difference was found for any of the other diagnostic groups in comparison with controls for V_{\max} or K_m .

By contrast, Meltzer and colleagues (1981) noted a tendency for a decrease in 5-HT uptake in four manic patients and an increase in seven manic patients, although manic patients as a group did not differ significantly from healthy controls. Similarly, Scott and colleagues (1979) reported no difference in 5-HT uptake in 8 manic patients compared with 26 healthy controls. Meagher and colleagues (1990) found increased 5-HT uptake in 15 manic patients compared with 19 healthy controls. In this study, however, manic patients as a group had a large variation in their 5-HT uptake compared with the control group that could very well have been due to the effects of medication. Indeed, when five drug-free manic patients in this study were compared with controls, there was no difference in 5-HT uptake between the two groups. Marazziti and colleagues (1991), by contrast, reported decreased 5-HT uptake in 7 manic patients compared with 12 healthy controls. Of these seven patients, only three were drug-free, which confounds the interpretation of results.

Challenge Studies

Tryptophan Depletion Challenge Studies. Serotonin is synthesized from tryptophan, an essential amino acid derived from the diet. The rate-limiting step in serotonin synthesis is the hydroxylation of tryptophan by the enzyme tryptophan hydroxylase to form 5-hydroxytryptophan. Under normal circumstances, this rate-limiting enzyme is not saturated by substrate; thus, tryptophan concentration can impact the rate of synthesis. Tryptophan is then taken up into the brain via a saturable carrier mechanism. Tryptophan actively competes with other large neutral amino acids for transport, and brain uptake of tryptophan is thus determined by both the amount of circulating tryptophan and the ratio of tryptophan to the other large neutral amino acids. (See Figure 14–3 for a diagram of the effects of tryptophan depletion.)

Pretreatment plasma tryptophan has been reported to be lower in depressed patients than in healthy controls and to be able to differentiate certain subgroups of depression (Meltzer and Lowy, 1987; Maes et al., 1990). Depressed patients exhibit reduced plasma concentrations of 5-hydroxytryptophan after ingestion of test doses of oral L-tryptophan (Deakin et al., 1990). Lower pretreatment plasma tryptophan has been reported to be predictive of response to antidepressant treatment (Moller et al., 1986;

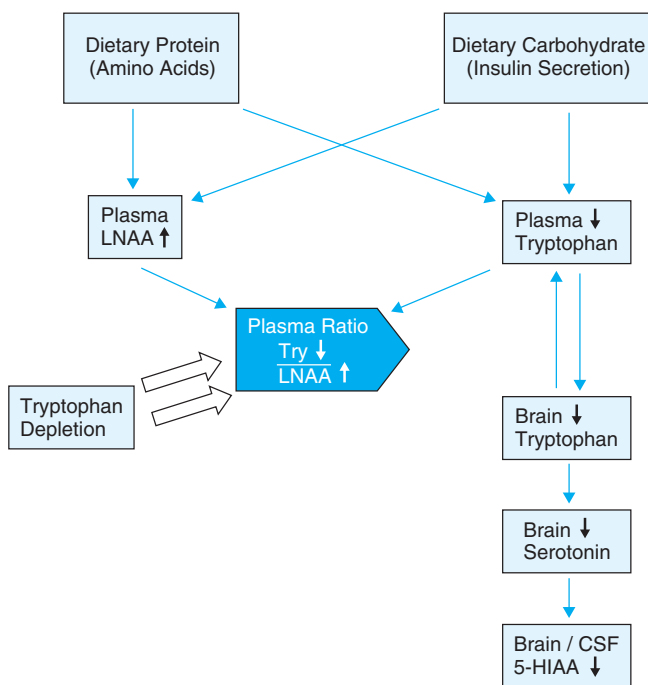

Lucca et al., 1992). The depletion of dietary L-tryptophan has also been reported to induce relapse in recently remitted depressed patients (Delgado et al., 1990; Neumeister et al., 1997).

In contrast to these findings, several studies have recently found that the effect may be less consistent than previously reported. Moore and colleagues (1998) observed no effect on mood in fully remitted patients medicated with SSRIs. Leyton and colleagues (1997) also reported that acute tryptophan depletion did not induce relapse or change in mood in fully remitted, medication-free former patients with major depression. Neumeister (2003) summarized the behavioral data for healthy controls with and without genetic risk for depression and for patient populations during the symptomatic phase of depression and in remission. Overall, these data indicate a trait abnormality of serotonin function in depression and suggest that antidepressants may compensate for the underlying deficit.

Of the 15 tryptophan depletion studies that have been conducted in depression, only 3 included some patients with bipolar depression (Delgado et al., 1990, 1999; Leyton et al., 1997). Only three such studies have been conducted specifically in bipolar disorder (Benkelfat et al., 1995; Capiello et al., 1997; Johnson et al., 2001). In one study, tryptophan depletion was found to be associated with increased manic symptoms for 3 days (Capiello et al., 1997). Two patients met criteria for a relapse. In two other studies, euthymic patients who were being treated with lithium were unaffected by tryptophan depletion (Cassidy et al., 1998b; Johnson et al., 2001). Patients in these studies had been in a long remission. In the study by Johnson and colleagues, tryptophan depletion was induced in 30 patients with manic-depressive illness (20 bipolar and 10 unipolar), all stabilized on lithium treatment for at least 1 year. The study was performed using a randomized, double-blind, controlled design. Plasma tryptophan was reduced by 80 percent in the experimental group and 16 percent in the control group. However, no clinically relevant mood changes were observed. Transient reduction in serotonergic function does not appear to affect mood in patients with affective disorders stabilized on lithium treatment.

Many of these studies are limited in that they included mixed samples of patients with major depression (recurrence not specified) or bipolar disorder (depressed phase, treated with antidepressants). Furthermore, most of these studies do not present results for bipolar and unipolar patients separately. Bipolar depressed patients treated with antidepressants do not appear to be more or less vulnerable to tryptophan depletion than unipolar patients; however, currently available studies suggest that tryptophan depletion does not produce a lowering of mood in lithium-treated euthymic patients.

Figure 14–3. The mechanisms by which tryptophan depletion reduces central nervous system serotonin. CSF = cerebrospinal fluid; LNAA = large, neutral amino acid; Try = tryptophan; 5-H_{LNAA} = 5-hydroxy-indoleacetic acid. (Source: Fernstrom and Wurtman, 1997.)

Most recently, investigators have studied unaffected relatives of bipolar patients to examine the possibility that sensitivity to the deleterious mood and cognitive effects of lowered serotonin may represent an endophenotype for bipolar disorder. In a double-blind, crossover design, 20 unaffected relatives (URs) from multiplex bipolar families and 19 control subjects underwent acute tryptophan depletion (ATD) (Quintin et al., 2001). Unlike the control subjects, URs experienced a lowering of mood during ATD but not during the placebo. Furthermore, URs tended to show increased impulsivity in the ATD condition. Measurements obtained before ingestion of the amino acid (AA) drink indicated that, relative to control subjects, URs exhibited lower serotonin platelet concentrations, lower affinity, and fewer binding sites of the serotonin transporter for imipramine; these differences were unaffected by tryptophan depletion.

In a more recent study, Sobczak and colleagues (2002) investigated the effects of ATD on cognitive performance in healthy first-degree relatives of bipolar patients (FHs) ($n=30$) and matched controls ($n=15$) in a placebo-controlled, double-blind, crossover design. Performance on planning, memory, and attention tasks was assessed at baseline and 5 hours after ATD. The authors found that speed of information processing on the planning task following ATD was impaired in the FH group but not in the control group. Furthermore, FH subjects with a bipolar-I relative (FH-I) showed impairments in planning and memory independent of ATD. In all subjects, ATD impaired long-term memory performance and speed of information processing; it did not affect short-term memory or focused and divided attention. These results suggest serotonergic vulnerability affecting frontal lobe areas in FH subjects, indicated by impaired planning.

Taken together, the above results suggest that vulnerability to reduced tryptophan availability may represent an endophenotype for bipolar disorder, a notion that warrants further investigation; also future studies should include a group with highly recurrent unipolar depression.

Neuroendocrine Challenge Studies. A series of neuroendocrine challenge paradigms has been investigated to examine more closely the presynaptic serotonergic neurons in patients with mood disorders (Shiah and Yatham, 2000; Mahmood and Silverstone, 2001). In healthy subjects, the IV infusion of tryptophan increases prolactin plasma levels (Price et al., 1991). In depressed patients, however, this release of prolactin to IV tryptophan is blunted compared with that in healthy controls (Price et al., 1991; Cappiello et al., 1996). As with most of the other serotonergic measures, only a few studies have been undertaken in bipolar patients, perhaps reflecting the difficulty of maintaining

bipolar patients medication-free for a sufficiently long period of time so as to be confident of the lack of confounding residual medication-related effects. The serotonin precursor tryptophan has been used to test neuroendocrine responses in patients and controls. In a placebo-controlled study, the cortisol and ACTH responses to tryptophan was blunted in remitted bipolar patients compared with those in controls (Nurnberger et al., 1990).

Neuroendocrine challenge with the appetite suppressant fenfluramine produces similar results to the IV infusion of tryptophan. The administration of fenfluramine causes a rapid increase in the plasma levels of prolactin in normal subjects. When fenfluramine is administered to depressed patients, however, the prolactin release is blunted (Mitchell and Smythe, 1990; Shapira et al., 1993). This blunted prolactin response has been reported to normalize with successful treatment and has been proposed as a test for predicting response to antidepressant treatment (Malone et al., 1993; Shapira et al., 1993).

Only two studies have employed the fenfluramine challenge test in homogeneous samples of manic patients (Newman et al., 1998). One found that the prolactin and cortisol responses of manic patients to either fenfluramine ($n=10$) or sumatriptan ($n=9$) did not differ from those of normal controls (discussed in Shiah and Yatham, 2000; Mahmood and Silverstone, 2001). Thakore and colleagues (1996), by contrast, found increased basal cortisol levels and reduced prolactin response to fenfluramine in nine manic patients compared with nine healthy controls matched for age and gender. They suggest that mania is associated with a state of decreased 5-HT responsiveness, similar to that found in the depressed state and reminiscent of the permissive hypothesis of bipolar disorder discussed earlier.

The growth hormone (GH) response was found to be blunted in depressed patients in a study using sumatriptan, a 5-HT_{1D} agonist, as the challenge agent (Yatham et al., 1997). Mahmood and colleagues (2002) found a blunted GH response to sumatriptan in bipolar patients with migraine compared with bipolar patients without migraine, "pure" migraine patients, and healthy controls.

Investigation of Serotonin Receptors

Several different serotonin receptor subtypes have been identified in recent years. Subtyping is based in part on the characteristics of binding to serotonin, other agonists, or antagonists. Three main classes—5-HT₁, 5-HT₂, and 5-HT₃ receptors—are further subdivided into subtypes 5-HT_{1A}, 5-HT_{1B}, 5-HT_{1D}, 5-HT_{1E}, and 5-HT_{1F}. The 5-HT₂ receptors may be divided into 5-HT_{2A}, 5-HT_{2B}, and 5-HT_{2C} subtypes.

The 5-HT_{1A} Receptor. The 5-HT_{1A} receptor has been implicated in the pathophysiology and treatment of mood

disorders on the basis of evidence that patients with major depression have blunted physiological responses to 5-HT_{1A} receptor agonists in vivo and abnormal 5-HT_{1A} receptor binding postmortem (Bowden et al., 1989; Lopez et al., 1998; Stockmeier et al., 1998). During 5-HT_{1A} receptor agonist challenge, physiological increases in plasma concentrations of ACTH and cortisol are attenuated in unmedicated subjects with unipolar depression (recurrence not specified) (Cowen, 2000). Postmortem studies of cerebral 5-HT_{1A} receptor binding and mRNA expression in unipolar depression and bipolar disorder suggest 5-HT_{1A} receptor dysfunction in mood disorders, but these data are limited to two studies with small sample sizes (Bowden et al., 1989; Lopez et al., 1998). Lopez and colleagues (1998) found that 5-HT_{1A} receptor mRNA levels were abnormally reduced in the hippocampus in six subjects with major depressive disorder who died by suicide, and Bowden and colleagues (1989) found reduced 5-HT_{1A} receptor binding to [³H] 8-hydroxy-2-(di-n-propyl)aminotetralin (8-OH-DPAT) in the temporal polar and posterior ventrolateral prefrontal cortex in seven patients with unipolar depression or bipolar disorder dying of natural causes.

Supporting the above postmortem findings, recent PET studies have yielded in vivo evidence of reduced pre- and postsynaptic 5-HT_{1A} receptor binding in both unipolar and bipolar depressed patients. Drevets and colleagues (2000) reported that the regional 5-HT_{1A} receptor binding of depressed subjects with primary, recurrent, familial mood disorders (i.e., part of the manic-depressive spectrum) as determined with PET was significantly reduced relative to healthy controls. The investigators found that the mean 5-HT_{1A} receptor binding potential was reduced by 42 percent in the midbrain raphe and 25–33 percent in the limbic and neocortical areas in the mesiotemporal, occipital, and parietal cortex. These findings are consistent with those of Sargent and colleagues (2000), who found decreased 5-HT_{1A} receptor binding, measured with PET and [carbonyl-¹¹C]WAY 100635, in 15 unmedicated depressed patients relative to 18 healthy controls in the raphe, medial temporal cortex, insula, anterior cingulate, temporal polar cortex, ventrolateral prefrontal cortex, and orbital cortex. Seven of the unmedicated subjects were naive to antidepressant drugs, and the other eight had been untreated for a mean of 63 weeks. No differences were found between depressed patients and controls in the inferior occipital cortex or angular gyrus. Ten of the subjects were scanned both before and after paroxetine treatment; it was found that 5-HT_{1A} receptor binding had not significantly changed in any area.

Cortisol Hypersecretion and 5-HT_{1A} Receptor Abnormalities. One factor that may contribute to the reduction in

5-HT_{1A} receptor binding in depression is increased cortisol secretion (known to occur in many depressed patients, as discussed below), since postsynaptic 5-HT_{1A} receptor mRNA expression is under tonic inhibition by corticosteroid receptor stimulation in some brain regions. The magnitude of the reduction in 5-HT_{1A} receptor density and mRNA levels due to stress-induced glucocorticoid secretion in rodents is similar to the magnitude of the differences seen between depressed and healthy humans. In rats, for example, chronic unpredictable stress was found to reduce 5-HT_{1A} receptor density an average of 22 percent across hippocampal subfields, similar to the 25 percent reduction in hippocampal 5-HT_{1A} receptor binding found in depression. Similarly in tree shrews, chronic social subordination stress (for 28 days) was found to decrease the density of 5-HT_{1A} receptors in posterior cingulate, parietal cortex, prefrontal cortex, and hippocampus by 11–34 percent, similar to the magnitude of reduced 5-HT_{1A} receptor binding found in other studies in these regions (Drevets et al., 2000; Sargent et al., 2000).

These findings are particularly noteworthy since chronic lithium has recently been demonstrated to attenuate the cytosol-to-nucleus translocation of the glucocorticoid receptor (Zhou et al., 2005). Movement (translocation) of the glucocorticoid receptor from the cytosol to the nucleus is required for its ability to regulate gene expression. By inhibiting this movement, lithium would be expected to attenuate the ability of glucocorticoids to regulate gene expression. This is precisely what has been observed in preclinical studies (Zhou et al., 2005). Furthermore, Drevets and colleagues (personal communication, 2003) have found that chronic lithium normalizes 5-HT_{1A} receptor binding potential in bipolar patients, an effect entirely consistent with an attenuation of glucocorticoid effects.

5-HT₂ Receptors. Mann and colleagues (1986) have reported an increased number of postsynaptic 5-HT₂ receptors in the brains of depressed patients, which is consistent with the work of Matsubara and colleagues (1991) who found an increase in the number of 5-HT₁ and 5-HT₂ receptors in the prefrontal cortex of suicide victims; however, another group did not replicate this finding (Stockmeier et al., 1997). Investigators have also used platelets from patients with mood disorders to study 5-HT₂ receptor binding to platelet membranes and serotonin-induced changes in platelet shape and aggregation to study 5-HT₂ receptors in patients with mood disorders.

There have been at least 12 independent studies in which the B_{max} for the 5-HT_{2A} receptor on platelets from depressed patients has been measured.¹⁶ One of these studies found no difference in this measure between patients suffering from depression and controls. All of the others

found a significant increase in the B_{\max} value for platelet 5-HT_{2A} receptors for depressed and suicidal patients compared with controls. Most of these studies either did not study bipolar patients or did not clearly separate unipolar and bipolar depressed patients. In one of the only studies of manic subjects, Velayudhan and colleagues (1999) used 125I-ketanserin as the radioligand for platelet 5-HT₂ receptors. They found no difference in the density or affinity of platelet 5-HT₂ receptors obtained from 29 manic patients and 29 healthy controls; moreover, 2 weeks of lithium treatment had no significant effect on these parameters.

Using SPECT, D'Haenen and colleagues (1992) found increased uptake of a 5HT₂ receptor antagonist, 2-ketaserin labeled with iodine 123 [¹²³I], in parietal cortex bilaterally and right greater than left asymmetry in the inferofrontal region of depressed patients compared with controls. A PET study (Biver et al., 1997) revealed a decrease in uptake of another 5HT₂ antagonist, altanserin labeled with fluorine [¹⁸F], in the right anterior portion of insular cortex and right posterolateral orbitofrontal cortex of depressed patients compared with controls. PET studies have yielded mixed results: two studies (Attar-Levy et al., 1999; Yatham et al., 2000) found a decrease in [¹⁸F] setoperone (5HT₂ antagonist) binding in the frontal cortex of depressed patients compared with controls, whereas one (Meyer et al., 1999) found no difference between the two groups. As with most studies of unipolar depression, the category itself is so heterogeneous (including nonrecurrent, minimally recurrent, and highly recurrent), that nonreplications are to be expected.

An exciting recent pharmacogenetic study searched for genetic predictors of treatment outcome in 1,953 patients with recurrent major depressive disorder (a mean of six previous episodes) who were treated with the antidepressant citalopram in the Sequenced Treatment Alternatives for Depression (STAR*D) study and prospectively assessed (McMahon et al., 2006). In a split-sample design, a selection of 68 candidate genes was genotyped with 768 single nucleotide polymorphism markers chosen to detect common genetic variation. A significant and reproducible association was found between treatment outcome and a marker in HTR2A ($p=1\times 10^{-6}$ to 3.7×10^{-5} in the total sample). Other markers in HTR2A also showed evidence of association with treatment outcome in the total sample. HTR2A encodes the serotonin 2A receptor, which is down-regulated by citalopram. Participants who were homozygous for the A allele had an 18 percent reduction in absolute risk of failing to respond to treatment, compared to those homozygous for the other allele. The A allele was six times more frequent in white than in black participants, for whom treatment was also less effective in this sample (McMahon et al., 2006). The A allele may thus contribute

to racial differences in outcomes of antidepressant treatment. Taken together with prior neurobiological findings, these new genetic data make a compelling case for a key role of HTR2A in the mechanism of antidepressant action.

Serotonin Transporter Binding. As discussed in Chapter 13, polymorphisms and variable tandem repeats in the serotonin transporter (*SERT*) gene have been the focus of extensive research in a variety of psychiatric disorders. Furlong and colleagues (1998) undertook a meta-analysis of over 1,400 individuals of European Caucasian origin. They used 772 controls and 375 bipolar and 299 unipolar patients to investigate the 5-HT transporter variable number tandem repeat (VNTR) polymorphism, and 739 controls and 392 bipolar and 275 unipolar patients to study the promoter polymorphism. They found a significant association with promoter allele 2 in the bipolar groups (estimated odds ratio 1.21; 95 percent confidence interval 1.00–1.45), unipolar groups (odds ratio 1.23; 95 percent confidence interval 1.01–1.42), and combined bipolar and unipolar groups (odds ratio 1.22; 95 percent confidence interval 1.04–1.42). These results raise the possibility that the promoter allele 2, previously shown to result in lower levels of *SERT* transcription, may be associated with risk for affective disorder. Preliminary reports have also linked *SERT* gene variants with antidepressant-induced mania (Mundo et al., 2001) and antidepressant response to sleep deprivation in bipolar patients (Benedetti et al., 1999).

Another method for evaluating presynaptic serotonergic function is measurement of *SERT* binding. A number of studies of postmortem brain tissue have been conducted to investigate *SERT* in projection regions of serotonergic cell bodies in suicide victims with depressive disorder. The results of these studies have been mixed. Early studies focused primarily on suicide victims and used [³H] imipramine, a less-than-optimum radioligand for measuring *SERT*. Those studies found increases, decreases, or no change in [³H] imipramine binding to frontal cortex in suicide victims (Stanley et al., 1982; Crow et al., 1984; Arora and Meltzer, 1989a). More recently, other radioligands, including [³H] paroxetine, [³H] citalopram, and [¹²⁵I]cyanoimipramine, have been identified as superior ligands for measuring *SERT* (Gurevich and Joyce, 1996). Unfortunately, the results obtained with these newer ligands in subjects with depression have also been mixed. Studies have found either significant decreases (Joyce et al., 1993; Arango et al., 1995) or no changes (Mann et al., 1996a; Bligh-Glover et al., 2000).

Since *SERT* is transcribed from a single copy gene, the platelet and CNS *SERT* are identical. Thus, abnormalities in platelet *SERT* may reflect abnormalities in CNS *SERT* (Owens and Nemeroff, 1998). A number of studies of platelet *SERT* density have been undertaken using [³H]-imipramine

binding or [³H]-paroxetine binding. Although the results of these studies are not entirely consistent, they suggest overall that the B_{\max} value for platelet is significantly lower in depressed subjects than in healthy subjects (Ellis and Salmond, 1994; Owens and Nemeroff, 1998).

Ichimiya and colleagues (2002) studied 13 antidepressant-naïve or antidepressant-free patients with mood disorders and 21 age-matched healthy control subjects. The patients consisted of seven with unipolar depression and six with bipolar disorder. PET scans were performed using a selective ligand for SERT, [¹¹C](+)-McN5652. Binding potential in the thalamus was found to be significantly increased in patients with mood disorders compared with controls, whereas binding potential in the midbrain did not differ between the groups. Subgroup comparison showed that unipolar depressed patients had significantly higher binding potential in the thalamus than that in controls.

In another endophenotype study, Leboyer and colleagues (1999) measured plasma 5-HIAA, platelet 5-HT, and [³H] imipramine in 20 unaffected relatives (URs) from families having at least two members with bipolar disorder and in 19 controls. They found that the URs manifested lower platelet SERT function than that in controls as revealed both by reduced number and diminished affinity of imipramine binding sites and diminished platelet 5-HT content. These preliminary results once again raise the possibility that reduced SERT function may represent an endophenotype in bipolar disorder and perhaps also in highly recurrent unipolar depression.

Lithium and the Serotonergic System

Preclinical studies show that lithium's effects on 5-HT function may occur at a variety of levels, including precursor uptake, synthesis, storage, catabolism, release, receptors, and receptor-effector interaction (Bunney and Garland-Bunney, 1987; Price et al., 1990). Overall, there is reasonable evidence from these studies that lithium enhances serotonergic neurotransmission, although its effects on 5-HT appear to vary depending on brain region, length of treatment, and 5-HT receptor subtype.¹⁷

In contrast to short-term studies, most long-term studies tend to show that 5-HT and 5-HIAA levels decrease with lithium administration.¹⁸ Treiser and colleagues (1981) found that long-term lithium increased basal and K⁺-stimulated 5-HT release in hippocampus but not cortex, while Friedman and Wang (1988) found that lithium increased 5-HT release in parietal cortex, hypothalamus, and hippocampus after 2–3 weeks, but not after a single injection or 1 week of treatment.

Taken together, these studies suggest that, rather than simply increasing or decreasing 5-HT release, lithium may

be serving to prevent excursions from the mean, thereby stabilizing 5-HT function (Knapp and Mandell, 1973).

Receptor binding studies have shown complex, regionally specific effects of acute or chronic lithium on the density of 5-HT₁ and 5-HT₂ receptors, although most findings suggest decreases in both sites, at least in hippocampus.¹⁹ Similarly, findings on the effects of both short- and long-term lithium treatment on 5-HT₂-mediated head-twitch behavior, as well as hyperactivity responses to the serotonin precursor 5-hydroxytryptophan, have been inconsistent.²⁰

The prolactin (PRL) response to 5-HT is, however, more consistently reported to be increased after short-term lithium use (Meltzer et al., 1981; Koenig et al., 1984; Meltzer and Lowy, 1987). Investigators using a variety of methodologies have provided evidence that lithium produces a subsensitivity of presynaptic inhibitory 5-HT_{1a} receptors,²¹ which may result in a net increase in the amount of 5-HT released per impulse.

In a series of important preclinical investigations, de Montigny and colleagues used electrophysiological recordings to measure the effects of lithium on the 5-HT system. They found that short-term lithium did not affect the responsiveness of the postsynaptic neurons to 5-HT or the electrical activity of the 5-HT neurons, but enhanced the efficacy of the ascending (presynaptic) 5-HT system (Blier and de Montigny, 1985; Blier et al., 1987). These observations led de Montigny and colleagues to propose that lithium may increase the efficacy of other antidepressant treatments (Blier and de Montigny, 1985; Blier et al., 1987). As reviewed in Chapter 19, several open and double-blind clinical investigations have now demonstrated that approximately 50 percent of nonresponders are converted to responders upon lithium administration within 2 weeks (de Montigny et al., 1981, 1983; Heninger et al., 1983). A number of the early human CSF studies are difficult to interpret, however, because of their methodology and study design, and their findings are most often confounded by concomitant alterations in mood state and neurovegetative symptomatology. Small increases in CSF 5-HIAA levels have been reported after subchronic lithium treatment in bipolar patients.²² Several studies have indicated that long-term lithium treatment “normalizes” previously low platelet 5-HT uptake in bipolar patients, an effect that may persist for several weeks after discontinuation (Born et al., 1980; Coppen et al., 1980; Meltzer et al., 1983; Poirier et al., 1988). Findings on the effects of lithium treatment on [³H] imipramine binding in platelets remain inconclusive.²³ Findings of neuroendocrine studies in patients have been more consistent, showing that acute or subacute lithium treatment results in augmented prolactin and/or cortisol responses to various challenges (fenfluramine, tryptophan, 5-hydroxytryptophan) in affectively ill patients. These findings suggest that lithium does indeed

facilitate serotonergic throughput in discrete brain areas.²⁴ However, recent studies in normal volunteers after 2 weeks of “therapeutic” lithium did not indicate increased neuroendocrine responses, suggesting that lithium’s effect on the serotonergic system may depend on its underlying activity (Manji et al., 1991a).

Overall, current evidence from both preclinical and clinical studies supports a role for lithium in enhancing presynaptic activity in the serotonergic system in the brain. Direct studies of lithium’s effects on serotonergic neurotransmission in humans have been limited in the past by the complexity of the widespread distribution of different types of serotonergic fibers throughout the brain, the only recently recognized multiple receptor subtypes, the relative lack of serotonin-specific pharmacological agents and outcome variables reflecting selective serotonergic responses, and inadequate attention to effects dependent on duration of treatment and affective and physiological state of the patient. Given the current understanding of the molecular neurobiology of both receptor subtypes and the transporter in the serotonergic system, we anticipate new, more specific pharmacological probes for future preclinical and clinical investigations.

Valproate and the Serotonergic System

Khaitan and colleagues (1994) found that chronic treatment (21 days in rats) with valproate did not significantly alter the hypothermia induced by 8-OH-DPAT, an agonist at 5-HT_{1A} receptors. Treatment with valproate also had no effect on radioligand binding to 5-HT_{1A} or 5-HT₂.

Maes and colleagues (1997) measured plasma cortisol response to l-5-hydroxytryptophan in 10 drug-free manic patients before and after treatment with valproate for 3 weeks. They found that administration of l-5-hydroxytryptophan produced an increase in cortisol responses both before and after valproate treatment; however, the l-5-hydroxytryptophan-induced cortisol response was significantly higher after treatment with valproate than before it. Their findings suggest that chronic treatment with valproate may enhance central 5-HT function in manic patients and appear to be consistent with the hypothesis that increasing 5-HT function plays a role in the antimanic effects of the drug.

Two other studies also have shown that valproate treatment leads to an increase in central 5-HT activity in humans. Fahn (1978) reported that treatment with valproate increased CSF levels of 5-HIAA in a patient with postanoxic intentional myoclonus. And Shiah and colleagues (1997) reported that 1 week of treatment with valproate significantly attenuated the hypothermic response to ipsapirone, a 5-HT_{1A} receptor agonist, in 10 healthy human males. This finding suggests that valproate enhances 5-HT neurotransmission

by causing a subsensitivity of presynaptic 5-HT_{1A} autoreceptors, because the hypothermic response to 5-HT_{1A} receptor agonists has been suggested to be mediated by those autoreceptors (although mixed pre- and postsynaptic activation has also been suggested for mediation of hypothermia in rats).

In contrast to the positive results of the above studies, Kusumi and colleagues (1994a) found no in vitro effect of valproate (100 M) on basal calcium or 5-HT-induced intracellular calcium mobilization in the platelets of 7 healthy subjects. Although the body of data investigating valproate’s effects on the serotonergic system is much smaller than that for lithium, it does tend to suggest nonidentical effects of the two drugs. Whether these differences account for observed clinical differences between the two drugs requires further study.

Carbamazepine and the Serotonergic System

Carbamazepine enhances serotonin levels in hippocampus in epilepsy-prone rats (Yan et al., 1992; Dailey et al., 1995) with a magnitude and time course suggesting a significance to its anticonvulsant effects. Moreover, depletion of serotonin inhibits carbamazepine’s actions in these animals (Dailey et al., 1995), although the mechanism of this effect is unknown. To our knowledge, no study to date has examined the effects of carbamazepine on 5-HT activity in manic patients. However, some human studies have shown evidence for an increase in 5-HT function during carbamazepine treatment.

For example, Elphick and colleagues (1990) studied plasma prolactin response to IV administration of tryptophan in seven healthy human males before and after a 10-day course of carbamazepine. They found that after the carbamazepine treatment, the prolactin response to tryptophan was significantly enhanced. Moreover, carbamazepine treatment has been reported to increase plasma total and free tryptophan in epileptic patients (Fernstrom, 1983), which could lead to an increase in brain 5-HT function.

In contrast, Post and colleagues (1984a) found no significant effect of carbamazepine on CSF levels of 5-HIAA in affectively ill patients. Likewise, Kusumi and colleagues (1994a) reported no in vitro effect of carbamazepine (10 M) for 1 or 4 hours on basal calcium or 5-HT-induced intracellular calcium mobilization in the platelets of seven healthy subjects.

Subsequently, Mannel and colleagues (1997) administered d, l-fenfluramine challenge tests to 30 mixed affective disorder patients after a mean period of 9.2 months of prophylactic treatment with either lithium or carbamazepine. Of the 30 patients, 15 were treated with lithium and the other 15 with carbamazepine. The authors found that the cortisol

response to d, l-fenfluramine was significantly increased in the lithium-treated patients compared with those receiving carbamazepine, whereas there was no significant difference in the prolactin response to d, l-fenfluramine between the two groups. These findings are in keeping with the enhancing effect of lithium, but not carbamazepine, on 5-HT function. However, interpretation of the study data was limited by a lack of placebo control, heterogeneity of diagnostic groups, and some patients taking neuroleptics within 72 hours before d, l-fenfluramine challenge testing.

The Serotonergic System in Manic-Depressive Illness: Summary

In summary, data from a variety of studies—including CSF 5-HIAA, neuroendocrine challenge, platelet and brain SERT, 5-HT receptor binding, and PET studies—suggest that abnormalities of the serotonergic system are present in depression. There have been far fewer studies of bipolar disorder in this regard, but the available data suggest the possibility of similar abnormalities. Most interesting are the PET studies demonstrating reduced 5-HT_{1A} binding in bipolar depressed patients and in unipolar depressed patients with bipolar relatives. Equally intriguing are recent reports that vulnerability to the deleterious effects of reduced tryptophan may represent an endophenotype for bipolar disorder. Boxes 14–6 and 14–7 summarize overall major findings and findings of newer studies supporting the involvement of the serotonergic system in the pathophysiology and treatment of bipolar disorder and recurrent unipolar depression.

The Cholinergic System

There has been a long-standing interest in the potential involvement of the cholinergic system in manic-depressive illness, based primarily on studies indicating the prominent mood and behavioral effects of cholinergic agonists and antagonists. Identification of this association initially stemmed from observations that industrial poisoning with cholinesterase inhibitors (which enhance acetylcholine [ACh] function by inhibiting its degradation) produced a depression-like clinical picture (Rowntree et al., 1950). In 1973, Janowsky and colleagues noted that physostigmine, a central cholinesterase inhibitor, caused brief but dramatic decreases in manic symptoms, a finding replicated by Modestin and colleagues (1973a,b) and Davis and colleagues (1978). These observations led Janowsky and colleagues to propose the cholinergic–aminergic balance hypothesis: that an increased ratio of cholinergic to adrenergic activity underlies the pathophysiology of depression, whereas the reverse occurs in mania. Because physostigmine made the patients in the study sick, questions were raised about the specificity of this finding. Yet proponents of the

BOX 14–6. A Summary of Major Findings Supporting Involvement of the Serotonergic System in the Pathophysiology and Treatment of Bipolar Disorder and Recurrent Unipolar Depression

- Reduced CSF 5-HIAA appears to be characteristic of both suicidal and impulsive/aggressive patients, whether unipolar or bipolar
- Reduced CSF 5-HIAA may be found in both depressive and manic states (consistent with a permissive hypothesis)
- Blunted neuroendocrine and temperature responses to various 5-HT agonists
- Reduced [³H]IMI binding in platelets and postmortem brain
- Reduced 5-HT_{1A} receptor binding in living brain and postmortem brain tissue
- Antidepressant efficacy of agents that increase intrasynaptic 5-HT
- Agents that increase intrasynaptic 5-HT are capable of triggering manic episodes, albeit less so than catecholamine-enhancing agents
- Tryptophan depletion induces a rapid depressive relapse in SSRI-treated patients (but not lithium-treated patients)
- Chronic antidepressants generally reduce 5-HT turnover in patients, even agents whose primary biochemical target is not the 5-HT system
- Chronic SSRIs reduce cell body 5-HT_{1A} density, thereby increasing 5-HT neuron firing
- Antidepressants generally decrease 5-HT₂ density in rat frontal cortex, but ECS increases it

CSF = cerebrospinal fluid; ECS = electroconvulsive stimulation; SSRI = selective serotonin reuptake inhibitor.

ACh hypothesis point out that the effect—inhibition of behavior and reduction of mania—generally precedes the associated nonspecific nausea and vomiting.

Physostigmine administration can also precipitate depression in euthymic bipolar patients maintained on lithium (Oppenheim et al., 1979) and in normal volunteers (Janowsky and Risch, 1984). Likewise, the direct muscarinic agonist arecoline produces depressive symptoms in euthymic bipolar patients off lithium and in normal volunteers (Nurnberger et al., 1983, 1989). And depressive symptoms, including psychomotor retardation and depressed mood, are often a complication of acetylcholinesterase inhibitor treatment of Alzheimer's disease. Such sensitivity to the mood-lowering effects of cholinergic drugs appears dependent on the presence of an underlying psychiatric disorder.

As described in Chapters 18 and 19, the cholinesterase inhibitor donepezil was added to various existing therapies in treatment-resistant bipolar patients in an open study, with benefits reported in over half the patients (Burt et al., 1999). However, manic episodes have also been associated with the

Genetic Studies

- Enzymes**
- TPH (tryptophan hydroxylase) gene intron 7 A218C polymorphism associated with BPD (Bellivier et al., 1998b)
 - TPH*A-containing variant may be a protective factor for depressive symptoms in male mood disorder patients (Serretti et al., 2001)
 - Differences in distribution of alleles for the MAO-A-CA repeat in female BPD (meta-analysis) (Preisig et al., 2000)
 - Increased frequency of COMT met158 and the short 5-HTTLPR (linked functional polymorphic region) alleles and genotypes in BPD without panic disorder (Rotondo et al., 2002)
- Transporter**
- Increased frequency of allele 12 of VNTR (variable number tandem repeat) polymorphism intron 2 of 5-HTT gene in BPD (Collier et al., 1996a)
 - 5-HTTLPR homozygous low-activity genotype reported to be associated with affective disorder (Collier et al., 1996b)
 - VNTR in the second intron of 5-HTT gene reported to be associated with BPD (Kunugi et al., 1997; Rees et al., 1997)
 - Polymorphism in 5-HT_{2C} receptor gene and 5-HTT gene reported to be found in BP-I females may represent a minor increase in susceptibility (Oruc et al., 1997)
 - Homozygosity for the short variant of the 5-HTTLPR reported to be more frequent in BPD (Bellivier et al., 1998a)
 - Promoter allele 2 of 5-HTT gene (that results in lower level of 5-HT transporter transcription) may be associated with risk for affective disorder (meta-analysis) (Furlong et al., 1998)
 - The 12 repeat of the VNTR in intron 2 of the 5-HTT gene reported to be a susceptibility (although small) factor in BPD (Kirov et al., 1999)
 - Individuals homozygous for the long variant 5-HTTLPR had better mood symptom amelioration after total sleep deprivation (Benedetti et al., 1999)
 - Increased 5-HTTLPR 3'UTR G/T polymorphism associated with BPD (Mynett-Johnson et al., 2000)
 - 5-HTT gene variations associated with susceptibility to puerperal psychosis in BPD (Coyle et al., 2000)
 - Increased 5-HTTLPR long allele reported in rapid cycling (Cusin et al., 2001)

- 5-HTTLPR short variant associated with poor response to fluoxetine in MDD and BPD (Zanardi et al., 2001)
 - Increased 5-HTTLPR short-allele gene and higher rate of homozygosity for the short variant in patients with history of induced mania by serotonergic antidepressants (Mundo et al., 2001)
- Receptors**
- 5-HT_{2C} receptor gene, Ser23 allele, may increase susceptibility to BPD in females (Gutierrez et al., 1996)
 - 5-HT_{5A} gene allelic association was found with the -19 G/C polymorphism and BPD, MDD, and schizophrenia (Birkett et al., 2000)
 - Variation in the 5-HT₆ gene may be associated with BPD (Vogt et al., 2000)
 - 5-HT_{2A} receptor gene promoter polymorphism 1438 A/G may be causally related to BPD (Chee et al., 2001)
 - Increase of 5-HT_{2C} receptor gene (Cys 23 Ser) allele in MDD-BPD (Lerer et al., 2001)
 - 5-HT_{3A} receptor C178T missense mutation may represent susceptibility to BPD (Niesler et al., 2001)
 - Increased frequency of A allele of 5-HT_{2A} receptor gene in subgroup of BP-I patients with low suicidal risk (Bonnier et al., 2002)
- Serotonin and metabolite levels**
- Increased plasma free 5-HT and 5-HIAA in BPD patients treated chronically with Li (Artigas et al., 1989)
 - Reduced 5-HIAA in frontal-parietal and 5-HIAA/5-HT ratio in temporal cortex in bipolar postmortem studies (Young et al., 1994b)
 - Increased 5-HT platelet levels in bipolar depressed patients (Shiah et al., 1999)

Challenge Studies

- Blunted response of prolactin to fenfluramine in manic patients inconsistently reported (Thakore et al., 1996) (Yatham 1996)
- Blunted GH response to sumatriptan (5-HT_{1D} agonist) reported in BPD patients who also suffered migraine (Mahmood et al., 2002)
- Sumatriptan-induced GH response reported to be blunted in depressed but not manic patients (Yatham et al., 1997)
- Decreased planning and memory function reported in first-degree relatives of BP-I patients after acute tryptophan depletion. Double-blind crossover trial (Sobczak et al., 2002)

(continued)

BOX 14-7. Newer Studies Supporting Involvement of the Serotonergic System in the Pathophysiology and Treatment of Manic-Depressive Illness (Primarily Bipolar) (continued)
Intracellular Signaling Related to 5-HT

- Increased basal membrane/cytosol PKC portioning, and increased 5-HT-elicited platelet PKC translocation and membrane/cytosol portioning in mania. Li (2 weeks) normalized the changes (Friedman et al., 1993; J. Wang et al., 1999)
- Decrease of 5-HT-induced Ca mobilization by pretreatment with PKC activator (PMA) (Suzuki, 2001)
- Enhanced 5-HT-receptor-mediated G protein coupling in frontal cortical membranes from postmortem BPD patients (Friedman and Wang, 1996)
- Increase in 5-HT-induced Ca mobilization of untreated manic patients (Yamawaki et al., 1996; Suzuki et al., 2001). Restored to control levels in treated euthymic BPD patients (Okamoto et al., 1995)
- Increased Ca response to 5-HT in platelets from BPD patients; 5-HT-induced intraplatelet Ca response reported to represent a good predictor of mood stabilizer response in a 5-year follow-up (Kusumi et al., 2000)

Treatment Related

- Challenge studies
- Increased prolactin response to tryptophan infusion after short-term Li treatment (Price et al., 1989)
 - Increase in plasma cortisol response to L-5-HTP (5-hydroxytryptophan) after treatment with valproate in manic patients (Maes et al., 1997)
 - Acute tryptophan depletion did not reverse beneficial effects of Li on mood and suicidality in BPD patients (Hughes et al., 2000)
 - TCA and MAOIs had higher rate of switch to mania than fluoxetine in BPD patients (Boerlin et al., 1998)

Receptor and transporter studies

- IMI and PXT had better antidepressant response than placebo only in patients with low plasma Li levels in bipolar depression. Possibly supportive of serotonergic effects of Li (Nemeroff et al., 2001)
- Potentiation of antidepressant effect of total sleep deprivation and prevention of short-term relapse reported to be produced by pindolol (5-HT_{1A} antagonist) in bipolar depression (Smeraldi et al., 1999). Overall, the pindolol augmentation strategy remains controversial
- Increased potency of 5-HT in a platelet shape change velocity paradigm (May represent a contributory factor in the cardiovascular risk associated with mood disorders); reduced after antidepressant treatment in unipolar and bipolar depression (Brusov et al., 1989)
- Increased 5-HT platelet uptake in mania patients; normalized at discharge (Meagher et al., 1990)
- Reduced V_{max} of 5-HT uptake in platelets in BPD patients (Marazziti et al., 1991)
- Reduced (trend) 5-HT uptake sites in frontal cortex in BPD depressed patients (Leake et al., 1991)
- Reduced platelet 5-HTT function in unaffected relatives of BPD patients (Leboyer et al., 1999)
- Reduced 5-HT_{1A} receptor binding potential in raphe and hippocampus-amygdala (PET), more marked in bipolar and unipolar depressive patients with bipolar relatives (Drevets et al., 1999)
- Increased binding potential of 5-HTT in thalamus in mood disorder patients (Ichimiya et al., 2002)

BPD = bipolar disorder; BP-I = bipolar-I; Ca = calcium; COMT = catechol-O-methyltransferase; GH = growth hormone; IMI = imipramine; Li = lithium; MAOI = monoamine oxidase inhibitor; MDD = major depressive disorder; PKC = protein kinase C; PXT = paroxetine; TCA = tricyclic antidepressant.

use of donepezil in case reports (Benazzi, 1998, 1999). A recent small, 6-week double-blind, placebo-controlled trial involving 11 patients with treatment-resistant mania found no difference in the efficacy of add-on donepezil compared to placebo in the treatment of manic symptoms in patients with treatment-resistant mania (Evins et al., 2006).

In a small open study, Stoll and colleagues (1996) gave choline bitartrate to six lithium-treated outpatients with rapid-cycling bipolar disorder. Five of the six patients were reported to have a reduction in manic symptoms and four to have a marked reduction in all mood symptoms during the choline therapy. Although these findings are intriguing, the small sample size and open nature of this study suggest that caution is required in the interpretation of the results.

Finally, the muscarinic agonist xanomeline has been reported to decrease mood swings and psychotic-like behaviors in Alzheimer's patients (Bodick et al., 1997). In preclinical studies, muscarinic agonists have been found to increase and antagonists to decrease immobility or "despair" in the forced swim test model of depression. Thus, the cholinesterase inhibitor physostigmine, but not the peripherally acting neostigmine, increases immobility in the forced swim test, suggesting depressogenic activity. Interestingly, the enhanced immobility produced by physostigmine was reversed by the α_1 -adrenergic agonist metoprolol, supporting the contention that a balance between the cholinergic and adrenergic systems may play an important role in modulating mood. The hypercholinergic Flinders

Resistant Line of rats has exaggerated immobility in the forced swim test, as do rats after chronic treatment with muscarinic antagonists to produce cholinergic supersensitivity (Janowsky et al., 1994).

The cholinergic hypothesis is also supported by a number of indirect observations documenting differences in the responses of patients and controls after specific interventions, such as cholinergic-induced REM sleep (Sitaram et al., 1982; Janowsky et al., 1994). REM occurs during discreet periods of sleep, but its onset can be induced earlier in normal volunteers by cholinergic agents.²⁵ Sitaram and colleagues (1980) found faster induction of REM sleep with arecoline (a cholinergic agonist) in two groups of drug-free euthymic patients with affective disorders (primarily bipolar disorder). The same research team followed up with a second report on 14 euthymic bipolar patients, again finding that the second REM period occurred significantly earlier (Sitaram et al., 1982). Two groups replicated these results nearly a decade later (Berger et al., 1989; Nurnberger et al., 1989).

A few studies have addressed the heritability of this trait. Nurnberger and colleagues (1983) investigated the cholinergic induction of REM during sleep in seven sets of identical twins. Overall, they found an intraclass correlation of .69 for REM latency time after cholinergic stimulation, suggesting a genetic component to REM latency findings.

Sitaram and colleagues (1987) studied REM latency after cholinergic exposure in 35 ill and 34 healthy first-degree relatives of 34 unipolar depressed probands, selected on the basis of their supersensitivity to cholinergics. Supersensitivity was observed in 66 percent of the ill relatives and 22 percent of the well relatives, again suggesting that REM latency tracks with affective illness. Unfortunately for our current goal of identifying subclinical endophenotypes in nonaffected relatives, these studies did not compare their findings with a control population.

In sum, findings on cholinergic-induced REM sleep in bipolar subjects have been consistent among studies. However, there is incongruence regarding the state versus trait status of this phenotype: some studies have identified state independence (Sitaram et al., 1980; Nurnberger et al., 1989), while others have not (Berger et al., 1989).

Although less extensively than for the serotonergic or noradrenergic systems, investigators have also used neuroendocrine challenge tests to examine the acetylcholine system in depression. An exaggerated GH response to pyridostigmine in major depression has been reported, an observation (with 63 percent sensitivity) that distinguished these patients with unipolar depression from those with schizophrenia and alcohol dependence syndrome (Cooney et al., 1997). Dinan and colleagues (1994) used the same test to investigate the cholinergic system in seven male manic

patients and seven male healthy controls. They found that the GH response to pyridostigmine (120 mg) was significantly enhanced in the manic patients. They conclude that the enhanced pyridostigmine/GH responsiveness in mania may be due to enhanced somatostatin tone or increased cholinergic receptor responsiveness.

Sokolski and DeMet (1999, 2000) have used pupillary constrictions following application of the cholinergic agonist pilocarpine as a means to investigate the cholinergic system. Cholinergic sensitivity was assessed prior to and following treatments by means of graded concentrations of pilocarpine eyedrops (.03–2.0 percent). Pupil size changes were quantified with an infrared pupillometer. The same group also found that lithium and valproate both potentiated the cholinergic responses, and that improvements in mania were closely correlated with decreases in ED₅₀ (i.e., amount of pilocarpine necessary to bring about half-maximal responses). These results are consistent with the suggestion that the antimanic effects of lithium and valproate may involve (at least in part) increasing cholinergic activity in relation to monoaminergic neurotransmission.

Investigators have also used magnetic resonance spectroscopy (MRS) to investigate “choline resonance.” The first reported *in vivo* proton MRS study of choline compounds in affective disorders found that elderly depressed patients had increased choline/chromium (Cho/Cr) ratios in basal ganglia compared with controls (Charles et al., 1994). Subsequently, a similar difference was found between muscular dystrophy and controls (Renshaw and Cohen, 1993; Charles et al., 1994). Early studies in bipolar patients (Sharma et al., 1992; Lafer et al., 1994) also indicated that Cho/Cr resonance was elevated in basal ganglia compared with that in controls. Two studies of cortical regions found that there were no choline-level differences in either the parietal or occipital regions in affective disorder patients compared with controls (Sharma, 1992; Stoll et al., 1992), suggesting that the finding of increased Cho/Cr may be limited to the subcortical region.

A number of studies have attempted to investigate the effects of medication on choline levels in affective disorder patients. Again examining the basal ganglia, studies by two groups have found elevated Cho/Cr levels in depressed subjects which normalized with therapy (Renshaw, 1993; Charles et al., 1994). A larger controlled study by the Renshaw group (Sonawalla et al., 1999) found that basal ganglia Cho/Cr levels increased compared with baseline in outpatients with unipolar depression treated for 8 weeks with fluoxetine. In bipolar patients, an early cross-sectional investigation by Lafer and colleagues (1994) found no difference in basal ganglia Cho/Cr levels between a group of lithium-treated and lithium-free bipolar subjects; however, other medications may have been an important confound.

A more recent longitudinal study of lithium's effects on medication-free bipolar patients, measured with quantitative MRS methods (G. Moore et al., 1999), found a significant decrease compared with baseline in frontal lobe choline concentration after 7 days of lithium treatment, an effect that persisted with chronic lithium treatment (4 weeks).

This study is interesting in several respects. Recent *in vitro* studies suggest that lithium, potentially through its effects on PKC, stimulates phospholipase D, resulting in the breakdown of phosphatidylcholine (PTC) to diacylglycerol (DAG) (discussed below). A mobile head group on the PTC molecule may make this compound partially visible by MRS, contributing in part to the total brain Cho signal observed through proton MRS.

Lithium and the Cholinergic System

Neurochemical, behavioral, and physiological studies have all indicated that the cholinergic system is involved in affective illness (Dilsaver and Coffman, 1989) and that lithium alters the synaptic processing of ACh in rat brain. The addition of up to 1 mM of lithium *in vitro* has no effect on ACh synthesis or release, but chronic *in vivo* lithium treatment appears to increase ACh synthesis, choline transport, and ACh release in rat brain (Simon and Kuhar, 1976; Jope, 1979). While some investigators have reported reductions in ACh levels in rat brain following subchronic administration (Krell and Goldberg, 1973; Ho and Tsai, 1975; Ronai and Vizi, 1975), Jope (1979) reported increased synthesis of ACh in cortex, hippocampus, and striatum following 10 days of lithium administration.

With respect to the density of muscarinic receptors, chronic lithium has been reported to increase (Kafka et al., 1982; Levy et al., 1982; Lerer and Stanley, 1985), decrease (Tollefson et al., 1982), or not change (Maggi and Enna, 1980) the binding of the cholinergic ligand [³H]quinuclidinyl benzilate (QNB) in various areas of rat brain. In human caudate nucleus, lithium is reported to reduce the affinity of [³H]QNB binding. The effects of lithium on both up- and downregulation of muscarinic receptors in brain have also been investigated. There have been reports that lithium is able to abolish the increase in [³H]QNB binding produced by atropine, but is without effect on the downregulation induced by the cholinesterase inhibitor diisopropylfluorophosphate (DFP); these data are variable and inconclusive, however (Levy et al., 1982; Lerer and Stanley, 1985). Ellis and Lenox (1990) examined both receptor binding and muscarinic receptor-coupled phosphoinositide (PI) response in rat hippocampus during atropine-induced upregulation. They found that chronic treatment with atropine results in an upregulation of muscarinic receptors and a supersensitivity of the PI response

in the hippocampus. Coadministration of chronic lithium prevented the development of supersensitivity of the muscarinic receptor PI response without significantly affecting the extent of upregulation of receptor binding sites. These findings suggest that lithium's actions are exerted at a point beyond the receptor binding site, possibly affecting the coupling of the newly upregulated receptors at the level of the signal-transducing G proteins. Thus, similar to the case for dopaminergic and fl-adrenergic receptors, it appears that lithium can block the development of cholinergic receptor supersensitivity. Chronic lithium has also been reported to increase intraerythrocyte concentrations of choline more than 10-fold.²⁶ This appears to be the result of not only inhibition of choline transport but also enhanced phospholipase D-mediated degradation of phospholipids, which may as well be mediated via PKC activation.

In behavioral studies, chronic lithium in clinically relevant doses is reported to enhance a number of cholinergically mediated responses, including catalepsy and hypothermia. The effect of lithium on pilocarpine-induced catalepsy and hypothermia was found to be of the same order of magnitude as the enhancement induced by chronic scopolamine pretreatment. Combined administration of both pretreatments resulted in additive effects, suggesting that different mechanisms may be involved (Russell et al., 1981; Lerer and Stanley, 1985; Dilsaver and Hariharan, 1988). Of interest in this regard is a study by Dilsaver and Hariharan (1989), who reported that chronic lithium treatment results in a supersensitivity of nicotine-induced hypothermia in rats.

Perhaps the most striking example of lithium's ability to potentiate muscarinic responses comes from the lithium-pilocarpine seizure model.²⁷ In large doses, pilocarpine and other muscarinic agonists cause prolonged, usually lethal seizures in rats. Although lithium alone is not a convulsant, pretreatment with lithium increases the sensitivity of pilocarpine almost 20-fold.²⁸ Interestingly, this behavioral effect of lithium is markedly attenuated by intracerebroventricular administration of myo-inositol in both rats and mice (Kofman et al., 1991; Tricklebank et al., 1991), representing perhaps the best correlation between a biochemical and behavioral effect of lithium (see later discussion of phosphoinositide turnover). A synergism with the cholinergic system also occurs in electrophysiological studies in hippocampal slices, in which pilocarpine and lithium together, but not alone, produce spontaneous epileptiform bursting (Jope et al., 1986; Ormandy and Jope, 1991). Elegant studies in rat hippocampus have demonstrated that lithium can reverse muscarinic agonist-induced desensitization, an effect that is mediated through PI hydrolysis and can be reversed by inositol (Pontzer and Crews, 1990). Studies by Evans and colleagues (1990)

have indicated that lithium's role in lithium–pilocarpine seizures is to increase excitatory transmission through a presynaptic facilitatory effect. Lithium alone was also found to augment synaptic responses; this effect of the drug could be blocked by a PKC inhibitor. These results suggest that lithium's effects in this model may occur through a PKC-mediated presynaptic facilitation of neurotransmitter release (discussed later). Biochemical, electrophysiological, and behavioral data suggest that chronic lithium administration stimulates ACh synthesis and release in rat brain and potentiates some cholinergic-mediated physiological events. Interestingly, similar to the situation observed with the catecholaminergic system, pharmacological studies indicate that chronic lithium prevents muscarinic receptor supersensitivity, most likely through postreceptor mechanisms. Overall, the preponderance of the data suggests that chronic lithium enhances cholinergic throughput.

By contrast, very few studies have examined the effects of valproate or carbamazepine on the cholinergic system. However, existing data suggest that carbamazepine, like lithium, may enhance cholinergic function. Zhu and colleagues (2002) showed through in vivo microdialysis that therapeutically relevant concentrations of carbamazepine increased basal ACh release in frontal cortex of freely moving rats, effects regulated by N-type voltage-sensitive Ca^{2+} channels. Acute administration of modest doses of carbamazepine (25 mg/kg) has been shown to increase both striatal and hippocampal extracellular levels of ACh, whereas both acute and chronic administration of carbamazepine (25 and 50 mg/kg, respectively, per day) were found to increase intracellular ACh levels in striatum and hippocampus (Mizuno et al., 2000).

The Cholinergic System in Manic-Depressive Illness: Summary

Overall, although not extensively, the data are consistent with Janowsky's original proposal that cholinergic–adrenergic balance may play a role in modulating affective behavior.

Although lithium clearly potentiates cholinergic responses, the therapeutic activity of other antidepressant and antimanic drugs does not consistently parallel effects on the cholinergic system, and a number of these agents, including MAOIs and various “second-generation” antidepressants, lack any interaction with cholinergic receptors (Rudorfer et al., 1984). Together these findings suggest that, although manipulation of the cholinergic system is capable of modulating affective state, it does not clearly represent a relevant therapeutic action of currently available agents. The possibility that additional means of augmenting the functioning of the cholinergic system may have utility is an interesting avenue that has not been extensively studied. Unfortunately, there have been few follow-up

BOX 14–8. Newer Studies of the Cholinergic System in the Pathophysiology and Treatment of Manic-Depressive Illness (Primarily Bipolar)

Clinical Studies

- Increased pilocarpine required to elicit 50 percent reduction in pupil size; correlated with severity of mania (Sokolski and DeMet, 2000)
- Increased pupillary responsiveness to pilocarpine (cholinergic agonist) after valproate and lithium treatment in mania (DeMet and Sokolski, 1999; Sokolski and DeMet, 1999)
- Increased pyridostigmine (acetylcholine esterase inhibitor)-induced release of GH in manic patients (Dinan et al., 1994)
- Increased erythrocyte choline concentration in patients with mania (Stoll et al., 1991)
- RS 86 (cholinergic agonist) exhibited antimanic and REM sleep-inducing properties (Berger et al., 1991)

In Vitro Studies

- Chronic valproate, but not lithium or carbamazepine, reduced carbachol-stimulated early growth response-1 (Egr-1) DNA binding activity by 60 percent in SH-SY5Y cells (Grimes and Jope, 1999)
- Lithium inhibited carbachol stimulation AP-1 gene expression in SH-SY5Y cells (Jope and Song, 1997)
- Selective effect of lithium on M1-mediated muscarinic neurotransmission in hippocampal slices in CA3 pyramidal neurons of guinea pigs (Muller et al., 1989)

GH = growth hormone; REM = rapid eye movement.

studies to investigate more fully the role of specific muscarinic receptor subtypes in mediating the antimanic effects of nonselective cholinomimetics. The poor selectivity and tolerability of muscarinic agonists and other cholinomimetics and the low efficacy of agonists for putative target receptors have precluded extensive study and development of these agents for affective disorders. Box 14–8 summarizes findings of newer studies supporting the involvement of the cholinergic system in the pathophysiology and treatment of manic-depressive illness, principally the bipolar subgroup.

The GABAergic System

Gamma aminobutyric acid (GABA), widespread in the CNS, is the major inhibitory neurotransmitter, diminishing the activity of its many target neurons. (See Figure 14–4 for a depiction of the various regulatory processes involved in GABAergic neurotransmission.) GABAergic neurons are much more diffusely located than catecholaminergic neurons, with similar GABA concentrations being found in diverse brain regions. Since GABA exerts a general inhibitory

Figure 14–4. The various regulatory processes involved in GABAergic neurotransmission. The amino acid (and neurotransmitter) glutamate serves as the precursor for the biosynthesis of gamma-aminobutyric acid (GABA). The rate-limiting enzyme for the process is glutamic acid decarboxylase (GAD), which utilizes pyridoxal phosphate as an important cofactor. Furthermore, agents such as L-glutamine- γ hydrazide and allylglycine inhibit this enzyme and thus the production of GABA. Once released from the presynaptic terminal, GABA can interact with a variety of presynaptic and postsynaptic receptors. Presynaptic regulation of GABA neuron firing activity and release occurs through somatodendritic (not shown) and nerve terminal GABA_B receptors, respectively. Baclofen is a GABA_B receptor agonist. The binding of GABA to ionotropic GABA_A receptors and metabotropic GABA_B receptors mediates the effects of this receptor. The GABA_B receptors are thought to mediate their actions by being coupled to Ca²⁺ or K⁺ channels via second messenger systems. Many agents are able to modulate GABA_A receptor function. Benzodiazepines, such as diazepam, increase chloride (Cl⁻) permeability and there are numerous antagonists available directed against this benzodiazepine-binding site. There is also a distinctive barbiturate-binding site on GABA_A receptors, and many psychotropic agents are capable of influencing the function of this receptor (see diagram). GABA is taken back into the presynaptic nerve ending by a high-affinity GABA uptake transporter (GAT) similar to that of the monoamines. Once inside the neuron, GABA breakdown can occur by GABA-transaminase (GABA-T), which is localized in the mitochondria; GABA that is not degraded is sequestered and stored into secretory vesicles by vesicular GABA transporters (VGAT), which differ from vesicular monoamine transporters in their bioenergetic dependence. (Source: Owens and Kriegstein, 2002. Reprinted with permission from Macmillan Publishers, Ltd.)

role on brain excitability, it is not altogether surprising that it has been postulated to be involved in a variety of disorders presumed to be associated with phasic regional neuronal hyperexcitability. Furthermore, the increased use of valproate as a treatment for mania in recent years has led to a resurgence of interest in the potential role of GABA in bipolar disorder.

Several investigators have reported significantly lower CSF and plasma GABA levels in patients with major

depression (predominantly unipolar) than in controls (Petty and Schlessler, 1981; Petty et al., 1990). In three other studies, however (Post et al., 1980b; Gerner and Hare, 1981; Joffe et al., 1986), investigators sampled a later aliquot higher up in the rostrocaudal gradient for GABA and found no significant difference between depressed patients and controls. Berrettini and colleagues (1986) sampled euthymic bipolar depressed patients and found them to be not significantly different from controls. Even in studies finding low levels

of GABA, the findings were not specific to cases of depression or mania but were also seen in alcoholism (Petty et al., 1993).

In a longitudinal study of one patient with rapid cycles, Joffe and colleagues (1986) found CSF GABA to be significantly higher during the patient's five manic episodes than in the four depressed episodes. Two well-state studies of CSF GABA (Berrettini et al., 1986; Joffe et al., 1986) produced conflicting results; the former noted lower levels compared with controls whereas the latter did not.

The relationship between GABA in plasma and in CSF is not clear. In one small study, no correlation was found (Berrettini and Post, 1984). In contrast, Petty and Sherman (1984) reported that plasma GABA levels were significantly lower than normal in a group of 62 medicated depressed patients. Only four of these patients were bipolar, however, and their mean levels were very close to those of the controls. Combining data from their four previous studies, Coffman and Petty (1986) found that manic and remitted bipolar patients had significantly higher levels of plasma GABA than those of control subjects, but when the patients were depressed, the plasma GABA levels did not differ from the controls. Of three studies of GABA in recovered bipolar patients, one, using lithium-treated patients, showed GABA levels significantly higher than normal levels (Petty and Sherman, 1984; Coffman and Petty, 1986), whereas the other two, using patients off all medication for 2 weeks, showed significantly lower than normal levels (Berrettini et al., 1983, 1985b). This apparent discrepancy might be explained by the longitudinal finding of the Berrettini group that plasma GABA levels fall significantly after lithium is discontinued. Interestingly, a small study of identical twins revealed that plasma GABA levels show a close intrapair correspondence (Berrettini and Post, 1984). However, it is too early to assess whether this measure will be useful as a trait marker for bipolar disorder. Low plasma GABA differentiates well from ill subjects in about one-third of bipolar patients (Petty et al., 1993) and is also seen in euthymic unmedicated bipolar patients (Berrettini et al., 1982). Plasma GABA levels do not correlate with severity of symptoms for either depression or mania (i.e., are state-independent); however, the key research for identifying whether the marker is familial and segregates with illness in families with affective disorders has not yet been done.

In a large multicenter trial of valproate in the treatment of mania (Bowden et al., 1994; see Chapter 18), plasma concentrations of GABA were measured before and after treatment in a subset of 63 patients. Interestingly, although treatment with both lithium and valproate resulted in reductions in plasma GABA levels, pretreatment levels of plasma GABA predicted response to valproate but not to lithium. However, it was the patients with higher levels of

plasma GABA who were more likely to show an antimanic response to valproate. Since valproate is believed to enhance GABA function (discussed below), these observations suggest a more complex relationship between the manic state and "too little GABA."

Krystal, Sanacora, and colleagues undertook a series of *in vivo* MRS studies to measure GABA in patients with mood disorders (Sanacora et al., 1999; Krystal et al., 2002). Measurement of GABA levels in occipital cortex (the only brain region demonstrated thus far to allow for reliable GABA quantitation using MRS) appeared to discriminate between unipolar and bipolar depressed patients. Thus, these investigators found significant reductions in occipital cortex GABA levels in unipolar but not bipolar depressed patients. Interestingly, among unipolar depressed patients, reductions were most prominent in patients with melancholic or psychotic depression compared with those meeting criteria for atypical depression, a form of depression with features that overlap considerably with bipolar depression.

Recently, Dean and colleagues (2005) measured the density of GABA ($[^3\text{H}]$ muscimol) and benzodiazepine ($[^3\text{H}]$ flumazenil) binding sites on the GABA(A) receptor in hippocampi, obtained postmortem, from schizophrenic, bipolar-I disorder and control subjects. In addition, they measured the amount of $[^3\text{H}]$ flumazenil binding that could be displaced with zolpidem and clonazepam. There were complex, regionally specific changes in $[^3\text{H}]$ muscimol binding in the hippocampus from subjects with bipolar disorder. Notably, there were also significant decreases in zolpidem-sensitive and increases in zolpidem-insensitive $[^3\text{H}]$ flumazenil binding in most regions of the sections of the hippocampal formation studied in bipolar disorder. Unlike $[^3\text{H}]$ flumazenil, zolpidem does not bind to the $\alpha 5$ subunit of the GABA(A) receptor; these findings therefore raise the possibility that there is an increase in GABA(A) receptors containing $\alpha 5$ subunit in the hippocampus from subjects with bipolar-I disorder.

Postmortem Brain Studies of GABA Synthetic Enzymes

In postmortem brain studies, Guidotti and colleagues (2000) identified unexpected abnormalities in the levels of reelin and the GABA synthetic enzymes glutamic acid decarboxylase (GAD_{65} and GAD_{67}) in schizophrenia and bipolar disorder. Reelin is a glycoprotein secreted preferentially by cortical GABAergic interneurons (layers I and II) that binds to integrin receptors located on dendritic spines of pyramidal neurons or on GABAergic interneurons of layers III through V expressing the disabled-1 gene product (Dab-1), a cytosolic adaptor protein that mediates reelin action (Guidotti et al., 2000). The authors found that prefrontal cortex and cerebellar expression of reelin

mRNA, GAD₆₇ protein and mRNA, and prefrontal cortex reelin-positive cells was significantly decreased by 30–50 percent in patients with schizophrenia or bipolar disorder with psychosis, but not in those with unipolar depression without psychosis, when compared with nonpsychiatric subjects.

Benes and colleagues (2000) developed techniques for immunolocalizing GAD₆₅ and applied these techniques to anterior cingulate and prefrontal cortices of 12 normal controls, 12 schizophrenic subjects, and 5 bipolar subjects. They found that in the bipolar subjects, the density of GAD₆₅-IR terminals was significantly reduced in all four layers of anterior cingulate cortex (layers II–VI), but these differences were most significant in layers II (27.8 percent) and III (37.2 percent), regardless of whether the subjects had been treated with neuroleptics. In prefrontal cortex, the bipolar subjects showed similar differences in terminal density for pyramidal neurons and nonpyramidal neurons but not neuropil in the four laminae examined. The bipolar group showed no differences in either the size of cell bodies or GAD₆₅ immunoreactive terminals; given the small sample size, however, the possibility of a Type II error cannot be excluded.

The same group (Heckers et al., 2002) investigated hippocampal sections from 15 bipolar subjects, 15 schizophrenic subjects, and 15 controls through an *in situ* hybridization for GAD₆₅ and GAD₆₇ mRNA. These investigators found that the density of GAD₆₅ and GAD₆₇ mRNA-positive neurons was decreased by 45 and 43 percent, respectively, in subjects with bipolar disorder, but only 14 and 4 percent, respectively, in subjects with schizophrenia. The decreased density of GAD₆₅ mRNA-positive neurons in subjects with bipolar disorder was significant in sectors CA2/3 and dentate gyrus, and that of GAD₆₇ mRNA-positive neurons was significant in CA4 but not other hippocampal sectors. Cellular GAD₆₅ mRNA expression was significantly decreased in subjects with bipolar disorder, particularly in CA4, but not in schizophrenic subjects. Cellular GAD₆₇ mRNA expression was normal in both groups.

Studies of Reelin

As discussed above, postmortem studies have revealed that an unexpected molecule may be involved in the pathophysiology of severe neuropsychiatric disorders, including bipolar disorder and schizophrenia (Impagnatiello et al., 1998; Fatemi et al., 2000a, 2001a,b; Guidotti et al., 2000). Reelin is a member of a growing group of diverse proteins whose absence is associated with an almost identical phenotype—inversion of cerebral cortical layers and reduction or absence of cerebellar foliation.

Costa and colleagues first showed that reelin protein

and mRNA were reduced in several brain areas in both schizophrenic and psychotic bipolar patients, leading to their suggestion that reelin deficiency may be a vulnerability factor for psychosis independent of diagnosis (Guidotti et al., 2000; Costa et al., 2001, 2002). Subsequently, Fatemi and colleagues confirmed Costa's findings, but found similar reductions in reelin protein in hippocampi of nonpsychotic bipolar and depressed patients, suggesting that reelin deficiency alone is not a marker of psychosis (Fatemi et al., 2000b, 2001a,b, 2002).²⁹

Recent results from Fatemi's group (unpublished observations) revealed that reelin 410 and 180 kilodalton species were significantly reduced in cerebellum of subjects with bipolar disorder (with and without psychosis) compared with normal controls. Bipolar subjects also demonstrated significant deficits in GAD proteins of 65 and 67 kilodalton (GAD₆₅ and GAD₆₇) compared with controls. In contrast, reelin deficiency was limited to the 180 kilodalton species in cerebella of schizophrenic subjects. All schizophrenic and depressed subjects also showed significant reductions in GAD₆₅ and GAD₆₇ proteins compared with levels in controls. These results confirm the findings of a recent study by Benes and colleagues (Heckers et al., 2002) showing a global deficit in levels of GAD₆₅ and GAD₆₇ in hippocampus of subjects with bipolar disorder. Interestingly, some brain GABAergic interneurons share the synthetic machinery for production of reelin and GAD₆₅ and GAD₆₇ proteins (Pesold et al., 1998a,b) and appear to be dysfunctional in bipolar subjects. Finally, deficits in hippocampal and cerebellar reelin levels in bipolar subjects (Fatemi et al., 2000b; unpublished observations; Guidotti et al., 2000) correlate well with decreases in levels of blood reelin in patients with bipolar disorder (Fatemi et al., 2001a). Future larger studies should aim to correlate the extent of reelin deficiency observed in hippocampus and cerebellum of subjects with bipolar disorder with blood and CSF levels of the same protein to better define the role of reelin in the etiology of bipolar disorder, recurrent depression, and other neurodevelopmental disorders, such as schizophrenia and autism.

Lithium and the GABAergic System

In contrast to the abundant literature on lithium's effects on monoamine neurotransmitters, much less work has been conducted on the amino acid neurotransmitters and neuropeptides (Bernasconi, 1982; Lloyd et al., 1987; Nemeroff, 1991). Studies have indicated that previously low levels of plasma and CSF GABA are normalized in bipolar patients being treated with lithium (Berrettini et al., 1983, 1986), paralleling reported GABA changes observed in several regions of rat brain (Gottesfeld et al., 1971; Maggi and

Enna, 1980; Ahluwalia et al., 1981). Interestingly, following withdrawal of chronic lithium, GABA levels return to normal in striatum and midbrain, but remain elevated in pons-medulla (Ahluwalia et al., 1981), possibly as a result of elevated levels of the GABA-synthesizing enzyme GAD.

Lithium has also been postulated to prevent GABA uptake, and chronic lithium has been shown to significantly decrease low-affinity [³H]GABA sites in corpus striatum and hypothalamus. Since lithium has no effect on in vitro [³H]GABA binding, these receptor changes have been interpreted as downregulation secondary to activation of the GABAergic system (Maggi and Enna, 1980). Although the clinical relevance of these findings remains unclear, it is noteworthy that decreases in CSF GABA have been reported in unipolar depressed patients (Post et al., 1980b; Berrettini et al., 1982).

In the GABAergic system, the chronic administration of lithium, valproate, or carbamazepine exerts important effects, decreasing GABA turnover in frontal cortex (Bernasconi, 1982). In addition, all three mood stabilizers are reported to increase GABA(B) receptors in hippocampus following chronic, but not acute, administration (Motohashi et al., 1989). These findings are interesting given that the GABA(B) agonist baclofen appeared to exacerbate depression in a small group of patients, and its discontinuation was associated with improvement in mood and behavior (Post et al., 1991). The data suggest the possibility that GABA(B) antagonists rather than agonists could have a useful antidepressant effect, and that the effect of mood stabilizers on GABAergic tone could be related to some of the drugs' psychotropic properties.

Valproate and the GABAergic System

A leading hypothesis of how valproate exerts its anti-convulsant effect is that it increases the availability of GABA in GABAergic synapses (Johannessen, 2000). GABA, an inhibitory amino acid neurotransmitter, would be expected to inhibit excessive firing of synapses, thus inhibiting epileptogenic activity. A number of studies show that valproate, at therapeutic concentrations, is an inhibitor of succinate semialdehyde dehydrogenase (SSADH).³⁰ This enzyme is critical for the GABA shunt, an enzymatic series of reactions that produces both glutamate and GABA by circumventing a portion of the tricarboxylic acid (TCA) cycle. GABA transaminase (GABA-T) converts GABA to succinate semialdehyde (SSA), which is then converted to succinate by SSADH. Valproate's effect on SSADH would be expected to increase levels of SSA, which has a strong inhibitory effect on GABA-T activity. Thus, GABA concentration should

increase as GABA-T is inhibited by an increasing SSA concentration.

Indeed, numerous studies have documented an increase in GABA concentration in rodent brain after valproate administration (Johannessen, 2000). It is possible that valproate exerts its antimanic effects through inhibition of SSADH. However, since the long-term effects of the drug are seen only following long-term treatment, the effect of SSADH on other cellular processes (perhaps not related to GABA concentration) may be related to the long-term changes in gene expression, protein concentration, and protein phosphorylation that are postulated to be the ultimate reason for valproate's mood-stabilizing effects (G. Gould et al., 2003, 2004c).

Farther downstream of SSADH, the GABA shunt reenters the TCA cycle; thus, inhibition of the GABA shunt could lead to lower overall activity of the TCA cycle. Indeed, lower TCA activity—or perhaps increased GABA—may explain the decreased glucose metabolism observed during valproate treatment (Leiderman et al., 1991; Gaillard et al., 1996; Johannessen, 2000). Valproate also inhibits SSA reductase, the enzyme that converts SSA to γ -hydroxybutyrate (GHB) with a K_i (the concentration of the drug required to inhibit enzymatic activity by 50 percent) of 85 micromolar (μ M) (Whittle and Turner, 1978; Johannessen, 2000). Valproate increases plasma (Loscher and Schmidt, 1980), CSF (Loscher and Siemes, 1984), and brain GABA (Patsalos and Lascelles, 1981) GABA, theoretically by inducing GAD (Nau and Loscher, 1982) as well as inhibiting GABA aminotransferase (Loscher, 1993). In addition, valproate increases GABA release (Gram et al., 1988) and interacts with GABA transporters (Nilsson et al., 1990).

The GABAergic System in Manic-Depressive Illness: Summary

Since GABA is the major inhibitory neurotransmitter and exerts a major effect on neuronal excitability, it is not surprising that abnormalities in the GABAergic system have been reported in mood disorders. However, the body of biochemical data is not very strong, and recent MRS studies suggest a GABAergic deficit (albeit only in occipital cortex) in unipolar but not bipolar patients. More intriguing are the several postmortem studies that have demonstrated a decrease in GAD₆₅ mRNA-positive neurons in CA2 and CA3 dentate gyrus and of GAD-67 mRNA-positive neurons in CA4 dentate gyrus in bipolar disorder (Heckers et al., 2002); decreased GAD-67 protein and mRNA and reelin (secreted by GABAergic interneurons) mRNA in prefrontal cortex and cerebellum of psychotic bipolar patients (Guidotti et al., 2000); and decreased immunoreactive density of GAD₆₅ in

layers II and III of anterior cingulate cortex in bipolar disorder (Benes et al., 2000). These findings raise the possibility of a GABAergic deficit in limbic and limbic-related areas (potentially due to loss of GABAergic neurons) in bipolar disorder, and warrant further study. Box 14–9 summarizes the findings of newer studies supporting the involvement of the GABAergic system in bipolar disorder.

The Glutamatergic System

It is surprising that the glutamatergic system has only recently undergone extensive investigation for its possible involvement in the pathophysiology of mood disorders, since it is the major excitatory neurotransmitter in the CNS, known to play a role in regulating the threshold for excitation of most other neurotransmitter systems. (For the regulatory processes involved in glutamatergic neurotransmission, see Figure 14–5.) Although much of the evidence for the potential involvement of the glutamatergic system in manic-depressive illness—derived from plasma, CSF, and postmortem studies—must be considered indirect, a growing body of data suggests that direct and indirect glutamate modulators may exert antidepressant effects, perhaps particularly so in bipolar depression (Krystal et al., 2002; Zarate et al., 2002).

Plasma and CSF Glutamate Levels

Altamura and colleagues (1993) reported that glutamate plasma levels were significantly higher in patients with mood disorders ($n=15$) than in neurological patients with tension headache ($n=10$). Glutamate plasma levels were also found to be higher for patients with mood disorders than for healthy volunteers and patients with schizophrenia,

BOX 14–9. Newer Studies Suggesting a Role for the GABAergic System in the Pathophysiology and Treatment of Manic-Depressive Illness (Primarily Bipolar)

Genetic Studies

- Increased genotype 1-1 GABRA3 gene (α_3 subunit GABA receptor) in Xq28 in females with bipolar disorder (Massat et al., 2002)
- GABA(A) receptor α_5 subunit gene polymorphism in cr 15 (GABRA5) associated with bipolar disorder (Papadimitriou et al., 1998)

Plasma Level Studies

- Higher pretreated GABA plasma levels in bipolar disorder are correlated with response to valproate (but not lithium); decrease after treatment (Petty et al., 1996)
- Decreased GABA plasma levels in manic and depressive phases of bipolar disorder (Petty et al., 1993)

Postmortem Studies

- Decreased glutamic acid decarboxidase (GAD_{65}) mRNA-positive neurons in CA2 CA3 dentate gyrus and GAD_{67} in CA4 in bipolar disorder (Heckers et al., 2002)
- Decreased GAD_{67} protein and mRNA, and reelin (secreted by GABAergic interneurons) mRNA in prefrontal cortex and cerebellum of psychotic bipolar patients (Guidotti et al., 2000)
- Decreased immunoreactive density of GAD_{65} in layers II and III of anterior cingulate cortex in bipolar patients (Benes et al., 2000)
- Increased density of flumazenil binding to GABA(A) in area 9 in bipolar disorder (Dean et al., 2001)
- Decreased density of calbindin-D28K-labeled neuron in layer 2, and increased clustering among parvalbumin-labeled neurons (markers of GABA populations) in cingulate cortex in bipolar patients (Cotter et al., 2002a)

Figure 14–5. The various regulatory processes involved in glutamatergic neurotransmission. The biosynthetic pathway for glutamate involves synthesis from glucose and the transamination of α -ketoglutarate; however, a small proportion of glutamate is formed more directly from glutamine by glutamine synthetase. The latter is actually synthesized in glia, and via an active process (requiring ATP) is transported to neurons where glutaminase is able to convert this precursor to glutamate (see upper part of diagram). (In astrocytes glutamine can undergo oxidation to yield α -ketoglutarate, which can also be transported to neurons and participate in glutamate synthesis.) Glutamate is either metabolized or sequestered and stored into secretory vesicles by vesicular glutamate transporters (VGluTs) (see inset in upper left corner of diagram). Glutamate can then be released by a calcium-dependent excitotoxic process. Once released from the presynaptic terminal, glutamate is able to bind to numerous excitatory amino acid (EAA) receptors, including both ionotropic (e.g., NMDA) and metabotropic receptors. Presynaptic regulation of glutamate release occurs through metabotropic glutamate receptors (mGluR_{2/3}) that subserve the function of autoreceptors. The middle part of the diagram shows glutamate receptors; in the upper left are ionotropic receptors. Activation of the AMPA receptor (AMPA R) by glutamate permits the depolarization of the membrane (1). When glutamate and glycine are present, this depolarization results in the release of magnesium from the NMDA receptor (NMDAR) channel (2). Calcium also enters through the NMDAR pore (3). Interchange of cations additionally occurs via NMDAR and the kainate glutamate receptor (KAR). In the upper right of the diagram metabotropic receptors are shown. Activation of Group I metabotropic glutamate receptors (mGlu 1), which are coupled with a G protein ($G_{q/11}$), produces activation of phospholipase C- β (PLC- β). Activation of Group II metabotropic glutamate receptors (mGlu 2), which are coupled with G_i or G_o , produces either inhibition of adenylyl cyclase (AC) or opening of potassium channels (not shown) respectively. At the bottom of the figure the subunit composition of known receptor subtypes are shown. It is now known that there are a number of important intracellular proteins able to alter the function of glutamate receptors (see middle section of diagram). Also, growth factors like GDNF and S100 β secreted from glial cells have been demonstrated to exert a tremendous influence on glutamatergic neurons and synapse formation. Of note, 5-HT_{1A} receptors have been documented to be regulated by antidepressant agents and to modulate the release of S100 β . (Source: Schatzberg and Nemeroff, 2004. Reprinted with permission from *The American Journal of Psychiatry*. Copyright 2004 by the American Psychiatric Association.)

anxiety disorders, and organic mental disorders. In addition, Mauri and colleagues (1998) found elevated plasma and platelet levels of glutamate in depressed patients compared with controls. Conversely, Maes and colleagues (1998) found no difference in the plasma glutamate levels of treatment-resistant depressed patients and age- and gender-matched controls. Berk and colleagues (2001) suggest that the platelet glutamate receptors may be supersensitive in schizophrenia and depression with psychotic features but not in mania with psychotic features, com-

pared with controls. At this point, however, the relationship between plasma and platelet indices of glutamatergic function and central neurotransmission is unclear.

Brain Imaging Studies

Magnetic Resonance Spectroscopy. The past decade has seen rapid advances in MRS and its application to the study of recurrent mood disorders (reviewed in Glitz et al., 2002; Moore and Galloway, 2002). It should be emphasized that although some investigations refer to measuring “glutamate,”

Receptor Subunit Types

Ionotropic			Metabotropic		
NMDA	AMPA R	Kainate	Group I	Group II	Group III

NR2 A-B-C-D	GluR 2	GluR 6	mGlu 5 a-b	mGlu 3	mGlu 6
NR3 A-B	GluR 3	GluR 7			mGlu 7 a-b
	GluR 4	KA 1			mGlu 8 a-b
		KA 2			

the spectral resolution at the field strength used suggests that “Glx” (a peak containing glutamate and additional compounds, including glutamine) may be more appropriate. Using *in vivo* proton MRS and tissue segmentation in 19 patients with major depression and 18 age-matched controls, Auer and colleagues (2000) found a significant decrease in absolute concentrations of anterior cingulate cortex glutamate (10–40 percent) in severely depressed patients compared with the controls, whereas in occipital cortex Sanacora and colleagues (2004) found MRS glutamate increased. In an MRS study of 10 children with bipolar disorder aged 6 to 12 elevated levels of glutamate/glutamine were found in both frontal lobes and basal ganglia compared with controls (Castillo et al., 2000).

Positron Emission Tomography. As discussed in Chapter 15, the glucose metabolic signal (which correlates closely with cerebral blood flow [CBF] during physiological activation) is thought to reflect primarily glutamatergic transmission (Magistretti and Pellerin, 1996). Thus, the findings of PET imaging studies of major depressive disorder and bipolar depression indicating abnormalities in regional CBF and glucose metabolism are compatible with those indicating abnormalities in glutamatergic transmission. Other types of experimental evidence suggest a consistent pattern of abnormalities in the neural circuitry implicated in emotional processing. Specifically, major depressive episodes are associated with elevated glucose metabolism in thalamus, amygdala, insula, pregenual anterior cingulate cortex, posterior orbital cortices, and ventral lateral prefrontal cortex (Drevets, 2000). Since the projections from the orbital frontal cortex to the limbic structures are glutamatergic, depression- and mania-related hypo- and hyperactivity may be suggestive of either decreased (depression) or increased (mania) activation of glutamatergic corticolimbic pathways. Thus, the hypothesis that a mood-stabilizing drug (for example, lamotrigine) might modulate glutamate release or the consequences of glutamate release could be consistent with these data from functional neuroimaging studies.

Postmortem Studies. Holemans and colleagues (1993) found no difference in the number of *N*-methyl-D-aspartate (NMDA) receptors in various brain regions of 22 suicide victims compared with age- and gender-matched controls; each of the suicide victims had a retrospective psychiatric diagnosis of depression and had not recently been treated with medication. Similarly, Palmer and colleagues (1994) examined the [³H] MK-801

binding characteristics of glycine and zinc and found no significant differences between suicide victims and controls; this assay theoretically measures allosteric modulatory sites on the NMDA receptor. Since the NMDA receptor is a target for drugs of abuse, such as PCP, it is noteworthy that toxicology screens were negative.

By contrast, Nowak and colleagues (1995a) found downregulation of the high-affinity glycine binding to the NMDA receptor in frontal cortex of suicide victims, of whom almost a third had a positive toxicology screen. It remains unclear, however, whether the subjects included in the study had received psychotropic medications. Finally, the diagnoses of the victims were also unclear; thus the relationship of these findings to patients with clinical depression remains unknown. The authors suggest that their finding supports the hypothesis that glutamatergic dysfunction is involved in the psychopathology underlying suicide and potentially in human depression.

Perhaps the greatest impetus for the recent interest in studying the glutamatergic system in severe, recurrent mood disorders has been a growing appreciation that these disorders, while neurochemical, are also characterized by impairments of neuroplasticity and cellular resilience. Although the precise mechanisms underlying the cell atrophy and death that occur in recurrent mood disorders are unknown, considerable data have shown that impairments of the glutamatergic system play a major role in the morphometric changes observed with severe stresses. Thus, microdialysis studies have shown that stress increases extracellular levels of glutamate in hippocampus, and NMDA glutamate receptor antagonists attenuate stress-induced atrophy of CA₃ pyramidal neurons (McEwen, 1999; Sapolsky, 2000b).

Although a variety of methodological issues remain to be fully resolved, the preponderance of the evidence to date suggests that the atrophy, and possibly death, of CA₃ pyramidal neurons arises at least in part from increased glutamate neurotransmission (McEwen, 1999a; Sapolsky, 2000a). (For a graphic of the cellular mechanisms by which stress and mood disorders may impair structural plasticity, see Figure 14–6.) It should be noted, however, that although NMDA antagonists block stress-induced hippocampal atrophy, no studies have demonstrated that they are able to block the cell death induced by severe stress. This suggests that the mechanisms underlying atrophy and death may lie on a continuum, with severe (or prolonged) stresses “recruiting” additional pathogenic pathways in addition to enhanced NMDA-mediated neurotransmission. As discussed earlier, stress increases extracellular levels of glutamate, and sustained activation of NMDA as well as of non-NMDA ionotropic receptors

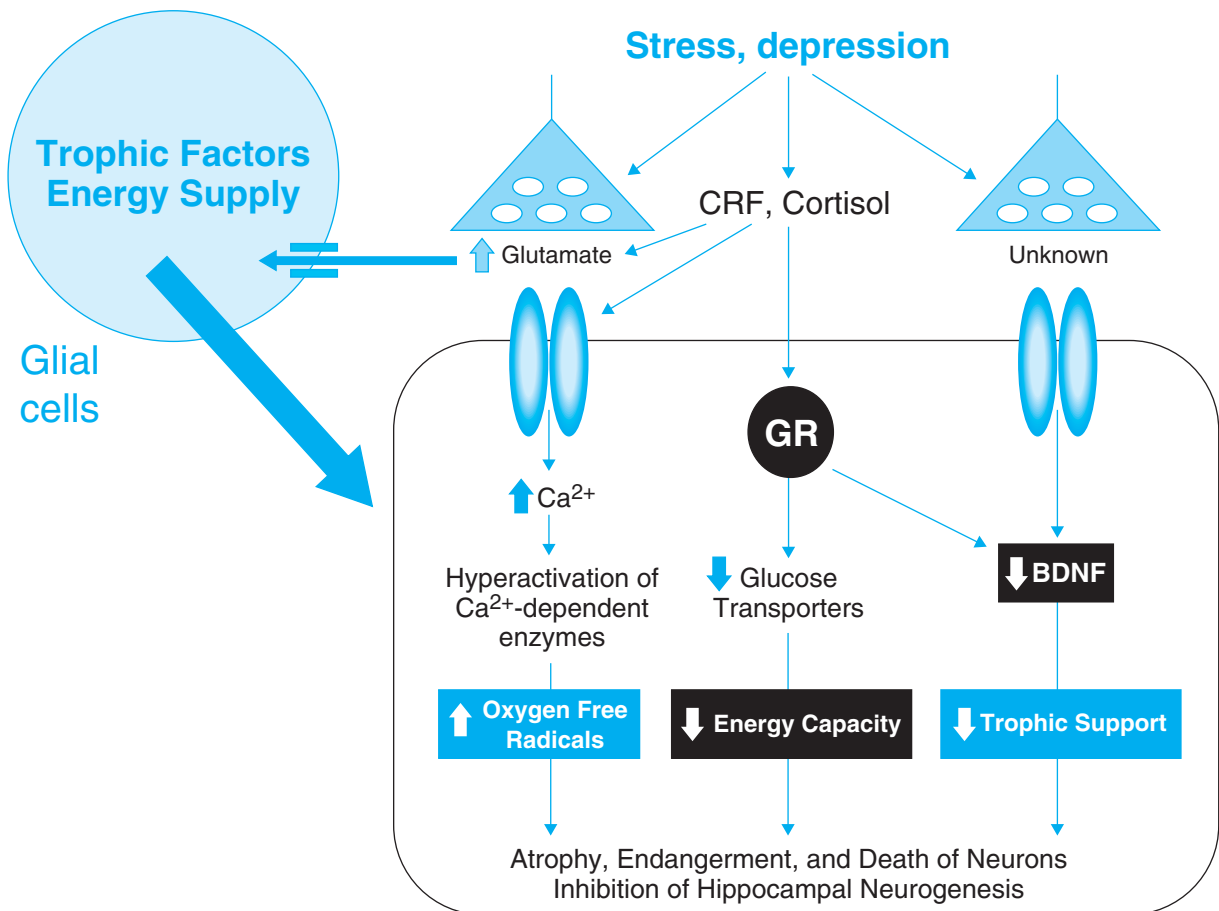

Figure 14–6. The multiple mechanisms by which stress and potentially affective episodes may attenuate cellular resiliency, resulting in atrophy, death, and endangerment of hippocampal neurons. The primary mechanisms appear to be (1) excessive NMDA and non-NMDA glutamatergic throughput; (2) downregulation of cell surface glucose transporters, which are involved in bringing glucose into the cell—reduced levels of glucose transporters thus reduce the neuron’s energetic reservoir, making it susceptible to energy failure when faced with excessive demands; and (3) reduction in the levels of brain-derived neurotrophic factor (BDNF), which is essential for the neuron’s normal trophic support and synaptic plasticity. The well-documented reduction in glial cells may contribute to impairments of neuronal structural plasticity by reducing the neuron’s energy supply and reduced glial-mediated clearing of excessive synaptic glutamate. CRF=corticotrophin releasing factor; GR=glucocorticoid receptor. (Source: Manji et al., 2003b.)

could result in high intracellular levels of calcium. Overactivation of the glutamate ionotropic receptors is known to contribute to the neurotoxic effects of a variety of insults, including repeated seizures and ischemia. Neurotoxicity follows as a response to overactivation of calcium-dependent enzymes and the generation of oxygen free-radicals. Stress or glucocorticoid exposure also compromises the metabolic capacity of neurons, thereby increasing the vulnerability to other types of neuronal insults. Activation of the HPA axis appears to play a critical role in mediating these effects, since stress-induced neuronal atrophy is prevented by adrenalectomy and duplicated by exposure to high concentrations of glucocorticoids (Sapolsky, 1996, 2000b; McEwen, 1999b). The role

of the corticotrophin-releasing hormone (CRH) and glucocorticoid signaling system is discussed in greater detail later.

Somatic Treatments and the Glutamatergic System

Findings of early studies suggested that D-cycloserine and amantadine, both of which have NMDA antagonistic effects, exert antidepressant effects (Krystal et al., 2002; Zarate et al., 2002). Berman and colleagues (2000) conducted a small placebo-controlled, double-blind trial assessing the treatment effects of a single dose of the NMDA receptor antagonist ketamine in seven patients with depression. The authors report that subjects with depression experienced significant improvement in depressive

symptoms shortly (within 72 hours) after taking ketamine but not placebo.

Perhaps the greatest evidence that glutamate modulation may be important in the pathophysiology and treatment of bipolar disorder comes from the clinical use of the anticonvulsant lamotrigine. It is particularly noteworthy that lamotrigine may be one of the few agents shown to have preferential efficacy in the treatment and prevention of bipolar depression (see Chapters 19 and 20).

Although the exact mechanism of action of lamotrigine is unknown, inhibition of an excessive release of glutamate is postulated as a likely candidate (Leach et al., 1986; Calabrese et al., 1996; J. Wang et al., 1996). Lamotrigine also exerts a cerebroprotective effect after focal ischemia (Smith et al., 1996). Recently, lamotrigine has been reported to reduce the hyperglutamatergic consequences of NMDA receptor dysfunction (cognitive dysfunction [learning and memory impairment] and psychomimetic effects) caused by ketamine in healthy volunteers (Anand et al., 2000a). One of the potential implications of this finding is that, in addition to having thymoleptic properties, lamotrigine may prove useful in treating the psychotic symptoms that frequently accompany mood episodes (Anand et al., 2000a).

Lithium and the Glutamatergic System

In view of the evidence that excessive synaptic glutamate may contribute to neuronal atrophy and loss, it is noteworthy that chronic treatment with lithium (plasma levels ~ 0.7 mM) has been shown to upregulate synaptosomal uptake of glutamate in mice (Dixon and Hokin, 1998). Furthermore, chronic treatment with therapeutically relevant concentrations of LiCl in cultured rat cerebellar, cortical, and hippocampal neurons protected against glutamate-induced excitotoxicity involving apoptosis mediated by NMDA receptors (Nonaka et al., 1998). The investigators reported that the protection could be attributed at least in part to inhibition of NMDA receptor-mediated Ca^{2+} influx (Nonaka et al., 1998; Hashimoto et al., 2002).

A growing body of data suggests that AMPA (alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid) glutamate receptor trafficking, including receptor insertion and internalization and delivery to synaptic sites, provides an elegant mechanism for activity-dependent regulation of synaptic strength. AMPA receptor subunits undergo constitutive endocytosis and exocytosis; however, the process is highly regulated, with a variety of signal transduction cascades being capable of producing short- or long-term changes in synaptic surface expression of AMPA receptor subunits. Indeed, although the mechanisms of long-term potentiation (LTP) and long-term depression (LTD) have

not been completely elucidated, it is widely accepted that AMPA receptor trafficking is the key player in these phenomena.

In view of the critical role of AMPA receptor trafficking in regulating various forms of plasticity, recent studies have sought to determine whether two structurally very dissimilar antimanic agents, lithium and valproate, exert effects on AMPA receptor trafficking. Interestingly, these two agents have been shown to exert robust effects on the same signaling pathways known to regulate AMPA receptor trafficking (see below). It has been shown that lithium and valproate have a common effect on downregulating AMPA GluR1 synaptic expression in hippocampus after prolonged treatment with therapeutically relevant concentrations, as assessed both *in vitro* and *in vivo* (Du et al., 2003). In cultured hippocampal neurons, lithium and valproate were found to attenuate surface GluR1 expression after long-term treatment. Further supporting the therapeutic relevance of this finding, an agent that provokes mania, the antidepressant imipramine, has an opposite effect as it upregulates AMPA synaptic strength in hippocampus (Du et al., 2003).

Additional support for the therapeutic relevance of these data is provided by studies indicating that AMPA receptor antagonists attenuate several “manic-like” behaviors produced by amphetamine administration. Thus, AMPA antagonists have been demonstrated to attenuate psychostimulant-induced development or expression of sensitization and hedonic behavior without affecting spontaneous locomotion. Additionally, some studies have demonstrated that AMPA receptor antagonists reduce amphetamine- and cocaine-induced hyperactivity.³¹

As discussed earlier, one current model of mania that has been used extensively and has reasonable heuristic value in the study of mood disorders involves the use of psychostimulants in appropriate paradigms. Psychostimulants such as amphetamine and cocaine are known to induce manic-like symptoms in healthy volunteers and to trigger frank manic episodes in individuals with bipolar disorder. The best-established animal models of mania therefore use the administration of amphetamine or cocaine to produce hyperactivity, risk-taking behavior, and increased hedonic drive—all important facets of the human clinical condition of mania. Moreover, these psychostimulant-induced behavioral changes are attenuated by the administration of chronic lithium in a therapeutically relevant time frame. Thus, the fact that AMPA receptor antagonists are capable of attenuating psychostimulant-induced sensitization, hyperactivity, and hedonic behavior provides compelling behavioral support for our contention that AMPA receptors play important roles in regulating affective behavior.

Taken together, findings of biochemical and behavioral studies investigating the effects of antimanic (lithium and valproate) and promanic (antidepressants, cocaine, amphetamine) agents on GluR1 suggest that AMPA receptor trafficking is an important target in the pathogenesis and treatment of certain facets of bipolar disorder. The mechanisms by which glutamate receptors are actively recruited to synapses have long intrigued the neuroscience community; the findings reviewed here suggest that they may also play important roles in the pathophysiology and treatment of complex neuropsychiatric disorders.

Valproate and the Glutamatergic System

In addition to the effects on AMPA receptor trafficking described above, valproate appears to affect glutamatergic neurotransmission through other mechanisms. Acute administration of valproate *in vitro* has been shown to augment the release of glutamate (Dixon and Hokin, 1997). Ueda and Willmore (2000) reported on the effect of valproate on glutamate transporter expression in hippocampus. With a dose of 100 mg/kg/day of valproate given for 14 days, they found an increase in EAAT1 levels and a decrease in EAAT2 levels. Hassel and colleagues (2001) reported that chronic treatment of rats with valproate (200 or 400 mg/kg/day for 90 days) led to a dose-dependent increase in hippocampal glutamate uptake capacity as measured by uptake of [³H]glutamate into proteoliposomes by increasing the levels of the glutamate transporters EAAT1 and EAAT2 in hippocampus. It is of note that the doses of 200 or 400 mg/kg/day used in this study are much higher than those used in humans, approximately 20–50 mg/kg/day. Thus overall, chronic valproate likely decreases intrasynaptic glutamate levels through a variety of mechanisms.

In rodent models, valproate has been shown to reduce seizure activity induced by AMPA glutamate receptor agonists (Turski, 1990; Steppuhn and Turski, 1993). In post-mortem human brain tissue, König and colleagues (1998) found that therapeutic levels of valproate decreased binding of AMPA to the AMPA glutamate receptors, thus effectively blocking them. Findings from a series of studies from different laboratories that used various preparations suggest that valproate blocks synaptic responses mediated by NMDA glutamate receptors as well (Loscher, 1999). As discussed above, lithium and valproate, at therapeutically relevant concentrations, also appear to share a common target in regulating AMPA receptor trafficking.

Carbamazepine and the Glutamatergic System

Carbamazepine has been shown to reduce NMDA-evoked depolarizations in preclinical studies (Davies, 1995) and

has been found to have antagonistic properties on the NMDA receptor subtype of glutamate receptors (Hough et al., 1996). In this latter study, therapeutically relevant concentrations of carbamazepine inhibited the rise in intracellular free Ca²⁺ concentration induced by NMDA and glycine in a rapid, reversible, and concentration-dependent manner. This inhibition produced by carbamazepine was noncompetitive with respect to NMDA and glycine.

The Glutamatergic System as an Indirect and Direct Target for Antidepressants

NMDA receptor antagonists, such as MK-801 and AP-7, and an AMPA receptor potentiator, the biarylpropylsulfonamide LY392098, have demonstrated “antidepressant” effects in animal models of depression. These studies have included the application of inescapable stressor, forced swim, and tail suspension–induced immobility tests; learned helplessness models of depression; and exposure of animals to a chronic mild stress procedure (Li et al., 2001). Furthermore, antidepressant administration has been shown to affect NMDA receptor function (Nowak et al., 1993, 1995b) and receptor binding profiles (Paul et al., 1992). Also consistent with the putative role of the glutamatergic system in the mechanism of action of antidepressants is the fact that repeated antidepressant administration regionally alters expression of mRNA that encodes multiple NMDA receptor subunits and radioligand binding to these receptors (see Fig. 14–7) within circumscribed areas of the CNS (Skolnick, 1999). According to two recent open-label studies, riluzole (U.S. Food and Drug Administration [FDA] approved for amyotrophic lateral sclerosis [ALS]), which is an inhibitor of glutamate release, was found to have antidepressant effects in patients with treatment-resistant unipolar and bipolar depression (Zarate et al. 2004a, 2005). See Figure 14–8 for an overview of the target receptors of new antidepressant drugs that act on the glutamatergic system. As noted above, NMDA receptor antagonists such as MK-801 and AP-7 have been shown to have antidepressant properties in animal models of depression, leading to two studies of IV ketamine in depression (Berman et al., 2000; Zarate et al., 2006b). Ketamine, a high-affinity noncompetitive NMDA antagonist, has been used as a standard anesthetic agent for many years in both pediatric patients and adults, with doses as high as 2 mg/kg IV. There is abundant preliminary evidence that ketamine has anxiolytic and antidepressant effects in animal models and may have rapid antidepressant properties (Zarate et al., 2006b). These studies in treatment-resistant unipolar major depressive disorder showed robust and rapid antidepressant effects resulting from a single IV dose of an NMDA antagonist. Interestingly, onset of antidepressant

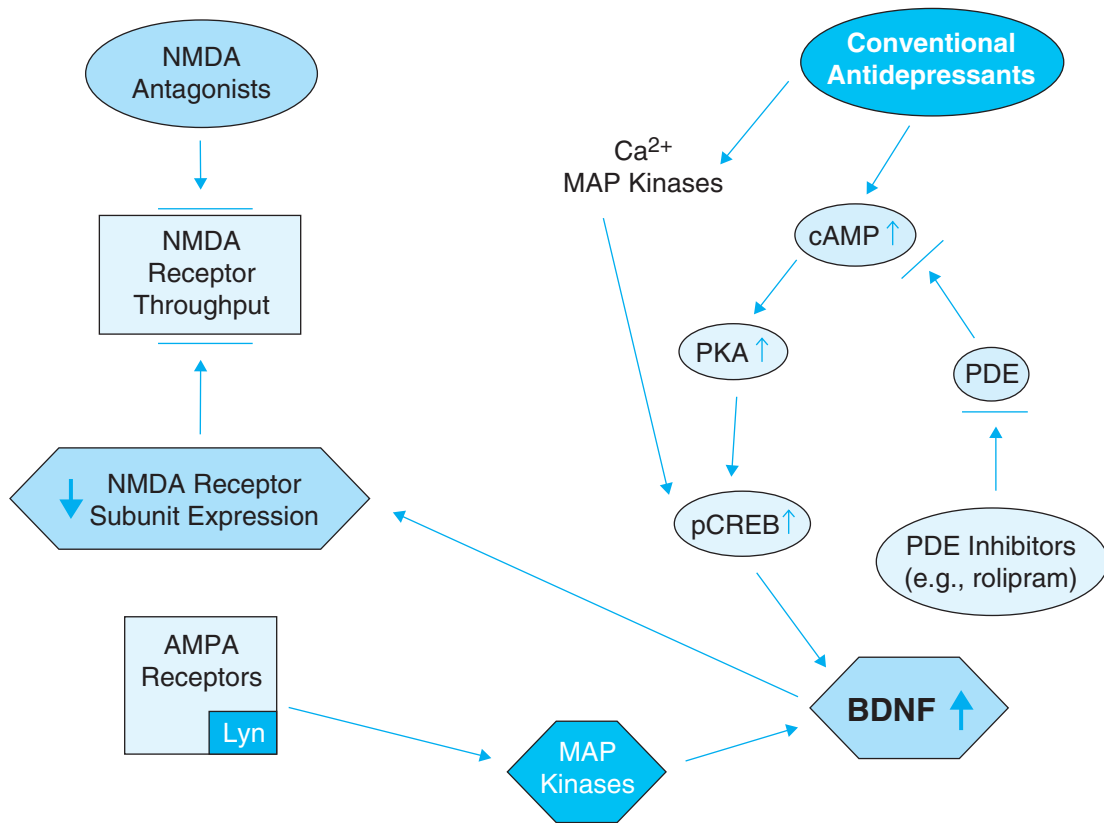

Figure 14–7. Schematic illustrating pathway convergence among conventional (biogenic amine-based) antidepressants, NMDA antagonists, and AMPA receptor potentiators (ARPs). (Source: Skolnick et al., 2001. Reprinted with permission from Elsevier.)

effects was seen very rapidly (occurring within 2 hours post-infusion) and remained significant for 1 week; studies in bipolar patients are ongoing (Zarate et al., 2006b). In contrast to the dramatic effects observed in this study, a previous controlled study did not show antidepressant effects of the low- to moderate-affinity noncompetitive NMDA antagonist memantine when administered orally (Zarate et al., 2006a). While it is likely that higher-affinity NMDA antagonists are necessary for antidepressant effects to occur, it must be acknowledged that IV administration may also be an important factor. Overall, the intriguing results observed with ketamine support the hypothesis that directly targeting the NMDA receptor complex may bring about rapid and relatively sustained antidepressant effects. This line of research holds considerable promise for developing new treatments for depression (see Fig. 14–8), with the potential to alleviate much of the morbidity and mortality associated with the delayed onset of action of traditional antidepressants.

Based largely on the observation that AMPA receptor activation increases expression of brain-derived neu-

rotrophic factor (BDNF, discussed in detail later), Skolnick and colleagues have undertaken a series of studies investigating the putative antidepressant efficacy of AMPA receptor potentiators in models of depression (Legutko et al., 2001; Li et al., 2001; Skolnick et al., 2001). AMPA receptors are a subfamily of ionotropic glutamate receptors mediating fast excitatory transmission in the CNS. As with most other ligand-gated ion channels, AMPA receptors possess multiple, allosteric modulatory sites that represent targets for fine-tuning the activity of the receptor by pharmacological means. In addition to their ionotropic properties, AMPA receptors have been functionally linked to a variety of signal transduction events involving G proteins and the mitogen-activated protein kinase (MAPK) (Bahr et al., 2002). This raises the possibility that more subtle modulation of AMPA receptors may be a useful strategy to activate MAPK neurotrophic cascades. One class of compounds, AMPA receptor potentiators (ARPs), dramatically reduces the rate of receptor desensitization and/or deactivation (Skolnick et al., 2001).³²

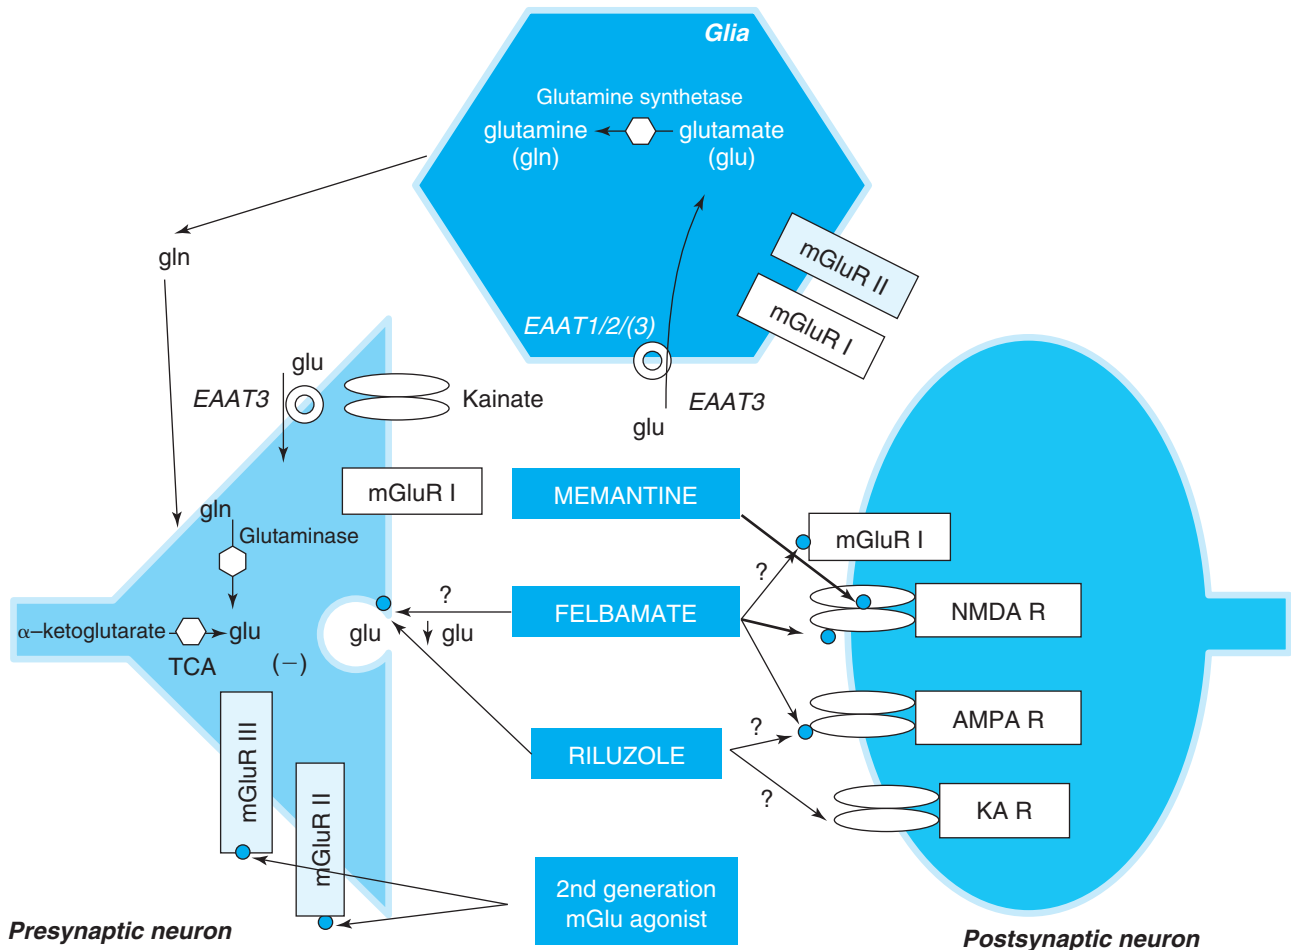

Figure 14–8. Receptors that may represent a target for novel agents for the treatment of depression. Glutamate (glu) is synthesized in neuron from α -ketoglutarate through the tricarboxylic acid (TCA) cycle. After release, glutamate is reuptaken by glutamate transporters (EAAT1/2/3), shown in glia and a presynaptic neuron (EAAT3). In the glia, glutamate is catabolized to glutamine (through the enzyme glutamine synthetase), diffuses to the neurons, and is then metabolized back to glutamate (through the enzyme glutaminase). The different glutamate receptors and the presumed antiglutamatergic drug sites of action are presented. Memantine is a noncompetitive antagonist at the NMDA receptor (NMDA R). Felbamate is a noncompetitive NMDA receptor antagonist (glycine NR1 and glutamate NR2B), an AMPA receptor (AMPA R) antagonist, an mGlu group I receptor antagonist, and a glutamate release inhibitor (acting through blockade of Ca^{2+} and Na^+ voltage-dependent channels). Riluzole is a glutamate release inhibitor (acting through blockade of Ca^{2+} and Na^+ voltage-dependent channels), a GABA(A) agonist and probably an AMPA and kainate antagonist. The sites for second-generation mGlu group II and III receptor agonists are also depicted. KA R=kainate glutamate receptor. (Source: Manji et al., 2003b.)

The Glutamatergic System in Manic-Depressive Illness: Summary

At present, the evidence for abnormalities in the glutamatergic system in manic-depressive illness is quite indirect. As we discuss in detail later, a growing body of data suggests that recurrent mood disorders, especially the bipolar subgroup, are associated with impairments of neuroplasticity and cellular resilience, but the direct evidence for glutamatergic excitotoxicity is lacking. The strongest support comes from pharmacological data, with lithium, valproate, carbamazepine, and lamotrigine all regulating facets of glutamatergic functioning. Perhaps the most

exciting recent preclinical finding is that lithium and valproate downregulate the synaptic expression of the AMPA receptor subunit GluR1, whereas the opposite effect is seen with promanic agents (psychostimulants and imipramine). These studies suggest that regulation of glutamatergically-mediated synaptic plasticity may play a role in the treatment of mood disorders. Indeed, one recent and very attractive hypothesis is that alterations in neural plasticity in critical limbic and reward circuits, mediated by increasing the postsynaptic AMPA to NMDA throughput, may represent a convergent mechanism for antidepressant action (Zarate et al., 2006b). Box 14–10 summarizes direct and indirect evidence supporting the involvement of the

BOX 14–10. Direct and Indirect Evidence Supporting a Role for the Glutamatergic System in the Pathophysiology and Treatment of Manic-Depressive Illness (Primarily Bipolar)

CSF, Plasma, and Platelet Studies

- CSF glutamine levels elevated in medication-free depressed patients vs. controls (2 BPD, 16 MDD) and correlated with CSF magnesium levels (Levine et al., 2000)
- Glutamine plasma levels higher in 59 depressive patients (MDD, BPD) vs. controls (Mathis et al., 1988)
- Increased plasma glutamate and decreased platelet levels in medication-free depressed patients (4 MDD, 11 BPD) vs. controls (Altamura et al., 1993)

MRS Studies

- Increased Glu/gln ratio in frontal lobe and basal ganglia in bipolar children (Castillo et al., 2000)
- Decreased Glu levels in anterior cingulate cortex of depressed patients vs. controls (7 patients were medication-free and 12 were under antidepressant treatment; 1 BPD and 18 MDD) (Auer et al., 2000)

Postmortem Brain Studies

- Decreased neuronal EAAT3 and 4 mRNA expression in striatum in BPD (McCullumsmith and Meador-Woodruff, 2002)
- NR2D (a subunit of NMDA receptor) mRNA higher in striatum in BPD (n = 15) than in MDD (15) (Meador-Woodruff et al., 2001)
- glur1 (a subunit of AMPA receptor) mRNA lower in BPD (n = 15) than in controls (15) (Meador-Woodruff et al., 2001)
- (³H)AMPA binding higher in BPD than in MDD (Meador-Woodruff et al., 2001)
- Reduced glutamate decarboxylase immunoreactive marked terminals in anterior cingulate cortex (most in layer II–III) (Benes et al., 2000)

glutamatergic system in the pathophysiology and treatment of bipolar disorder.

Neuroendocrine Systems and Neuropeptides

Neuroendocrine Systems

The contribution of altered endocrine function to pathological mood states was among the earliest themes in biological psychiatry. The modern era of clinical neuroendocrinology began in the early 1960s, spurred by the development of simple, reliable assay methods for hormones in blood and urine; in due course this field became one of the most

prolific research areas in biological psychiatry. Affective disorders became the major focus as it became increasingly apparent that hypothalamic function was intimately involved in many of depression's core symptoms, such as poor regulation of appetite and sleep and decreased sex drive (Gold et al., 1988; Holsboer et al., 2001; Gold and Chrousos, 2002). However, with the revolution in molecular medicine and a much greater focus on intracellular events, there has been much less emphasis on neuroendocrine systems in research on recurrent mood disorders. Furthermore, there is a growing appreciation that simply measuring plasma levels of various hormones—regardless of how

precisely the new technologies allow—does not provide a true window into the brain as was once hoped because of the large number of variables (e.g., hypothalamic/pituitary blood flow, degree of stress, sleep, diet, activity levels) that are likely to be altered with these disorders and are difficult to control for. Nevertheless, the study of peptide hormones of the hypothalamic–pituitary axis measured in body fluids under both baseline and challenge conditions has provided some important clues, and these findings are reviewed here.

The emerging animal data on the effects of neurohormones on brain function (i.e., the brain as a gland) have added impetus for the trend toward evaluating neuroendocrine findings in their own right, not simply as a reflection of amine neurotransmitter changes. The actions of a single neurohormone peptide on a wide range of brain receptors characteristically span a much longer time period than the actions of monoamines. The influence of neurohormones on neurons may have been elaborated for teleological reasons. Also, the possibility that one substance effectively commands and organizes multiple coordinated physiological and behavioral responses is consistent with the importance of certain peptides in the long-term phasic changes typical of manic-depressive illness.

One new and intriguing approach to interpreting neuroendocrine data is to assess their variability, either within individual patients or across patient groups. The study of neuroendocrine variability may bring us closer to the pathophysiology of bipolar illness and recurrent depression.

With the isolation of the specific peptide factors responsible for release of individual hormones from the pituitary, clinical endocrinology has developed increasingly sophisticated challenge tests for assessing the dynamics of hypothalamic–pituitary function, and these new techniques have spurred renewed interest in neuroendocrine research in affective disorders. Knowledge has developed rapidly on the hypothalamic neurotransmitter systems that regulate the release of trophic factors to the pituitary. This growing knowledge has increased the potential of neuroendocrine strategies as a window into midbrain neurotransmitter function, particularly of the biogenic amines. It is fair to say that the amine hypotheses is still the major conceptual prism through which neuroendocrine data in affective illness are viewed.

To reiterate, the neuroendocrine literature can be divided into two distinct but overlapping categories. The first includes studies that have used baseline neuroendocrine measures and provocative challenge tests to unravel subclinical endocrine abnormalities in depressed patients. The second encompasses studies in which neuroendocrine measures have been used as a window into central neurotransmitter function (e.g., as a measure of receptor activity or neurotransmitter turnover).

The Hypothalamic–Pituitary–Thyroid Axis. Of all the endocrine systems hypothesized to be linked to recurrent mood disorders, the hypothalamic–pituitary–thyroid (HPT) axis is a prime candidate. In 1864, Graves noted that patients with endemic goiter often showed a markedly “morbid and melancholic turn of mind.” Since that time, it has repeatedly been noted that disorders of thyroid function frequently are accompanied by changes in mood (Prange et al., 1974; Joyce, 1991; Styra et al., 1991), and patients with recurrent mood disorders (particularly those with rapid bipolar cycles) frequently have HPT axis abnormalities (Wehr et al., 1988; Zach and Ackerman, 1988; Hendrick et al., 1998). Thyroid hormones reportedly alter the clinical course of some forms of cyclic depressive illness, potentiate the actions of various antidepressants (Goodwin et al., 1982), and can precipitate mania in bipolar patients (Josephson and Mackenzie, 1979, 1980; Wehr and Goodwin, 1987a). The more recent and carefully controlled reports of HPT axis function in depressed patients have, in fact, revealed subtle but significant abnormalities in many manic-depressive patients. Finally, both lithium and carbamazepine have been shown to alter HPT axis function, and some investigators have suggested that the therapeutic effects of these drugs may correlate with their effects on this axis.

The regulation of thyroid hormone secretion—triiodothyronine (T_3) and thyroxine (T_4)—is initiated by the release of a hypothalamic tripeptide, thyrotropin-releasing hormone (TRH). TRH is released into the portal circulation from axons that originate in the median eminence of the hypothalamus. It is then transported to the pituitary, where it binds to specific thyrotropic cells, which release thyroid-stimulating hormone (TSH). This hormone, in turn, is released into the general circulation and stimulates the thyroid gland to synthesize and release T_3 and T_4 . Thyroid hormones have widespread metabolic effects and can directly alter many aspects of the peripheral nervous system, as well as CNS function.³³

Clinically, it was observed that hypothyroidism was often associated with depression. Less frequently, hyperthyroidism (or the administration of thyroid hormone) was associated with euphoric states, including full manic reactions. In pioneering studies during the 1930s, Gjessing substantially ameliorated periodic catatonia in some patients through sustained use of hypermetabolic doses of thyroid hormone, one of the earliest prophylactic treatments in psychiatry. In his classic monograph, Gjessing (1938) speculated that reduced or poorly regulated thyroid function is important to the pathophysiology of various cyclic mental disturbances, including manic-depressive illness. Although Gjessing's studies did not have widespread influence at the time, recent developments have rekindled interest in his work.

As noted above, most neuroendocrine researchers view the phenomena they study as secondary to disturbances in brain neurotransmitters—occurring downstream in a cascade of neuronal events. A major exception to this view is the relationship between decreased thyroid function and rapid cycling in bipolar patients. Here, the endocrine dysfunction itself may cause the increased cycling. This hypothesis led to evaluation of high-dose thyroid as a treatment for rapid cycling, and some positive results have been reported; unfortunately, cardiovascular side effects, along with a lack of industry support, for research on compounds that are generic, have precluded more extensive study (see Chapter 18).

Despite the existence of numerous studies, the status of peripheral thyroid indices in affective illness remains unclear. Bauer and Whybrow (1988) concluded that the most frequent thyroid abnormality associated with major depression (although not specific to this diagnosis) is a relative increase in plasma T_4 without accompanying changes in its active (T_3) or inactive (rT_3) metabolites. In contrast, Gold and colleagues (1981a) found mild hypothyroidism in 9 percent of their large unipolar sample (usually reflected by slight increases in TSH), and antithyroid antibodies have been reported in up to 20 percent of patients with depression.³⁴ If T_4 actually is increased in depression, disagreement exists as to whether this is part of the pathophysiology of the depressive symptoms (Joffe et al., 1984) or is a compensatory peripheral increase to “allow delivery of more thyroxine to a brain whose homeostatic mechanisms have gone awry—an effect achieved without subjecting the organism to increased metabolic demands due to increased circulating levels of T_3 ” (Bauer and Whybrow, 1988, p. 82).

Styra and colleagues (1991) found a 12 percent prevalence of elevated T_4 levels in 99 bipolar and unipolar patients. No statistically significant difference in response to antidepressant treatment was observed between the hyperthyroxinemia group and the normal serum T_4 group. In another study, free T_4 index (FT_4I) and T_4 levels were measured in 31 manic patients shortly after admission to a psychiatric hospital (Joyce, 1991). Over one-third had elevated thyroid hormone levels (due to increases in FT_4I). Low FT_4I levels prospectively predicted more hospital admissions in the 12 months from index admission. Joffe and colleagues (1994) reported that the overall frequency of Grade II subclinical hypothyroidism was 20 percent in 66 bipolar patients, with no difference in frequency of subclinical hypothyroidism or in mean thyroid hormone levels between the mixed-state and non-mixed-state groups. Interestingly, somewhat akin to the results seen with the HPA axis discussed later, Zarate and colleagues (1997) found in a study of first-episode patients that TSH was higher in mixed than in manic bipolar patients.

This latter finding may be most applicable to bipolar illness, where there is some evidence of a subtle decrease in thyroid function, especially among those with rapid cycles,³⁵ although not all studies agree on this.³⁶ Evidence of thyroid dysfunction in bipolar illness may have emerged because of the antithyroid effects of lithium, in effect unmasking subtle preexisting thyroid pathology.

The association between lithium-induced hypothyroidism and rapid cycling is observed predominantly in women. As noted in Chapter 18, women may also be more sensitive to the cycle-inducing effects of tricyclic antidepressants. If hypothyroidism (either in the presence or absence of lithium treatment) is related to the development of rapid-cycling bipolar depression, it is not yet clear how. Several individual case reports have described cyclical mood disturbances developing in patients following subtotal thyroidectomy (Hertz, 1964). However, thyroidectomy per se is not sufficient for the development of rapid cycling; clearly, other predisposing factors must be present. In Chapter 16, we suggest that the effects of thyroid hormones on the periodicity of biological clocks in animals, coupled with altered circadian pacemaker function in bipolar patients, may explain the apparent inductive effect of hypothyroidism in rapid-cycling patients. Almost all rapid-cycling bipolar patients are female (Wehr et al., 1988). Likewise, thyroid dysfunction, including the antithyroid effects of lithium, is much more common among women (Joffe et al., 1988). These observations link female sex, hyperthyroidism, and rapid cycling.

Hatterer and colleagues (1988) propose that relatively reduced thyroid function among bipolar patients on lithium may be associated with poor outcome. They report that plasma T_3 levels were significantly lower among patients who relapsed on lithium, although all values remained in the normal range (see Frye et al., 1999a). As discussed earlier, Gjessing (1938) described a group of patients with periodic catatonia who, when given large doses of thyroid hormone, responded with rapid (less than 1 week) and long-lasting improvement. In a somewhat larger group of patients with periodic psychoses, Wakoh and Hatotani (1973) found similar beneficial effects of treatment with large doses of thyroid hormone. As noted in Chapter 3, these patients share many clinical features with rapid-cycling bipolar patients, and their conditions probably represent the same illness.

In a later study, Stancer and Persad (1982) gave hypermetabolic doses of T_4 (300 to 500 $\mu\text{g}/\text{day}$) to 10 rapid-cycling bipolar patients. Of the seven women, five responded dramatically, whereas two men and an adolescent did not. Consistent with this finding are reports that thyroid hormone in combination with standard mood-stabilizing

drugs can attenuate cycles in bipolar patients (Goodwin, 1982; Bauer and Whybrow, 1988). High-dose T_4 ($482 \pm 72 \mu\text{g}/\text{day}$) proved to have excellent antidepressant effects in approximately 50 percent of severely therapy-resistant depressed patients (5 unipolar and 12 bipolar) in an 8-week open label and 27.2 ± 22.0 -month follow-up of responders (Bauer et al., 1998a).

In another study, six resistant bipolar patients (non-rapid-cycling) were treated with supraphysiological doses of T_4 (250 to 500 $\mu\text{g}/\text{day}$) adjunctively and followed up for 27.8 ± 12.8 months. The mean number of relapses declined from 5.3 ± 3.1 to $.8 \pm .8$, compared with the number of relapses during the same length of time for each patient before the start of treatment with high-dose T_4 (Bauer et al., 1998a,b).³⁷

Another approach to the HPT axis involves the study of circadian patterns of TSH release. Normally, TSH secretion peaks during the night (Weeke, 1973), but this peak is absent in some patients with affective disorders (Weeke and Weeke, 1978; Goldstein et al., 1980), including those with rapid-cycling bipolar disorder (Kasper et al., 1988; Sack et al., 1988). Sleep deprivation represents another challenge test in that it is associated with an increase in nocturnal TSH. Both bipolar (Sack et al., 1988) and unipolar depressed patients (Kasper et al., 1988) have been shown to have blunted TSH response to total sleep deprivation.³⁸

Potential Involvement of Thyrotropin-Releasing Hormone. Preclinical studies have shown that TRH has an extensive extrahypothalamic distribution including the limbic system, amygdala, and frontal cortex, and in addition to its neurohormonal role, appears to act as a neurotransmitter (Griffiths, 1985). Thus in preclinical animal studies, administration of TRH appears to have a mild stimulant effect including increased arousal and motor activity (Nemeroff et al., 1984a).

In humans, at least two clinical studies have reported elevated levels of CSF TRH in patients with acute depression (Kirkegaard et al., 1979; Banki et al., 1988), while a third found no difference from control subjects (Roy et al., 1994). A more recent and larger study included both bipolar and unipolar medication-free depressed patients ($n=56$) compared with normal controls ($n=34$) and again found no differences in CSF TRH. However, there was a gender difference, with females having, on average, lower TRH levels than men—a finding most significant in the bipolar group (Frye et al., 1999b).

The TRH stimulation test uses a challenge dose and measures the plasma TSH concentration at baseline and at 30-minute intervals. Multiple studies have used this test in depressed patients, and all have found that approximately

25–30 percent have a blunted TSH response despite being euthyroid at the time.³⁹ Using a modified TRH stimulation test in which TRH is administered at 8 AM and then again at 11 PM, Duval and colleagues (1990) were able to achieve a 95 percent specificity and 89 percent sensitivity for the diagnosis of major depression in patients who had a markedly blunted nocturnal TSH response. An attempt to correlate low CSF TRH with a blunted TSH response to TRH stimulation was negative (Frye et al., 1999b).

TRH analogues have been shown to have antidepressant properties, effects that have been postulated to occur independently of thyroid hormone secretion (Redei et al., 1999; Lloyd et al., 2001). Furthermore, in rodents, electroconvulsive shock (the animal model of ECT) was shown to induce the synthesis of TRH in multiple subcortical limbic and frontal cortical regions (Sattin, 1999). Early studies that tested TRH as an antidepressant were quite promising. Prange and colleagues (1972) found that IV TRH given in a double-blind, crossover design produced a striking improvement in mood that lasted for a few hours and then faded; however, subsequent studies found no such improvement (Amsterdam et al., 1981).

To determine whether these variable results were due at least in part to the presumed poor blood–brain barrier permeability, a study of intrathecal TRH administration was conducted (Marangell et al., 1997). The investigators administered TRH (500 μg) to eight medication-free inpatients with refractory depression by means of a lumbar intrathecal injection and an identical sham lumbar puncture procedure, separated by 1 week, in a double-blind, crossover design. They found that five of the eight patients responded to intrathecal TRH. The responses were rapid and clinically robust, but they were short-lived.

The same laboratory also compared the antidepressant effect of intrathecal and IV TRH administered in a double-blind design to two treatment-refractory patients with bipolar-II disorder (Callahan et al., 1997). Each patient experienced a robust antidepressant response by both routes; subsequent open trials also showed IV TRH to be effective until apparent tolerance developed. Intrathecal TRH was readministered, and both subjects again experienced robust antidepressant responses. These preliminary data suggest that there is a differential mechanism of tolerance to the two routes of administration and that IV TRH may exert antidepressant effects by indirect, secondary mechanisms. In a recent study, 20 patients with bipolar type I or type II major depressive episode (MDE) were given nocturnal IV TRH 500 μg ($n=10$) or saline ($n=10$) at midnight in a randomized, double-blind fashion. Sixty percent of the TRH group and 10 percent of the saline group showed a greater than or equal to 50 percent reduction in baseline total HAM-D score within 24 hours ($p=.03$).

BOX 14–11. Recent Studies Investigating Abnormalities of the Hypothalamic–Pituitary–Thyroid Axis in Manic-Depressive Illness

- Unipolar and bipolar patients were studied for 1 year, either continuing usual lithium dosage or reduced dosage by up to 50 percent. There was an association between lower dosage/level of lithium and lower side effects, including lower TSH levels (with no association between affective morbidity and lithium dosage/level) (Abou-Saleh and Coppen, 1989)
- Depressive and manic symptoms decreased significantly compared with baseline in 11 refractory rapid-cycling bipolar disorder patients treated with high-dose levothyroxine as add-on therapy. (Supranormal circulating levels of free thyroxine were necessary to induce clinical response) (Bauer and Whybrow, 1990)
- The diagnostic value of the TRH test was not conclusive for any subgroups of depressed patients including bipolar patients (Vanelle et al., 1990)
- A 12 percent prevalence of elevated thyroxine levels was found in 99 bipolar or unipolar patients. No statistically significant difference in response to antidepressant treatment was observed between the hyperthyroxinemia group and the normal serum thyroxine group (Styra et al., 1991).
- Euthymic bipolar patients were studied after lithium discontinuation. Significant increases ($p < .001$) in plasma thyroxine (T_4) levels and a decrease ($p < .01$) in TSH levels were observed 1 month after lithium withdrawal. No relationship could be demonstrated between the magnitude of the change in hormone levels and the probability of relapse of manic symptoms (Souza et al., 1991).
- Free thyroxine index (FTI) and thyroxine (T_4) levels were measured in 31 manic patients shortly after admission to a psychiatric hospital. Over one-third had elevated thyroid hormone levels (due to increases in FT4I). Low FT4I levels prospectively predicted more hospital admissions in the 12 months from index admission (Joyce, 1991).
- The overall frequency of Grade II subclinical hypothyroidism was 20 percent in 66 bipolar patients. There was no difference in frequency of subclinical hypothyroidism or in mean thyroid hormone levels between the mixed state and non-mixed-state group (Joffe et al., 1994)
- In 20 female patients (major depression, schizophrenia, mania), TRH tests were administered before, during, and after a course of ECT. No significant changes in the mean TSH response were found over the course of ECT and the initial TSH response did not predict the treatment outcome (Hofmann et al., 1994).
- Six resistant bipolar patients (non-rapid-cycling) were treated with supraphysiological doses of thyroxine (250–500 micrograms/day) as add-on and followed up for 27.8 ± 12.8 months. The mean number of relapses declined from 5.3 ± 3.1 to $.8 \pm .8$ compared to the same length of time for each patient before the start of treatment with high-dose T_4 (Baumgartner et al., 1994).
- TSH was higher in a first-episode study in mixed vs. manic bipolar patients (Zarate et al., 1997)
- High-dose T_4 (482 ± 72 micrograms/day) proved to have excellent antidepressant effects in approximately 50% of severely therapy-resistant depressed patients (5 unipolar and 12 bipolar) in an 8-week open-label study and at 27.2 ± 22.0 months follow-up of responders (Bauer et al., 1998)
- In 30 bipolar patients in a 3-year study (CBZ and/or Li), a low level of ft_4 during lithium treatment was associated with more affective episodes and greater severity of depression (Frye et al., 1999)
- There was no correlation between CSF TRH and TSH and the severity of depression (Frye et al., 1999)
- The switchover rate to mania in bipolar depressed patients (16 of 158 inpatients) was significantly higher in patients with lower basal TSH (15.4%) than in the group of patients with higher basal TSH (5.1 %) (Bottlender et al., 2000).

CBZ = carbamazepine; CSF = cerebrospinal fluid; ECT = electroconvulsive therapy; Li = lithium; TRH = thyrotropin-releasing hormone; TSH = thyroid-stimulating hormone.

HAM-D ratings fell by an average of 52 percent after TRH administration versus 12 percent after saline administration ($p = .038$). Antidepressant effects of TRH lasted up to 48 hours. There was no correlation between Δ TSH, Δ T₄, or Δ T₃ measures after TRH (or saline) administration and the change in HAM-D scores (Szuba et al., 2005).

In summary, while there are many suggestions that the HPT axis is altered in mood disorders, many of the clinical studies of TRH have yielded mixed results. The extent to which there is a subgroup of patients having alterations in the HPT axis that may have clinical and ultimately

treatment significance remains unclear. There are important gaps in the literature on TRH, including comparisons of unipolar and bipolar patients, studies of bipolar patients while in a manic state, and postmortem and receptor studies of TRH—subjects that should be further explored. Box 14–11 summarizes findings of recent studies implicating abnormalities of the HPT axis in bipolar disorder.

Corticotropin-Releasing Factor and the Hypothalamic-Pituitary-Adrenal Axis. Evidence of HPA axis activation

in bipolar disorder is suggested by multiple lines of evidence. Cushing's syndrome secondary to chronic high levels of endogenous glucocorticoids is associated with a number of psychiatric and psychological disturbances, regardless of its etiology. Major depression, mania, anxiety disorders, cognitive dysfunction and delirium, and hippocampal atrophy have commonly been reported (Krystal et al., 1990; Sonino and Fava, 2001). In a prospective study, for example, 81 percent of subjects diagnosed with Cushing's syndrome developed a psychiatric disorder, most frequently a mood disorder (Kelly et al., 1996). Interestingly, treatment with antiglucocorticoid therapeutics has been reported to result in an improvement in mood and cognitive dysfunction (Kelly et al., 1996), as well as an increase in hippocampal volume in proportion to the treatment-associated decrement in urinary-free cortisol after corrective surgery (Starkman et al., 1999; Simmons et al., 2001).

In subjects without Cushing's, multiple case reports, as well as pharmaco-epidemiological studies, have noted the effects of exogenous steroids on mood (Brown et al., 1999). In a recent review, Sirois (2003) found that 75 percent of patients treated with exogenous corticosteroids exhibited affective symptoms, including mania and depression. At least one study found that mania or hypomania occurred on the day of treatment with corticosteroids, and depression was seen on nontreatment days (Sharfstein et al., 1982).

Measurements of HPA activity in patients are also overwhelmingly supportive. Indeed, overactivity of the HPA axis in depression (either unipolar or bipolar) is among the most consistently replicated biological findings in psychiatry. The anatomical sites and neurohumoral mediators involved in the regulation of this complex neuroendocrine cascade, defined largely in the past decade, are among the best characterized of all neuroendocrine systems (Owens and Nemeroff, 1998; Holsboer, 2000; Gold and Chrousos, 2002).

Discovery of the physiological regulation of human cortisol secretion was soon challenged by further evidence clarifying interactions among adrenal steroids, neuropeptides, and catecholamines. These interactions, which determine the absolute level and periodicity of cortisol secretion from both the hypothalamus and the pituitary, are considerably more complex than had previously been suspected (Axelrod and Reisine, 1984). Such complexity must be kept in mind when relating clinically observed abnormalities in the function of the HPA axis to a specific neuroendocrine defect.

Despite these complexities, the HPA abnormalities reviewed can probably be traced to central (i.e., hypothalamic) rather than peripheral dysregulation of cortisol secretion (Gold et al., 1984b). In brief, the secretion of cortisol from the adrenal cortex is initiated in the CNS through a neurotransmitter-mediated release of hypothalamic CRF, which in turn stimulates pituitary corticotropin (ACTH)

secretion. Various neurotransmitters and neuromodulators, including acetylcholine, NE, serotonin, and GABA, have been implicated in stimulating CRF release (Pepper and Krieger, 1984); different ones predominate at different times, depending on environmental stress, circadian periodicity, and other physiological conditions. Human cortisol secretion can be inhibited by corticosteroids, such as dexamethasone, and this feedback inhibition can readily be demonstrated at both central and pituitary locations. Preliminary data indicate that the central components of the axis are ordinarily more sensitive to glucocorticoid negative feedback than are those in the pituitary gland (P. Gold, unpublished observations). Such distinctions become important in interpreting clinical data on cortisol secretion (with and without dexamethasone).

The earliest studies showed that depressed patients had elevated plasma cortisol levels, which decreased after recovery in most but not all patients (Board et al., 1957; Gibbons, 1964). By and large, these studies included a mixed population of depressive patients and used rather primitive techniques for assaying cortisol. More recent studies, using highly specific radioimmunoassays, more frequent sampling of cortisol (to take into account the well-known diurnal rhythm in cortisol secretion), and more homogeneous groups of patients, including children (Weller and Weller, 1988), have consistently shown significant cortisol hypersecretion in many but not all depressed patients.

Although cortisol hypersecretion has been reported in both bipolar and unipolar patients (Sachar et al., 1973), whether it occurs with the same frequency in both groups remains an open question. Several investigators have examined bipolar patients longitudinally and observed significant hypercortisolemia (and/or elevations of urinary cortisol metabolites) during the depressed but not manic phase (Rizzo et al., 1954; Bunney et al., 1965; Kennedy et al., 1989). These results were confirmed and extended by Rubinow and colleagues (1984), who found that both unipolar and bipolar depressed patients have higher urinary free cortisol levels than patients in the manic phase or healthy controls. The urinary free cortisol levels in Rubinow's manic patients were significantly lower than those of normal controls.

Dexamethasone Suppression Test. In addition to cortisol hypersecretion, other state-dependent abnormalities in HPA function have been reported in affective illness. The most common finding is an early escape, or rebound, of cortisol from the suppression induced by dexamethasone (Carroll et al., 1968; Stokes et al., 1975). This phenomenon, the basis for the dexamethasone suppression test (DST), has been used extensively in psychiatric patients (Goodwin and Jamison, 1990; Rush et al., 1996).

As we reviewed in the first edition of this text, the DST is an indicator of the sensitivity of the HPA axis to feedback suppression by exogenously administered steroid (dexamethasone). Approximately 40–50 percent of endogenously depressed patients respond abnormally to the test (Brown et al., 1979; Carroll, 1980). The specificity of the test in depression is questionable, however, since several confounding variables, such as weight loss and various medications, can produce false-positive (abnormal) results. Also arguing against specificity is evidence that other psychiatric disorders (particularly in their acute phases) may be associated with abnormal dexamethasone suppression. Nevertheless, even a conservative analysis of the many studies of dexamethasone suppression must conclude that positive tests occur far more frequently among severely depressed patients than among those with other major psychiatric diagnoses, even when the known confounding factors are taken into account. Among depressed patients, correlations have been found among dexamethasone suppression, levels of anxiety, somatization (Greden et al., 1984), guilt, anorexia, and weight loss (Feinberg and Carroll, 1984).

At first glance, abnormal dexamethasone suppression would appear to be consistent with the hypercortisolemia seen in depression, which might downregulate functional receptors for glucocorticoids at either the hypothalamic or pituitary level. However, hypercortisolemia and dexamethasone nonsuppression are apparently independent—one can be present without the other (Asnis et al., 1981). This finding suggests that the two may not be causally related or may be separate phenomena stemming from the same process but separated in time. For example, dexamethasone suppression may persist for a short time after a brief episode of hypercortisolemia has passed.

Dexamethasone suppression has been relatively well studied in bipolar illness. During depression, between 25 and 60 percent of bipolar patients have abnormal DST results. According to some investigators (Carroll, 1976; Greden, 1982), but not all (Graham et al., 1982; Godwin et al., 1984; Deshauer et al., 1999), these results revert to normal during the hypomanic and manic phases. The large variability in the rates of abnormal DST results among bipolar patients is also seen in unipolar patients (Stokes et al., 1984). Most investigators have found no significant difference in the rates of abnormal DST results among bipolar and unipolar depressed patients, but some do report that unipolar depressed patients have significantly higher post-dexamethasone cortisol values than those of bipolar patients (see Rothschild et al., 1982), primarily because of the very high values in psychotic unipolar patients.

In the initial DST findings for manic patients, the rates of nonsuppression were not significantly greater than those reported in controls (Carroll, 1976; Greden, 1982). Subsequent

studies, however, found that variable proportions of manic patients failed to suppress.⁴⁰ In fact in some studies, nonsuppression in mania is as frequent as it is in bipolar depression (Graham et al., 1982; Arana et al., 1983; Godwin et al., 1984).

How can we account for these discrepancies? Patients with dysphoric manias—that is, mixed manic-depressive states—frequently have abnormal DST results (Evans and Nemeroff, 1983; Krishnan et al., 1983). If the proportion of such manias differed substantially from one study to another, variable nonsuppression in the manic groups might be expected. However, some reports of dexamethasone nonsuppression in mania specify that the patients were not simultaneously depressed (Graham et al., 1982; Arana et al., 1983). Of special interest is a small group of longitudinal studies in which the DST was used during both phases of the illness in the same patient. In one of these studies (Godwin et al., 1984), most of the bipolar patients showed similar DST results (either abnormal or normal) in both the manic and depressive phases. This finding suggests that there may be a subgroup of bipolar patients in whom HPA axis dysregulation underlies both phases of illness.

When the entire literature on the DST in bipolar disorder is examined critically, it becomes clear that nonsuppression occurs more frequently in the depressive and mixed phases of the illness, but is also not at all uncommon in mania. Clearly, if one considers all studies measuring some aspect of cortisol secretion in manic-depressive patients, the evidence indicates that hypercortisolemia occurs more frequently in the depressed phase than in the hypomanic, manic, or euthymic phases. When cortisol hypersecretion clearly differentiates depression from mania, why does dexamethasone suppression not do the same?

Studies by Meltzer and colleagues (1982), Klein and colleagues (1984), and Atkinson and colleagues (1986) may shed some light on this question. These investigators showed that dexamethasone administration also decreases pituitary prolactin secretion and that, in psychiatric patients with affective symptoms, there is a significant association between nonsuppression of both cortisol and prolactin. Thus, abnormal dexamethasone suppression could indicate a nonspecific abnormality in the feedback sensitivity of the pituitary gland rather than a specific limbic system disturbance, as was previously postulated. This interpretation is not, however, consistent with findings of subsequent studies employing CRF infusions (Gold et al., 1984b, 1986; Gold and Chrousos, 1985), which found normal feedback at the pituitary level.

Virtually all studies agree that both hypercortisolemia and DST results become more normal after recovery from manic or depressive episodes (Carroll, 1982; Joyce and Paykel, 1989). Such evidence indicates that the abnormalities are state-dependent and do not provide a marker for the underlying vulnerability to bipolar disorder or recurrent

depression. Also, the fact that these HPA axis abnormalities are not specific to manic-depressive illness or even to major affective illness means they probably reflect downstream physiological concomitants of depression and arousal. It is possible that recurrent affective disorders involve some episodic vulnerability in these systems, perhaps initially requiring activation by stress.

Detailed studies of glucocorticoid receptor (GR) and mineralocorticoid receptor (MR) in subjects with mood disorders are still ongoing. In this context, one post-mortem brain study suggested that decreased GR mRNA may be present in the hippocampus of individuals with bipolar and unipolar disorder (Webster et al., 1999). Additionally, another postmortem brain study found significantly lower GR and MR protein and mRNA levels in prefrontal cortex of patients with major depressive disorder compared with those in controls (Lopez et al., 2004). GR mRNA levels were reported to be decreased in layers III and VI in the entorhinal cortex in patients with mood disorders (Webster et al., 2002). As discussed below, Nemeroff and colleagues (1988) have additionally shown a marked decrease in CRF binding sites in the frontal cortex of suicide victims. In an in vivo study using spiroolactone to assess MR function in subjects with depression (an MR antagonist), Young and colleagues (2003) found that subjects with depression had higher functional activity of the MR system, with an increased secretion of cortisol in response to spiroolactone in comparison with matched controls. Furthermore, transgenic mice with reduced GR have HPA axis and cognitive disturbance that may parallel depression in humans and that normalizes with antidepressant exposure. Antisense oligonucleotides targeted to GR (a genetic strategy to reduce the levels of GR mRNA and protein) were found to reduce immobility on the forced swim test, as did the antiglucocorticoid drug mifepristone (RU-486) (Korte et al., 1996). As discussed below, these observations have led to clinical trials of novel therapeutics targeting the glucocorticoid system. Xing and colleagues (2004) determined MR mRNA expression in the postmortem prefrontal cortex of patients with major depression (recurrence not specified) bipolar, and schizophrenic disorders and nonpsychiatric controls ($n=15$ for each patient group, and $n=14$ for controls) by in situ hybridization. In the dorsolateral prefrontal cortex Brodmann's area 9 (BA 9), MR mRNA was significantly lower ($p<.05$) in all laminae (I–VI) in bipolar disorder patients, and in laminae I, III, IV and VI in patients with schizophrenia than in the controls. MR mRNA in BA 9 was negatively correlated with the duration of psychiatric illnesses. Whether these findings may be linked to the abnormal prefrontal function, HPA axis activation, or the deficits in slow-wave sleep (SWS) found in these major psychiatric illnesses remains to be further

explored. In another study, GR mRNA expression was reduced in the basolateral/lateral nuclei in schizophrenia and bipolar disorder patients ($n=15$ /per group) compared to that in controls (Perlman et al., 2004). To determine if the GR modulates these features of emotional responsiveness, Wei and colleagues (2004) generated transgenic mice overexpressing GR specifically in forebrain. These mice displayed a significant increase in anxiety-like and depressant-like behaviors relative to wild-type (control) mice. Intriguingly, the mice were also supersensitive to antidepressants and showed enhanced sensitization to cocaine. These intriguing findings parallel the human observation that glucocorticoids are capable of inducing both manic and depressive symptomatology. Furthermore, as we describe in greater detail below, very recent microarray studies have shown that both lithium and valproate robustly upregulate the expression of a chaperone protein BAG-1, (Bcl-2 associated atahogene) that inhibits GR function. Together, these results suggest the forebrain overexpressing GR in mouse may represent a very useful model to delineate some of the circuitry and molecular mechanisms underlying the range of behavioral phenotypes observed in manic-depressive disorder and is worthy of further study.

Role of Corticotropin-Releasing Factor. CRF has become one of the most extensively studied of all the neuropeptides in relation to its potential role in affective disorders. CRF is a 41-amino acid peptide and is a direct regulator of secretion of ACTH from the anterior pituitary. In addition, it acts as a neurotransmitter in extrahypothalamic brain areas. CRF is thought to mediate the neuroendocrine, autonomic, and behavioral response to stress and to underlie some of the observed abnormalities, such as hypercortisolemia, dexamethasone nonsuppression, and stress intolerance, found in depressed patients.

There have been numerous studies of the CSF concentration of CRF in untreated depressed patients, most of which have replicated elevated levels (Nemeroff et al., 1984b; Banki et al., 1987; France et al., 1988; Arato et al., 1989). Elevated levels have also been observed in the CSF of suicide victims (Arato et al., 1989). In contrast to somatostatin, elevated CRF in the CSF appears to be secondary to increased production of the peptide, as elevated levels of mRNA have also been found in the hypothalamus of depressed suicide victims (Plotsky et al., 1995). In addition, the mean number of CRF immunoreactive neurons in the hypothalamus were increased in a postmortem study of depressed patients (Raadsheer et al., 1994). The elevated CSF levels appear to normalize after treatment with ECT or antidepressants (Nemeroff et al., 1991), and failure of normalization may be predictive of relapse (Banki et al., 1992). CSF levels of CRF in patients

with mania are not significantly different from those in control subjects (Banki et al., 1992).

Nemeroff and colleagues (1988) found a 23 percent reduction in the number of CRF binding sites in the frontal cortex of suicide victims compared with that in controls; these reductions in CRF binding sites have been postulated to represent a compensatory downregulation in the face of sustained CRF elevations. In contrast, Leake and colleagues (1991) found no differences in CRF immunoreactivity or receptor binding in a small group of depressed patients who died from natural causes. In addition, Hucks and colleagues (1997) found no difference between both medicated and medication-free suicide victims and matched controls. Whether these differences are secondary to differences in postmortem time or in clinical sample characteristics remains unclear.

The CRF stimulation test uses a standard dose of CRF and measures the ACTH response. A subset of depressed patients (both unipolar and bipolar) displayed a suppressed ACTH response to CRF (Holsboer et al., 1987; Young et al., 1990). These results have been interpreted as downregulation of CRF receptors as a result of CRF hypersecretion.

In a study by Gold and colleagues (1984b), the CRF-induced release of ACTH was found to be normal in a group of manic and euthymic bipolar patients, further supporting the findings above of normal or low HPA axis function in manic patients as reflected by urinary free cortisol. Apparently, the central mechanisms responsible for the hypersecretion of CRF in depression revert to normal following the switch to mania or euthymia. As noted previously, several major neurotransmitter systems (noradrenergic, adrenergic, serotonergic, cholinergic, and GABAergic) have been implicated in the regulation of CRF release from the paraventricular nucleus of the hypothalamus. In studies of CRF release by hypothalamic organ culture, Gold's group showed that GABA is inhibitory, whereas NE, acetylcholine, and serotonin are excitatory (Calogero et al., 1988, 1989). Drugs that mimic the actions of acetylcholine have been reported to increase ACTH and cortisol secretion in animals and humans, and there is evidence that cholinergic agonists work on the HPA axis through a receptor-mediated release of hypothalamic CRF. In animals, atropine (a muscarinic-cholinergic antagonist) has been shown to block both stress-induced elevations of ACTH and cortisol (Hedge and Smelik, 1968; Hedge and de Wied, 1971) and the normal circadian rhythm of cortisol secretion (Krieger et al., 1968; Ferrari et al., 1977). The previously discussed depressive-like behavioral effects of physostigmine (a reversible cholinesterase inhibitor) are highly correlated with increased blood levels of ACTH, beta-endorphin, cortisol, and prolactin (Risch et al., 1980, 1981). These same investigators also report that depressed bipolar and unipolar patients secrete significantly more ACTH and

beta-endorphin after physostigmine administration than do controls (Risch et al., 1983).

To test the hypothesis of increased cholinergic sensitivity in major depression, Rubin and colleagues (1999) administered physostigmine (PHYSO) to patients and control subjects at a dose that elevated plasma ACTH, cortisol, and arginine vasopressin (AVP) concentrations but produced few or no side effects. These hormone increases following PHYSO occurred primarily in female depressive patients and male controls and were not significantly related to the presence or absence of side effects. These preliminary results support the hypothesis of heightened cholinergic sensitivity in premenopausal female but not in male patients with major depression.

Preclinical studies using animal behavior models have indicated that CRF receptor antagonists, specifically of the CRF receptor-1 subtype, have anxiolytic and antidepressant activity (Mansbach et al., 1997). These results led to the testing of a CRF receptor-1 antagonist, R121919, in an open trial in 24 patients with depression (Zobel et al., 2000). Initial results were encouraging, and further clinical studies are anticipated. Given the number of abnormalities in the HPA axis, as well as the strong evidence for CRF hypersecretion in both unipolar and bipolar depression, an associated abnormality in the CRF gene might be hypothesized. However, at least two genetic linkage and association studies have failed to support the linkage of CRF polymorphisms to bipolar illness (Stratakis et al., 1997; Alda et al., 2000).

Combined Dexamethasone/Corticotropin-Releasing Hormone Test. The combined dexamethasone (DEX)/CRH challenge test has increasingly been used to assess the dysregulation of the HPA axis because of its purported greater sensitivity than that of either the DST or CRH test used alone. The sensitivity of the DEX/CRH test for major depressive episodes is about 80 percent, exceeding the 44 percent sensitivity of the standard DST reported in a meta-analysis of the literature (Heuser et al., 1994). Furthermore, the DEX/CRH test has been reported to be more closely associated with the diurnal activity of the HPA axis than the standard DST in healthy and depressed subjects (Deuschle et al., 1998).⁴¹

Recent studies have shown that the ACTH response to the DEX/CRH test is significantly higher in patients with unipolar depression than in controls (Holsboer et al., 1995; Rybakowski and Twardowska, 1999; Oshime et al., 2000). As a prognostic tool, this test showed that remitted patients previously suffering from unipolar depression with a high cortisol response at admission and discharge or with a substantially increased cortisol response at discharge were at much greater risk for relapse within the next 6 months

(four- to six-fold higher than individuals with a normal cortisol response) (Zobel et al., 1999, 2000).

This test has also been investigated as a vulnerability marker in a population of first-degree relatives of affectively ill patients. It was found that these relatives released more cortisol after stimulation with the DEX/CRH test than a control group, but less than a group of patients with an acute major depressive episode (Holsboer et al., 1995). Furthermore, 4 years later, the same test results were obtained in this vulnerable group of subjects (Modell et al., 1998).

After the DEX/CRH test, significantly higher cortisol release has been described in patients with depression in the course of bipolar illness than in those with unipolar depression, with both groups having higher release than control subjects (Rybakowski and Twardowska, 1999). Both manic and depressed patients have been reported to have an increased release in response to the DEX/CRH test. Remitted patients have had a significant decrease in cortisol release, but still higher than normal controls (Schmider et al., 1995). A potential confounding variable here is medication. Thus recent studies have shown that chronic lithium and valproate increase the levels of a protein that inhibits GR function; such effects would be entirely consistent with the recent observations of enhanced DEX/CRH responses after chronic lithium treatment (Bschor et al., 2002, 2003).

Role of Stress and Glucocorticoids in Modulating Neural Plasticity. As noted earlier, there has been a growing appreciation that stress and glucocorticoids are capable of causing atrophy and death of neurons in a variety of brain areas (McEwen, 1999, 2001; Sapolsky, 2000). Indeed, one of the most consistent effects of stress on cellular morphology is atrophy of hippocampal neurons (McEwen, 1999b; Sapolsky, 2000).⁴² As discussed in Chapters 9 and 15, some data suggest that the magnitude of hippocampal atrophy observed in individuals with unipolar depression may be related to the duration of illness. This finding suggests that ongoing illness-related neurochemical changes may contribute to impairments of cellular plasticity and resilience. Study of the effects of stressors that bring about some of the behavioral and biochemical abnormalities seen in depression is therefore highly pertinent.

To date, most studies of atrophy and survival of neurons in response to stress, as well as hormones of the HPA axis, have focused on the hippocampus, in part because of the well-defined and easily studied neuronal populations of this limbic brain region, including the dentate gyrus granule cell layer and the CA1 and CA3 pyramidal cell layers. (See Figure 14–9 for the effects of stress on this area.) These cell layers and their connections (mossy fiber pathway and Schaffer collateral) have also been used as cellular

models of learning and memory (i.e., long-term potentiation). Another major reason the hippocampus has been the focus of stress research is that the highest levels of glucocorticoid receptors are expressed in this brain region (Lopez et al., 1998). However, it is clear that stress and glucocorticoids also influence the survival and atrophy of neurons in other brain regions (e.g., prefrontal cortex; see below) that have not yet been studied in the same detail as the hippocampus.

Caution in the interpretation of clinical findings is suggested by the results of recent longitudinal studies undertaken to investigate the effects of early life stress and inherited variation in monkey hippocampal volumes (Lyons et al., 2001). In these studies, paternal half-siblings raised apart from one another by different mothers in the absence of fathers were randomized to one of three postnatal conditions that disrupted diverse aspects of early maternal care. The researchers found that paternal half-siblings with small adult hippocampal volumes responded to the removal of all mothers after weaning with initially larger relative increases in cortisol levels (Lyons et al., 2001). Plasma cortisol levels 3 and 7 days later and measures of cortisol-negative feedback in adulthood were not, however, correlated with hippocampal size. Thus, these studies suggest that small hippocampi also reflect an inherited characteristic of the brain, and their findings highlight the need for caution in attributing causality in cross-sectional human morphometric studies of the hippocampus.

Although not as extensively studied as the hippocampus, recent research has demonstrated histopathological changes in rat prefrontal cortex after corticosterone administration (Wellman, 2001).⁴³ An intriguing finding of this study, similar to the hippocampal findings summarized above, was a strong heritability of the right ventral medial prefrontal volume. Thus in this study, certain fathers produced offspring with large right ventral medial prefrontal volumes, whereas others produced offspring with small right ventral medial prefrontal volumes (Lyons, 2002). Since the paternal half-siblings were raised apart by different mothers in the absence of fathers, the phenotypic similarities in right ventral medial prefrontal volumes likely represent a major genetic contribution, effects not seen for other prefrontal regions.

Mechanisms Underlying Stress-Induced Morphometric Changes. As discussed earlier, considerable data suggest that abnormal activation of the glutamatergic system plays a major role in mediating stress-induced morphological changes. Furthermore, it is clear that activation of the HPA axis plays a critical role in mediating these effects, since stress-induced neuronal atrophy is prevented by adrenalectomy and duplicated by exposure to high concentrations

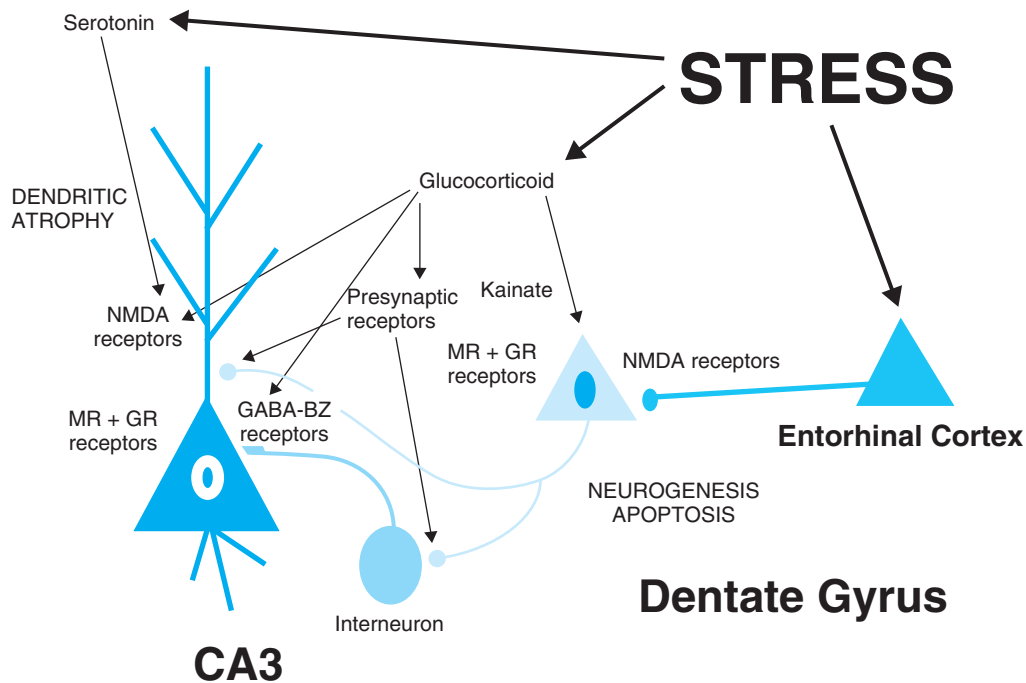

Figure 14–9. Molecular and cellular determinants underlying the opposing actions of stress and antidepressant treatment on hippocampal structure. Stress can have multiple effects depending on the subregion of the hippocampus examined. In the dentate gyrus, acute or chronic stress results in decreased neurogenesis of new neurons. In the CA3 pyramidal cell layer, repeated stress results in atrophy or remodeling of pyramidal neurons, decreasing the number and length of apical dendrites. Glucocorticoid administration causes a similar effect, and decreased expression of brain-derived neurotrophic factor could contribute to pyramidal cell atrophy. Chronic antidepressant administration can reverse the atrophy of CA3 neurons. The effects of antidepressant treatment occur via acute regulation of 5-HT and norepinephrine and the regulation of intracellular signaling and gene expression. GABA-BZ = gamma amino butyric acid-benzodiazepine; GR = glucocorticoid receptors; MR = mineralocorticoid receptors. (Source: Adapted from Warner-Schmidt and Duman, 2006. Reprinted with permission.)

of glucocorticoids (Sapolsky, 1996, 2000b; McEwen, 1999a). More recent data also suggest a critical role for CRF in the long-term effects of early-life stress on hippocampal integrity and function. Thus, the administration of CRF to the brains of immature rats has been demonstrated to reduce memory function throughout life; these deficits are associated with progressive loss of hippocampal CA3 neurons and chronic upregulation of hippocampal CRF expression, effects that do not require the presence of stress levels of glucocorticoids (Brunson et al., 2001).⁴⁴

In addition to directly causing neuronal atrophy, stress and glucocorticoids appear to reduce cellular resilience, thereby making certain neurons more vulnerable to other insults, such as ischemia, hypoglycemia, and excitatory amino acid toxicity (Sapolsky, 2000a). Thus recurrent stress (and presumably recurrent mood disorder episodes, which are often associated with hypercortisolemia) may lower the threshold for cellular death and atrophy in response to a variety of physiological (e.g., aging) and pathological (e.g., ischemia) events. The potential functional significance of these

effects is supported by the finding that overexpression of the glucose transporter blocks the neurotoxic effects of neuronal insults (Sapolsky, 2000a; Manji and Duman, 2001). Such processes may conceivably play a role as well in the relationship between mood disorders and cerebrovascular events, considering that individuals who develop their first depressive episode in later life have an increased likelihood of showing MRI evidence of cerebrovascular disease (see Chapter 15).

The precise mechanisms by which glucocorticoids exert these deleterious effects remain to be fully elucidated, but likely involve the inhibition of glucose transport (thereby diminishing the capability for energy production and augmenting susceptibility to hypoglycemic conditions) and the aberrant, excessive facilitation of glutamatergic signaling (Sapolsky, 2000a). The reduction in the resilience of discrete brain regions, including hippocampus and potentially prefrontal cortex, may also reflect the propensity for various stressors to decrease the expression of BDNF in this region (Smith et al., 1995; Nibuya et al., 1999). The

mechanisms underlying the downregulation of BDNF by stress have not been fully elucidated, however. Adrenal-glucocorticoids do not appear to account for these actions of stress, since administration of a high dose of glucocorticoid is not sufficient to decrease BDNF, and adrenalectomy does not block the effect of stress.

Role of Stress and Glucocorticoids in Impairing Hippocampal Neurogenesis. The finding that neurogenesis occurs in the adult human brain has reinvigorated research into the cellular mechanisms by which the birth of new neurons is regulated in the mammalian brain (Eriksson et al., 1998). The localization of pluripotent progenitor cells and neurogenesis occurs in restricted brain regions. The greatest density of new cell birth is observed in the subventricular zone and the subgranular layer of the hippocampus. Cells born in the subventricular zone migrate largely to the olfactory bulb and those born in the subgranular zone to the granule cell layer. The newly generated neurons send out axons and appear to make connections with surrounding neurons, indicating that they are capable of integrating into the appropriate neuronal circuitry in hippocampus and cerebral cortex.

Neurogenesis in the hippocampus is increased by enriched environment, exercise, and hippocampal-dependent learning (Kempermann et al., 1997; Van Praag et al., 1999; Gould et al., 2000). Upregulation of neurogenesis in response to these behavioral stimuli and the localization of this process to hippocampus have led to the proposal that the birth of new cells is involved in learning and memory (Gould et al., 2000). Subsequent studies have shown that decreased neurogenesis occurs in response to both acute and chronic stress (Gould et al., 2000). Removal of adrenal steroids (i.e., adrenalectomy) increases neurogenesis, and treatment with high levels of glucocorticoids reproduces the downregulation of neurogenesis that occurs in response to stress. Aging also influences the rate of neurogenesis; although neurogenesis continues into late life, the rate is significantly reduced (Cameron and McKay, 1999). The decreased rate of cell birth may result from upregulation of the HPA axis and higher levels of adrenal-steroids that occur in later life. Lowering glucocorticoid levels in aged animals restores neurogenesis to levels observed in younger animals, a finding indicating that the population of progenitor cells remains stable but is inhibited by glucocorticoids (Cameron and McKay, 1999).

Studies have examined the effects of knocking out the glucocorticoid receptor or mineralocorticoid receptors on neurogenesis in mice (Gass et al., 2000). A reduction of granule cell neurogenesis (to 65 percent of control levels) was found in mineralocorticoid receptor mice (MR^{-/-} mice), whereas glucocorticoid receptor mice (GR^{-/-} mice) did not show neurogenic disruption, a finding that eventually related the

mineralocorticoid receptor to the pathogenesis of hippocampal changes observed in chronic stress and affective disorders (Gass et al., 2000). These observations raise the interesting possibility that CRF and GR antagonists, currently being developed for the treatment of mood and anxiety disorders, may have particular utility in the treatment of elderly depressed patients.

Also of potential relevance for our understanding of the neurobiology and treatment of mood disorders is the finding that ovariectomy decreases the proliferation of new cells in the hippocampus, effects that are reversed by estrogen replacement. The rate of neurogenesis fluctuates over the course of the estrus cycle in rodents, and the total rate of cell birth is higher in female rodents than in males. In addition to potentially playing a role in the beneficial cognitive effects of estrogen, the regulation of neurogenesis by this gonadal steroid may provide important clues about certain sexually dimorphic characteristics of mood disorders.

Targeting of the HPA Axis as a Strategy for the Treatment of Severe Mood Disorders. Given the evidence reviewed above, there is a growing appreciation of the potential role of abnormalities of the HPA axis in mediating the phenotypic expression of certain affective states (Gold and Chrousos, 2002). Not surprisingly, then, there is increasing interest in targeting this system for the development of novel therapeutics (see also Chapter 19). Published double-blind, placebo-controlled clinical studies aimed at modulating the HPA axis have employed inhibitors of glucocorticoid synthesis (Malison et al., 1999; Wolkowitz et al., 1999a), antagonists of the glucocorticoid receptor (Belanoff et al., 2001; Young, 2006), hydrocortisone to downregulate the HPA axis (in a proof-of-concept study reported by DeBattista et al., 2000), and dehydroepiandrosterone (Bloch et al., 1999; Wolkowitz et al., 1999b). Some of these drugs have been investigated for proof of concept rather than for use as a standard of care, and it is expected that modified and improved medications would lack some of the limiting side effects observed with these compounds. We describe below some of the drugs currently under investigation in clinical and/or preclinical trials.

CRF₁ Receptor Antagonist. A number of small-molecule CRF 1R antagonists have been evaluated using in vivo paradigms in animal models to attenuate CRF-induced ACTH release (Saunders and Williams, 2003). Several classes of CRF 1R inhibitors have been identified, including peptides (astressin, α -helCRF) and small-molecule nonpeptides (CP-154526, antalarmin, DMP-695, DMP-696, CRA-1000, R-121919, SSR-125543, NBI 35965, NBI 27914) (Holmes et al., 2003; Saunders and Williams, 2003). Preclinical studies have shown that CRF 1R antagonists reduce CRF-induced ACTH

release and CRF-induced cAMP production (Saunders and Williams, 2003).

Antalarmin, a novel pyrrolopyrimidine compound (Webster et al., 1996), administered to primates in oral doses of 20 mg/kg, significantly diminished CRF-stimulated ACTH release and the pituitary–adrenal, sympathetic, and adrenal medullary responses to stress, and also reversed stress-induced inhibition of exploratory and sexual behaviors (Habib et al., 2000). In the chronic stress model in mice, both antalarmin (10 mg/kg) and fluoxetine (10 mg/kg) were found to improve measures of physical state, weight gain, and emotional response in the light–dark test compared with those of stressed, untreated animals (Ducottet et al., 2003).

CP-154,526, developed by Pfizer, has been evaluated in animal paradigms for treatment of anxiety. It has high penetrability like antalarmin and decreases synthesis of CRF in the paraventricular nucleus (Seymour et al., 2003). Mansbach and colleagues (1997) showed its efficacy in the learned helplessness model of depression in rats. SSR125543A, a 2-aminothiazole derivative that displays a high affinity for human CRF 1 receptors, showed efficacy in the forced swim test and chronic mild stress models in rats in a study comparing it with antalarmin and fluoxetine (Griebel et al., 2002). In other studies, CRA 1000, a nonpeptide pyrimidine CRF 1R antagonist being developed by Taisho Pharmaceuticals (Okuyama et al., 1999), reduced immobility in the learned helplessness paradigm in male wistar rats when given by intraperitoneal injection (Harro et al., 2001). DMP696, developed by Dupont, is a selective, potent, and highly bioavailable nonpeptide CRF 1R antagonist that has been tested in behavioral models of anxiety and is being tested in behavioral paradigms for depression (Li et al., 2003).

Interestingly, R-121919 reduced anxiety and depressive symptoms in patients with unipolar depression in an open-label clinical trial (Zobel et al., 2000). Its clinical development was discontinued, however, probably in response to two cases of healthy volunteers with elevated liver enzymes receiving a high dose of the compound (Kunzel et al., 2003). Yet in an extended data report of the clinical study in major depression patients, no serious side effects were noted in the hypothalamic–pituitary–gonadal system, the HPT axis, the renin–angiotensin system, and prolactin or vasopressin secretion. In addition, no effects on clinical laboratory parameters (including liver enzymes) were observed, encouraging the development of CRF 1R antagonists as antidepressant medications (Kunzel et al., 2003).

Dehydroepiandrosterone. Dehydroepiandrosterone (DHEA) serves as a precursor for both androgenic and estrogenic steroids and, together with its sulphated form (DHEA-S), is secreted by the adrenal gland and produced

in the CNS. Thus, DHEA and DHEA-S are neuroactive steroids having a number of effects that can be described as “functional antagonism” of the actions of glucocorticoids (although DHEA does not directly interact with the glucocorticoid receptor, and there is no known receptor for DHEA in any tissue) (McEwen, 2003). Among its effects, DHEA counteracts the actions of glucocorticoids to inhibit memory and primed-burst potentiation (a form of long-term potentiation) and antagonizes oxidative damage in brain (and in other organs) produced by acute hyperglycemia. Although mediated by an unknown cellular and molecular mechanism, DHEA also interacts with neurotransmitters (serotonin, GABA, excitatory amino acids, and DA), in addition to its glucocorticoid antagonism (reviewed by McEwen, 2003).

DHEA's antidepressant efficacy has been suggested by clinical trials in dysthymic and depressed patients. Wolkowitz and colleagues (1997) reported on a case series comprising six middle-aged and elderly patients with unipolar depression and low basal plasma DHEA and/or DHEA-S levels who received DHEA 30–90 mg/day for 4 weeks. A decrease in depression ratings and an improvement in memory performance, correlated with increases in plasma levels of DHEA and DHEA-S, were observed. The effects of DHEA were also investigated in a double-blind, placebo-controlled, randomized crossover treatment study using 90 and 450 mg of DHEA in patients with midlife-onset dysthymia (a total of 6 weeks on medication and 6 weeks on placebo). The study was completed by 15 of 17 patients; 60 percent of those patients responded to DHEA, compared with 20 percent on placebo (Bloch et al., 1999). Finally, a double-blind, placebo-controlled study was conducted in 22 patients with unipolar depression (medication-free or on stabilized antidepressant regimens) using DHEA at a maximum dose of 90 mg/day or placebo for 6 weeks. A decrease of 50 percent or greater in depressive symptoms was seen in 45 percent of the patients and none in the placebo group (Wolkowitz et al., 1999b). In a recent double-blind, randomized, placebo-controlled crossover study involving 23 men and 23 women with midlife-onset major or minor depression, 6 weeks of DHEA (90–450 mg/day) was found to be superior to placebo in reducing depressive symptoms (Schmidt et al., 2005).

Glucocorticoid Receptor Antagonists. Mifepristone (RU-486) is a nonselective antagonist of the GR receptor that has shown efficacy in treating psychotic depression (Murphy et al., 1993; Belanoff et al., 2001, 2002) and is being used in ongoing trials in bipolar disorder (Manji et al., 2003b). Young and colleagues (2004) have reported preliminary data on mifepristone (600 mg) compared with placebo in 19 subjects with bipolar depression. They found a beneficial effect on mood and neurocognitive functioning. In a separate

study not yet published, 208 patients were randomized to receive 7 days of mifepristone or placebo in addition to their ongoing treatment for psychotic unipolar depression. Although both groups improved significantly, there was no statistical difference between them. A post hoc analysis indicated that the mifepristone patients improved more rapidly than the placebo group (DeBattista et al., 2003). In a recent study, 20 bipolar patients were treated with 600 mg/day of the corticosteroid receptor antagonist mifepristone (RU-486) or placebo for 1 week in a double-blind crossover design (Young et al., 2004). Following treatment with mifepristone, selective improvement in neurocognitive functioning was observed. Spatial working memory performance was significantly improved compared to that of placebo. Hamilton Depression Rating Scale scores and Montgomery-Asberg Depression Rating Scale scores were also improved. These data provide preliminary evidence that glucocorticoid receptor antagonists may have useful cognitive-enhancing and possibly antidepressant properties in bipolar disorder and perhaps also in recurrent depression.

Other GR antagonists being developed are ORG 34517 (Organon), AL082D06 (Abbott), and cyproterone acetate (Schering). Bachmann and colleagues (2003) synthesized three derivatives of mifepristone with higher selectivity for binding to the glucocorticoid receptor, secondary to decreased binding to progesterone receptors (ORG 34517, ORG 34850, and ORG 34116). Among these agents, ORG 34517 is highly potent at the glucocorticoid receptor. Preliminary data for its antidepressant efficacy were presented at the 2002 Collegium Internationale Neuro-psychopharmacologicum (CINP) meeting by Hoyberg and colleagues (2002). This compound is now in Phase III trials.

Miner and colleagues (2003) have reported on a new compound, AL082D06 (D06), discovered by screening compound libraries, that binds specifically to the glucocorticoid receptor with no measurable binding affinity to the progesterone receptor. This compound was found to antagonize glucocorticoid-mediated transcriptional regulation in *in vitro* cell-based models of transcriptional activation.

Cyproterone acetate is available outside the United States as an antiandrogen approved for paraphilias. It is used as a contraceptive agent added to an estradiol combination that is also widely used for hair growth. Honer and colleagues (2003) report on its GR antagonism properties, and while it could be tested in depression, it is unlikely to be clinically useful because of its antiandrogenic properties and risk of severe liver damage.

Inhibition of glucocorticoid synthesis has also been investigated as an antidepressant strategy in unipolar and bipolar patients. This research has included the compounds ketoconazole (which poses a risk for hepatotoxicity and drug interaction), metyrapone, and aminogluthethimide.

Recently, in a double-blind, randomized, placebo-controlled study, 63 inpatients with major depression were randomized to receive either placebo or metyrapone (1g/day) for the first 3 weeks of a 5-week trial with nefazodone or fluvoxamine. A higher proportion of patients receiving metyrapone showed a positive treatment response at day 21 and at day 35 compared with placebo patients. The clinical course of patients treated with metyrapone showed an earlier onset of action beginning in the first week. The plasma concentrations of corticotropin and deoxycortisol were significantly higher during metyrapone treatment, whereas cortisol remained largely unchanged (Jahn et al., 2004).

Corticotropin-Releasing Factor and the Hypothalamic–Pituitary–Adrenal Axis in Manic-Depressive Illness: Summary. In summary, there is a great deal of support for alterations in the HPA axis, as well as in CRF, in affective disorders. HPA axis hyperactivity in mood disorder patients is generally manifested by increased cortisol levels in plasma (especially at the circadian nadir), urine, and CSF; increased cortisol response to ACTH; blunted ACTH response to CRH challenge; enlarged pituitary and adrenal glands; and postmortem downregulation of frontal cortical CRH. Reduced corticosteroid receptor feedback has been implicated in this process by challenge studies using the DST and the DEX/CRH test.

With respect to bipolar disorder, increased HPA axis activity has been associated more consistently with mixed manic states and depression and less with classic manic episodes (Garlow et al., 1999). As we discuss in greater detail later, a growing body of data suggests that recurrent mood disorders are associated with impairments of neuroplasticity and cellular resilience. The potential contribution of abnormalities of glucocorticoid secretion to these effects and the therapeutic utility of CRF and GR antagonists is an area of extensive current research. Box 14–12 summarizes evidence supporting the involvement of the HPA axis in bipolar disorder and unipolar depression.

Gonadal Steroids

Gonadal steroids as a group have wide-ranging neuro-modulatory actions. In fact, gonadal steroids play a role in all stages of neurodevelopment, including neurogenesis, synaptogenesis, neural migration, growth, differentiation, cell survival, and death (Pilgrim and Hutchison, 1994). These various actions, in general, stem from the fact that gonadal steroids are able to modulate genomic transcription and therefore direct and modulate the synthesis of various enzymes and receptor proteins. These actions are tissue-specific and are directed by the presence or absence of tissue-specific coactivators or corepressors (Katzenellenbogen et al., 1996). Further, gonadal steroid actions on

BOX 14–12. Evidence Supporting the Involvement of the Hypothalamic–Pituitary–Adrenal Axis in Severe, Recurrent Mood Disorders

- Increased CRF in the CSF
- Blunted ACTH hormone, beta-endorphin, to CRF stimulation
- Reduced CRF receptors in frontal cortex in suicide (may represent compensatory downregulation in the face of overstimulation)
- Pituitary gland enlargement in depressed patients
- Adrenal gland enlargement in depressed patients and suicide victims
- Increased cortisol production during depression
- DST nonsuppression in UP depression
- DST nonsuppression in BP depression and mixed states
- Increased urinary free cortisol concentrations in depression
- Depressogenic and anxiogenic behavioral effects of CRF agonists in rodents
- Preliminary data suggest efficacy of CRF antagonists and GR-blocking drugs in depression

ACTH = adrenocorticotropic hormone; BP = bipolar; CRF = corticotropin-releasing factor; CSF = cerebrospinal fluid; DST = dexamethasone suppression test; GR = glucocorticoid receptor; UP = unipolar.

the brain may be dependent on context and developmental stage. In addition, classic neurotransmitters and other chemicals can directly activate gonadal steroid receptors in the absence of the steroid ligand, and conversely, gonadal steroids have been shown to have modulatory effects on classic neurotransmitter receptors. Thus there appears to be an avenue of “cross talk” between the two systems. Unbound steroid receptors have also been shown to have transcriptional activator and repressor actions. In summary, gonadal steroids appear to have widespread effects that are contextually dependent.

Testosterone. To date there have been relatively few studies examining potential links between testosterone and affective disorders. Early studies focused on group differences between those with affective illness, including depression and mania, and those with schizophrenia. For example, Mason and colleagues (1988) found higher testosterone levels in patients with paranoid schizophrenia than in those with affective disorders, including mania. Subsequent reports have confirmed that testosterone levels are not elevated in patients with mania compared with controls, although luteinizing hormone concentrations do appear to be elevated (Whalley et al., 1985, 1987; Hunter et al., 1989). An early small study by Sanchez and colleagues (1976) indicated that lithium may lower levels of testosterone, but findings of a more recent and larger study indicate that most patients treated with lithium for 5 years

have normal testosterone levels (Kusalic and Engelsmann, 1996).

Most recent work has focused on the exogenous use of anabolic–androgenic steroids both in medical treatment and illicitly in the bodybuilding and sports industries. Several studies have indicated that the exogenous use of testosterone can increase manic ratings and aggression in some normal men (Pope et al., 2000), as well as affectively vulnerable individuals (Weiss et al., 1999). Pope and Katz (1988) interviewed 41 bodybuilders and football players who had used steroids and were able to retrospectively diagnose manic episodes in 12.2 percent and a major depressive episode in another 12.2 percent, specifically while withdrawing from steroids. Thus, although the preponderance of the evidence supports the induction of affective symptoms by the exogenous use of testosterone, there is little evidence to date to support any role of testosterone in “naturally” occurring affective syndromes.

Estradiol. The rates of unipolar depression in male and female children are roughly equal until puberty. At that time, the rate for females becomes double that for males. The Epidemiologic Catchment Area (ECA) Study and the National Comorbidity Study (NCS) both report the highest 12-month prevalence ratio for major depression in women during their reproductive years, compared with premenarchal girls, postmenopausal women, and men of all ages (Weissman et al., 1988; Kessler et al., 1993). The difference in prevalence does not appear to be secondary to differences in course, recurrence rates, or number of episodes, as evidenced by a study (Simpson et al., 1997) that followed 96 men and 101 women for 8.4 years. Thus it appears that women are at greater risk for a first episode of major depression during their reproductive years (Joffe and Cohen, 1998). This observation has led some to propose that the monthly hormonal fluctuations experienced by women beginning at puberty somehow play a role in the pathophysiology of depression in vulnerable individuals (Nolen-Hoeksema, 1987; Joffe and Cohen, 1998).

By contrast, the rate of bipolar disorder is very close to equal in men and women—.9 percent 1-year prevalence rates of .9 and 1.1 percent, respectively, according to the ECA (see Chapter 5). The question of whether hormonal fluctuations play a role in the pathophysiology of bipolar disorder does not appear at first glance to be as pertinent as in major depression. However, the risk of postpartum (puerperal), premenstrual, and even menopausal affective symptoms seem to be increased in bipolar disorder. For example, in the NIMH Genetics Initiative study (Blehar et al., 1998), almost half of women with bipolar-I disorder reported severe emotional disturbances in relation to child-bearing, with one-third reporting episode onset during

pregnancy. In addition, two-thirds of women with bipolar-I disorder reported frequent premenstrual mood disturbances, and 20 percent reported emotional disturbances during the menopause transition. Reich and Winokur (1970) found that 20 percent of women with bipolar disorder suffered from postpartum mania. Dean and colleagues (1989) found a 50 percent relapse rate (both depression and mania) in the 6 weeks following childbirth in women with bipolar disorder. Thus, although hormonal fluctuations may not play a role in the risk of onset of bipolar disorder, they may in fact influence the course and exacerbation of the illness.

Rapid-cycling bipolar disorder is generally defined as four or more affective episodes (depression, mania, or hypomania) in 1 year. As discussed in Chapter 4, the majority of patients with rapid-cycling bipolar disorder are female. In reviewing the available studies on rapid cycling, Leibenluft (1996) calculated that approximately 71–74 percent of patients in these studies were female. Further, when the definition is made more stringent to require 12 or more cycles per year, the proportion of women in a sample increases dramatically (Bauer and Whybrow, 1990).

It does not appear that fluctuations in mood symptoms are correlated with menstrual cycle phase in rapid-cycling patients. For example, although a retrospective study found that 60 percent of 25 rapid-cycling patients experienced severe premenstrual symptoms (Price and DeMarzio, 1986), a prospective study of 47 women found no relationship between mood fluctuations and menstrual cycle phase (Wehr et al., 1988). This latter finding is supported by a subsequent prospective study involving 25 women with rapid-cycling bipolar disorder (Leibenluft et al., 1999). The fact remains, however, that women with bipolar disorder appear to be more vulnerable to rapid cycling. There is some evidence to suggest that rapid cycling can be induced by antidepressant treatments. It is unclear, however, whether the vulnerability in women is secondary to an interaction between antidepressants and the female hormonal system or women being more likely to receive antidepressants (Leibenluft et al., 1999).

What potential role, then, do estrogen and progesterone play in the underlying pathophysiology of bipolar and recurrent depressive disorders? Both have been shown to modulate serotonin function, and estrogen, as well as other gonadal steroids, may influence the effects of antidepressant treatment.⁴⁵

Estrogen has also been shown to increase the expression of nerve growth factors as well as their receptors (Sohrabji et al., 1994). Preclinical studies in rats indicate that ovariectomy reduces the expression of BDNF in parts of the hippocampus as well as the frontal and temporal cortex, and that estrogen replacement increases BDNF expression in

some but not all of these areas (Singh et al., 1995; Simpkins et al., 1997). As we discuss later, BDNF has recently been hypothesized to be involved in the mechanism of action of antidepressants, thus estrogen's effect on BDNF parallels BDNF's antidepressant action.

There are several case reports of estrogen-induced mania or rapid cycling in bipolar patients and at least one case of late-life mania associated with estrogen administration in a patient with no previous history of bipolar illness (Young et al., 1997). Further, Chouinard and colleagues (1987) reported on two cases of bipolar disorder that were stabilized by the addition of an estrogen–progesterone combination in addition to mood stabilizers.

Several preclinical studies have found that estrogen increases the expression of PKC, an important intracellular messenger (Maizels et al., 1992; Rebas et al., 1995). As noted below, both lithium and valproate have been shown to be inhibitors of PKC. Further, a pilot study using tamoxifen (a potent PKC inhibitor) in the treatment of mania was significantly positive.

Taken together, the findings of these studies suggest that in general, estrogen may have a more positive effect on mood and progesterone a more negative effect. Both of these gonadal steroids exert significant intracellular effects as well as more global effects on neurotransmitter levels that may ultimately affect mood and mood regulation. Thus women with an inherent vulnerability to a mood disorder, whether depression or bipolar disorder, may be affected by the monthly fluctuations of estrogen and progesterone or by the more rapid changes induced by delivery. Obviously, the situation is a complex one that deserves further exploration.

Neuropeptides

The Endogenous Opioid System. The discovery of the opiate receptor and its endogenous ligand provided the tools for characterizing endogenous opiate systems involving the endorphins and enkephalins. The fact that these systems modulate behavior related to mood, such as pleasure, pain, and self-stimulation, suggests that they may be involved in affective illness. One straightforward hypothesized formulation involves decreased endogenous opiate function in depression and increased opiate function in mania. Such alterations could occur either in the endogenous opiate neuromodulator or in the density or sensitivity of opiate receptors.

Evaluation of these hypotheses has been approached through several experimental paradigms, such as administering opiate agonists or antagonists to patients, assessing endorphins and related opiate-binding activity in spinal fluid and plasma, conducting neuroendocrine tests following a challenge with exogenous opiates, and examining the

effects of mood-altering drugs on opiate systems (see Stengaard-Pedersen and Schou, 1982).

Trials of Opiate Antagonists in Mania. Endorphins have been studied more extensively than any other group of peptides, not only because they were among the first peptides localized in brain after the discovery of their receptors (Pert and Snyder, 1973), but also because the availability of the relatively pure opiate antagonist naloxone facilitated clinical dissection of the opiate system's function in manic-depressive illness. Despite this scientific activity, however, only tenuous links have been drawn between opiate systems and recurrent affective disorder.

In light of morphine's obvious effects on mood and motor activity in animals and humans, the strategy of blocking endogenous opiate receptors with naloxone in manic patients was viewed with considerable anticipation. The initial study (Janowsky et al., 1978) showed small but significant decreases in manic symptoms following a daily 20 mg IV infusion of naloxone, but subsequent studies have not been as positive.⁴⁶

These negative results were later replicated by the World Health Organization Collaborative Study (Pickar et al., 1982b), a double-blind, placebo-controlled, crossover study of 26 manic patients, although this group did observe significant naloxone-associated reduction in psychotic symptoms in schizophrenic patients concurrently treated with neuroleptics. Emrich and colleagues (1979) actually found exacerbation of manic symptoms in one of two bipolar patients. Thus, the initial observations of antimanic effects with high-dose naloxone have not held up to more extensive efforts at replication. Naloxone-sensitive mania, if it exists, appears to be relatively rare and may require very large doses. It should be noted that several opiate-receptor subsystems in the brain are relatively resistant to blockade by naloxone, so that even with high doses, the naloxone strategy does not provide an unequivocal test of the theory that mania is associated with excess function of some endogenous opiate system in a localized region of the brain.

Trials of Opiates and Opiate Analogs in Depression. The complementary strategy, administering opiates to depressed patients, has also been pursued. Synthetic opiates were among the earliest drugs used in the treatment of depression (see Chapter 19), and work in this area has begun anew with trials of the endogenous opiate-like peptides, p-endorphin, and enkephalin analogs. The bipolar-unipolar distinction was, understandably, not used in the classic opiate literature. Surprisingly, some recent peptide studies also failed to distinguish these groups, and none of these studies focused on recurrent depression, per se.⁴⁷

Three case reports from different patient populations have noted euphoric or confusional states with opiate

administration (Foley et al., 1979; Oyama et al., 1982; Pickar et al., 1984). The fact that large amounts of an endogenous opiate substance administered directly into the CNS can produce a manic-like state does not, however, really bear on the question of whether disturbances in the endogenous opiate systems are involved in the pathophysiology of bipolar disorder. More recently, there have been sporadic reports of mania associated with tramadol (Watts and Grady, 1997), with a tramadol-fluoxetine combination (Gonzalez-Pinto et al., 2001), and with codeine and paracetamol (Orr et al., 1998). However, acute or chronic naloxone has little positive effect or even a negative effect in depressed patients (Terenius et al., 1977; Davis et al., 1979; Janowsky et al., 1979).

Measurement of Opiates in Body Fluids and Postmortem Brain Tissue. The role of opioid substances in mood disorders has been assessed by measuring their concentrations in CSF. These studies have not revealed any consistent abnormalities.⁴⁸

Peckys and Hurd (2001) examined the prodynorphin and kappa opioid receptor mRNA expression levels in the anterior cingulate and dorsolateral prefrontal cortices of subjects diagnosed with schizophrenia, bipolar disorder, or major depression compared with controls without a psychiatric diagnosis. Multivariate analyses failed to reveal any differences in mRNA expression levels among the four diagnostic groups, though a group trend (nonsignificant) was evident for expression of the kappa opioid receptor and prodynorphin mRNAs in the prefrontal cortex.

More recently, Hurd (2002) used *in situ* hybridization histochemistry to characterize the anatomical distribution and expression levels of prodynorphin mRNA within amygdaloid complexin postmortem brain obtained from patients with depression, bipolar disorder, schizophrenia, and controls. Individuals with major depression had significantly reduced (41–68 percent) expression of prodynorphin mRNA in the accessory basal (both parvicellular and magnocellular divisions) and amygdalohippocampal areas compared with that in controls. The bipolar group also showed a significant reduction in mRNA expression levels in the amygdalohippocampal area and in the parvicellular division of the accessory basal area.

Lithium administration has been reported to produce time- and dose-dependent increases in met-enkephalin and leu-enkephalin levels in the basal ganglia and nucleus accumbens. It has also been found to increase dynorphin levels (as determined by immunoreactive dynorphin A [1-8] peptide) in the striatum (Sivam et al., 1986, 1988).⁴⁹

In one of the few applicable clinical studies, CSF levels of various pro-opiomelanocortin (POMC) peptides were examined in euthymic bipolar patients before and during

lithium treatment. No significant effects of lithium on the CSF levels of any of the peptides were observed (Berrettini et al., 1985b, 1987).

In summary, trials of opiate agonists and antagonists in depression and mania have thus far failed to produce any convincing evidence that these systems are significantly involved in the pathophysiology of affective illness. The same can be said about the study of these peptides in body fluids, and postmortem studies are too preliminary. By contrast, preclinical studies suggest that lithium does regulate the opioidergic systems.

Somatostatin. Somatostatin is a hypothalamic tetradecapeptide originally identified as an inhibitor of GH release. Since then it has been found in the gastrointestinal tract and the pancreatic islet cells; it is also widely distributed throughout the CNS. Somatostatin has been implicated in sleep, eating behaviors, activity state, memory, and concentration, as well as nociception.⁵⁰

Five of six studies of CSF somatostatin of depressed patients (N=167) compared with normal controls or other patient populations showed significantly lower levels among the depressed patients. In a study by Rubinow and colleagues (1983), lowered somatostatin levels were observed in both unipolar and bipolar depressed patients. Low somatostatin levels in depression appear to be state-dependent, increasing to normal levels with improvement to a euthymic state or a switch to mania. These findings are consistent with those of Berrettini and colleagues (1987), who reported that in 30 euthymic bipolar patients (10 free of medication and 20 receiving lithium), somatostatin levels in CSF did not differ from those of 20 normal volunteers.

Initial studies (Doran et al., 1986), confirmed by Rubinow (1986), suggest that somatostatin is lower in patients who have abnormal DST results regardless of diagnosis, a finding consistent with a role for this peptide in the regulation of ACTH secretion (Reisine, 1984). Also, somatostatin in CSF is lower in patients with Cushing's disease (Kling et al., 1993), suggesting that elevated cortisol levels may suppress somatostatin release.

Carbamazepine is associated with significantly decreased levels of somatostatin in CSF compared with medication-free values (Rubinow, 1986). Whether this lowered level of somatostatin is in any way related to the clinical effects of carbamazepine is not clear. Lithium and antidepressants do not appear to have this effect.

Vasopressin. Extensive animal data indicate that central vasopressin is involved in regulating memory, pair sensitivity, sleep, the synchronization of circadian rhythms, and fluid and electrolyte balance. Noting the parallel between these functional roles of vasopressin and the syndrome of affective illness, Gold and colleagues (1978) hypothesize

that a deficiency in central vasopressin function is involved in the pathophysiology of depression, especially alterations in cognitive functioning, circadian rhythms, and fluid and electrolyte balance.⁵¹

Subsequently, abnormalities in vasopressin expression or receptor activity have been found in both major depression and rodent genetic models of depression (Zhou et al., 2001; Keck et al., 2003). The nonpeptide V_{1b} receptor antagonist SSR149415 has been reported to exert marked anxiolytic-like and antidepressant-like effects in rodents (Griebel et al., 2002). In contrast to the marked effects of pharmacological V_{1b} receptor antagonism, mice with a targeted mutation in the V_{1b} receptor show reduced aggression but normal anxiety-like behavior and neuroendocrine stress responses, postulated to arise from a compensatory change at the level of the V_{1a} receptor or CRF system (Wersinger et al., 2002). Taken together, the findings of current research suggest that blockade of central V_{1b} receptors may represent a novel therapeutic strategy for the treatment of stress-related psychiatric disorders (Holmes et al., 2003). A recent study found that orally active vasopressin V_{1a} receptor antagonist, SRX251, selectively blocks aggressive behavior (Ferris et al., 2006).

Two important drugs for recurrent affective disorders, lithium and carbamazepine, affect vasopressin function in apparently opposite directions. Lithium is associated with the induction of diabetes insipidus, presumably by inhibiting renal vasopressin-induced adenylate cyclase activity, and carbamazepine has been used in treating hypothalamic diabetes insipidus (even though it will not reverse the condition when induced by lithium) (Post et al., 1984a). A study of the effects of ECT on vasopressin levels in depressed patients showed a sharp rise in plasma vasopressin levels after treatment, which continued in most patients 4–8 days thereafter (Devanand et al., 1987).

Substance P. Substance P is an undecapeptide neurotransmitter that appears to play an important role in pain sensation and analgesia. It acts as an excitatory neurotransmitter in primary afferent (dorsal root) nerve terminals in the mammalian spinal cord and regulates sympathetic noradrenergic function. Substance P is also found in discrete areas in the CNS, including the substantia nigra, caudate-putamen, amygdala, hypothalamus, and cerebral cortex, where it is thought to act as an excitatory neurotransmitter. It is usually colocalized with one of the more classic neurotransmitters, frequently serotonin. Early reports indicated elevated CSF substance P immunoreactivity in depressed and schizophrenic patients (Rimon et al., 1984). However, these results were not confirmed by Berrettini and colleagues (1985c), who found no differences in immunoreactivity between unmedicated acutely

manic, euthymic, or depressed unipolar and bipolar subjects and normal volunteers.

Substance P receptors, also known as neurokinin-1 (NK-1) receptors, are highly expressed in brain regions that regulate affective behavior and response to stress, such as the limbic system. An examination of NK-1 receptors in post-mortem brain of subjects with bipolar disorder ($n=13$), unipolar depression ($n=13$), and schizophrenia ($n=14$) and normal controls ($n=14$) (Burnet and Harrison, 2000) found no differences in autoradiographic binding in the anterior cingulate gyrus among the four groups, although the possibility of a Type II error cannot be excluded. However, the ratio of superficial to deep laminar binding was lower in the group with unipolar depression, which the authors theorize could reflect alterations in specific neural circuits expressing the NK-1 receptor. Given the important role of the amygdaloid complex in the regulation of emotional behavior, Carletti and colleagues (2005) compared the mRNA levels of preprotachykinin A (PPT-A, a precursor of both substance P and neurokinin A [NKA]) and 3H-SP binding sites in the amygdala of patients affected by bipolar disorder, major depression, or schizophrenia with those of matched controls. A significant reduction in PPT-A mRNA expression levels was detected in all three diagnostic groups, mainly in the basal, lateral, and accessory basal amygdaloid nuclei, but not in the temporal cortical area proximal to the amygdala. While these results support the involvement of the tachykinins in bipolar disorder, they suggest that there is a generalized impairment of the substance P system in the amygdala in mood disorders and schizophrenia rather than this being a disease-related phenomenon.

Lithium has been shown to increase the substance P content of striatum when administered chronically to rats, an effect antagonized by the concurrent administration of haloperidol (Hong et al., 1983). More recent studies have demonstrated a lithium-induced increase in tachykinin levels that appears to be associated with an increase in transcription of the rat preprotachykinin gene (Sivam et al., 1989). Studies of the effects of subchronic lithium on regional brain concentrations of substance P, neurokinin A, and neuropeptide Y have demonstrated a regionally specific increase in the immunoreactivity of all the peptides (Mathe et al., 1990; Husum et al., 2001).

Preclinical studies have suggested that NK-1 antagonists may have anxiolytic effects (File, 1997) and that substance P agonists have anxiogenic properties (Aguiar and Brandao, 1996). These findings have led to the development of potential antidepressants, such as MK-869, an NK-1 antagonist. MK-869 was shown to be as effective as paroxetine in treating depressive symptoms in a double-blind, placebo-controlled study (Kramer et al., 1998). Unfortunately, the further development of MK-869 as an antidepressant has

been suspended because of side effects. At any rate, subsequent large clinical studies, which included an active SSRI comparator, showed no efficacy of an NK-1 antagonist in the treatment of depression.

Neuropeptide Y. Neuropeptide Y (NPY) is a 36 amino acid peptide synthesized in the arcuate nucleus of the hypothalamus and found in the raphe nucleus. It is stimulated by stress and corticosteroids. Preclinical studies have indicated that antidepressants, lithium, and ECT all increase the concentration of NPY (by immunoreactivity) (Stenfors et al., 1989; Wahlestedt et al., 1990) and mRNA expression (Weiner et al., 1992; Zachrisson et al., 1995) in many brain regions in rats. Further, reduced concentrations of NPY have been observed in the CSF (Widerlöv et al., 1988b) and plasma (Hashimoto et al., 1996; Nilsson et al., 1996) of patients with major depression. There have been some results conflicting with the hypothesis that NPY is downregulated in depression; for example, Berrettini and colleagues (1987) found no difference in CSF NPY immunoreactivity among diagnostic groups, and Irwin and colleagues (1991) actually found an increase in plasma NPY immunoreactivity in depressed patients. Widdowson and colleagues (1992) found reduced immunoreactivity of NPY in the prefrontal cortex and caudate nucleus of suicide victims, particularly in those with a diagnosis of major depression. Caberlotto and Hurd (1999) studied NPY mRNA levels in the prefrontal cortex of patients diagnosed with schizophrenia, bipolar disorder, and unipolar depression, as well as in normal controls. NPY mRNA levels were found to be reduced in bipolar patients only, with no correlation with suicide.

NPY acts through at least five distinct receptor subtypes, with the Y₁ and Y₂ subtypes being most abundant in the CNS. Preclinical studies in animal models of depression have indicated that the Y₁ receptor mRNA is decreased in specific limbic and cortical regions, while the Y₂ receptor mRNA appears to be unaltered. Caberlotto and Hurd (2001), however, found no alterations of the expression of either Y₁ or Y₂ mRNA levels in the prefrontal cortex in subjects with bipolar disorder, unipolar depression, or schizophrenia compared with matched controls. Thus, despite the conflicting findings on NPY levels in CSF, further exploration of NPY mRNA levels, receptor levels, and clinical effects is warranted.

Studies from the Mathe laboratory (Zachrisson et al., 1995; Husum et al., 2001) have demonstrated that lithium, electroconvulsive treatments (ECT in humans and electroconvulsive shock in rodents), and antidepressants affect NPY in a specific temporal manner and in specific brain regions. More recently, the same laboratory investigated brain NPY-like immunoreactivity (NPY-LI) under basal conditions and following a series of electroconvulsive shocks in

both male and female Flinders Sensitive Line (FSL) rats, an animal model of depression, and their controls, Flinders Resistant Line (FRL) rats (Jimenez-Vasquez et al., 2000). Hippocampal NPY-LI in both sexes was significantly lower in the “depressed” FSL rats than in the control FRL rats. Electroconvulsive shock increased NPY-LI in both male and female rats of both strains in hippocampus, frontal cortex, and occipital cortex. In the hypothalamus, the increase was found only in the FSL rats. In both FSL and control rats, basal NPY-LI was lower in the hippocampus of female rats than in male rats. Overall, although the data are limited, NPY remains a neuropeptide with potential involvement in the pathophysiology and treatment of manic-depressive illness, and warrants additional study.

Cholecystokinin. The peptide cholecystokinin (CCK) is of interest in affective illness primarily as a potential mediator of appetite disturbance, since it can produce anorexia in various animals. Moreover, in light of the previously reviewed evidence that DA may be involved in bipolar disorder (and perhaps also in recurrent depression), it is of interest that CCK has been found to coexist with DA in individual neurons.

Some but not all clinical trials of CCK or its analogs in psychotic patients suggest that these peptides can alter psychotic symptomatology. Gemer and Yamada (1982) and Gjerris and colleagues (1984) found no significant differences among normal volunteers and depressed or manic patients in CSF levels of CCK. In contrast, Verbanck and colleagues (1984) reported a significant decrease in CCK in the CSF of patients with bipolar depressive illness compared with controls. In examining the range of values in their control group, however, it appears that the bipolar patients were well within the normal range, although they lacked the relatively greater high tail of values observed in the normal volunteers. Zachrisson and colleagues (1996) showed that both chronic lithium and electroconvulsive shock inhibit CCK synthesis in the caudate-putamen.

Neurotensin. Neurotensin has complex interactions with mesolimbic dopaminergic systems and displays neuroleptic-like properties in some animals, making it an interesting peptide for study in affective illness. Indeed, clinical studies in schizophrenia have shown low levels of CSF neurotensin concentration, effects that were normalized by effective antipsychotic drug treatment. Furthermore, the behavioral and biochemical effects of centrally administered neurotensin resemble remarkably those of systemically administered antipsychotic drugs, and antipsychotic drugs increase neurotensin neurotransmission (Binder et al., 2001). In cultured cells (with a catecholamines phenotype), lithium has been demonstrated to dramatically potentiate increases in intracellular levels of neurotensin and

the mRNA encoding it, caused by combinations of nerve growth factor, dexamethasone, and the adenylate cyclase activator forskolin (Dobner et al., 1988). To date, the few clinical studies of neurotensin in CSF in bipolar disorder have indicated no abnormalities (Berrettini et al., 1983). Furthermore, Austin and colleagues (2000) found no association between three sequence variants of the proneurotensin gene and bipolar disorder.

Vasoactive Intestinal Polypeptide. Vasoactive intestinal polypeptide (VIP), a peptide with very high concentrations in the cerebral cortex, is thought to have important interactions with muscarinic–cholinergic receptors (Hedlund et al., 1983). VIP is also of interest because it is an agonist in the release of ACTH cortisol secretion. In two separate studies, Gjerris and colleagues (1981, 1984) found that VIP levels in the CSF of patients with endogenous depression or mania did not differ from those of controls. However, they found decreased levels in patients with nonendogenous atypical depression characterized by dysphoric hysterical features, reversed diurnal variation, and lack of clearly circumscribed past depressive episodes. Berrettini and Post (1984) reported no difference in VIP levels between euthymic bipolar patients and controls.

Oxytocin. Oxytocin is similar to vasopressin in its structure, anatomical distribution, and wide-ranging effects in the CNS. Secretion of these peptides into CSF has been demonstrated to be independent of their secretion into plasma (Perlow et al., 1982; Kalin et al., 1985). Thus, CSF measures may provide a window into the brain that cannot be obtained by peripheral sampling.

Demitrack and Gold (1988) measured oxytocin in the CSF of patients with affective illness and normal volunteers, with findings roughly comparable to those for vasopressin: manic patients had lower levels of oxytocin than depressed patients. If this interesting finding is replicated, it may be relevant to the opposite effects of oxytocin and vasopressin on learning and memory in animals; that is, oxytocin produces effects resembling amnesia (Bohus et al., 1978). More recently, Purba and colleagues (1996) found elevated numbers of oxytocin immunoreactive neurons in the paraventricular nucleus of the hypothalamus in eight patients with either unipolar or bipolar depression compared with controls.

Calcitonin. Animal studies indicate that calcitonin is involved in regulating a variety of functions, including motor activity, appetite, and pain. It is for this reason, as well as its effects on calcium metabolism, that calcitonin is an interesting candidate for study in affective disorders.

Carman and colleagues (1984) observed significantly lower levels of immunoreactive calcitonin in the CSF of

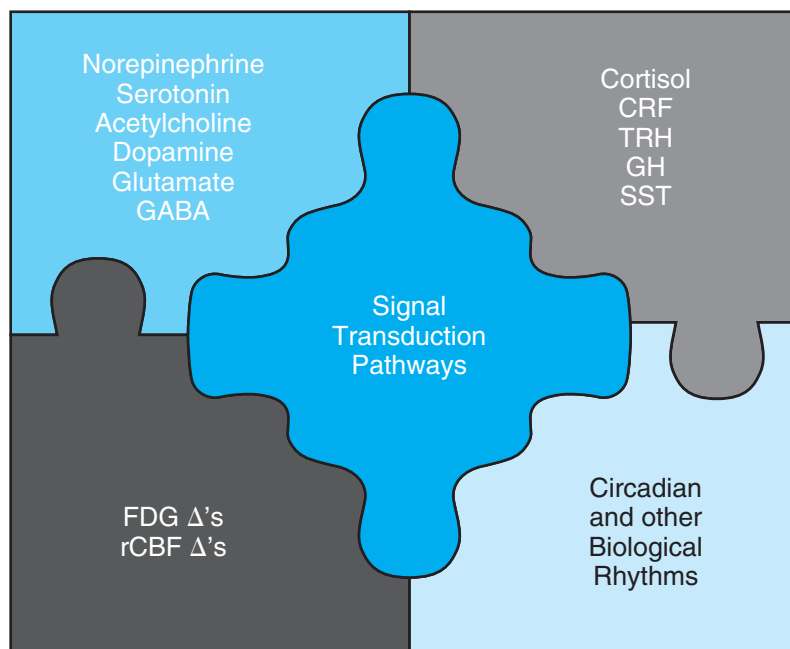

Figure 14–10. Signal transduction pathways provide good explanatory power for understanding the complex neurobiology of manic-depressive illness. CRF = corticotropin-releasing factor; FDG = fluorodeoxyglucose; GH = growth hormone; rCBF = regional cerebral blood flow; SST = serum sialyl transferase; TRH = thyrotropin-releasing hormone.

manic versus bipolar depressed or euthymic patients or normal controls. Carmen's group followed up its preliminary CSF investigations with a double-blind clinical trial of calcitonin in mania and observed a significant and substantial reduction in hyperactivity in 85 percent of the manic patients. A later study found that calcitonin gene-related peptide immunoreactivity (CGRP-LI) concentrations in CSF were increased in depressed patients compared with schizophrenic and control subjects (Mathe et al., 1994).

Most recently, Buervenich and colleagues (2001) investigated the frequency of four novel polymorphisms in the calcitonin/CGRP α (CALCA) gene in a number of neuropsychiatric disorders. They found that a 16–base pair microdeletion polymorphism was present in a family with multiple cases of unipolar or bipolar depressive disorder. Furthermore, using this polymorphism as a marker, cosegregation with the phenotype was observed in the majority of individuals. These intriguing findings await independent replication.

Neurotransmitter and Neuropeptide Systems in Manic-Depressive Illness: Summary

Overall, there is a growing appreciation that while abnormalities in these multiple neurotransmitter and neuropeptide systems are involved in mood disorders,⁵² they likely represent the downstream effects of other, more primary

abnormalities.⁵³ Signal transduction pathways are in a pivotal position in the CNS, able to affect the functional balance among multiple neurotransmitter systems, and have therefore been postulated to play a role in mediating the more-downstream abnormalities in multiple neurotransmitter systems and physiological processes (Manji et al., 2000a; Warsh et al., 2000; Bezchlibnyk and Young, 2002). (Figure 14–10 illustrates the pivotal position of signal transduction pathways.) Moreover, as we discuss in greater detail below, signaling pathways are clearly targets for our most effective pharmacological treatments for recurrent mood disorders.

SIGNALING NETWORKS: THE CELLULAR MACHINERY

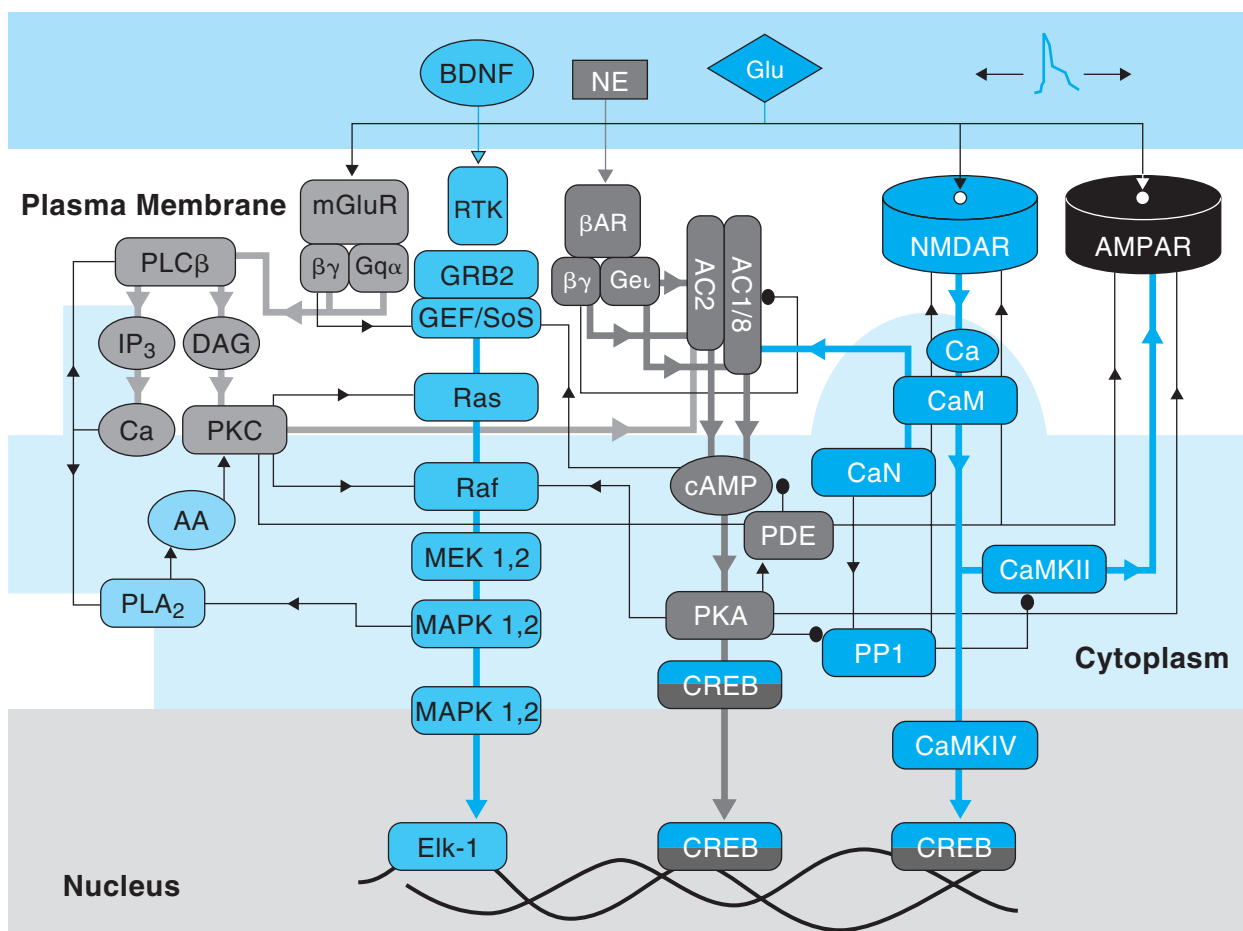

Multicomponent, cellular signaling pathways interact at various levels, thereby forming complex signaling networks that allow cells to receive, process, and respond to information (Bourne and Nicoll, 1993; Bhalla and Iyengar, 1999) (see Fig. 14–11). These networks facilitate the integration of signals across multiple time scales and the generation of distinct outputs, depending on input strength and duration, and regulate intricate feedforward and feedback loops (Weng et al., 1999). These properties of signaling networks suggest that they play critical roles

in cellular memory; thus, cells with different histories, and therefore expressing a different repertoire of signaling molecules and interacting at different levels, may respond quite differently to the same signal over time. Given their widespread and crucial role in the integration, regulation, amplification, and fine-tuning of physiological processes, it is not surprising that abnormalities in signaling pathways have now been identified in a variety

of human diseases (Milligan and Wakelam, 1992; Weintraub, 1995; Spiegel, 1998). Pertinent for the present discussion is the observation that a variety of diseases manifest relatively circumscribed symptomatology despite the widespread, often ubiquitous expression of the affected signaling proteins.

Complex signaling networks are likely present in all eukaryotic cells and control various metabolic, humoral,

Figure 14–11. Four major signaling pathways in the postsynaptic region of a neuron that combine to form a local signaling network. The major linear routes of signal flow are depicted by the thick arrows of four different colors: light grey (phospholipase C [PLC] pathway), light blue (Ras pathway), dark grey (adenylyl cyclase pathway), and dark blue (Ca^{2+} /calmodulin [CaM] pathway). The interactions between different pathways are represented by black lines with arrows (representing activation) or dots (representing inhibition). Although most major interactions in the network are shown, these connections are not meant to be all-inclusive; additional connections could exist. The three different shades of background represent three different cell compartments: the plasma membrane (top level), cytosol (middle level), and nucleus (bottom level). Some of the signaling proteins that translocate between different compartments are shown in both compartments. Examples include mitogen-activated protein kinase (MAPK), which when activated translocates from the cytoplasm to the nucleus to phosphorylate and activates transcription factors; and the transcription factor CREB, which upon phosphorylation by protein kinase A (PKA) translocates to the nucleus. BOX 14–13. Putative Roles for Signaling Pathways in Mood Disorders

- Amplify, attenuate, and integrate multiple signals, the basis of intracellular circuits and cellular modules
- Regulate multiple neurotransmitter and peptide systems, the basis of neuronal circuits and systems modules
- Critical role in cellular memory and long-term neuroplasticity
- Dynamic regulation of complex signaling networks form the basis for higher-order brain function, mood, and cognition
- Major targets for many hormones implicated in mood disorders, including gonadal steroids, thyroid hormones, and glucocorticoids
- Abnormalities are indeed compatible with life—many human diseases arise from defects in signaling pathways
- Brain regional dysregulation and circumscribed symptoms are possible despite the relatively ubiquitous expression of signaling proteins
- Signaling proteins have been identified as targets for medications that are most effective in treatment of mood disorders

and developmental functions. Yet they may be especially important in the CNS, where they serve the critical roles of first amplifying and “weighting” numerous extracellularly generated neuronal signals and then transmitting these integrated signals to effectors, thereby forming the basis for a complex information processing network (Manji, 1992; Bourne and Nicoll, 1993). The high degree of complexity generated by these signaling networks may be one mechanism by which neurons acquire the flexibility required for generating the wide range of responses observed in the nervous system. These pathways are thus undoubtedly involved in regulating such diverse vegetative functions as mood, appetite, and wakefulness, and are therefore likely to be involved in the pathophysiology of manic-depressive illness. We now turn to a discussion of the direct and indirect evidence supporting a role for abnormalities in signaling pathways in the pathophysiology and treatment of this illness with an emphasis on the bipolar subgroup. Box 14–13 summarizes findings to date on the putative roles of signaling pathways in mood disorders. Table 14–1 presents findings of studies examining the role of signaling abnormalities in bipolar disorder.

Evidence for the Involvement of the G_s /cAMP-Generating Signaling Pathway

G Proteins Regulating AC Activity

Several independent laboratories have examined G proteins in patients with mood disorders.⁵⁴ (Figure 14–12 shows the effects of G proteins on the AC system.) Young

and colleagues were the first to report increased levels of $G\alpha_s$ in bipolar patients in two separate studies (Young et al., 1993; Wang et al., 1997). Compared with controls matched for age, postmortem interval, and brain pH, increased levels of $G\alpha_s$ were found in frontal, temporal, and occipital cortex, but not in hippocampus, thalamus, or cerebellum, in postmortem brain tissue from patients with bipolar disorder. This group also found increases in forskolin (FSK)-stimulated AC activity in postmortem brain, compatible with a postreceptor abnormality in bipolar disorder. The findings of elevated $G\alpha_s$ levels and/or function are also supported by recent work of Wang and Friedman (1996), who noted increased agonist-activated [³⁵S]GTP γ S binding to G protein α subunits in frontal cortical membrane preparations from postmortem brain of bipolar patients. Garcia-Sevilla and colleagues (1999) reported increased levels of $G\alpha_{i1/2}$ in prefrontal cortical samples obtained postmortem from depressed patients who committed suicide, effects that were apparently attenuated by antemortem antidepressant treatment. Overall, the findings in postmortem brain tissue in unipolar depression have been less consistent perhaps related to the heterogeneity of unipolar patient samples with respect to recurrence (Warsh et al., 2000; Bezchlibnyk and Young, 2002).

In keeping with the G protein abnormalities in brain tissue obtained postmortem from bipolar patients, Schreiber and colleagues (1991) reported “hyperfunctional” G protein function in leukocytes of untreated manic patients, demonstrating that agonist-stimulated binding of [³H]Gpp(NH)p (a stable, nonhydrolysable analog of guanosine triphosphate [GTP]) was enhanced in leukocyte membranes of untreated manic patients compared with controls. These findings suggest the presence of increased levels of G proteins and/or enhanced receptor-mediated activation of G proteins in leukocytes from untreated manic subjects.

Subsequent studies have found significantly higher levels of $G\alpha_s$ in mononuclear leukocytes from depressed bipolar but not unipolar patients (Young et al., 1994a). Manji and colleagues (1995b) quantitated the levels of the major G protein α subunits in leukocytes and platelets from both untreated (predominantly manic) and lithium-treated, euthymic bipolar patients. In both platelet and leukocyte membranes, there were higher levels of the 45 kilodalton form of $G\alpha_s$ in the overall group of bipolar patients (treated or untreated) than in the controls. A recent study found elevated levels of $G\alpha_s$ mRNA in granulocytes obtained from bipolar but not unipolar patients (Spleiss et al., 1998). This study also found nonsignificant elevations in the levels of $G\alpha_{i5}$ in unmedicated bipolar patients, which intriguingly were modulated by lithium in bipolar (but not unipolar) patients (Spleiss et al.,

TABLE 14–1. Clinical Studies of Second Messenger System Abnormalities in Patients with Manic-Depressive Illness (Primarily Bipolar)

Intracellular Messengers	Tissue	Physiological Change	Study

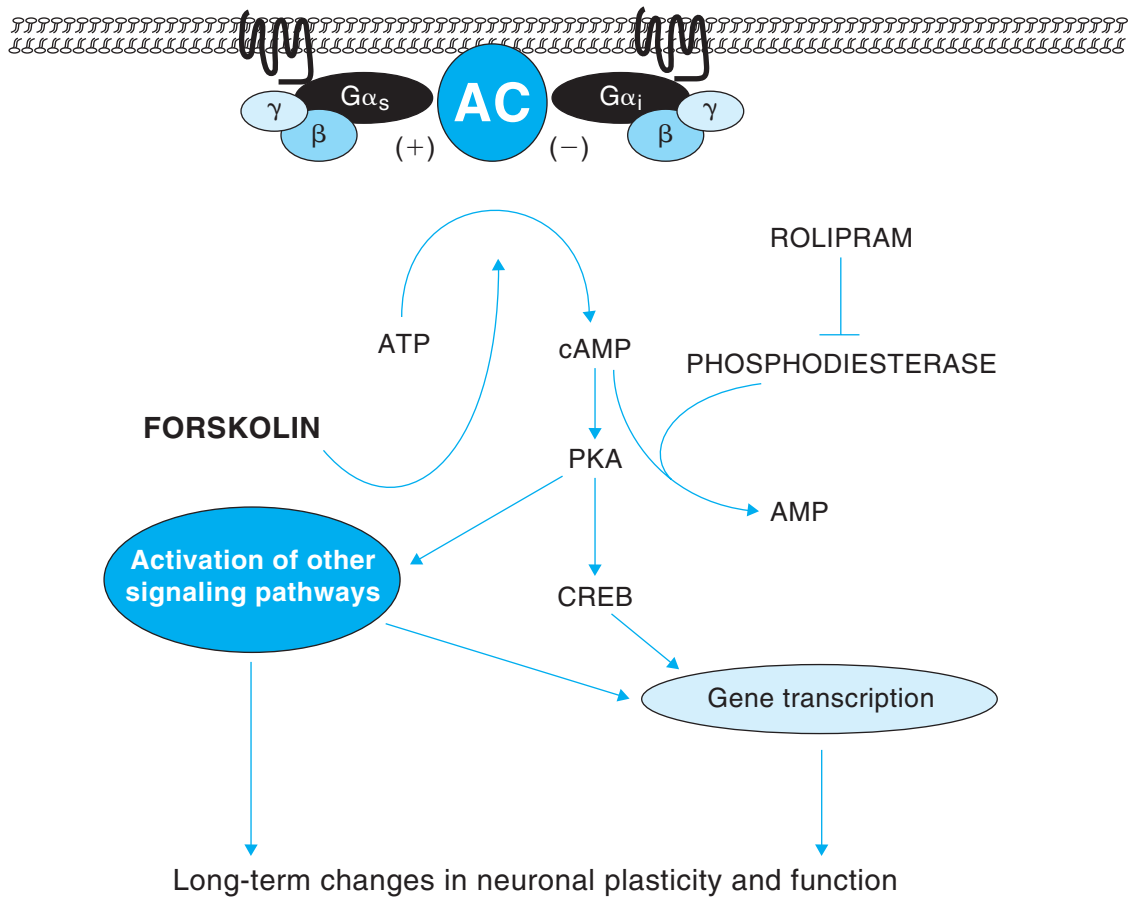

Figure 14–12. The cAMP signaling pathway. Receptors can be both positively (e.g., β -adrenergic, D_1) or negatively (e.g., 5-HT_{1A} , D_2) coupled to adenylyl cyclase (AC) to regulate cAMP levels. The effects of cAMP are mediated largely by activation of protein kinase A (PKA). One major downstream target of PKA is CREB (cAMP-responsive element-binding protein). After activation, the phosphorylated CREB binds to the cAMP-responsive element (CRE), a gene sequence found in the promoter of certain genes. Recent data suggest that antidepressants may activate CREB, bringing about increased expression of a major target gene, BDNF. Phosphodiesterase is an enzyme that breaks down cAMP to AMP. Some antidepressant treatments have been found to upregulate phosphodiesterase. Drugs such as rolipram, which inhibit phosphodiesterase, may be useful as adjunct treatments for depression. Forskolin is an agent used in preclinical research to stimulate AC. (Source: Schatzberg and Nemeroff, 2004. Reprinted with permission from *The American Journal of Psychiatry*. 1998). (See Table 14–2 for a list of findings from studies involving G protein signaling in bipolar disorder.) Similar to what has been observed in the CNS, one recent study evaluated the role of platelet G proteins as “signal coincidence detectors,” and found this function to be impaired in depressed patients (Mooney et al., 1998).⁵⁵

Another G protein subunit ($G\alpha_{olf}$) is located at a “linkage hotspot” on chromosome 18, identified by several groups (see Chapter 13). $G\alpha_{olf}$ is highly homologous to $G\alpha_s$ and is now known to be expressed in DA-rich areas of the brain, including caudate-putamen, nucleus accumbens, and olfactory tubercle (Herve et al., 1993). Using double in situ hybridization, Corvol and colleagues (2001) showed that virtually all striatal efferent neurons, identified by the expression of preproenkephalin A, substance P, or D_1

receptor mRNA, contained high amounts of $G\alpha_{olf}$ mRNA and undetectable levels of $G\alpha_s$ mRNA. Interestingly, heterozygous $G\alpha_{olf}$ knockout mice, which have half the normal $G\alpha_{olf}$ levels, showed a markedly reduced locomotor response to psychostimulants (Corvol et al., 2001). As discussed earlier, there is unquestionable evidence for the involvement of the dopaminergic system in bipolar disorder, thus the possibility of an abnormality in a G protein coupled to D_1 receptors and regulating behavioral responses to psychostimulants has generated considerable interest. To date, however, no mutations have been identified in the $G\alpha_{olf}$ gene, although studies are ongoing.

Overall, the most consistent finding to emerge is that in both peripheral cells and postmortem brain tissue from bipolar patients, elevations are observed in the predominant

subspecies of $G\alpha_s$ present in the tissues examined. Since $G\alpha_s$ is a ubiquitously expressed protein, it may appear counter-intuitive that an abnormality in this protein may play a role in the pathophysiology of bipolar disorder. However, there is already a precedent for clinical disorders arising from abnormalities in the levels of $G\alpha_s$, which present with limited clinical manifestations despite the ubiquitous expression of the protein (Spiegel, 1998). These heterogeneous clinical effects and tissue-specific manifestations have been postulated to arise from differences in receptor, G protein, and effector stoichiometries in different tissues, as well as from tissue-specific differences in the ability of various cells to compensate for the abnormality.

It should be emphasized, however, that there is at present no evidence to suggest that the alterations in the levels of $G\alpha_s$ are due to a mutation in the $G\alpha_s$ gene itself (Ram et al., 1997). Indeed, there are numerous transcriptional and posttranscriptional mechanisms that regulate the levels of G protein α subunits, and the elevated levels of $G\alpha_s$ could potentially represent the sequelae of alterations in any one of these other biochemical pathways. Thus, at this point, considerable caution is required in interpreting the data, since they derive primarily from peripheral cell models and may not adequately reflect CNS pathology. The possibility of the presence of aberrant biochemical pathways that regulate $G\alpha_s$ levels in bipolar

disorder is currently undergoing further study (Warsh et al., 2000).

cAMP/Protein Kinase A Signaling

The most commonly used strategy has been to characterize receptor function in readily accessible blood elements, and much clinical research has focused on the activity of the cAMP-generating system in mood disorders. Overall, the preponderance of the evidence suggests altered receptor and/or postreceptor sensitivity of the cAMP-generating system in the absence of consistent alterations in the number of receptors themselves (Wang et al., 1997; Warsh et al., 2000).

Higher levels of cAMP-stimulated phosphorylation of a protein with a molecular weight of ~22 kilodaltons have been found in platelets obtained from 10 treated euthymic bipolar patients compared with controls; by contrast, no significant difference was found in basal phosphorylation between the groups (Perez et al., 2000). Follow-up studies identified the approximately 22 kilodalton protein as Rap1, and once again found higher cAMP-stimulated phosphorylation in the bipolar patients (Perez et al., 2000).

Warsh and colleagues have undertaken the most thorough series of studies investigating the cAMP/protein kinase A (PKA) system in postmortem human brain in bipolar disorder. They found that the levels of PKA regulatory subunits (as assessed by [³H]cAMP binding) were

significantly lower in cytosolic fractions of frontal, temporal, occipital and parietal cortex, cerebellum, and thalamus of bipolar patients than in matched controls (Rahman et al., 1997). Furthermore, preliminary findings indicate that the reduction of regulatory subunits of PKA in the cytosolic fractions of temporal cortex of bipolar patients is accompanied by higher basal kinase activity in the cytosolic fractions of those patients' temporal cortex (Fields et al., 1999). These observed changes in PKA provide additional important evidence for dysregulation

in the $G\alpha_s$ -mediated cAMP cascade in bipolar disorder. (See Table 14–3 for findings related to cAMP signaling in bipolar disorder.)

Finally, as discussed in more detail in Chapter 13, genetic abnormalities in cAMP response element binding protein (CREB) and BDNF may also occur in depression. Sequence variations in the CREB1 gene have been reported to cosegregate with major depression in women. To our knowledge, similar studies have not yet been undertaken in bipolar disorder.

Effects of Mood Stabilizers and Antidepressants on the G_s/cAMP-Generating Signaling Pathway

Lithium and G Proteins

Although it appears that lithium (at therapeutic concentrations) does not affect G proteins directly, considerable evidence indicates that chronic lithium administration affects G protein function indirectly.⁵⁶ Interestingly, for both G_s (the G protein stimulating cAMP production) and G_i (the G protein inhibiting cAMP production), lithium's major effects in both humans and rodents are most compatible with a stabilization of the heterotrimeric, undissociated, inactive alpha beta gamma ($\alpha\beta\gamma$) conformation of the G protein.⁵⁷ Lithium also exerts complex effects on the activity of AC, with the preponderance of the data demonstrating an elevation of basal AC activity but an attenuation of receptor-stimulated responses in both preclinical and clinical studies.⁵⁸ It has been postulated that these elevations of basal cAMP and dampening of receptor-mediated stimulated responses may play an important role in lithium's ability to prevent "excessive excursions from the norm" (Manji et al., 1995a; Jope, 1999). These complex effects likely represent the net effects of direct inhibition of AC, upregulation of certain AC subtypes, and effects on the stimulatory and inhibitory G proteins (Chen et al., 1996a; Li and El-Mallahk 2000; Manji and Lenox, 2000a).⁵⁹

Consistent with this hypothesis, lithium has been shown to potentiate the hyperactivity induced by intra-accumbens cholera toxin administration (which activates the stimulatory G proteins, G_s and G_{olf}) (Kofman et al., 1998). An investigation of the effects of lithium on the striatum revealed that 2 weeks (but not 1 week) of lithium increased the protein levels by about 50 percent (Miki et al., 2001). Furthermore, it was found that G_{olf} returned to baseline levels 1 week after withdrawal of lithium. These investigators postulated that the increased G_{olf} expression after chronic lithium represents a compensatory adaptation to the suppression of the AC system by lithium (see below) and may be responsible (at least in part) for the "rebound" increase in manic episodes observed after abrupt lithium discontinuation (see Chapter 19). These results suggest that direct inhibitors of AC (such as carbamazepine) may have utility in the prevention of lithium-discontinuation emergence of mania.

Overall, many of the long-term effects of chronic lithium on G proteins are likely attributable to an indirect post-translational modification of the G protein(s) and a relative change in the dynamic equilibrium of the active and inactive states of protein conformation. In this context, it is noteworthy that investigators have demonstrated that lithium alters the levels of endogenous ADP-ribosylation in C6 glioma cells (Young and Woods, 1996) and in rat brain (Nestler et al., 1995), suggesting another mechanism

by which chronic lithium may indirectly regulate the activity of these critical signaling proteins.

Lithium and the AC System

As stated above, lithium has been demonstrated to exert complex effects on AC activity, with the preponderance of data demonstrating an elevation of basal AC activity along with attenuation of a variety of receptor-mediated responses (Manji et al., 1995b; Wang et al., 1997). Lithium in vitro inhibits the stimulation of AC by guanyl imidodiphosphate, or Gpp(NH)p (a poorly hydrolyzable analogue of GTP), and calcium-calmodulin, both of which can be overcome by Mg²⁺ (Andersen and Geisler, 1984; Newman and Belmaker, 1987; Mork and Geisler, 1989). Lithium also competes with both Mg²⁺ and Ca²⁺ for membrane-binding sites, and lithium's inhibition of solubilized catalytic units of AC can be overcome by Mg²⁺. These findings suggest that lithium's inhibition of AC in vitro may be due to competition with Mg²⁺ on a site on the catalytic unit of AC (Andersen and Geisler, 1984; Newman and Belmaker, 1987). However, the inhibitory effects of chronic lithium treatment on rat brain AC are not reversed by Mg²⁺, and these effects still persist after washing of the membranes but are reversed by increasing concentrations of GTP (Mork and Geisler, 1989). These results suggest that the physiologically relevant effects of lithium (i.e., those seen on chronic drug administration and not reversed immediately with drug discontinuation) may be exerted at the level of signal-transducing G proteins at a GTP-responsive step (discussed below).⁶⁰

More recently, lithium's effects on the phosphorylation and activity of CREB have been examined in rodent brain and in cultured human neuroblastoma cells, with somewhat conflicting results (Ozaki and Chuang, 1997; Wang et al., 1999b). As we discuss later, however, CREB is now known to be phosphorylated and regulated by the MAPK signaling cascade, which is also a target for lithium's actions (see below). Thus lithium's effects on CREB levels and phosphorylation may be temporally and spatially specific, and reflect the relative contributions of these two major signaling pathways in different tissues.

A series of studies have also examined lithium's effects on AC in humans. In a longitudinal study of healthy volunteers, 2 weeks of lithium administration was found to significantly increase platelet basal and postreceptor-stimulated AC activity (Risby et al., 1991), effects strikingly similar to those observed in rodent brain. Consistent with a lithium-induced increase in basal cAMP and AC levels, a subsequent study found that platelets obtained from lithium-treated euthymic bipolar patients showed an enhanced basal and cAMP-stimulated phosphorylation into Rap1 (a PKA substrate) as well as into a 38 kilodalton phosphoprotein (Perez et al., 2000). Interestingly,

these investigators did not find similar effects of lithium in healthy subjects, raising the possibility of a perturbed phosphorylation/dephosphorylation homeostatic mechanism in bipolar disorder.

Carbamazepine and the AC System

In contrast to the effects observed with lithium, carbamazepine has very modest effects on G proteins (H. Manji, unpublished observations). It has, however, been demonstrated to have many effects on the cAMP signaling pathway, which plays a major role in the regulation of neuronal excitability and has been postulated to play a role in the pathophysiology of both seizure disorders (Kuriyama and Kakita, 1980; Ludvig and Moshe, 1989) and bipolar disorder. It is thus noteworthy that carbamazepine decreases the basal concentrations of cAMP in mouse cerebral cortex and cerebellum, and reduces cAMP production induced by NE (Palmer, 1979), adenosine (Palmer, 1979; Van Calker et al., 1991), and the epileptogenic compounds ouabain and veratridine in brain slices (Lewin and Bleck, 1977; Ferrendelli and Kinscherf, 1979). In manic patients, carbamazepine was found to decrease elevated CSF levels of cAMP (Post et al., 1982). Recent studies have also demonstrated that carbamazepine inhibits FSK-induced *c-fos* gene expression in cultured pheochromocytoma (PC-12) cells (Divish et al., 1991). Thus overall, considerable evidence indicates that carbamazepine inhibits cAMP formation.

More recent studies have investigated the possible mechanisms by which carbamazepine inhibits the cAMP-generating system. It was found that carbamazepine, at therapeutically relevant concentrations, inhibited both basal AC and FSK-stimulated cAMP accumulation in C6 glioma cells (Chen et al., 1996b). Within the clinical therapeutic range (~50 μ M), carbamazepine inhibited basal cAMP levels by 10–20 percent and FSK-stimulated cAMP production by 40–60 percent. Taken together, these data indicate that carbamazepine is more effective in inhibiting the activated AC system, although the possibility of “floor effects” (that is, an inability to lower basal cAMP levels beyond certain levels in this system) cannot be ruled out. To further characterize the site at which carbamazepine exerts its inhibitory effects, ACs were purified from rat cerebral cortex with an FSK affinity purification column. It was found that, similar to the situation observed in intact C6 cells and in C6 cell membranes, carbamazepine inhibited both basal and FSK-stimulated activity of purified AC (Chen et al., 1996b).

Taken together, the data suggest that carbamazepine inhibits cAMP production by acting directly on AC and/or through factor(s) that are closely associated with and copurify with AC. Consistent with these results, it has been demonstrated that carbamazepine attenuates FSK-induced expression of *c-fos* (an immediate early gene) in PC-12

cells and inhibits FSK-induced phosphorylation of CREB in C6 glioma cells. Since *c-fos* and CREB are known to be involved in mediating a number of long-term neuronal responses, these effects might be postulated to play a role in the delayed therapeutic effect of carbamazepine.

Valproate and the G_s /AC System

Recent studies have examined the effects of valproate on components of the β -adrenergic receptor-coupled cAMP-generating system (Chen et al., 1996b). Chronic valproate has been shown to produce a significant alteration of the β -adrenergic receptor-coupled cAMP-generating system in cultured cells *in vitro*; these effects were observed at concentrations of valproate similar to those attained in plasma in the clinical treatment of neuropsychiatric disorders. In contrast to what has been observed with chronic lithium treatment (discussed above), it was found that chronic valproate produced a significant reduction in the density of β -adrenergic receptors. Interestingly, the decrease in number of β -adrenergic receptors (approximately 30 percent) was accompanied by an even greater decrease in receptor- and postreceptor-mediated cAMP accumulation, suggesting that chronic valproate also exerts effects at the β -adrenergic receptor/ G_s interaction, or at postreceptor sites (e.g., G_s , AC). Consistent with this contention, it was indeed found that chronic but not acute valproate incubation induced a marked decrease in the levels of $G\alpha_s$ 45 but not any other G protein α subunits examined ($G\alpha_s$ 52, $G\alpha_{i1-2}$, $G\alpha_o$, or $G\alpha_{q/11}$). In view of the suggested involvement of G_s in the pathophysiology of bipolar disorder (discussed above), as well as the effects of lithium on the β -adrenergic receptor/ G_s /AC system, these effects may play a role in valproate's therapeutic effects and are worthy of further study.

Antidepressants and the G_s /AC System

The cAMP signaling cascade appears to be a major target for the action of chronic antidepressant treatments. Recent studies have demonstrated an enhanced coupling between $G\alpha_s$ and the catalytic unit of AC (Rasenick et al., 2000) and activation of cAMP-dependent protein kinase enzyme activity (Nestler et al., 1989; Popoli et al., 2000). Antidepressants have also been demonstrated to activate cAMP-dependent and calcium/calmodulin-dependent protein kinases, effects that are accompanied by increases in the endogenous phosphorylation of selected substrates (microtubule-associated protein 2 and synaptotagmin) (Popoli et al., 2000).

Duman and colleagues (1997, 2000) have undertaken an elegant series of studies demonstrating that the chronic treatment of rats with a variety of antidepressants increases the levels of CREB mRNA, CREB protein, and CRE (cyclic AMP response element) DNA binding activity in

hippocampus. Furthermore, the same group has demonstrated that chronic antidepressant treatment increases the expression of two important genes known to be regulated by CREB—BDNF and its receptor TrkB (Duman et al., 1997, 2000). Preliminary postmortem human brain studies have also indicated increased levels of CREB and hippocampal BDNF (B. Chen et al., 2001) in patients treated with antidepressants, providing indirect support for the rodent and cell culture studies (Dowlatshahi et al., 1998).

Interestingly, recent studies have shown that short-term sleep deprivation brings about changes in pCREB and BDNF similar to those seen with chronic antidepressants. This finding raises the intriguing possibility that antidepressant- or sleep deprivation-induced activation of these plasticity cascades may play a role not only in the antidepressant effect but also in the mania-inducing effect of these modalities. This possibility is discussed in greater detail later.

The Phosphoinositide Signaling Cascade

The impetus for the study of this major second messenger system in bipolar disorder was the seminal observation by Allison and Stewart (1971) that lithium reduces brain levels of inositol. Subsequently, Hallcher and Sherman (1980) showed that this reduction was due to inhibition of the enzyme inositol monophosphatase, an effect that occurred at therapeutically relevant concentrations (the enzyme was inhibited by 50 percent at a lithium concentration of ~ 8 mM). Because the mode of lithium's inhibition is uncompetitive (that is, the more active the system, the greater the inhibition), Berridge and colleagues (1982, 1989) suggested that lithium selectively inhibits PI-derived second messengers of systems that are "overly activated" in mania without interfering with basal function. Furthermore, since inositol depletion is presumed to occur more readily in the CNS than in the periphery, Berridge's inositol depletion hypothesis of lithium action has gained considerable attention.

Although inositol phospholipids are relatively minor components of cell membranes, they play a major role in receptor-mediated signal transduction pathways and are involved in a diverse range of responses in the CNS (Berridge and Irvine, 1989; Chuang, 1989; Fisher et al., 1992). Furthermore, several subtypes of adrenergic, cholinergic, and serotonergic receptors are coupled to phosphatidylinositol-4,5-bisphosphate (PIP₂) hydrolysis in the brain, resulting in the production of two very important second messengers—IP₃ (which mobilizes calcium) and diacylglycerol (which activates PKC). Thus, the inositol depletion hypothesis offers a very attractive explanation for lithium's therapeutic efficacy in treating multiple aspects of bipolar disorder and highly recurrent depressive disorders.

As we discuss in greater detail below, it is indeed quite likely that some of lithium's effects do indeed stem from inhibition of inositol monophosphatase, and this initiates a cascade of signaling and gene expression changes that ultimately produce many of the drug's therapeutic effects. Does lithium, in fact, correct an underlying abnormality in the PI signaling pathway in recurrent mood disorders? The data relevant to this question must be considered preliminary; nevertheless, converging data from peripheral cell studies and postmortem brain studies suggest that the PI/PKC signaling system may play a role in the pathophysiology of cyclic mood disorders, perhaps especially bipolar disorder. (See Table 14-4 for study findings related to PI signaling.)

One study measured membrane phospholipids in platelets of seven medication-free patients in the manic phase of bipolar disorder and seven healthy controls. It was found that the relative percentage of platelet membrane PIP₂ was significantly higher in the manic patients than in the controls (Brown, 1993). In a more recent study of nine medication-free bipolar depressed patients, the same group showed that these patients had significantly increased levels of platelet membrane PIP₂ compared with levels in controls (Soares et al., 2001). Studies have also investigated inositol monophosphatase (IMPase) mRNA levels in lymphocytes. It was found that a small group of medication-free bipolar patients exhibited a reduction in IMPase mRNA levels, whereas mood stabilizer-treated patients had normalized values (Nemanov et al., 1999).

Investigators have also attempted to determine whether there are any abnormalities in the PI signaling system in postmortem brain in bipolar disorder. In a postmortem study by Shimon and colleagues (1997), free inositol levels were found to be lower in prefrontal cortex from bipolar patients than in controls. Another postmortem study found increased G $\alpha_{q/11}$ immunoreactivity in postmortem occipital cortex from patients with bipolar disorder (Mathews et al., 1997). However, these elevated levels of G $\alpha_{q/11}$ were accompanied by reduced agonist-induced PI turnover (Jope et al., 1996), although the potential effects of long-term lithium treatment remained to be fully delineated. A number of studies have also investigated the mediators of PI signaling—Ca²⁺ and PKC.

Protein Kinase C in the Pathophysiology of Recurrent Mood Disorders

Protein Kinase C Signaling in Animal Models of Mood Disorders

As discussed earlier, two current models of mania that have been used and have reasonable heuristic value in the study of mood disorders are kindling and behavioral sensitization

TABLE 14–4. Phosphoinositide Signaling in Manic-Depressive Illness (Primarily Bipolar)

Tissue	Physiological Change	Study
Postmortem cerebral cortex	↑ $G\alpha_{q/11}$ and PLC- β immunoreactivity; \leftrightarrow $G\beta$	Matthews et al., 1997

BOX 14–14. Protein Kinase C and the Pathophysiology of Manic-Depressive Illness (Primarily Bipolar)

- Amphetamine produces increases in protein kinase C (PKC) activity, and GAP-43 phosphorylation (implicated in neurotransmitter release)
- PKC inhibitors block biochemical and behavioral responses to amphetamine and cocaine and also block cocaine-induced sensitization
- Increased membrane/cytosol PKC partitioning in platelets from manic subjects; normalized with lithium treatment
- Increased PKC activity and translocation in bipolar disorder patients' brains compared to controls
- Increased levels of RACK-1 (receptor for activated C kinase) in bipolar patients' brains compared to controls
- Lithium and valproate regulate PKC activity, PKC α , PKC ϵ , and myristoylated alanine-rich C kinase substrate (MARCKS)
- Preliminary data suggest that PKC inhibitors may have efficacy in treatment of acute mania

Source: Manji and Lenox, 1999.

(Lyon, 1991; Post and Weiss, 1992). Considerable evidence implicates long-term alterations in midbrain dopaminergic transmission in the development of behavioral sensitization, but the cellular mechanism(s) underlying the long-term changes in excitability observed in kindled or stimulant-sensitized animals have not been fully elucidated. A growing body of evidence implicates alterations in both PKC and certain G proteins (especially G_i and G_o).⁶¹ In particular, dramatic increases in membrane-associated PKC have been observed in the bilateral hippocampus at up to 4 weeks and in the amygdala/pyriform cortex at 4 weeks after the last kindled seizure (Daigen et al., 1991).

Studies have also implicated alterations in PKC activity as mediators of long-term alterations in neuronal excitability in the brain following chronic stimulant use. Several independent laboratories have now demonstrated that both acute and chronic amphetamine exposure produces an alteration in PKC activity and its relative cytosol-to-membrane distribution, as well as the phosphorylation of a major PKC substrate, GAP-43, which has been implicated in long-term alterations of neurotransmitter release (Giambalvo, 1992a,b; Gnegy et al., 1993; Iwata et al., 1997a,b). (See Box 14–14 for a summary of research findings related to PKC activity.) In a few studies, pharmacological inhibition of PKC results in behavioral changes similar to mood stabilizers. Direct injection of the specific PKC inhibitor RO31-8220 into the nucleus accumbens inhibited amphetamine hyperactivity (Browman et al., 1998). Inhibition of PKC in the ventral tegmental area (VTA) with the PKC inhibitor H7 reduced cocaine hyperactivity (Steketee, 1994)

and a similar injection to A10 area (where the VTA is located) disrupted cocaine sensitization (Steketee, 1994).

Increased hedonistic drive and increased tendency to abuse drugs are well known facets of manic behavior. Two models of such behaviors are consumption of reward and conditioned place preference (CPP) (Papp et al., 1991). PKC inhibition with H7 in the A10 area blocked the development of cocaine CPP (Steketee, 1994), ICV injections of the PKC inhibitor calphostine blocked morphine CPP (Narita et al., 2001), and intra-accumbens injections of the PKC inhibitor NPC-15437 blocked amphetamine CPP (Aujla and Beninger, 2003). Furthermore, PKC inhibition in the accumbens inhibited the development of morphine dependence, a measure that may be related to increased drug craving (Valverde et al., 1996).

PKC-related targeted mutations also support the involvement of PKC in affective-like behaviors. PKC γ knockout (KO) mice show reduced morphine-induced CPP (Narita et al., 2001) and PKC ϵ KO mice demonstrate reduced ethanol self-administration (Olive et al., 2000).

Indeed, abundant evidence has now accumulated to show that activation of PKC enhances both depolarization-mediated and basal release of DA (Robinson, 1991; Cowell and Garrod 1999), a neurotransmitter implicated in the manic syndrome (as discussed above). Release of DA by PKC activation has been demonstrated in a variety of tissues, including striatal synaptosomes, effects that have been demonstrated to be independent of extracellular calcium. The ability of amphetamine to produce heightened locomotor activity is thought to be due to its ability to enhance DA release from mesolimbic DA neurons. Furthermore, PKC inhibitors have been demonstrated to markedly reduce amphetamine-induced DA release (Giambalvo, 1992a,b). It is now believed that in addition to blocking the reuptake of NE and DA, psychostimulants facilitate the release of these neurotransmitters in large part by activation of PKC (Giambalvo, 1992a,b; Gnegy et al., 1993; Iwata et al., 1997a,b). Finally, recent nonhuman primate studies investigating cognitive deficits similar to those observed in mania have also demonstrated the efficacy of a selective PKC inhibitor. Birnbaum and associates (2004) have demonstrated that excessive activation of PKC dramatically impaired the cognitive functions of the prefrontal cortex, exposure to stress activated PKC and resulted in prefrontal dysfunction, and inhibition of PKC (including indirectly with mood stabilizers) protected cognitive function. These data suggest that PKC may play an important role in some of the cognitive features of mania.

As noted earlier, abnormalities of circulating glucocorticoids are well known to be associated with affective symptomatology (Banki et al., 1987), and interestingly, elevated glucocorticoids have been associated with both depressive

and manic symptomatology (Haskett, 1985; Banki et al., 1987; Ur et al., 1992). It is noteworthy that a recent study found the repeated administration of dexamethasone for 10 days caused a significant increase in B_{\max} of phorbol dibutyrate ($[^3\text{H}]\text{PDBu}$) binding to PKC, increased PKC activity, and increased levels of PKC α and ϵ in rat and hippocampus (Dwivedi and Pandey, 1999).

It is indeed striking that behavioral sensitization and kindling (which have been postulated as models for bipolar disorder and mania), as well as dexamethasone administration, produce robust alterations in the PKC signaling pathway in critical limbic structures, given that lithium and valproate aim for these same biochemical targets. Although considerable caution obviously must be employed when extrapolating results from rodent brain, the fact that these two models and glucocorticoid administration are associated with effects on PKC signaling opposite to those observed with chronic lithium or valproate is compelling indeed. Interestingly, there is also evidence suggesting that chronic antidepressants may modulate PKC activity in limbic and limbic-associated areas of rat brain (Nalepa, 1993, 1994). Moreover, PKC was recently demonstrated to regulate the activity of NE, DA, and serotonin transporters (Apparsundaram et al., 1998; Blakely et al., 1998; Zhang et al., 1998). Whether these complex effects of antidepressants on PKC activity underlie their apparent ability to trigger manic episodes and perhaps promote rapid cycling in susceptible individuals (Goodwin and Jamison, 1990) remains to be determined.

Human Studies Implicating Protein Kinase C in the Pathophysiology of Recurrent Mood Disorders

To date, only a limited number of studies have directly examined PKC in bipolar disorder (Hahn and Friedman, 1999). Although undoubtedly an oversimplification, particulate (membrane) PKC is sometimes viewed as the more active form of PKC; thus an examination of the subcellular partitioning of this enzyme can be used as an index of the degree of activation. Friedman and colleagues (1993) investigated PKC activity and translocation in response to serotonin in platelets obtained from bipolar subjects before and during lithium treatment. They found that ratios of platelet membrane-bound to cytosolic PKC activities were elevated in the manic subjects compared with the euthymic, lithium-treated bipolar patients. In addition, serotonin-elicited platelet PKC translocation was enhanced in those subjects.

In postmortem brain tissue from bipolar patients, Wang and Friedman (1996) measured PKC isozyme levels, activity, and translocation. They found increased PKC activity and translocation in the brains of the bipolar patients compared with controls, effects accompanied by elevated levels of selected PKC isozymes in the cortex of the bipolar subjects.

More recently, the same group found that postmortem brains of bipolar subjects showed increased association with receptor for activated C kinase 1 (RACK1) (Wang and Friedman, 2001). Since PKC is anchored to the membrane by RACK1, these results suggest that increased association of RACK1 with PKC isozymes may be responsible for the increases in membrane PKC and its activation previously observed in frontal cortex of brains of bipolar patients.

In comparison with the studies in bipolar disorder discussed above, two recent studies used $[^3\text{H}]\text{PDBu}$, a radioligand that binds to PKC, to investigate particulate and cytosolic PKC in postmortem brain samples obtained from depressed patients and/or individuals who had committed suicide. Pandey and colleagues (1997) found that the B_{\max} of $[^3\text{H}]\text{PDBu}$ binding sites was significantly decreased in both membrane and cytosolic fractions from Brodmann's areas 8 and 9 in teenage suicide subjects compared with matched controls; no unipolar–bipolar distinctions were made and there was no quantification of recurrence among the unipolar patients. Coull and colleagues (2000) found increased $[^3\text{H}]\text{PDBu}$ binding in the soluble fraction (suggesting less in the active membrane fraction) in antidepressant-free suicides compared with controls in frontal cortex. The results of these two studies could potentially be interpreted as reflecting reduced PKC function, due either to a reduction in the absolute levels or a reduction in the particulate/soluble fractions. Considerable additional research is required, however, to adequately justify such a conclusion.

Abnormalities of Calcium Signaling in Bipolar Disorder

Acting through intracellular proteins such as myristoylated alanine-rich C kinase substrate (MARCKS) and calmodulin and enzymes such as PKC, AC, and CaM kinase, calcium ions have been shown to regulate the synthesis and release of neurotransmitters, neuronal excitability, cytoskeletal remodeling, and long-term neuroplastic events. Thus it is not surprising that a large number of studies have investigated intracellular Ca^{2+} in peripheral cells in bipolar disorder (Dubovsky et al., 1992b; Emamghoreishi et al., 1997; Wang et al., 1997; see Tables 14–5, 14–6, and 14–7). In view of the caveats associated with studies of peripheral circulating cells, the remarkable consistency of the findings of this research is surprising indeed. Studies have consistently shown elevations in both resting and stimulated levels of intracellular Ca^{2+} in platelets, lymphocytes, and neutrophils of patients with bipolar disorder. These calcium abnormalities have been postulated to represent state-dependent findings (Dubovsky et al., 1992b), but recent studies using transformed lymphoblasts from bipolar patients have revealed similar abnormalities, suggesting that they may be trait-dependent (Emamghoreishi et al., 1997).

TABLE 14–5. Intracellular Calcium in Blood Elements of Manic-Depressive Illness (Primarily Bipolar): Platelets

^cFollow-up of 5 years.

The regulation of free intracellular Ca^{2+} is a complex process involving extracellular entry, release from intracellular stores following receptor-stimulated PI hydrolysis, uptake into specific organelles, and binding to specific proteins (see Fig. 14–13). Thus, the abnormalities observed in bipolar disorder could arise at a variety of levels, and recent studies suggest that they lie beyond the receptor (Hough et al., 1999). In this context, since PKC is known to regulate

calcium signaling at multiple levels (Shibata et al., 1996; Si-Tahar et al., 1996; Ozaki and Chuang, 1997), more recent studies have investigated its putative role in mediating the calcium abnormalities in bipolar disorder. Preliminary analysis suggests that alterations in tonic PKC activity may play an important role in mediating the abnormal intracellular calcium responses observed in bipolar patients (H. Manji and R. Post, unpublished observations).

^bDifference not statistically significant.

In an effort to understand the relationship between possible abnormalities of the PI cascade and intracellular calcium, Warsh and colleagues (2000) have investigated IMPA1 and IMPA2 gene expression and calcium homeostasis in B lymphoblast cell lines (BLCLs) from bipolar-I patients (Yoon et al., 2001). They found that IMPA2 mRNA levels were significantly lower in BLCLs from male bipolar-I patients with high $[Ca^{2+}]$ ($n=6$) than in healthy male subjects ($n=5$), male bipolar-I patients with normal BLCL $[Ca^{2+}]$, and female bipolar-I patients with high $[Ca^{2+}]$. Furthermore, they found a negative correlation between IMPA2 mRNA levels and $[Ca^{2+}]$ in the male patients.

In view of the extensive cross talk between calcium (Ca^{2+})- and cAMP-mediated signaling systems, Emamghoreishi and colleagues (1997) have postulated that abnormalities in Ca^{2+} homeostasis in bipolar disorder may be linked to disturbances in the function of G proteins that mediate cAMP signaling. To investigate this hypothesis, they phenotyped bipolar-I patients on the basis of basal intracellular Ca^{2+} and then investigated the cAMP system. They found that isoproterenol-stimulated cAMP formation was lower in intact B lymphoblasts from bipolar-I patients with high Ca^{2+} (greater than or equal to 2 standard deviations above the mean concentration of healthy subjects) compared with patients having normal B lymphoblast Ca^{2+} and healthy subjects. Furthermore, although basal and NaF-stimulated cAMP production was found to be greater in B lymphoblast membranes from male bipolar-I patients with high versus normal Ca^{2+} , there were no differences in the

percent stimulation. These findings raise the intriguing possibility that trait-dependent disturbances in G protein-mediated cAMP signaling occur in conjunction with altered Ca^{2+} homeostasis in those bipolar-I patients with high B lymphoblast Ca^{2+} and are worthy of further study. The possible basis for a gender difference in the responses also warrants more extensive investigation.

The Phosphoinositide/Protein Kinase C Signaling Pathway as a Target

Lithium and the Phosphoinositide Cycle: The Inositol Depletion Hypothesis

As discussed earlier, lithium at therapeutically relevant concentrations is an uncompetitive inhibitor of the intracellular enzyme inositol monophosphatase (concentration of lithium required to inhibit enzymatic activity by 50 percent (K_i) ~ 8 mM). This inhibition results in an accumulation of inositol monophosphate (IP) and a reduction in the generation of free inositol (Allison and Stewart, 1971; Hallcher and Sherman, 1980; Sherman et al., 1986)⁶² (see Fig. 14–14).

A number of studies have been conducted to examine the effects of lithium on receptor-mediated PI response in brain in a variety of neurotransmitter systems (e.g., cholinergic, serotonergic, noradrenergic, and histaminergic). Although some investigators have found a reduction in agonist-stimulated PIP_2 hydrolysis in brain slices from rats exposed acutely and chronically to lithium, these findings have often been small, inconsistent, and subject to methodological differences.^{63,64}

Source: Bezchlibnyk and Young, 2002.

A number of recent studies have investigated the possibility that lithium and other putative mood stabilizers may regulate the PI system independently of inhibiting IMPase. In this context, investigators have examined lithium's effects on the PI system distal to the receptor since, as noted above, experimental evidence has shown that lithium may alter receptor coupling to PI turnover.⁶⁵

A most interesting potential new target for the actions of structurally dissimilar mood stabilizers is a high-affinity myoinositol transport system (called "SMIT"—Sodium sensitive high-affinity *Myo*-Inositol Transporter) that has been characterized in various cell types, including those of neural origin (van Calker and Belmaker, 2000). Thus it was recently demonstrated that the activity of the SMIT and the expression of its mRNA in astrocytes are downregulated after chronic treatment with therapeutic concentrations

of lithium (van Calker and Belmaker, 2000). Interestingly, downregulation of the SMIT was also observed after administration of valproate and carbamazepine. If replicated in vivo, these findings suggest that the SMIT may represent a novel target for the development of new drugs. Most recent finding implicating PI signaling in the actions of mood stabilizers comes from Benes and colleagues (2000), who used a novel tissue-culture assay that measures sensory neuron growth-cone stability to infer that mood stabilizers have a common mechanism of action—depletion of neuronal inositol (1,4,5) trisphosphate (IP₃).⁶⁶

In human studies, researchers have used MRS to investigate lithium's effects on brain myoinositol levels in bipolar patients undergoing chronic lithium treatment. In a longitudinal study, Moore and colleagues (1999c) quantitated myoinositol in medication-free bipolar depressed

Figure 14–13. In neurons, Ca²⁺-dependent processes represent an intrinsic, nonsynaptic feedback system that provides the competence for adaptation to different functional tasks. Ca²⁺ is generally mobilized in one of two ways in the cells: either by mobilization from intracellular stores or from the outside of the cell via plasma membrane ion channels and certain receptors (e.g., NMDA). The external level of Ca²⁺ is approximately 2mM, yet resting intracellular Ca²⁺ levels are in the range of 100nM (2×10^{-4} lower). Local high levels of calcium result in activation of enzymes, signaling cascades, and at extremes, cell death. Release of intracellular stores of calcium is primarily regulated by IP₃ receptors, which are activated upon generation of IP₃ by phospholipase C activity, and the ryanodine receptor that is activated by the drug ryanodine. Ca²⁺ is sequestered in the endoplasmic reticulum (the vast web and framework for Ca²⁺-binding proteins to capture and sequester Ca²⁺). Ca²⁺-buffering and triggering proteins are nonuniformly distributed—thus the considerable subcellular variation of Ca²⁺ concentrations (e.g., near a Ca²⁺ channel). The primary mechanism for Ca²⁺ calcium exit from the cell is via sodium calcium exchange or by means of a calcium pump. (Source: Schatzberg and Nemeroff, 2004. patients at baseline and after acute (5-day) and chronic (4-week) blinded lithium administration. They found that therapeutic administration of lithium produces significant reductions in myoinositol levels in bipolar patients in brain regions previously implicated in the pathophysiology of

bipolar disorder. However, the major lithium-induced myoinositol reductions are observed after only 5 days of lithium administration, at a time when the bipolar patient's clinical state is completely unchanged. Similar results have been obtained in independent studies of both child and

adult bipolar patients (Davanzo et al., 2001; Yildiz et al., 2001).

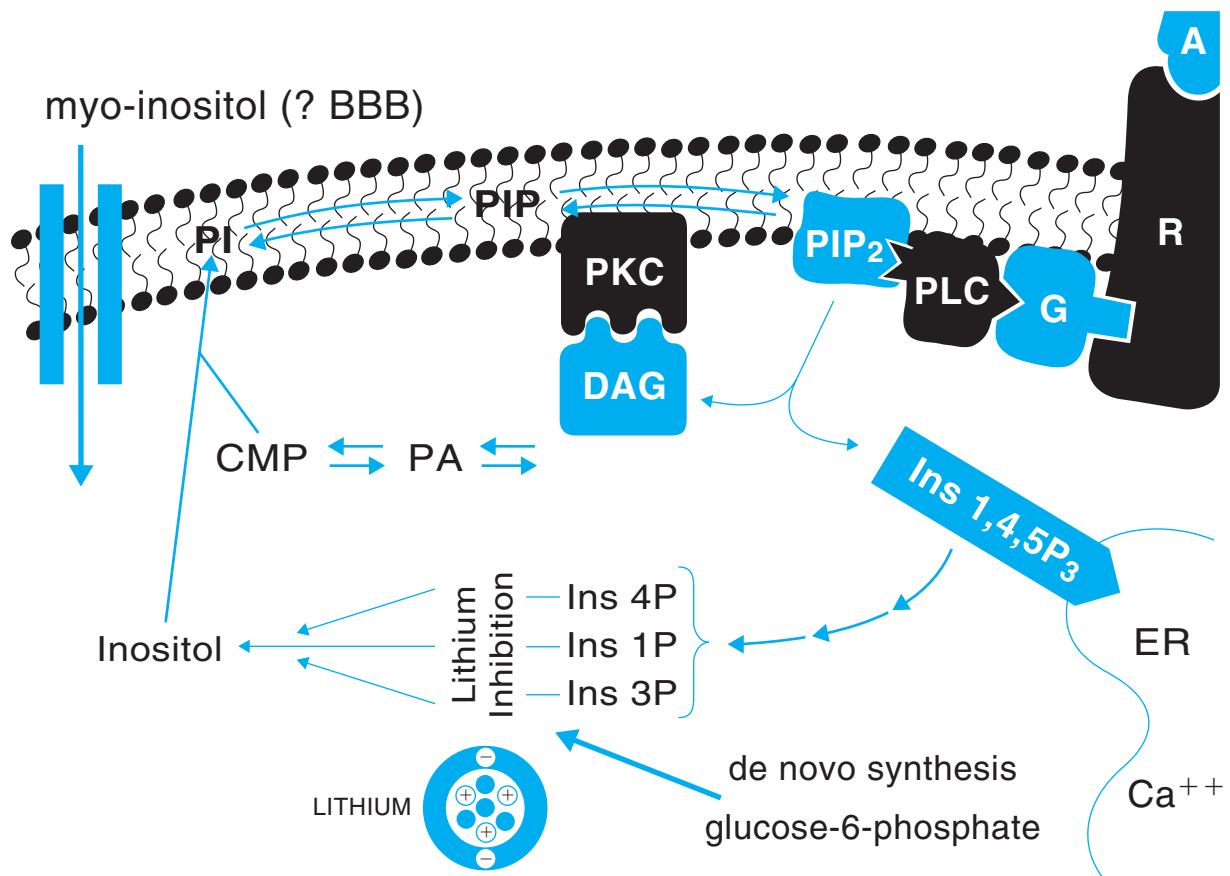

The evidence reviewed here suggests that the PI signaling cascade is a target for the action of mood stabilizers and that IMPase inhibition likely represents an important primary biochemical target for the actions of lithium. However, the therapeutic actions of lithium occur only after chronic treatment and usually remain in evidence for some time after discontinuation—actions that cannot be attributed only to inositol reductions evident in the presence of lithium. Thus, although the preponderance of the data suggests that the initial actions of lithium may occur with a relative depletion of inositol and thereby alterations in receptor-coupled PI response, the effects of chronic lithium

(and likely the therapeutically relevant ones) are more likely to be mediated by resultant changes at different levels of the signal transduction processes, including the level of PKC (Jope and Williams, 1994; Manji et al., 1995a,b; Manji and Lenox, 1998). We now turn to the growing body of evidence implicating PKC as a target for the actions of mood stabilizers.

Protein Kinase C in the Treatment of Bipolar Disorder

In view of the pivotal role of the PKC signaling pathway in the regulation of neuronal excitability, neurotransmitter release, and long-term synaptic events (Conn and Sweatt, 1994; Chen et al., 1997; Hahn and Friedman, 1999), it has been postulated that the attenuation of PKC activity

Figure 14–14. Effects of lithium on the phosphoinositide (PI) cycle. A number of receptors in the central nervous system (including M_1 , M_2 , M_3 , M_4 , M_5 , 5-HT_2) are coupled, via $G_{q/11}$, to activation of PI hydrolysis. Activation of these receptors induces phospholipase C hydrolysis of phosphoinositide 4,5-bisphosphate (PIP_2) to diacylglycerol (DAG) and inositol-1,4,5-triphosphate ($Ins\ 1,4,5P_3$). DAG activates protein kinase C (PKC), an enzyme that has many effects including the activation of phospholipase A-2 (PLA_2 ; an activator of arachidonic acid signaling pathways). IP_3 binds to the IP_3 receptor, resulting in the release of intracellular calcium from intracellular stores, most notably the endoplasmic reticulum (ER). Calcium, an important signaling molecule, initiates a number of downstream effects such as activation of calmodulins and calmodulin-dependent protein kinases. IP_3 is recycled back to PIP_2 by the enzymes inositol monophosphate phosphatase (IMPase) and inositol polyphosphate phosphatase (IPPase), both of which are targets of lithium. Thus, lithium may initiate many of its therapeutic effects by inhibiting these enzymes, bringing about a cascade of downstream effects involving PKC and gene expression changes. A=agonist; BBB=blood–brain barrier; G=protein; R=receptor. (Source: Schatzberg and Nemeroff, 2004. Reprinted with permission from *The American Journal of Psychiatry*. Copyright 2004 by the American Psychiatric Association.)

may play a role in the antimanic effects of lithium and valproate. Recently, a pilot study found that tamoxifen (a nonsteroidal antiestrogen known to be a PKC inhibitor at higher concentrations [Baltuch et al., 1993]) may indeed possess antimanic efficacy (Bebchuk et al., 2000). Clearly these results must be considered preliminary because of the small sample sizes thus far. In view of preliminary data suggesting the involvement of the PKC signaling system in the pathophysiology of bipolar disorder, however, these results suggest that PKC inhibitors may be very useful agents in the treatment of mania. Larger double-blind, placebo-controlled studies of tamoxifen are currently under way, and if positive, may soon lead to the development of completely novel, potentially very rapidly acting antimanic agents.

Evidence from various laboratories has clearly demonstrated that lithium at therapeutically relevant concentrations exerts major effects on the PKC signaling cascade (see Fig. 14–15). Currently available data suggest that acute lithium exposure facilitates a number of PKC-mediated responses, whereas longer-term exposure results in an attenuation of phorbol-ester-mediated responses, which is accompanied by downregulation of specific PKC isozymes (Manji and Lenox, 1999; J. Wang et al., 1999). Studies in rodents have demonstrated that chronic (but not acute) lithium produces an isozyme-selective reduction in PKC α

and ϵ in frontal cortex and hippocampus in the absence of significant alterations in the β , γ , δ , or ζ isozymes (Manji et al., 1993; Manji and Lenox, 1999; Chen et al., 2000). Concomitant studies carried out in immortalized hippocampal cells in culture exposed to chronic lithium show a similar reduction in the expression of both the PKC α and ϵ isozymes in the cell, as determined by immunoblotting (Manji and Lenox, 1999). Furthermore, chronic lithium has been demonstrated to dramatically reduce the hippocampal levels of a major PKC substrate, MARCKS, a protein implicated in regulating long-term neuroplastic events (Lenox et al., 1992; see Table 14–8).

Although the effects of lithium on PKC isozymes and MARCKS are striking, a major problem inherent in neuropharmacological research is the difficulty of attributing therapeutic relevance to any observed biochemical finding. It is thus noteworthy that the structurally dissimilar antimanic agent valproate produces effects very similar to those of lithium on PKC α and ϵ isozymes and MARCKS protein.⁶⁷ Interestingly, lithium and valproate appear to have their effects on the PKC signaling pathway through distinct mechanisms (Manji and Lenox, 1999; Lenox and Hahn, 2000). These biochemical observations are consistent with the clinical observations that some patients show preferential response to one or the other of the agents, and that

Figure 14–15. The potential mechanisms by which chronic lithium (Li^+) or valproate (VPA), or direct-acting protein kinase C (PKC) inhibitors, may be useful in the treatment of acute mania. Activation of PKC, which is known to occur through psychostimulants or stress, results in the phosphorylation of key substrates, notably GAP-43 (growth-cone-associated protein) and MARCKS (myristoylated alanine-rich C kinase substrate), facilitating the release of neurotransmitters. Chronic lithium or valproate attenuates PKC signaling, an effect that may be responsible for the treatment of various facets of the manic syndrome. (Source: Bachman et al., 2005. additive, or even synergistic therapeutic effects are often seen in patients when the two agents are coadministered.

As discussed in Chapters 18, 19, and 20, a growing body of data suggests that omega-3 fatty acids (ω -3 FA) may have some benefit in the treatment of bipolar disorder (see below). It is thus noteworthy that the ω -3 FA eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), as well as the combination of DHA and EPA, were found to inhibit PKC activity at concentrations as low as 10 μ M (Kim et al., 2001). By contrast, arachidonic acid had no effect on PKC activity. Thus, in toto, the biochemical data indicate that structurally dissimilar antimanic agents—lithium, valproate, and ω -3 FA—attenuate PKC function in a therapeutically relevant time frame, whereas promanic psychostimulants activate PKC. These findings suggest that PKC modulation may indeed play a critical role in the treatment of mania. However, one of the major difficulties inherent in neuropharmacological research is the attribution of therapeutic relevance to any observed molecular or cellular findings. This difficulty is exacerbated in the case of mood stabilizers, since the prototypical drugs for bipolar disorder were developed serendipitously and exert multiple biochemical and cellular effects, but also some, such as lithium, have therapeutic effects in the prevention and treatment of recurrent depression as well.

With respect to the treatment of mania, attempts to develop improved, potentially more rapidly acting medications are dependent on identifying therapeutically relevant targets, and one of the most important routes to linking cellular and therapeutic effects is by studying final outcomes—behavior (Holmes et al., 2003; Williams et al., 2003). A series of studies was therefore undertaken to assess more directly the possible involvement of PKC inhibition in manic-like behavior in established animal models for the manic syndrome (Einat et al., 2000, 2003b). To explore a wide range of manic-like behaviors, three different behavioral models were used, all induced by amphetamine: (1) hyperactivity, (2) increased risk-taking, and (3) increased hedonic behavior. As we noted in the first edition of this text, these behaviors were chosen because they reflect some

of the most important and consistently observed facets of mania in patients. Amphetamine-based models were used because of their ability to trigger manic episodes in susceptible humans.

Given the desire to extrapolate the findings—if positive—directly to large-scale clinical research, the studies were undertaken using the only compound with appreciable CNS PKC inhibitory activity that has been approved for human use—tamoxifen (O'Brian et al., 1988; Baltuch et al., 1993). Tamoxifen has been widely used in the treatment of breast cancer (Catherino et al., 1993; Jordan, 1994). A number of its effects are due to estrogen receptor antagonism (Jordan, 1994), but recent research has shown that it is also a potent and selective PKC inhibitor at therapeutically relevant concentrations (Horgan et al., 1986; O'Brian et al., 1988; Couldwell et al., 1993). Tamoxifen clearly crosses the blood–brain barrier and has already been used safely in women, men, and children (Pollack et al., 1997; Jordan, 2003), including for the treatment of a CNS disorder, malignant glioma (Couldwell et al., 1996; Mastronardi et al., 1998). It was found that acute tamoxifen significantly reduced acute or chronic amphetamine-induced hyperactivity in a large open field without affecting spontaneous activity levels. Furthermore, the same treatment normalized amphetamine-induced increase in visits to the center of an open field (representing risk-taking behavior) and reduced hedonic-like amphetamine-induced conditioned place preference. Biochemical results were consistent with the behavioral changes, and tamoxifen attenuated amphetamine-induced phosphorylation of GAP-43, consistent with PKC inhibition.

The Role of Fatty Acids

As noted above, the possible involvement of fatty acids (in particular the ω -3 FA) in the treatment of mood disorders has recently received considerable attention. The predominant naturally occurring ω -3 FA are DHA, EPA, and linolenic acid. The ω -3 FA appear to cross the blood–brain barrier easily and are incorporated into neuronal membranes. Because of their highly folded chemical structure, ω -3 FA increase the fluidity of the membrane lipid bilayer, thereby changing transmembrane protein function. This has been proposed to represent the mechanism by which membrane phospholipids become more resistant to hydrolysis by phospholipases.⁶⁸

In a series of studies, investigators have used in vivo brain-imaging methodologies to investigate the potential effects of mood-stabilizing agents on CNS fatty acids. It was found that lithium and valproate produce selective reductions in the turnover rate of the phospholipid arachidic acid (AA) in rat brain (Chang et al., 1996, 2001). Lithium produced a reduction of 80 percent accompanied by a reduction in the expression of the gene and protein of

an AA-specific phospholipase A2 (cPLA2). Valproate decreased the turnover of AA by 33 percent with no effect on cPLA2 protein levels, and was postulated to act directly in the incorporation of AA into brain phospholipids. Ongoing studies should serve to delineate the facets of recurrent mood disorders (perhaps especially bipolar disorder) that these membrane changes may modulate.

The Role of Synaptic Vesicle Proteins

Because synaptic proteins are downstream targets of many signaling pathways implicated in the pathophysiology and/or treatment of mood disorders, and because alterations in presynaptic function could modulate synaptic plasticity and therefore CNS information flow, the role of these proteins in mood disorders merits attention. The presynaptic machinery controls the processes of exocytosis and endocytosis at the synapse, and is composed of a large number of proteins interacting in complex ways. These proteins are phosphoregulated by many major serine/threonine kinases and phosphatases, including PKC, PKA, calcium/calmodulin-dependent kinases (CaMK) I and II, MAPK, casein kinase II (caskII), cyclin-dependent kinase (cdk), and the protein phosphatases 2a and 2b (PP2A and calcineurin, respectively). Some of these phosphorylations appear to reflect presynaptic mechanisms of synaptic plasticity (Turner et al., 1999). Expression-level regulation is also effected by many processes and pathways, including spatial learning (Gomez-Pinilla et al., 2001), stress (Thome et al., 2001), estrogen (Brake et al., 2001), BDNF (Tartaglia et al., 2001), CREB (Hoesche et al., 1995; Ryabinin et al., 1995), and POU-family transcription factors (Morris et al., 1996; Deans et al., 1997).

Evidence of Pathological Alterations in the Presynaptic Release Machinery

Postmortem studies have shed much light on the potential dysfunction of the synapse in psychiatric disorders. Most studies have focused on schizophrenia, although similar results have often been found in bipolar disorder when included. Eastwood and Harrison (2001) recently reviewed findings on synaptic markers in schizophrenia and mood disorders and assayed several proteins in anterior cingulate cortex. They found that GAP-43, synaptophysin, and complexin II were reduced in bipolar disorder, correlated with length of illness. In general, however, the results were more suggestive of an overall atrophy of excitatory synaptic connections rather than a specific pathology related to the machinery of neurotransmitter release.⁶⁹

Overall, many suggestive findings implicate presynaptic proteins in the pathophysiology of schizophrenia and severe mood disorders. It remains to be seen, however, whether these changes are directly related to the psychopathology of the disease, or are epiphenomena of altered neurotrans-

mission, impaired cellular growth and survival, substance abuse, and/or some other causative factor. Suggestive of the former hypothesis, three genes encoding synaptic proteins have been identified with possible risk-conferring alleles. Several variant alleles of synaptojanin (at the 21q22 locus) appeared to be more frequent in bipolar patients (Saito et al., 2001a). Synaptojanin is a polyphosphoinositide 5-phosphatase and is believed to have a role in clathrin uncoating in the final stages of slow synaptic vesicle endocytosis. Homozygous synaptojanin-null mutant mice display abnormal phosphoinositide metabolism and a large increase in clathrin-coated vesicles, which may be related to the observation of enhanced long-term depression (Cremona et al., 1999). A mutant splice acceptor in the gene encoding synaptobrevin (at the Xq28 locus) may occur with greater frequency in male bipolar patients (Saito et al., 2000). Synaptobrevin (also called VAMP) is part of the SNARE (N-ethylmaleimide-sensitive fusion factor attachment protein receptor) complex, which is essential for docking of vesicles prior to release. Knockout mice display large deficits in spontaneous and particularly calcium-evoked release of synaptobrevin (Schoch et al., 2001). Finally, a mutation in the promoter of SNAP-29, a SNAP-25 homologue mapping to the velocardiofacial syndrome (VCFS) critical region at 22q11, was demonstrated to be more common in schizophrenic patients (Saito et al., 2001b).

Presynaptic Proteins as Targets of Psychiatric Drugs

CaMKII is highly enriched in both presynaptic and postsynaptic terminals. Chronic, but not acute, treatment with paroxetine or fluvoxamine (both SSRIs) or with venlafaxine (a dual 5-HT/NE reuptake inhibitor) was found to increase CaMKII activity in vesicle-enriched fractions of rat hippocampus (Popoli et al., 1995). This effect may be attributable at least in part to an increase in tyrosine autophosphorylation. Treatment with desmethylimipramine, imipramine, electroconvulsive shock (the animal model of ECT), and s-adenosylmethionine (a methyl donor with putative antidepressant properties with an unknown mechanism) was found to produce similar effects on CaMKII activity in hippocampus and/or frontal cortex (Pilc et al., 1999; Consogno et al., 2001a,b).⁷⁰

The involvement of presynaptic proteins in mood-stabilizer treatment is much less well studied. An increase in synapsin in cultured cerebellar granule cells has been reported (Lucas and Salinas, 1997), and it has been shown that lithium stimulation of synapsin expression probably occurs through the inhibition of glycogen synthase kinase 3 β (GSK-3 β), a fairly well-documented effect of lithium. Further work by this group revealed that lithium and valproate induced the clustering of synapsin into bright punctae in a variety of primary neurons (Hall et al., 2002).

Changes in the mRNA of several synaptic proteins following lithium treatment were found in a microarray study of nerve growth factor (NGF)-differentiated PC12 cells (Cordeiro et al., 2000). Likewise, preliminary data from this group demonstrated an increase in the expression of several synaptic proteins following treatment with valproate in rat hippocampal slices. Published findings suggest, however, that synapsin is unchanged or downregulated following in vivo chronic treatment with lithium (Vawter et al., 2002) or valproate (Hassel et al., 2001), respectively. Additional data from the Manji group suggest no effect of lithium or valproate on synapsin levels (N.A. Gray et al., unpublished observations). The observation that effects are distinct in cell culture and in vivo suggests that the increase seen in culture may be a function of increased synaptogenesis (an effect that would presumably be more apparent in a growth-intensive environment such as cell culture).⁷¹

Current work by the Manji group indicates that phosphorylation of synapsin at site 1 is increased following chronic treatment with lithium or valproate in rat hippocampus. Site 1 of synapsin is phosphorylated by PKA and/or CaMKI, and dephosphorylated by PP2A. While we could find no study exploring effects of mood stabilizers on CaMKI, many studies have investigated PKA activity following lithium treatment. In general, the effects appear to be quite complex and dependent on brain region, subcellular fraction, stimulation, and length of treatment. There is some indication that the catalytic PKA and adenylylase type 1 may be somewhat increased in soluble fractions of rat hippocampus following chronic lithium treatment (Mori et al., 1998; Jensen et al., 2000), although stimulated phosphorylation may be reduced (Jensen and Mork, 1997). This observation parallels that of earlier work suggesting elevated basal but reduced stimulated cAMP levels in cortex of treated rats (Manji et al., 1991b). The effects of lithium and valproate on serine/threonine phosphatases have not been demonstrated. The authors of a recent study hypothesize that lithium's rescue of (PKB/Akt) dephosphorylation under low-K⁺ conditions may be due to inhibition of a protein phosphatase (Mora et al., 2001); however, they do not rule out an upstream increase in phosphorylation.

Glycogen Synthase Kinase-3 as a Target

Recently, considerable excitement has been generated by the identification of a completely unexpected and novel target for lithium—a crucial kinase that functions as an intermediary in numerous intracellular signaling pathways called glycogen synthase kinase-3 (GSK-3).⁷² GSK-3 plays a critical role in the survival of neurons, and this role has been postulated to be the target of lithium and valproate (Gould and Manji, 2002a; Li et al., 2002). As discussed later, a growing body of data has demonstrated neuroprotective effects

of lithium in many preclinical models. It is possible that the effect of lithium on GSK-3 plays a role in these phenomena.⁷³ (See Figure 14–16 for more details on the effects of lithium and valproate on the GSK-3 cascade.)

At this point, it is critical to note that evidence suggests an association between mood disorders and impairments of neuroplasticity and cellular resilience, with both in vivo and postmortem studies suggesting neuron and/or glial cell loss or atrophy in circumscribed brain areas. Importantly, lithium has effects suggestive of neuroprotection clinically, as well as in rodent and cell-based models. Lithium may exert these neuroprotective effects, at least in part, by inhibition of GSK-3. (See Box 14–15 for findings related to the neuroprotective effects of GSK-3 inhibition.)

A second putative target pathway resulting from GSK-3 inhibition is suggested by research exploring the underlying circadian cycle of *Drosophila*. The *Drosophila* orthologue of GSK-3 (SHAGGY or ZW3/Sgg) regulates circadian rhythms in this species. A decrease in SHAGGY activity results in a longer circadian period (Martinek et al., 2001)—precisely the effect noted in numerous species, including *Drosophila*, after treatment with lithium (Klemfuss, 1992). While there are many differences between the molecular components of circadian cycles in mammals and *Drosophila*, there are also many similarities (Wager-Smith and Kay, 2000; Reppert and Weaver, 2001; Williams and Sehgal, 2001). Thus it is interesting to speculate that GSK-3 has a similar general action in the function of the mammalian circadian clock (Gould and Manji, 2002a; Lenox et al., 2002). This putative function of GSK-3 in mammals therefore represents another possible therapeutic target for the actions of lithium on GSK-3. In fact, longer circadian periods after lithium exposure have been observed in unicellular organisms, plants, invertebrates, and vertebrates, including such mammals as mice, rats, squirrel monkeys, and humans.⁷⁴ (See Figures 14–17 for the circadian cycles in *Drosophila* and mammals, Figure 14–18 for the effects of lithium on the circadian cycle, and see Chapter 16.)

Very recent data from a variety of leading laboratories have greatly strengthened the case for an important role for GSK-3 in the pathophysiology and treatment of recurrent mood disorders, especially bipolar disorder (see Gould and Manji, 2005, and references therein):

- GSK-3 is markedly regulated by serotonin, dopamine, psychostimulants, and antidepressants, and is at the nexus of multiple neurotransmitter and signaling cascades putatively involved in these disorders.
- GSK-3 is a major regulator of apoptosis and cellular plasticity and resilience. Generally, increased activity of GSK-3 is pro-apoptotic, while inhibiting GSK-3 attenuates or prevents apoptosis (see Gould and Manji, 2005,

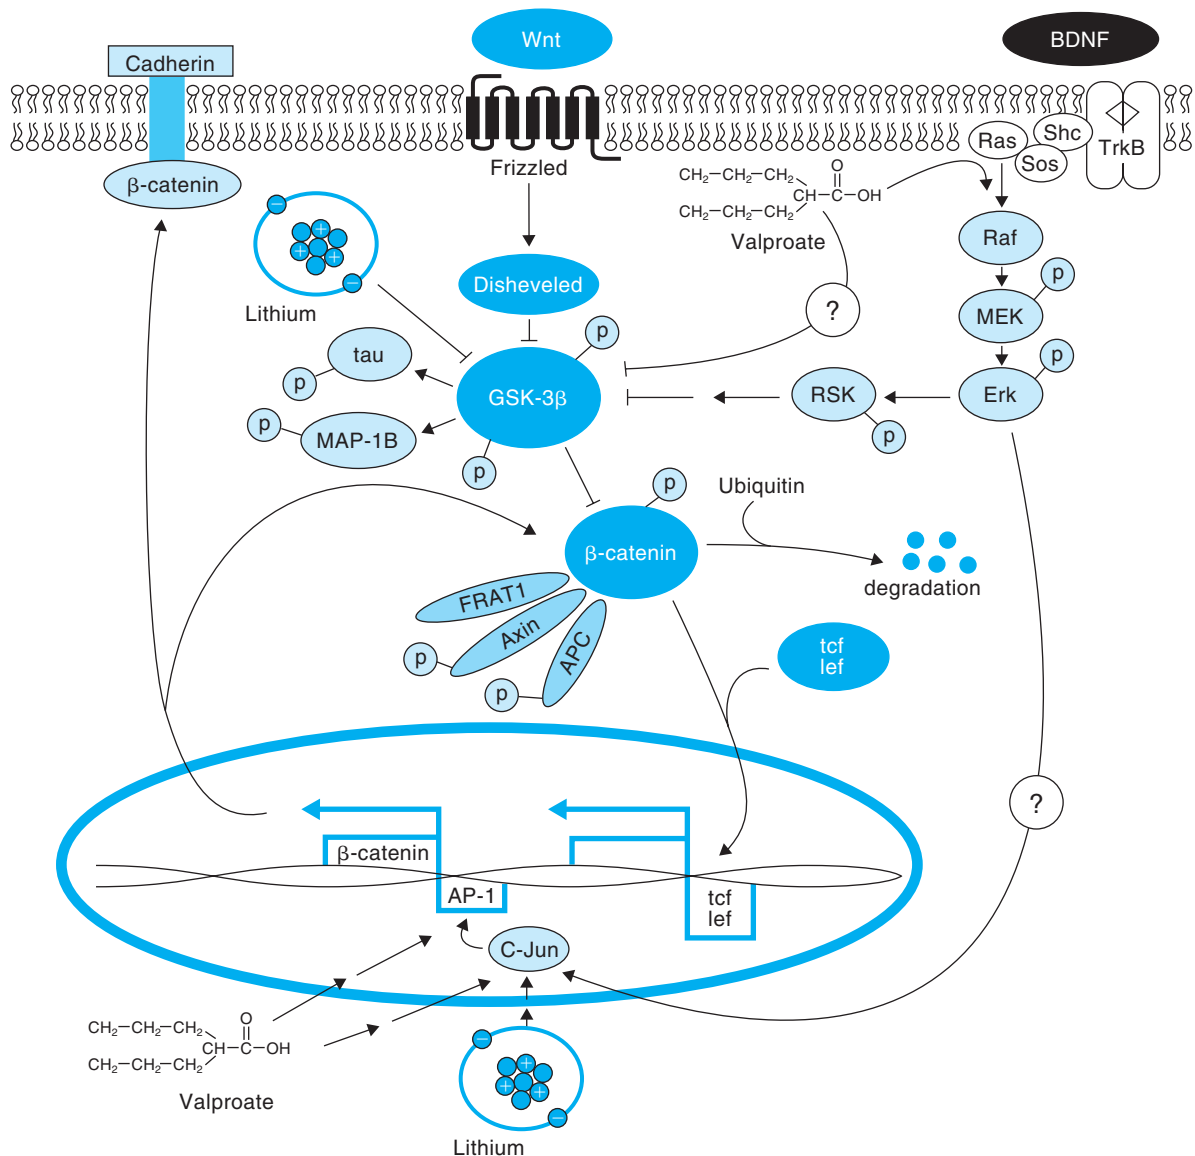

Figure 14-16. Signaling through Wnt glycoproteins and frizzled receptors activates disheveled, resulting in inhibition of glycogen synthase kinase-3 β (GSK-3 β). Phosphorylation of β -catenin by GSK-3 β results in its degradation by ubiquitin. Non-degraded (nonphosphorylated) β -catenin binds to *lef/tcf* transcription factors, targeting transcription of specific genes. Lithium competes with Mg^{2+} to inhibit GSK-3 β (Ryves and Harwood, 2001). Valproate may be an inhibitor of GSK-3 β . Alternatively, it may exert its action on Wnt signaling through inhibition of histone deacetylase, by its known actions on C-Jun, through upregulation of β -catenin mRNA, or by its action on the Ras/RSK pathway (Chen et al., 1997, 1999; Phiel and Klein, 2001; Yuan et al., 2001). BDNF = brain-derived neurotrophic factor; MAP = mitogen-activated protein kinase; MEK = MAP kinase kinase. (Source: Gould and Manji, 2002b. Reprinted by permission of SAGE Publications, Inc.)

for review). (See Figure 14-19 for details on the GSK-3 signaling convergence.)

- As noted above, GSK-3 has a major effect on regulating the circadian period in diverse species, an effect it shares with lithium (Gould et al., 2004a,b). Notably, treatment strategies are being developed that derive from a chronobiological model of recurrent mood disorders.
- Recent animal behavioral data (from pharmacologic and genetic models) have shown that manipulation of the GSK-3 signaling cascade produces both antidepressant and antimanic effects in models of depression or mania. To the best of our knowledge, other than lithium, this is the only manipulation that has been demonstrated to exert both antidepressant and antimanic effects.

BOX 14–15. GSK-3 β Inhibition is Neuroprotective

- GSK-3 β activity required for β -amyloid-induced neurotoxicity in primary hippocampal cultures (Takashima et al., 1995)
- GSK-3 β overexpression induces apoptosis in Rat-1 and PC-12 cells (Pap and Cooper, 1998)
- Dominant negative GSK-3 β prevents apoptosis following inhibition of PI3K (Pap and Cooper, 1998)
- FRAT-1 (a protein that interacts with the β -catenin/axin/GSK-3 β complex) rescues primary sympathetic neurons from PI3K inhibition-induced cell death (Crowder and Freeman, 2000)
- Dominant negative form of GSK-3 β or an inhibitory GSK-3 β binding protein attenuates serum deprivation of PI3K-induced apoptosis (Hetman et al., 2000)
- Synthetic GSK-3 β inhibitors protect primary sensory and granule neurons from potassium deprivation of PI3K-induced cell death (Cross et al., 2001)
- Rat-1 cells stably overexpressing Wnt-1 are resistant to vincristine and vinblastine apoptosis (B. Chen et al., 2001)

In view of their therapeutic effects not only in bipolar disorder but also in Alzheimer's disease and other neurodegenerative disorders, it is not surprising that specific, brain-penetrant GSK-3 inhibitors are actively under development by numerous pharmaceutical companies. Unless side effects prove to be prohibitive, GSK-3 inhibitors may represent a completely novel class of treatments for bipolar disorder (Gould and Manji, 2005).

We now turn to discussion of an emerging field of research in manic-depressive illness that has generated considerable excitement in the clinical neuroscience community and is reshaping our views about the pathophysiology of severe mood disorders: the critical role of impairments of cellular plasticity and resilience.

The Role of Cellular Plasticity Cascades

Although traditionally viewed exclusively as a neurochemical disorder, recent evidence suggests the possibility that the underlying primary pathophysiology of bipolar disorder may involve intracellular signaling cascades that produce not only functional but also morphological impairments, rather than specific alterations in a particular neurochemicals per se. In this regard, it is noteworthy that increasingly neuroimaging, neuropathologic, and biochemical studies suggest impairments in cellular plasticity and resilience in patients who suffer from severe, recurrent mood disorders.

Atrophic Changes in Manic-Depressive Illness: Primary Illness Pathology or the Ravages of Illness Progression?

As discussed in Chapters 9 and 15, recent morphometric MRI and postmortem investigations have demonstrated

abnormalities of brain structure that persist independently of mood state and may contribute to corresponding abnormalities in metabolic activity (Manji and Duman, 2001; Manji et al., 2001a). Structural imaging studies have demonstrated reduced gray matter volumes in areas of the orbital and medial prefrontal cortex, ventral striatum, and hippocampus and enlargement of the third ventricle in patients with mood disorders relative to controls (Drevets, 2001; Beyer and Krishnan, 2002; Strakowski et al., 2002). Also consistent is the presence of white matter hyperintensities in the brains of elderly depressed patients and patients with bipolar disorder; these lesions may be associated with poor treatment response.⁷⁵

Postmortem Morphometric Findings. In addition to the accumulating neuroimaging evidence (see Chapter 15), several postmortem brain studies now provide direct evidence for reductions in regional CNS volume, cell number, and cell body size (see Box 14–16).

Baumann and colleagues (1999a, 1999b) reported reduced volumes of the left nucleus accumbens, the right putamen, and bilateral pallidum externum in postmortem brain samples obtained from patients with unipolar major depressive disorder or bipolar disorder. Several recent postmortem stereological studies of the prefrontal cortex have also demonstrated reduced regional volume, cell numbers, and/or cell sizes. Morphometric analysis of the density and size of cortical neurons in the dorsolateral prefrontal cortex (DLPFC) and orbitofrontal cortices has revealed significant reductions in mood disorder patients compared to control subjects (Rajkowska et al., 1999; Rajkowska, 2000; see Table 14–9). The neuronal reductions have generally been more subtle than the corresponding glial alterations (see below) and detected only when specific morphological size-types of neurons were analyzed in individual cortical layers. For example, marked reductions in the density of large neurons (corresponding to pyramidal glutamatergic excitatory neurons) were found in layers III and V of the DLPFC in bipolar disorder and major depressive disorder. In other prefrontal regions such as rostral orbitofrontal cortex, the most prominent neuronal reductions in major depressive disorder are confined to layer II cells (mostly corresponding to nonpyramidal inhibitory local circuit neurons). Reductions in the density of specific populations of layer II nonpyramidal neurons containing the calcium binding protein calretinin have also been reported in the anterior cingulate cortex in subjects with a history of mood disorders.

Decreases in laminar neuronal densities have also been reported in the dorsolateral prefrontal cortex (Rajkowska et al. 2001) and anterior cingulate cortex (Benes et al., 2001; Bouras et al., 2001; Cotter et al., 2002a) in bipolar disorder, although not all studies have observed these findings

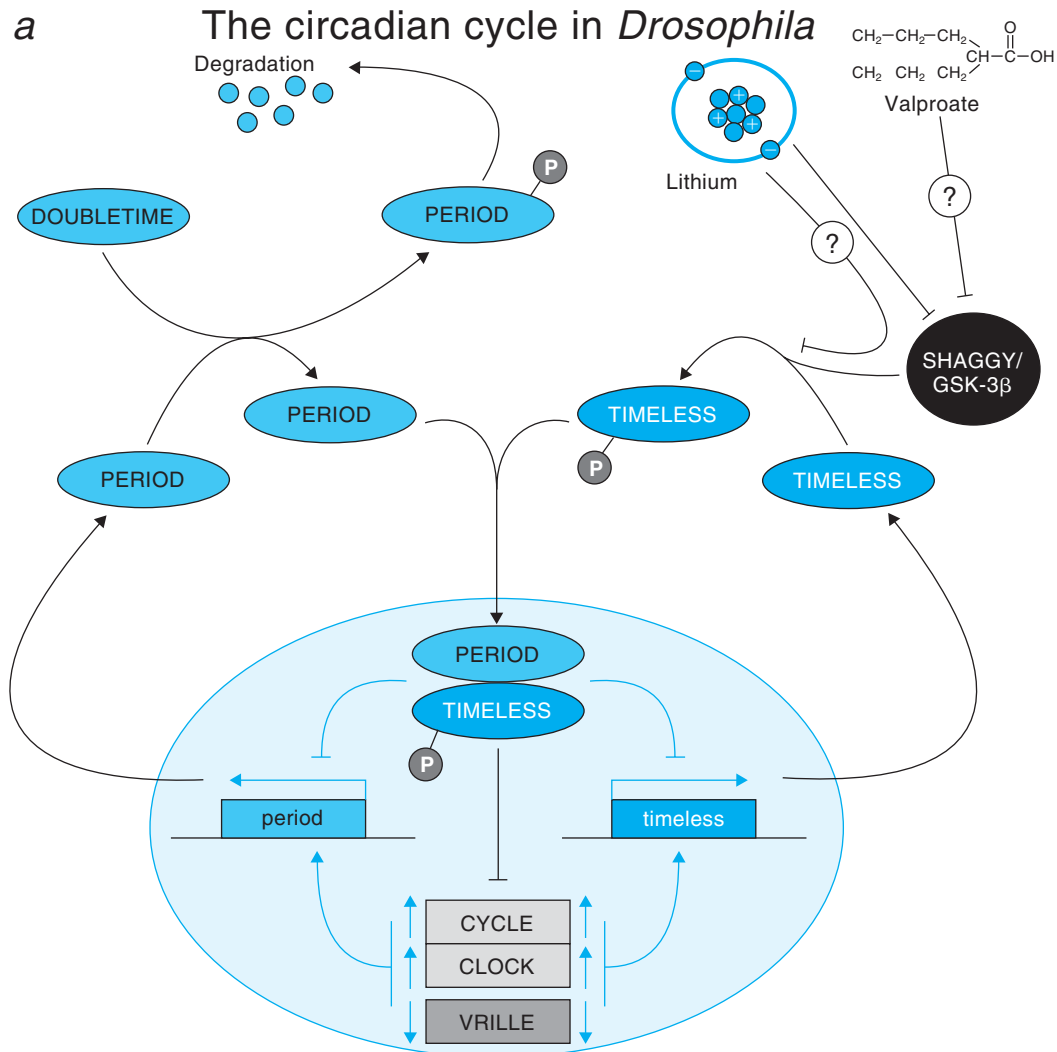

Figure 14–17. Schematic of genes involved in the circadian cycles of *Drosophila* (a) and mammals (b). The molecular mechanism regulating circadian rhythms relies on a daily cycle of interactions between positive and negative regulators. In *Drosophila* (a), CYCLE (*Drosophila* BMAL1) and CLOCK help mediate transcription of TIMELESS and PERIOD genes. PERIOD binds to TIMELESS in the cytoplasm. These proteins then enter the nucleus and act as negative regulators of CLOCK and CYCLE (Allada et al., 2001). SHAGGY (the *Drosophila* orthologue of GSK-3β) appears to phosphorylate TIMELESS, advancing the entry of this protein into the nucleus (Martinek et al., 2001). Lithium is a direct inhibitor of SHAGGY (Klein and Melton, 1996; Stambolic et al., 1996), suggesting a method by which lithium lengthens the circadian period in diverse species, including *Drosophila* (Klemfuss, 1992). The mammalian circadian cycle (b) has many similarities (Allada et al., 2001) as well as notable differences, for example, lack of a true TIMELESS orthologue (Reppert and Weaver, 2001). The role of GSK-3β in mammalian circadian cycles is unknown (see also Chapter 16). (Source: Gould and Manji, 2002b. Reprinted by permission of SAGE Publications, Inc.)

(Ongur et al., 1998; Cotter et al., 2001; see Table 14–9). Moreover, reduced density of pyramidal neurons in cortical layers III and V (Rajkowska et al., 2001) and nonpyramidal neurons in layer II (Benes et al., 2001) have been observed in the same regions. This last observation coincides with reports on reductions in the density of layer II nonpyramidal neurons that are identified with specific antibodies against the calcium binding protein calbindin in

the anterior cingulate cortex (Cotter et al., 2002a) and dorsolateral prefrontal cortex (Reynolds et al., 2002) in bipolar disorder. (Calbindin-immunoreactive neurons are known to colocalize with GABA). Elegant detailed studies from the Rajkowska laboratory have undertaken measurements of the density and size of calbindin-immunoreactive neurons in layers II and upper part of layer III of the dorsolateral prefrontal cortex, revealing a 43 percent reduction

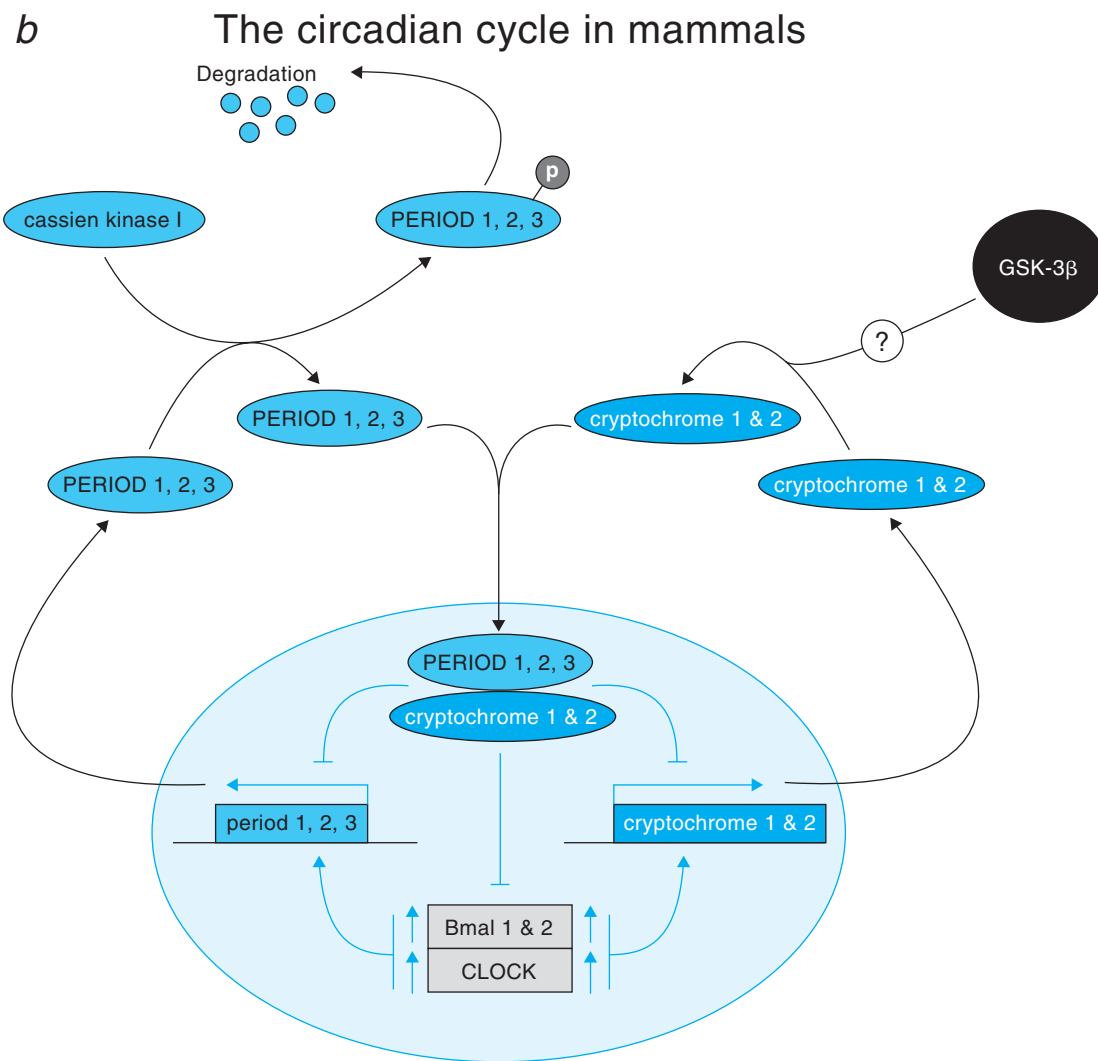

Figure 14–17. (continued)

in the density of these neurons in major depressive disorder compared with controls (Rajkowska, 2002a,b). Notably, in the rostral orbitofrontal cortex there was a trend for a negative correlation between the duration of depression and sizes of neuronal cell bodies (Rajkowska et al., 1999). The longer the duration of illness, the smaller the neurons were, suggesting changes associated with disease progression. More subtle than in major depressive disorder, reductions in neuronal soma size have been observed in bipolar disorder by some investigators (Rajkowska et al., 2001; Chana et al., 2003) but not by all (Ongur et al., 1998; Bouras et al., 2001; Cotter et al., 2001). In one other study a minor increase in the size of small nonpyramidal neurons was noted in the anterior cingulate cortex in bipolar subjects (Benes et al., 2001). However, given the major trophic effects of lithium and valproate, it is quite possible that the more modest findings in bipolar disorder actually represent a long-term protective effect of these medications.

Additional morphometric studies have also reported layer-specific reductions in interneurons in the anterior cingulate cortex) and reductions in nonpyramidal neurons (~ 40 percent lower) in CA2 of the hippocampal formation in bipolar subjects compared with controls (Benes et al., 1998). Overall, the layer-specific cellular changes observed in several distinct brain regions, including the prefrontal cortex, anterior cingulate cortex, and hippocampus, support the contention that multiple neuronal circuits underlie the neuropathology of mood disorders. (Manji and Lenox, 2000b; Rajkowska et al., 2004). Notably, some disorganization in neuronal clusters in layers II and III of the entorhinal cortex was also observed (Beckmann and Jakob, 1991; Bernstein et al., 1998). In a large study in which neuronal and glial cell packing density and soma size were estimated in the hippocampal subfields in 19 patients with major depression and 21 age-matched controls, prominent abnormalities in the CA regions and dentate gyrus were

Figure 14-18. Chronic lithium treatment and circadian rhythms. The most prominent rhythmic component under normal conditions has a period of 24 hours. This rhythm usually reflects a complex interaction between endogenous rhythmic and other mechanisms (homeostatic, adaptive, pathological, etc.). The 24-hour rhythms with a proven endogenous component are called *circadian*, reflecting the observation that under constant external conditions the rhythms free run with an endogenous period that is close to 24 hours. Chronic (but not acute) lithium treatment prolongs the free-running period in almost all studied biological systems, including humans. The mechanism of lithium's action on the diverse circadian rhythms probably involves combined effects at the level of the circadian clock and at the integration of circadian rhythmicity with other regulatory systems (see also Chapter 16). (Source: Ikononov and Manji, 1999.)

found in major depressive subjects (Stockmeier, 2003). Neuronal density in major depressive disorder was markedly increased by 30–40 percent above the control level and neuronal cell body size was significantly decreased in the CA1–3 subfields and dentate gyrus. An increase in packing density paralleled by smaller cell sizes in major depressive disorder suggests a decrease in neuropil consisting of neuronal and glial processes and their synapses (Stockmeier, 2003).

Glial Cell Pathology. In addition to neuronal pathology, unexpected reductions in glial cell number and density have recently been found in postmortem brains of both patients with major depression and bipolar disorder. Marked decreases in overall and laminar (layers III–IV) glial cell packing densities were found in subjects with major depressive disorder compared with nonpsychiatric control subjects (Rajkowska et al., 1999). Comparable reductions in glial densities were also detected in DLPFC from subjects with bipolar disorder across all cortical layers except layer IV (Rajkowska 1997, 2000). Further immunohistochemical examination of PFC glial cells in major depressive disorder indicated that the reductions in the population of astroglial cells account at least in part for the global glial deficit that has also been found in this disorder (Miguel-Hidalgo et al., 2000). In bipolar disorder, however, it is possible that a dif-

ferent population of glial cells (oligodendroglia and/or microglia) may be involved in this pathology, since reductions in a different morphological type of glial cell were consistently observed in all cortical layers of DLPFC in bipolar subjects (Rajkowska, 2000). An independent histological study of area sg24 located in the subgenual prefrontal cortex also found striking reductions in glial cell numbers in patients with familial major depressive disorder (24 percent reduction) and bipolar disorder (41 percent reduction) compared to controls (Ongur et al., 1998). However, when familial and nonfamilial subgroups of depressed patients were combined, the reductions were not found; these intriguing findings raise the possibility that the subgenual prefrontal cortex glial cell findings may be most apparent in a particularly strongly genetic form of the illness. This observation is consistent with this group's neuroimaging report on reductions in cortical gray matter volume found in the same brain region in a similar diagnostic group. While these results are intriguing, further immunohistochemical and molecular studies are needed to definitively determine if the same types of glial cells underlie the glial deficit that has been observed in both major depressive disorder and bipolar disorder, and if this glial loss occurs via similar mechanisms. While the most prominent findings thus far have been from the frontal cortex, a growing body of data suggests that glial pathology extends beyond the frontal

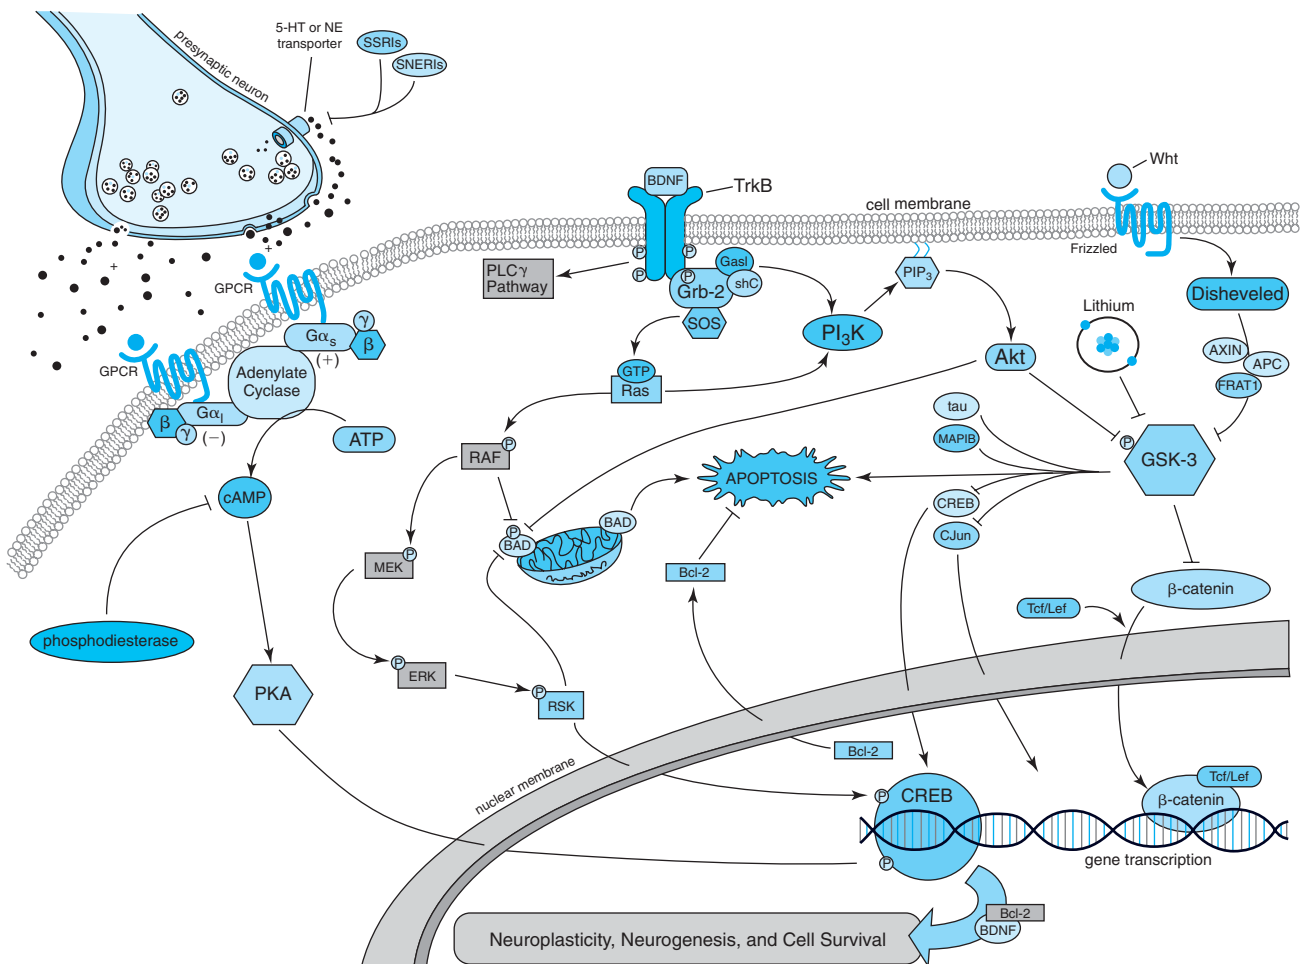

Figure 14–19. Glycogen synthase kinase-3 (GSK-3) is a component of diverse signaling pathways. These include G protein–coupled receptor signaling (left), neurotrophic factor signaling (center), and the Wnt signaling pathway (right). Neurotrophins such as brain-derived neurotrophic factor (BDNF) act through Trk receptors A, B, and C to activate phosphoinositide-3 kinase (PI₃K) and Akt and inhibit GSK-3. Many effectors have been implicated in GSK-3’s neurotrophic effects, including transcription factors (e.g., C-Jun, p53, CREB) and recently the proapoptotic Bcl-2 family member BAX. In the Wnt signaling pathway, secreted Wnt glycoproteins interact with the frizzled family of receptors and through disheveled-mediated signaling inhibit GSK-3. Stability of this process requires the scaffolding proteins axin and adenomatous polyposis coli (APC). Normally, active GSK-3 phosphorylates β-catenin, leading to its ubiquitin-dependent degradation. However, when GSK-3 is inhibited in the Wnt pathway, β-catenin is not degraded, allowing for its interaction with T-cell-specific transcription factor (Tcf) to act as a transcription factor. (Source: Gould and Manji, 2005. Reprinted with permission from Macmillan Publishers, Ltd.)

cortex to the hippocampus. A recent study of the hippocampus in 40 patients with major depression and age-matched control subjects reported marked increases in glial cell density and unchanged sizes of glial nuclei in all hippocampal CA subfields and the granule cell layer of the dentate gyrus (Stockmeier et al., 2004). Increases in glial cell packing density detected postmortem in patients with major depression are suggestive of reduction in surrounding neuropil (see above) and may be related to decreases in hippocampal volume noted by neuroimaging studies in major depression disorder (see Chapter 15).

Glial Cell Type Affected in Mood Disorders. Glial cells do not represent a single subtype, and in addition to their

traditional roles in neuronal migration (radial glia), myelin formation (oligodendrocytes), and inflammatory processes (astrocytes and microglia), glia (predominantly astrocytes) are now accepted to have roles in providing trophic support to neurons, neuronal metabolism, and the formation of synapses and neurotransmission. To date, the exact identity of the glial cell subtypes most affected in mood disorders remains to be fully established, but considerable data suggest the involvement of several subtypes. Alterations in glial fibrillary acidic protein (GFAP) (generally considered to represent a marker for astrocytes in areas of the brain such as frontal cortex) in both bipolar disorder and major depressive disorder are suggested by a proteomic study in which different forms of GFAP displayed

BOX 14–16. Postmortem Morphometric Brain Studies in Mood Disorders Demonstrating Cellular Atrophy and/or Loss

Reduced Volume or Cortical Thickness

- Cortical thickness rostral orbitofrontal cortex, major depressive disorder (MDD)
- Laminar cortical thickness in layers III, V, and VI in subgenual anterior cingulate cortex (area 24) in bipolar disorder (BPD)
- Volume of subgenual prefrontal cortex in familial MDD and BPD
- Volumes of nucleus accumbens (left), basal ganglia (bilateral) in MDD and BPD
- Parahippocampal cortex size (right) in suicide

Reduced Neuronal Size and/or Density

- Pyramidal neuronal density, layers III and V in dorsolateral prefrontal cortex in BPD and MDD
- Neuronal size in layer V (–14%) and VI (–18%) in prefrontal cortex (area 9) in BPD
- Neuronal size in layer VI (–20%) in prefrontal cortex (area 9) in MDD
- Neuronal density and size in layer II–IV in rostral orbitofrontal cortex, in layer V/VI in caudal orbitofrontal cortex, and in supra- and infragranular layers in dorsolateral prefrontal cortex in MDD
- Neuronal size in layer VI (–23%) in anterior cingulate cortex in MDD
- Neuronal density in layers III, V, and VI in subgenual anterior cingulate cortex (area 24) in BPD
- Layer-specific interneurons in anterior cingulate cortex in BPD and MDD
- Nonpyramidal neuronal density in layer II (–27%) in anterior cingulate cortex in BPD
- Nonpyramidal neurons density in the CA2 region in BPD

Reduced Glia

- Density/size of glia in dorsolateral prefrontal cortex and caudal orbitofrontal cortex in MDD and BPD—layer-specific
- Glial cell density in sublayer IIIc (–19%) (and a trend to decrease in layer Va) in dorsolateral prefrontal cortex (area 9) in BPD
- Glial number in subgenual prefrontal cortex in familial MDD (–24%) and BPD (–41%)
- Glial cell density in layer V (–30%) in prefrontal cortex (area 9) in MDD
- Glial cell density in layer VI (–22%) in anterior cingulate cortex in MDD
- Glial cell counts, glial density, and glia-to-neuron ratios in amygdala in MDD

disease-specific abnormalities (Johnston-Wilson et al., 2000). Another type of glial cell, oligodendroglia, may also be involved in the general glial pathology, as reduced density, immunoreactivity, and ultrastructural changes in oligodendrocytes were found in the dorsolateral prefrontal and anterior frontal cortex in patients with bipolar and major depressive disorder (Orlovskaya et al., 2000; Uranova et al., 2001). Moreover, a reduction of key oligodendrocyte-related and myelin-related gene expression was reported in the dorsolateral prefrontal cortex in bipolar disorder (Tkachev et al., 2003). Recently, Aston and associates (2005) undertook a microarray study examining approximately 12,000 genes in temporal cortex in 12 patients with major depression (recurrence not qualified) and 14 controls (bipolar subjects were not included in this study). They found that 17 genes related to myelination were significantly reduced. Eight of these genes encode for structural components of myelin, whereas five other genes encode enzymes that are involved in the synthesis of myelin or are essential in the regulation of myelin formation and metabolism. These intriguing findings support the neuroimaging data for abnormalities of white matter in critical circuits in manic-depressive illness (see Chapter 15).

It is clear that considerably more work is needed to fully elucidate the precise pathophysiological significance of the glial cell findings in major depressive disorder and bipolar disorder. There has nonetheless been tremendous progress in our understanding of the critical roles of glial cells in the regulation of neuronal function and in their involvement in a variety of neuropsychiatric diseases. Compelling evidence now exists that radial glial cells have the potential to not only guide newly born neurons but also self-renew and generate *both neurons and astrocytes*. Furthermore, recent data have shown that astrocytes increase the number of mature, functional synapses on CNS neurons seven-fold, demonstrating that CNS synapse number can be profoundly regulated by glia. Glial cells are also known to play critical roles in the regulation of synaptic glutamate levels, CNS energy homeostasis, and the liberation of trophic factors, and they indeed form dynamic, complex synaptic networks with neurons.⁷⁶ All of these findings suggest that the prominent glial loss observed in major depressive and bipolar disorders may be integral to the pathophysiology of the disorders and worthy of further study.

While total reproducibility does not exist among either the neuroimaging or postmortem studies, the differences likely represent variations in experimental design (including medication effects—see below), and in patient populations (as would be expected in heterogenous conditions such as mood disorders). Overall, the data suggest that although clearly not classic degenerative disorders, severe mood disorders are illnesses associated with atrophic brain

TABLE 14–9. Morphological Abnormalities in the Cerebral Cortex in Mood Disorders

Disease (No. of Subjects)	Area; Hemisphere	Methods	Neurons	Glia	Study
<i>Prefrontal Cortex</i>					
MDD (12)/C (12)	DLPFC (BA 9); left	Nissl	↓ Density of large neurons (20–60% LII, III, VI) ↑ Density of small neurons ↓ Size (5% LIII, 7% LVI)	↓ Density (20–30% in LIII, V) ↑ Size (6% LIIIa)	Rajkowska et al., 1999
BPD (10)/C (11)	DLPFC (BA 9); left	Nissl	↓ Density of all (19% LIII) and pyramidal neurons (17–30% LIII, V)	↓ Density (19% LIIIc; 12%LVb) ↑ Size (9% LI, 7% LIIIc)	Rajkowska et al., 2001
MDD (15)/BPD (15)/C (15)	DLPFC (BA 9) left+right	Nissl	↓ Size (20% LVI in MDD) ↓ Size (14% LV, 18% LVI in BPD)	↓ Density (30% LV, MDD) = Size (MDD, BPD)	Cotter et al., 2002a
MDD (14)/C (15)	DLPFC (BA 9); left	GFAP-IHC	Not examined	↓ Area fraction and ↓ density (LIII–V; in subgroup of young MDD subjects) = Area and density (young and old subjects combined)	Miguel-Hidalgo et al., 2000
MDD (12)/C (12)	ORB (BA 10–47); left	Nissl	↓ Density of large neurons (20–60% LII–IV); ↑ density of small neurons (LIII); ↓ size (9% LII, III)	= Density	Rajkowska et al., 1999
	ORB (BA 47); left		↓ Density (LIIIa, Va); ↓ size (6% LII)	↓ Density (15–18%, LIIIc–VI)	
<i>Anterior Cingulate Cortex</i>					
MDD (4f)/BPD (4f)/C (5f)	Subgenual (BA 24) left+right	Nissl	= Density (MDD, BPD) = Number (MDD, BPD) = Size (MDD, BPD)	↓ Number (24% overall, MDD) ↓ Number (41% overall, BPD) = Size (MDD, BPD)	Ongur et al., 1998
MDD (15)/BPD (15)/C (15)	Supragenual (BA 24) left+right	Nissl	↓ Size (18% LVI in MDD) = Density (MDD, BPD)	↓ Density (22% LVI, MDD) = Density (BPD)	Cotter et al., 2001
MDD (20)/BPD (21)/C (55)	Supra- and subgenual (BA 24) left	Nissl	↓ Density (LIII, V, VI in BPD but not in MDD) = Size (MDD, BPD)	Not examined	Bouras et al., 2001
BPD (10)/C (12)	Pregenual (BA 24) (no hemisphere specified)	Nissl	↓ Density (27% LII) and ↑ size (LII, III) of nonpyramidal neurons	= Density	Benes et al., 2001

changes. Thus research is required to understand whether more rigorously defined subtypes of depression or mood disorders are associated with any particular abnormality (Lenox et al., 2002; Hasler et al., 2006). Nevertheless, the marked reduction in glial cells in these regions has been particularly intriguing. Abnormalities of glial function could thus prove integral to the impairments of structural plasticity and overall pathophysiology of mood disorders.

It must be acknowledged that it is not currently known if these impairments of structural plasticity (cell loss, cell atrophy, white matter changes) constitute developmental abnormalities conferring vulnerability to severe mood episodes, compensatory changes to other pathogenic processes, or the sequelae of recurrent affective episodes (Carlson et al., 2006). Indeed, data suggest that multiple factors may be operative. In support of the potential primary etiologic role of cellular plasticity cascades, some studies have observed reduced gray matter volumes and enlarged ventricles in mood disorder patients at first onset and in children (see Chapter 9). Moreover, in contrast to the situation seen in unipolar patients, studies suggest that some young bipolar patients exhibit white matter hyperintensities on T2-weighted MRI scans. White matter hyperintensities are associated with a number of events, most notably aging and cerebrovascular disorders, thus their presence in some young bipolar patients is noteworthy (since they would not be expected to have overt cerebrovascular disease).

While these studies do not demonstrate that the changes precede illness onset, they certainly suggest that these changes do not simply represent the toxic sequelae of decades of illness. Resolving these issues will depend partly on experiments that delineate the onset of such abnormalities within the illness course and determine whether they precede depressive episodes in individuals at high familial risk for mood disorders. In this context, a recent report showed that individuals at high risk of developing mood disorders exhibited reduced subgenual prefrontal cortical volumes, raising the possibility that this endophenotype may constitute a heritable vulnerability factor in these patients (discussed in Carlson et al., 2006). Additional studies of high-risk individuals are currently under way.

There are, however, data to suggest that some of the brain changes may be associated with duration of illness and the consequences of affective episodes per se. Sheline and colleagues (1996) measured hippocampal volumes of subjects with a history of major depressive episodes but currently in remission and with no known medical comorbidity and compared them to matched normal controls. Subjects with a history of major depression had significantly smaller left and right hippocampal volumes; moreover, the degree of hippocampal volume reduction correlated with total duration of major depression. In a follow-up

study, the same research group found that longer durations during which depressive episodes went untreated with antidepressant medication were associated with reductions in hippocampal volume (Sheline et al., 2003). MacQueen and associates (2003) compared 20 never-treated depressed subjects in a first episode of depression with matched healthy control subjects. They also compared 17 depressed subjects with multiple past episodes of depression with matched healthy controls and with the first-episode patients. Notably, although both first- and multiple-episode depressed groups (who were therefore part of the manic-depressive spectrum) had hippocampal dysfunction apparent on several tests of recollection memory, only depressed subjects with multiple depressive episodes had hippocampal volume reductions (MacQueen et al., 2003). Finally, curve-fitting analysis revealed a significant logarithmic association between illness duration and hippocampal volume. These data suggest that in unipolar depression, hippocampal volumetric changes may be related to the number and duration of depressive episodes. It is noteworthy that similar changes have not been reported in bipolar patients. While this may represent distinct pathophysiologies, it is our contention that this more likely reflects the fact that, compared to recurrent unipolar patients, most bipolar patients are on neuroprotective mood stabilizers (see below). In studies of other brain regions (subgenual prefrontal cortex or amygdala), bipolar patients do not show atrophic changes when treated chronically with mood stabilizers.

It is perhaps most useful to conceptualize the cell death and atrophy that occur in mood disorders as arising from an impairment of "cellular resiliency." McEwen (2000) has elegantly elaborated on the concept of allostatic load and its potential involvement in mood disorders. Many factors that are essential for survival can, over long time intervals, exact a cost (allostatic load) that can accelerate disease processes (McEwen, 2000). At this point, it is unclear whether the regional cellular atrophy in mood disorders occurs because of the magnitude and duration of biochemical perturbations, an enhanced vulnerability to the deleterious effects of these perturbations (due to genetic factors and/or early life events), or a combination thereof. In this context, a growing body of data demonstrates that early stress can have a major impact on brain development (Graham et al., 1999). Furthermore, while there are undoubtedly genetic contributions (conferring both susceptibility and protection) to the impact of neonatal stresses on brain development, it is noteworthy that it has also been demonstrated that nongenomic transmission can occur across generations not only of maternal behavior but also stress responses (Francis et al., 1999). The possibility that these neurochemical alterations produce a state of neuroendangerment (see above) that contributes to the subsequent development of

morphological brain changes in adulthood requires further investigation. A growing body of data is also demonstrating a relationship (potentially bidirectional) between mood disorders and cardiovascular and cerebrovascular disease (see Chapter 7), suggesting that at least in a subset of patients (perhaps those who have been “primed” for impairments of cellular resiliency by genetic factors), CNS vascular insufficiency may be a contributory factor.⁷⁷

Overall, it seems likely that the impairments of cellular plasticity represent both etiologic factors and the consequence of disease progression. Furthermore, there is almost no doubt that these atrophic brain changes contribute to illness pathophysiology by disrupting the circuits that mediate normal affective, cognitive, motoric and neurovegetative functioning. We now turn to one of the most exciting recent advances in manic-depressive illness research—the observations that neurotrophic signaling cascades represent the targets for mood-stabilizing agents.

Neurotrophic Signaling Cascades: Critical Targets in Treatment

Neurotrophins are a family of regulatory factors that mediate the differentiation and survival of neurons, as well as the modulation of synaptic transmission and synaptic plasticity. They can be secreted constitutively or transiently, and often in an activity-dependent manner. Recent observations support a model in which neurotrophins are secreted from the dendrite and act retrogradely at presynaptic terminals to induce long-lasting modifications. Within the neurotrophin family, BDNF is a potent physiological survival factor that has also been implicated in a variety of pathophysiological conditions. The cellular actions of BDNF are mediated through two types of receptors: a high-affinity tyrosine receptor kinase (TrkB) and a low-affinity pan-neurotrophin receptor (p75). TrkB is preferentially activated by BDNF and NT4/5, and it appears to mediate most of the cellular responses to these neurotrophins.

BDNF and other neurotrophic factors are necessary for the survival and function of neurons, which implies that a sustained reduction of these factors could affect neuronal viability. What is sometimes less appreciated, however, is the fact that BDNF also has a number of much more acute effects on synaptic plasticity and neurotransmitter release and facilitates the release of glutamate, GABA, DA, and serotonin.⁷⁸

As discussed earlier, BDNF is best known for its long-term neurotrophic and neuroprotective effects, which may be very important for its putative role in the pathophysiology and treatment of mood disorders. In this context, it is noteworthy that although endogenous neurotrophic factors have traditionally been viewed as increasing cell survival by providing necessary trophic support, it is now clear

that their survival-promoting effects are mediated largely by inhibition of cell death cascades. Increasing evidence suggests that neurotrophic factors inhibit cell death cascades by activating the extracellular receptor-coupled kinase (ERK) MAPK signaling pathway (Chen and Manji, 2006). The best characterized molecular mechanisms of this pathway include upregulation of expression of anti-apoptotic proteins such as B-cell CLL/lymphoma/leukemia-2 (Bcl-2) through a transcriptional mechanism, direct phosphorylation-inactivation of pro-apoptotic proteins such as BAD, and direct phosphorylation-inactivation of key enzymes in the apoptosis process such as caspase-9. Many of these pathways converge at the level of mitochondrial function. We now turn to a discussion of the possibility of neurotrophic signaling-mediated mitochondrial dysfunction in bipolar disorder.

Neurotrophic-Signaling-Mediated Mitochondrial Function

Kato and colleagues anticipated recent developments in the field when they first proposed that mitochondrial dysfunction may play an important role in the pathophysiology of bipolar disorder (Kato and Kato, 2000; Murashita et al., 2000; Kato, 2001). Since then, findings of a host of human neuroimaging and postmortem brain studies, as well as preclinical molecular and cellular biology studies, have strongly supported the contention that mitochondria play a central role in the impairments of plasticity and cellular resilience manifest in bipolar disorder.

It is not our contention that bipolar disorder is a classic mitochondrial disorder. Individuals with mitochondrial dysfunction often manifest psychiatric symptoms, but the vast majority of bipolar patients do not show the symptoms of classic mitochondrial disorders, such as optic and retinal atrophy, seizures, dementia, ataxia, myopathy, exercise intolerance, cardiac conduction defects, diabetes, and lactic acidosis (Fadic and Johns, 1996).

Studies of fibroblasts from patients with mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes (MELAS, frequently caused by a mutation in the mitochondrial transfer RNA) have shown an elevated basal level of ionized Ca^{2+} , with impairments in normal sequestration of Ca^{2+} influxes induced by depolarization and alterations in maintaining normal mitochondrial membrane potentials (Moudy et al., 1995; Rothman, 1999). This inability to buffer intracellular Ca^{2+} may cause toxic cell injury and compromise the long-term viability of neurons in patients with mitochondrial encephalomyopathies. It is thus clear that dysregulation of Ca^{2+} homeostasis is an essential component of the pathophysiology of classic mitochondrial pathologies. As discussed above, calcium is a very common signaling element and plays a critical role in the CNS

by regulating the activity of diverse enzymes and facilitating neurotransmitter release (Szabo et al., 2003). Excessively high levels of calcium are also a critical mediator of cell death cascades within neurons, necessitating diverse homeostatic mechanisms to regulate intracellular calcium levels very precisely.

Interestingly, impaired regulation of Ca^{2+} cascades has been found to be the most reproducible biological measure of abnormalities described in research on bipolar disorder. For this reason, mechanisms involved in Ca^{2+} regulation have been postulated to underlie aspects of the pathophysiology of bipolar disorder. To date, 15 studies have consistently revealed elevations in basal intracellular Ca^{2+} levels in platelets, lymphocytes, or neutrophils of patients with bipolar disorder. By contrast, there have been only four negative studies. Although this may partly represent publication bias, elevation in basal Ca^{2+} represents one of the most replicated findings in research on bipolar disorder. More exaggerated platelet intracellular Ca^{2+} elevations have also been found in bipolar patients in response to stimulation with thrombin, platelet-activator factor (PAF), serotonin, DA, and thapsigargin (see Tables 14–5 and 14–6).

Most recently, Kato and colleagues (2003) investigated cytosolic and mitochondrial Ca^{2+} responses to PAF, carbonyl cyanide *m*-chlorophenylhydrazone (CCCP) (a mitochondrial uncoupler that abolishes mitochondrial Ca^{2+} uptake), and thapsigargin in lymphoblastoid cells from bipolar subjects. They found that the thapsigargin-induced cytosolic Ca^{2+} response was significantly higher in patients with bipolar disorder, a result not seen when the effects of Ca^{2+} influx from outside the plasma membrane were eliminated with a Ca^{2+} -free measurement buffer. By contrast, response to thapsigargin tended to be higher in patients with bipolar disorder when in the Ca^{2+} -free condition. Furthermore, CCCP-induced Ca^{2+} responses differed significantly between mitochondrial DNA 5178/10398 haplotypes that had previously been reported to be associated with bipolar disorder (Kato et al., 2003).

Taken together, these results clearly suggest that the mitochondrial–endoplasmic reticulum (ER) calcium regulation system contributes to the Ca^{2+} abnormalities seen in bipolar disorder. In an elegant series of recent studies, Kakiuchi and colleagues (2003) identified XBP1, a pivotal gene in the ER stress response, as contributing to the genetic risk for bipolar disorder. Using DNA microarray analysis of lymphoblastoid cells derived from two pairs of twins discordant with respect to the illness, they found downregulated expression of genes related to ER stress response in both affected twins. Furthermore, polymorphism (–116C→G) in the promoter region of XBP1, affecting the putative binding site of XBP1, was not only significantly more common in Japanese patients but also overtransmitted to affected offspring in trio

samples of the NIMH Bipolar Disorder Genetics Initiative. This research group further showed that XBP1-dependent transcription activity of the –116G allele was lower than that of the –116C allele, and furthermore, in cells with the G allele, induction of XBP1 expression after ER stress was markedly reduced (Kakiuchi et al., 2003). Finally, it was found that valproate at therapeutically relevant concentrations rescued the impaired response by inducing ATF6, the gene upstream of XBP1.

Overall, these findings are of great importance in view of the growing body of evidence demonstrating the potential toxic effects of elevated intracellular Ca^{2+} in neuronal and glial cerebral cells. In fact, it has been demonstrated that both the subcellular compartmentalization of Ca^{2+} and the source of the Ca^{2+} may be greater determinants of neurotoxicity than the absolute intracellular Ca^{2+} levels per se (Sapolsky, 2000b), and that there are major relationships between Ca^{2+} released from IP_3 -sensitive ER stores and mitochondrial Ca^{2+} uptake (Mattson et al., 2000). As discussed in Chapter 15, there is also a growing body of data from neuroimaging and postmortem studies demonstrating impairments of cellular plasticity and resilience in recurrent mood disorders.

Konradi and colleagues (2004) undertook an elegant series of postmortem brain microarray studies, providing additional evidence for mitochondrial dysregulation processes in bipolar disorder. They found that nuclear mRNA coding for mitochondrial proteins was decreased in bipolar disorder compared with schizophrenia. These findings involved expression of genes regulating oxidative phosphorylation in the mitochondrial inner membrane and the ATP-dependent process of proteasome degradation. Most recently, Benes and associates (2006) performed a post hoc analysis of an extant gene expression profiling database obtained from the hippocampus using a novel methodology with improved sensitivity. Postmortem brain tissue from bipolar disorder patients showed a marked upregulation of 19 out of 44 apoptosis genes; by contrast, the schizophrenia patients showed a downregulation of genes associated with apoptotic injury and death. Additionally, antioxidant genes showed a marked downregulation in bipolar disorder patients, suggesting that accumulation of free radicals might occur in the setting of a previously reported decrease of the electron transport chain in this disorder. Notably, the changes seen in bipolar disorder and schizophrenia patients did not appear to be related to exposure to either neuroleptics or mood stabilizers.

Since a growing body of indirect clinical, genetic and neuroimaging studies implicate mitochondrial dysfunction in the pathophysiology of bipolar disorder and schizophrenia, Kakiuchi and colleagues (2005) assessed mtDNA deletion(s) by comparing the copy number of two regions in mtDNA—nd1 and nd4—by means of real-time quantitative

PCR in the frontal cortex of 84 subjects (30 control, 27 with bipolar disorder, and 27 with schizophrenia). Although they observed no association between mtDNA deletions and the two major mental disorders in the frontal cortex, they found that the relative amount of mtDNA decreased with age in bipolar disorder ($p = .016$); these results suggest inherited or acquired abnormalities in the system maintaining replication of mtDNA may play a role in the pathophysiology of bipolar disorder.

We have outlined here evidence to support the contention that neurotrophic signaling (and its downstream effects on mitochondrial function) is integral to many facets of bipolar disorder. It needs to be reiterated that although some studies suggest a parent-of-origin effect, we are not suggesting that bipolar disorder is a classic mitochondrial disorder, rather, that many of the upstream abnormalities (likely nuclear genome codes) converge to regulate mitochondrial function implicated in both abnormalities of neurotransmitter synaptic plasticity and long-term cellular resilience. Indeed, Stork and Renshaw (2005) have also posited that the many facets of the complex neurobiology of bipolar disorder can be fit into a more cohesive bioenergetic and neurochemical model. Specifically—similar to what we are proposing here—they propose that the existence of mitochondrial dysfunction in bipolar disorder involves impaired oxidative phosphorylation, a resultant shift toward glycolytic energy production, a decrease in total energy production and/or substrate availability, and altered phospholipid metabolism.

How then is one to conceptualize neurotrophic signaling and mitochondrial-associated impairments of cellular plasticity and resilience in the pathophysiology and treatment of severe mood disorders (bipolar disorder and major depression)? There is growing appreciation of the diverse functions that mitochondria play in regulating integrated CNS function. Mitochondria are intracellular organelles best known for their critical roles in regulating energy production via oxidative phosphorylation, regulation of intracellular Ca^{2+} , and mediation of apoptosis. However, increasing evidence suggests that mitochondria may be integrally involved in the general processes of synaptic plasticity. Indeed, increased synaptic activity has been shown to induce the expression of mitochondrial-encoded genes, indicating that the regulation of metabolism is an important component in the long-term regulation of synaptic strength. All in all, these findings suggest that mitochondrial Ca^{2+} sequestration has a key role in modulating the tone of synaptic plasticity in a variety of neuroanatomical regions, including those implicated in the pathophysiology of anxiety disorders. Regulation of mitochondrial function is likely to play important roles in regulating synaptic strength and in neuronal circuitry—mediating complex behaviors. In support of this contention, Hovatta and associates (2005) have

used a combination of behavioral analysis of six inbred mouse strains with quantitative gene expression profiling of several brain regions. Intriguingly, they found that genes involved in oxidative stress metabolism were related to complex affective behaviors. Together, these results suggest that the mitochondrially mediated impairments of plasticity observed in bipolar disorder may have ramifications for not only long-term disease progression, course of illness, and functional impairments but also “here-and-now” symptomatology. Indeed, it has recently been demonstrated that short-term lithium-induced increases in subgenual prefrontal cortex gray matter were related to treatment response (see below). These observations raise the interesting possibility that enhancing mitochondrial vigor may represent an important adjunctive strategy for the optimal long-term treatment of bipolar disorder and perhaps of highly recurrent depression as well. Novel molecular targets to improve mitochondrial function include pharmacological attempts to bypass defects in the respiratory chain, scavenging excessive oxygen radicals and enhancers of mitochondrial membrane stabilization, including, theoretically, inhibitors of the permeability transition pore (PTP). In addition, strategies already being investigated or under consideration include MAPK phosphatase inhibitors that increase expression of the anti-apoptotic protein Bcl-2, presynaptic glutamate receptor subtypes that attenuate glutamate release, AMPA potentiators that increase BDNF expression, and NMDA antagonists that enhance cellular plasticity.

Next we discuss the consistent body of data demonstrating that mood stabilizers (most notably lithium and valproate) robustly regulate the expression and function of genes and proteins associated with major roles in neuronal plasticity and resilience.

Activation of the Extracellular Receptor-Coupled Kinase Signaling Cascade by Lithium and Valproate

In view of the important role of the ERK signaling cascade in mediating long-term neuroplastic events (see Fig. 14–20), a series of studies has been undertaken to investigate the effects of lithium and valproate on this signaling cascade.⁷⁹ These studies have shown that lithium and valproate, at therapeutically relevant concentrations, robustly activate the ERK MAPK cascade in human neuroblastoma SH-SY5Y cells (Yuan et al., 2001; Chen et al., 2002). Follow-up studies have recently shown that, similar to the effects observed in neuroblastoma cells in vitro, chronic lithium and valproate also robustly increase the levels of activated ERK in areas of brain that have been implicated in the pathophysiology and treatment of bipolar disorder—the anterior cingulate cortex and hippocampus (Chen et al., 2002; Einat et al., 2003b; Hao et al., 2004). In animal behavioral studies it was found that chemical inhibition of the brain

Neurotrophins and the ERK MAP Kinase Signaling Cascade

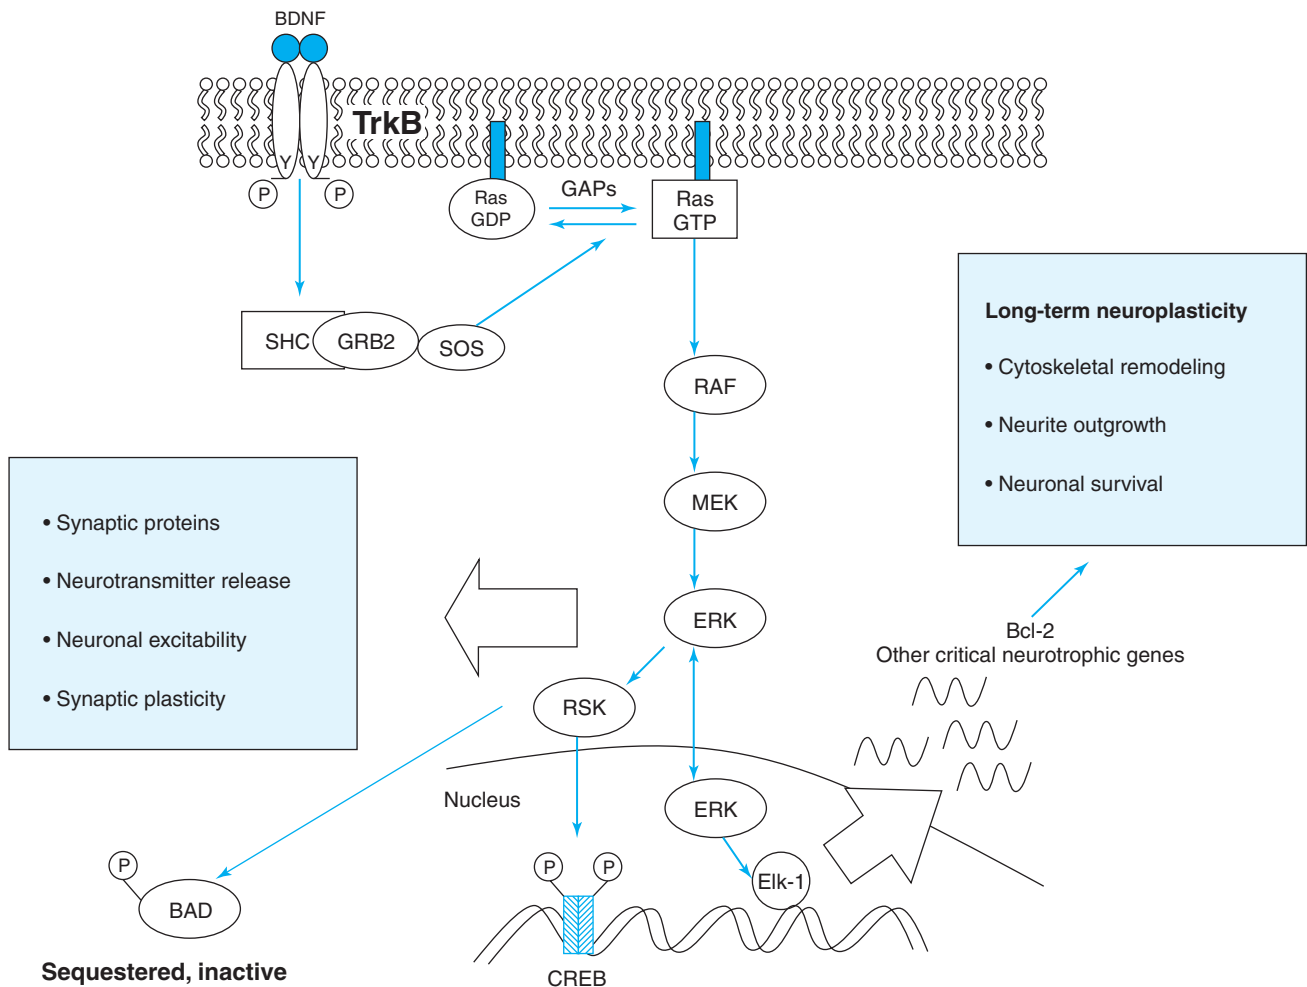

Figure 14–20. The influence of neurotrophic factors on cell survival, as mediated by activation of the mitogen-activated protein (MAP) kinase cascade. Activation of neurotrophic factor receptors, also referred to as Trks, results in activation of the MAP kinase cascade via several intermediate steps, including phosphorylation of the adaptor protein SHC and recruitment of the guanine nucleotide exchange factor SOS. This results in activation of the small guanosine triphosphate-binding protein Ras, which leads to activation of a cascade of serine/threonine kinases. This includes Raf, MAP kinase kinase (MEK), and MAP kinase (also referred to as extracellular response kinase, or ERK). Ras also activates the PI_3 kinase pathway, a primary target of which is the enzyme glycogen synthase kinase (GSK-3). Activation of the PI_3 kinase pathway deactivates GSK-3. GSK-3 has multiple targets in cells including transcription factors (β -catenin and C-Jun) and cytoskeletal elements such as tau. Many of the targets of GSK-3 are pro-apoptotic when activated. Thus, deactivation of GSK-3 via activation of the PI_3 kinase pathway results in neurotrophic effects. Lithium inhibits GSK-3 and this may be partially responsible for lithium's psychotropic effects. One target of the MAP kinase cascade is RSK, which influences cell survival in at least two ways. Rsk phosphorylates and inactivates the pro-apoptotic factor BAD. RSK also phosphorylates CREB and thereby increases the expression of the anti-apoptotic factor Bcl-2 and brain-derived neurotrophic factor (BDNF). (Source: Manji et al., 2003a.)

ERK pathway in rats reduces immobility in the forced swim test and increased locomotive and explorative activity in the large open field test. These studies also showed that ERK1 (one of two ERK subtypes) knockout mice have brain region-specific functional deficits of the ERK pathway and exhibit reduced immobility in the forced swim test, increased activity in the open field test, persistently increased home-cage wheel running activity for at least 30

days, and enhanced response to psychostimulants (reviewed in Chen and Manji, 2006). Very recent studies have therefore examined the role of the ERK pathway as a behavioral modulator in left anterior cingulate cortex, one of the brain regions being implicated in the pathophysiology of mood disorders by human brain imaging and post-mortem studies (Chen and Manji, 2006). Rats chronically infused with an ERK pathway inhibitor directly to left

anterior cingulate cortex showed significant reduction of immobility in the forced swim test, increase in locomotive activities in the open field test, and enhancement of locomotive response to amphetamine. To further verify these findings, a method was developed to regionally express dominant negative ERK1 (to inhibit function of endogenous ERK) in left anterior cingulate cortex by injection of lentiviral vectors. Compared to the controls, rats injected with a dominant negative ERK1 expression vector showed reduced immobility in the forced swim test, significant increases in activity in the open field test, significant increases in numbers of arm entries (without changing overall time spent in either open or closed arms) in the elevated plus maze test, and a significantly higher response to amphetamine. These rats also consumed more sweetened water in the sucrose and saccharin preference tests than did control rats. Taken together, this body of data supports the role of the anterior cingulate in modulation of behaviors relevant to mood disorders; furthermore, the ERK pathway in the left anterior cingulate cortex is one of the intracellular loops of neuronal circuitry that mediates hedonic and locomotive and explorative activities.

As discussed above, one of the major downstream targets of the ERK MAP kinase cascades is arguably one of the most important neuroprotective proteins, Bcl-2. Bcl-2 is the acronym for the B-cell lymphoma/leukemia-2 gene. This gene was first discovered because of its involvement in B-cell malignancies, where chromosomal translocations activate the gene in the majority of follicular non-Hodgkin's B-cell lymphomas (discussed in Manji et al., 1999b, and references therein). Although the precise mechanisms of action of Bcl-2 are unknown, it is now clear that Bcl-2 is a protein that inhibits both apoptotic and necrotic cell death induced by diverse stimuli. Indeed, it is likely that Bcl-2 is very effective against diverse insults because many different several cellular mechanisms are involved in its protective effects; these likely include sequestering of the proforms of caspases, inhibition of the effects of caspase activation, antioxidant effects, enhancement of mitochondrial calcium uptake, and attenuation of the release of calcium and cytochrome c from mitochondria (reviewed in Adams and Cory, 1998).

A role for Bcl-2 in protecting neurons from cell death is now supported by abundant evidence; Bcl-2 has been shown to protect neurons from a variety of insults in vitro including growth factor deprivation, glucocorticoids, ionizing radiation, and oxidant stressors such as hydrogen peroxide, tert-butylhydroperoxide, reactive oxygen species, and buthionine sulfoxamine (Adams and Cory, 1998; Bruckheimer et al., 1998). In addition to these potent in vitro effects, Bcl-2 has also been shown to prevent cell death in numerous studies in vivo. In the absence of pharmacological

means of increasing CNS Bcl-2 expression until recently (see below), all the studies up to this time have used transgenic mouse models or viral vector-mediated delivery of the Bcl-2 gene into the CNS. In these models, Bcl-2 overexpression has been shown to prevent motor neuron death induced by facial nerve axotomy and sciatic nerve axotomy, save retinal ganglion cells from axotomy-induced death, protect against the deleterious effects of MPTP or focal ischemia, and protect photoreceptor cells from two forms of inherited retinal degeneration. Interestingly, neurons that survive ischemic lesions or traumatic brain injury in vivo show upregulation of Bcl-2.⁸⁰ Overexpression of Bcl-2 has also been shown to prolong survival and attenuate motor neuron degeneration in a transgenic animal model of amyotrophic lateral sclerosis (Kostic et al., 1997).

Most recently, it has been clearly demonstrated that not only does Bcl-2 overexpression protect against apoptotic and necrotic cell death, it can also promote *regeneration* of axons in the mammalian CNS, leading to the intriguing postulate that Bcl-2 acts as a major regulatory switch for a genetic program that controls the *growth* of CNS axons (Chen et al., 1997). Since Bcl-2 has also recently been shown to promote neurite sprouting, it has been convincingly argued that increasing CNS Bcl-2 levels may represent a very effective therapeutic strategy for the treatment of many neurodegenerative diseases (Chen et al., 1997). As articulated already, the only means of therapeutically increasing CNS Bcl-2 levels in the adult brain has been by the use of complex gene transfer methodologies. Thus pharmacological means of robustly increasing CNS Bcl-2 levels represents a major potential advance for the long-term treatment of certain neurodegenerative disorders. In the next section we discuss the exciting findings demonstrating that Bcl-2 is robustly increased by lithium and valproate.

Robustly Increased Expression of Bcl-2 with Lithium and Valproate

Chronic treatment of rats with therapeutic doses of lithium and valproate produced a doubling of Bcl-2 levels in the frontal cortex, effects due primarily to a marked increase in the number of Bcl-2-immunoreactive cells in layers II and III of the anterior cingulate cortex (Chen et al., 1999; Manji et al., 1999a, 2000a; see Fig. 14–21). Interestingly, the importance of neurons in the anterior cingulate has recently been emphasized, since these areas are important for providing connections with other cortical regions and are targets for subcortical input (Chapter 9). Chronic lithium was also found to markedly increase the number of Bcl-2 immunoreactive cells in the dentate gyrus and striatum (Manji et al., 1999b), and detailed immunohistochemical studies following chronic valproate treatment are currently under way.

Saline Control

Valproate

Lithium

Bcl-2 Peptide Blocking

Figure 14–21. Effects of chronic lithium and valproate treatment on Bcl-2 immunolabeling in frontal cortex. Rats were chronically treated with saline, lithium, or valproate, and immunohistochemistry of Bcl-2 was performed in parallel for each of the groups. Chronic lithium and valproate treatment resulted in a doubling of Bcl-2 levels in FCx. (Source: Manji et al., 1999b. Reprinted with permission.)

Subsequent to these findings, lithium was demonstrated to increase Bcl-2 levels in C57BL/6 mice (Chen et al., 1999), human neuroblastoma SH-SY5Y cells in vitro (Manji and Chen, 2000), and rat cerebellar granule cells in vitro (Chen and Chuang, 1999). This latter work was undertaken as part of research investigating the molecular and cellular mechanisms underlying the neuroprotective actions of lithium against glutamate excitotoxicity (see below). The investigators found that lithium produced a remarkable increase in Bcl-2 protein and mRNA levels. Moreover, lithium was found to reduce levels of the pro-apoptotic protein p53 in both cerebellar granule cells (Chen and Chuang, 1999) and SH-SY5Y cells (Lu et al., 1999).

Overall, then, the data clearly show that chronic lithium exposure robustly increases levels of the neuroprotective protein Bcl-2 in areas of rodent frontal cortex, hippocampus, and striatum in vivo, and in cultured cells of both rodent and human neuronal origin in vitro. Furthermore, at least in cultured cell systems, lithium has been demon-

strated to reduce levels of the pro-apoptotic protein p53. Most recently, it has been demonstrated that repeated ECT significantly increases precursor cell proliferation in the dentate gyrus of the adult monkey, effects that appear to be due to increased expression of Bcl-2 (Perera et al., submitted). These results suggest that stimulation of neurogenesis and enhanced expression of Bcl-2 may contribute to the therapeutic actions of ECT. Behavioral studies have also been undertaken to determine if Bcl-2 plays a role in the pathogenesis and treatment of depression (Yuan et al., 2005). Bcl-2 +/- mice and wild-type littermates were studied in the learned helplessness paradigm. Bcl-2 +/- mice and wild-type littermates were also treated with antidepressant citalopram (10 mg/kg/day) acutely and chronically, and responses in the tail suspension and learned helplessness tests were examined. In the learned helplessness test, there was a significantly higher rate of escape failures in the Bcl-2 +/- mice. Furthermore, while chronic citalopram increased escape failures in the wild-type mice, it was without effect in the Bcl-2 +/- mice. Similarly, citalopram was

effective in the tail suspension test but was without effect in the Bcl-2+/- mice. These data demonstrate that Bcl-2+/- mice are insensitive to the SSRI antidepressant citalopram in two animal models of depression, indicating that some of the therapeutic effects of antidepressants may be mediated through actions of Bcl-2. In total, these observations suggest that regulation of Bcl-2-mediated plasticity is likely to play important roles in regulating synaptic strength and neuronal circuitry—mediating complex behaviors (Yuan and Manji, unpublished observations).

Neuroprotective Effects of Lithium: Compelling Preclinical Evidence

Lithium's robust effects on Bcl-2 and GSK-3 β in the mature CNS indicate that it may possess significant neuroprotective properties. Indeed, several studies conducted before the identification of Bcl-2 or GSK-3 β as targets for lithium's actions had already demonstrated the drug's neuroprotective properties.⁸¹ The protective effects of lithium have been investigated in a number of *in vitro* studies, particularly those using rat cerebellar granule cells, PC12 cells, and human neuroblastoma SH-SY5Y cells. In these studies, lithium was shown to protect against the deleterious effects of glutamate, NMDA receptor activation, low potassium, and toxic concentrations of anticonvulsants (see Box 14–17). Lithium also protected PC12 cells from serum and nerve growth factor deprivation (Volonte and Rubenstein, 1993), protected both PC12 cells and human neuroblastoma SH-SY5Y cells from ouabain toxicity (Li et al., 1994), and protected SH-SY5Y cells from cell death induced by both thapsigargin (which mobilizes intracellular Ca²⁺) and MPP⁺. Most recently, lithium has been shown to protect cultured neurons from beta-amyloid-induced cell death (Alvarez et al., 1999) and to protect against the deleterious effects of GSK-3 β overexpression coupled with staurosporine addition (Bijur et al., 2000).

In addition to studies demonstrating lithium's protective effects *in vitro*, there have been a number of investigations of its neuroprotective effects *in vivo*. In this context, the effects of lithium on the biochemical and behavioral manifestations of excitotoxic lesions of the cholinergic system have been investigated (Pascual and Gonzalez, 1995; Arendt et al., 1999). These studies have demonstrated that lithium pretreatment attenuates both the behavioral deficits (passive avoidance and ambulatory behavior) and the reduction in choline acetyl transferase activity associated with forebrain cholinergic system lesions (Pascual and Gonzalez, 1995).⁸²

In another study investigating lithium's effects against excitotoxic insults, it was demonstrated that lithium attenuated the kainic acid–induced reduction in glutamate decarboxylase levels and [³H]D-aspartate uptake (Sparapani et al., 1997). Chronic lithium has also been shown to exert dramatic

BOX 14–17. Neurotrophic and Neuroprotective Effects of Lithium

Protects cultured cells of rodent and human neuronal origin *in vitro* from

- Glutamate, NMDA
- High concentrations of calcium
- MPP⁺
- β -amyloid
- Aging-induced cell death
- HIV regulatory protein, Tat
- Glucose deprivation
- Growth factor or serum deprivation
- Toxic concentrations of anticonvulsants
- Platelet activating factor (PAF)
- Aluminum toxicity
- Low K⁺
- C2-ceramide
- Ouabain
- GSK-3 β + staurosporine/heat shock

Enhances hippocampal neurogenesis in adult mice

Protects rodent brain *in vivo* from

- Cholinergic lesions
- Radiation injury
- Middle cerebral artery occlusion (stroke model)
- Quinolinic acid (Huntington's model)

Human Effects

- No subgenual prefrontal cortex gray matter volume reductions in cross-sectional MRI studies
- No reductions in amygdala glial density in postmortem cell counting studies
- Increased total gray matter volumes on MRI compared to untreated bipolar disorder patients in cross-sectional studies
- Increased NAA (marker of neuronal viability) levels in bipolar disorder patients in longitudinal studies
- Increased gray matter volumes in bipolar disorder patients in longitudinal studies

Source: Gould and Manji, 2002b.

protective effects against middle cerebral artery occlusion, reducing not only the infarct size (by 56 percent) but also the neurological deficits (abnormal posture and hemiplegia) (Nonaka and Chuang, 1998). Most recently, the same group found that chronic *in vivo* lithium treatment robustly protected neurons in the striatum from quinolinic acid–induced toxicity in a putative model of Huntington's disease (Senatorov et al., 2004; see Fig. 14–22).

In addition to its effects on ERK MAPK, Bcl-2, and GSK-3 β , lithium's effects on other signaling pathways and

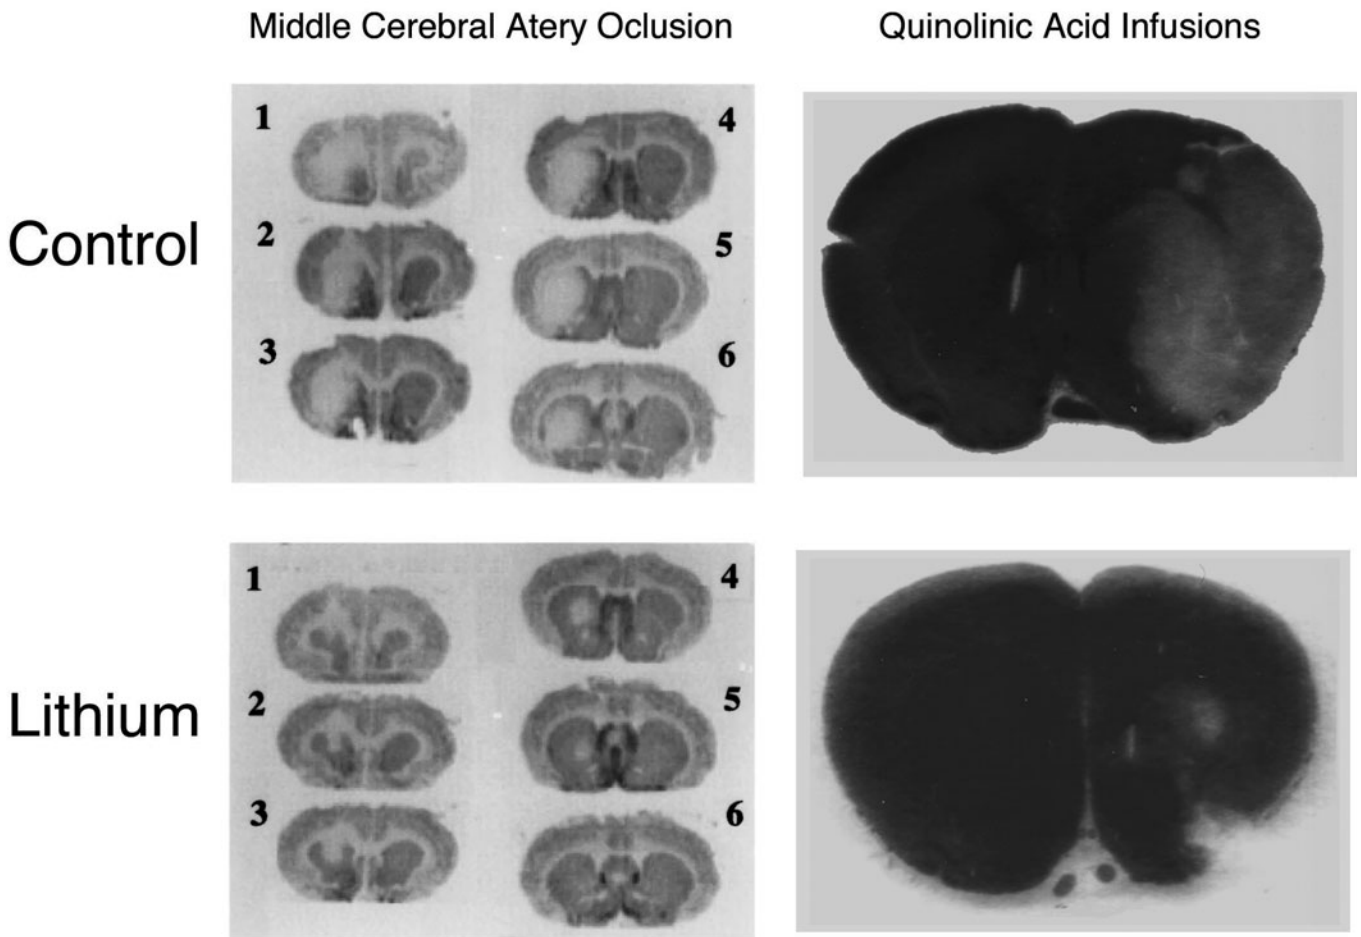

Figure 14–22. Chronic lithium protects against quinolinic acid (QA)–induced toxicity and against middle cerebral artery occlusion. *Left panel:* Sixteen days of lithium pretreatment decreases the size of QA-induced striatal lesion determined by GAD₆₇ mRNA in situ hybridization. Rats ($n=10$) were subcutaneously pre-injected with lithium chloride (LiCl) for 16 days and then intrastrially infused with QA (30nmol). Control rats ($n=8$) received subcutaneous injections of normal saline instead of LiCl. Animals were killed 7 days after QA infusion and brains were sectioned for in situ hybridization using a ³³P-labeled antisense oligonucleotide probe complementary to 67kDa GAD mRNA. Shown here are autoradiograms of GAD₆₇ mRNA in situ hybridization from a typical saline control and lithium-pretreated experiment. *Right panel:* Chronic lithium treatment protects against ischemic brain damage in a focal cerebral ischemia model in rats. Representative photomicrographs show ischemic brain damage in a saline-treated control (top) and LiCl-treated rat (bottom) 24 hours after left middle cerebral artery (MCA) occlusion. Note that ischemic damage was observed in the cerebral cortex of the frontal, sensorimotor, and auditory areas and in the lateral segment of the caudate nucleus. Chronic lithium reduced the area of ischemic brain damage. (Source: Nonaka and Chuang, 1998; Wei et al., 2001. Reprinted with permission from Lippincott Williams & Wilkins.)

transcription factors (Manji et al., 1995a; Jope, 1999) may contribute to its neuroprotective effects. In this context, it is noteworthy that recent studies have shown that modulation of Akt-1 activity is involved in glutamate excitotoxicity and may play a role in lithium's neuroprotective effects in rat cerebellar granule cells (Chalecka-Franaszek and Chuang, 1999).

Neurotrophic and Neuroprotective Effects of Valproate

Valproate's effects on Bcl-2 and GSK-3 β suggest that this mood stabilizer may also possess neuroprotective/ neurotrophic properties. Additionally, it has been

demonstrated that valproate increases the expression of the molecular chaperone GRP78, a protein that binds Ca²⁺ in the endoplasmic reticulum and protects cells from the deleterious effects of damaged proteins (J. Wang et al., 1999). Although valproate has not been as extensively studied as lithium, a growing body of data suggests that it does indeed exert neuroprotective effects (Bruno et al., 1995; Mark et al., 1995; Mora et al., 1999).

More recent studies have used the SH-SY5Y model system to investigate the protective effects of valproate and lithium. SH-SY5Y cells were incubated with lithium (1.0 mM) or valproate (.6 mM) for 3 days. Cells were then exposed to two different toxins—thapsigargin (which mobilizes intracellular

calcium; .5 mM for 16 hours) or MPP⁺ (25 mM for 16 hours). The mitochondrial dehydrogenase activity that cleaves 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl tetrazolium bromide (MTT) was used to determine cell survival in a quantitative colorimetric assay. It was found that treatment with lithium and valproate exerted significant protective effects against both toxins.

In an extension of their studies, Ren and colleagues recently sought to determine whether valproate, like lithium, exerts protective effects in a middle cerebral artery occlusion (MCAO) stroke model. They found that post-insult treatment with valproate reduced brain infarct size when measured at 24 or 48 hours after the onset of MCAO-induced ischemia (Ren et al., 2004). Valproate also facilitated functional recovery from neurological deficits under these experimental conditions; these effects occurred at a dose (300 mg/kg) similar to that used in animal studies to control seizures. Valproate-induced neuroprotection was further demonstrated by a reduction in MCAO-induced caspase-3 activation in the ischemic area, as shown by immunohistochemistry and western blotting analysis (Ren et al., 2004). These results suggest that valproate neuroprotection in the MCAO model involves anti-apoptotic actions in the ischemic penumbra. It is noteworthy that lithium-induced neuroprotection in the rat MCAO/reperfusion model is also associated with suppression of ischemia-induced caspase-3 activation (Ren et al., 2003; Xu et al., 2003).

Facilitation of Retinal Ganglion Cell Survival and Axon Regeneration with Lithium

Based on the remarkable neurotrophic and neuroprotective effects of lithium, studies were undertaken to determine whether lithium supports the survival and axon regeneration of retinal ganglion cells (RGCs), a model that has been used to study glaucoma, optic nerve neuritis, and the degeneration of RGCs (Chen et al., 1995, 1997; Quigley et al., 1995). In general, following injury, the postnatal mammalian optic nerve, like many other axonal pathways in the CNS, regenerates poorly; most often, injured RGCs undergo apoptotic cell death (Chen et al., 1995, 1997; Quigley et al., 1995). While this regenerative failure has long been attributed to extrinsic inhibitors in the environment of the mature brain, seminal research by the Chen and Tonegawa group (Chen et al., 1995, 1997) demonstrated that mature RGCs lack an intrinsic component to initiate axonal growth following injury, and that this intrinsic component is the neurotrophic protein Bcl-2. Investigators have therefore postulated that a prerequisite for successful regeneration of severed optic nerves in adult mammals is the activation of an intrinsic regenerative mechanism of RGC axons—namely, the induction of Bcl-2 expression in neurons.

Lithium was the first medication demonstrated to robustly upregulate Bcl-2 in rodent brain in vivo and in cells with a human neuronal phenotype (see above). Furthermore, these effects of lithium occur well within its therapeutic range (indeed, robust effects occur at levels less than those required to treat acute mania). Studies were therefore undertaken to determine whether lithium would not only prevent injury-induced degeneration of RGCs and other CNS neurons but also promote the regeneration of their axons (Huang et al., 2002) (see Fig. 14–23). These studies showed that lithium, acting directly on RGCs, supports both neuronal survival and axon regeneration at its established therapeutic concentrations (.5–1.2 mM) (Huang et al., 2002). These intriguing results not only offer new clues to a better understanding of the regulation of retinal and CNS regeneration but also suggest that lithium may have considerable utility in treating retinal and optic nerve neurodegeneration (e.g., glaucoma and optic nerve neuritis) and conditions involving optic nerve damage and/or RGC loss. In view of lithium's well-established safety profile in humans and the fact that robust effects are observed at well-tolerated levels, clinical trials should be undertaken for treatment of these devastating illnesses.

Increases in Hippocampal Neurogenesis with Lithium

As discussed already, through use of a method for labeling cell division directly in the adult human brain, it has been shown that the dentate gyrus (an area where robust lithium-induced increases in Bcl-2 levels are observed) can produce new neurons during adulthood in humans. A large number of the newborn daughter cells are known to die rapidly, likely through apoptosis (Kempermann and Gage, 1999). Thus increasing Bcl-2 levels could enhance the survival of the newborn cells, allowing them to differentiate into neurons. Additionally, Bcl-2 has been shown to have robust effects on the regeneration of CNS axons (Chen et al., 1997).

Programmed cell death is present in neurogenic regions of the adult brain, and a significant portion of the adult-born cells is eliminated during the first months of maturation. Kuhn and colleagues (2005) therefore investigated if overexpression of the anti-apoptotic protein Bcl-2 would improve the survival of neural progenitor cells and, as a consequence, increase neurogenesis in the adult hippocampus. They found that transgenic animals, which express human Bcl-2 under the neuron-specific enolase promoter (NSE-huBcl-2), show a significant reduction of apoptotic cells in the hippocampal granule cell layer to about half of the wild-type level. Furthermore, they found that the rate of adult neurogenesis is doubled in the dentate gyrus of Bcl-2-overexpressing mice, as demonstrated by quantification of progenitor cells with DCX and of new neurons through bromodeoxyuridine (BrdU)/neuronal nuclei antigen (NeuN) double-labeling.

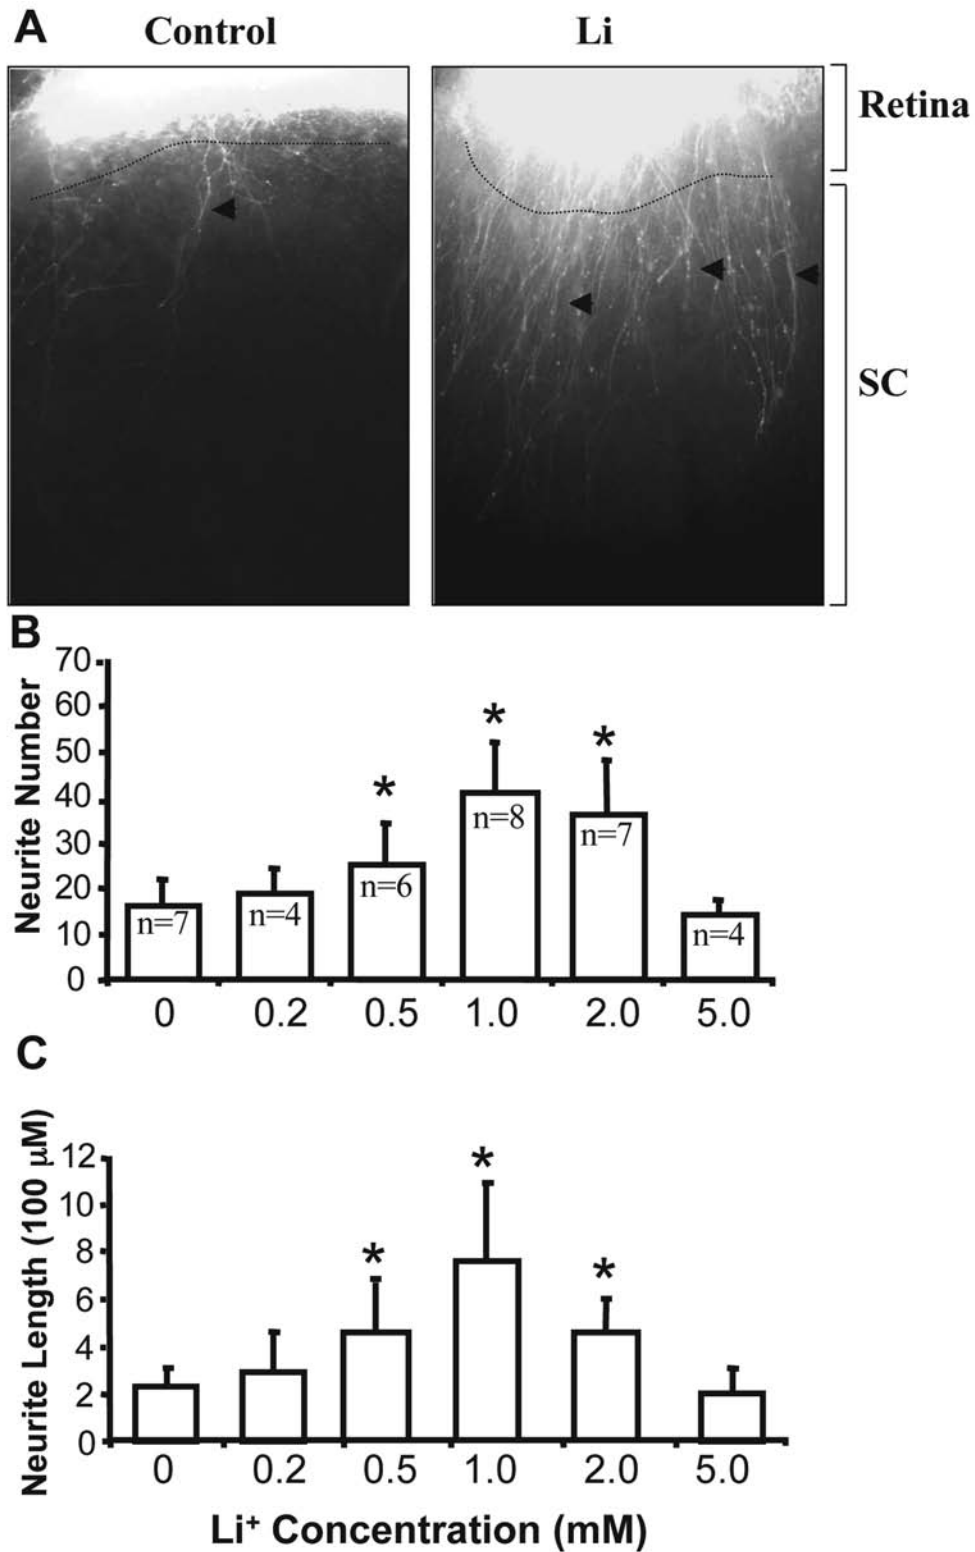

Figure 14–23. Li⁺ promotes retinal ganglion cell (RGC) axon regeneration in a dose-dependent manner in culture. **A:** Epifluorescence photomicrographs of representative retina-brain slice cocultures in the absence and presence of lithium chloride (LiCl). Regenerating axons were labeled by placing DiI (a lipophilic fluorescent label) into retinal explants and were visualized by fluorescence microscope. Arrows indicate labeled axons growing into the brain slices. **B, C:** Dose-response curve of Li⁺ on axon regeneration. **B:** The number of labeled axons extending into the brain slices. **C:** Quantification of the longest distances of axon regeneration into the brain slices, measured from the interfaces of the retinal explants and brain slices. **p* < .05 compared with control. In view of Bcl-2's major neuroprotective and neurotrophic role, a study was undertaken to determine whether lithium, administered at therapeutically relevant concentrations, affects neurogenesis in adult rodent brain. To investigate the effects of chronic lithium on neurogenesis, mice were treated with therapeutic lithium (plasma levels $.97 \pm .20$ mM) for approximately 4 weeks. After treatment with lithium for 14 days, the mice were administered single doses of BrdU, a thymidine analog that is incorporated into the DNA of dividing cells, for 12 consecutive days. Lithium treatment continued throughout the duration of the BrdU administration. Following BrdU immunohistochemistry (Chen et al., 2000), three-dimensional cell counting was performed with a computer-assisted image analysis system (see Rajkowska, 2000). This system is based on the optical disector method and estimates the number of cells independent of section thickness and cell shape. It was found that chronic lithium administration does in fact result in an increase in the number of BrdU-positive cells in the dentate gyrus (Chen et al., 2000) (see Fig. 14–24). Moreover, approximately two-thirds of the BrdU-positive

cells also double-stained with the neuronal marker NeuN, confirming their neuronal identity. Double-staining of BrdU and Bcl-2 was also observed; studies with Bcl-2 transgenic animals are currently under way to delineate the role of Bcl-2 overexpression in the enhanced hippocampal neurogenesis. These results have also been replicated by Kim and associates (2004), who have demonstrated that lithium selectively increases neuronal differentiation of hippocampal neural progenitor cells both in vitro and in vivo. Most recently, Perera and colleagues (2006, submitted) examined the effects of repeated electroconvulsive shock (the animal model of ECT) on dentate neurogenesis in nonhuman primates. Similar to the effects observed with chronic lithium (see above), they found that ECS-induced neurogenesis was accompanied by increases in Bcl-2 levels.

The ability of valproate to promote neurogenesis from embryonic rat cortical or striatal primordial stem cells was recently examined; 6 days of valproate increased by up to five-fold the number and percentage of tubulin β III-immunopositive neurons, increased neurite outgrowth, and decreased by five-fold the number of astrocytes

Figure 14–24. Effects of chronic lithium neurogenesis in the dentate gyrus of adult mice. C57BL/6 mice were treated with lithium for 14 days and then received once-daily bromodeoxyuridine (BrdU) injections for 12 consecutive days while lithium treatment continued. Twenty-four hours after the last injection, the brains were processed for BrdU immunohistochemistry. Cell counts were performed in the hippocampal dentate gyrus at three levels along the dorsoventral axis in all the animals. BrdU-positive cells were counted using unbiased stereological methods. Chronic lithium produced a significant 25% increase in BrdU immunolabeling in both right and left dentate gyrus ($p < .05$). Many BrdU-labeled neurons also stained with NeuN, a neuron-specific marker. (Source: Chen et al., 2000; Gray et al., 2003. Reprinted with permission from Blackwell Publishing Ltd.)

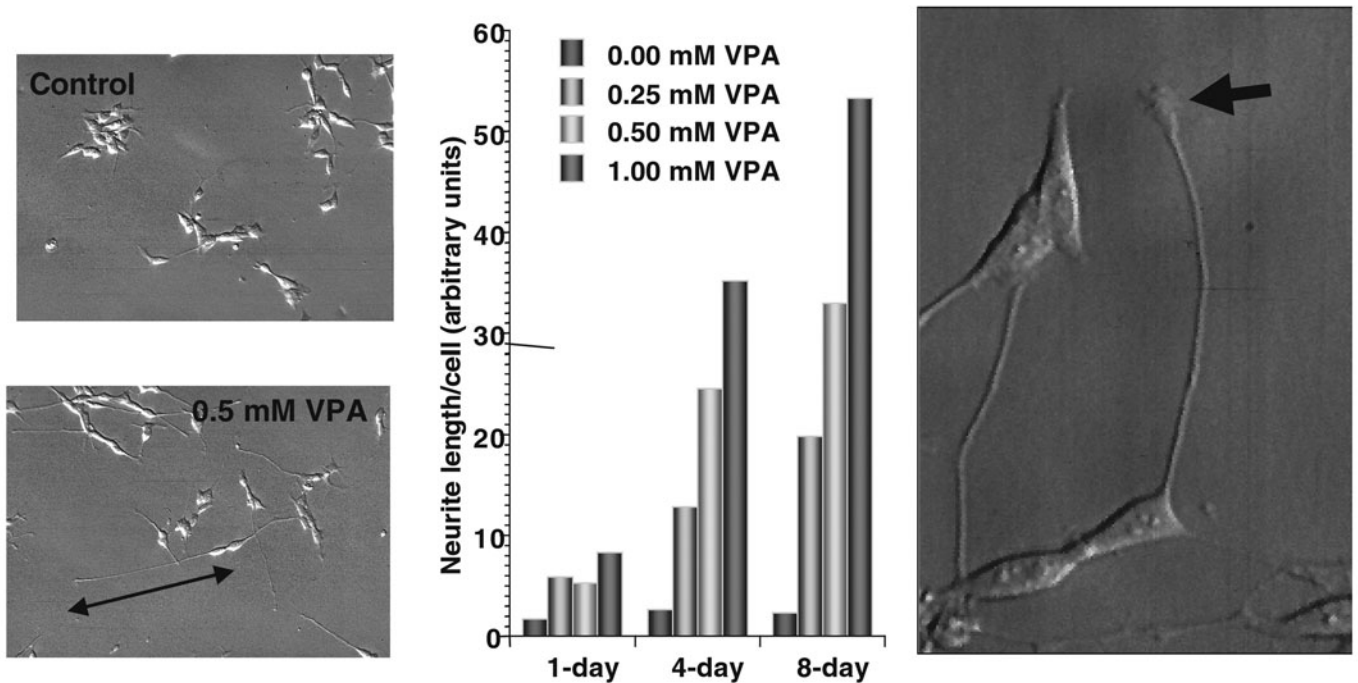

Figure 14–25. Valproate promotes neurite growth in a time- and concentration-dependent manner. The photographs from a representative experiment were taken after 1-, 4-, 8-day treatments with valproate (VPA). Data shown in bar graph are mean \pm standard error of 30–100 cells measured in the photographs. Similar results were obtained from two additional independent experiments. Arrow in right panel indicates growth cone. (Source: Adapted from Yuan et al., 2001. Reproduced with permission of American Society for Biochemistry and Molecular Biology.)

without changing the number of cells (Laeng et al., 2004). Valproate also promoted neuronal differentiation in human fetal forebrain stem cell cultures. Intriguingly, the neurogenic effects of valproate on rat stem cells exceeded those obtained with BDNF or NT-3. Similar effects were observed with lithium, but not carbamazepine. Most of the newly formed neurons were GABAergic, as shown by 10-fold increases in neurons that immunostained for GABA and the GABA-synthesizing enzyme GAD65/67. The enhancement of GABAergic neuron numbers, neurite outgrowth, and phenotypic expression via increases in the neuronal differentiation of neural stem cells may contribute to the therapeutic effects of valproate in the treatment of bipolar disorder. (Figure 14–25 shows valproate’s promotion of neurite outgrowth.)

Increased N-acetylaspartate and Gray Matter with Lithium

To investigate the potential neurotrophic effects of lithium in humans more definitively, a longitudinal clinical study was undertaken with proton MRS to quantitate N-acetylaspartate (NAA) levels. NAA is a putative neuronal marker, localized to mature neurons and not found in mature glial cells, CSF, or blood. A number of studies have now shown that initial abnormally low brain NAA measures may increase and even normalize with remission

of CNS symptoms in disorders such as demyelinating disease, amyotrophic lateral sclerosis, mitochondrial encephalopathies, and HIV dementia. NAA is synthesized within mitochondria, and inhibitors of the mitochondrial respiratory chain decrease NAA concentrations, effects that correlate with reductions in ATP and oxygen consumption (Manji et al., 2000a). Thus, NAA is now generally regarded as a measure of neuronal viability and function, rather than strictly as a marker for neuronal loss per se (for an excellent review of NAA, see Tsai and Coyle, 1995).

It has been found that chronic lithium administration at therapeutic doses increases NAA concentration in the human brain in vivo (Moore et al., 2000). This finding provides intriguing indirect support for the contention that, similar to observations in rodent brain and in human neuronal cells in culture, chronic lithium increases neuronal viability and function in the human brain. Furthermore, a striking correlation of approximately .97 between lithium-induced NAA increases and regional voxel gray matter content was observed (Moore et al., 2000), thereby providing evidence for colocalization with the region-specific Bcl-2 increases observed (e.g., gray versus white matter) in rodent brain cortices. These results suggest that chronic lithium may exert not only robust neuroprotective effects (as has been demonstrated in a variety

of preclinical paradigms) but also neurotrophic effects in humans (see Fig. 14–26).

In follow-up studies to the above work on NAA, it was hypothesized that, in addition to increasing functional neurochemical markers of neuronal viability, lithium-induced increases in Bcl-2 would lead to neuropil increases and thus to increased brain gray matter volume in bipolar patients. In this clinical investigation, brain tissue volumes were examined with high-resolution three-dimensional MRI and validated quantitative brain tissue segmentation methodology to identify and quantify the various components by volume, including total brain white and gray matter content. Measurements were made at baseline (medication-free, after a minimum 14-day washout) and then repeated after 4 weeks of lithium at therapeutic doses. This study showed that chronic lithium significantly increases total gray matter content in the human brain of patients with bipolar disorder (see Fig. 14–27). No significant changes were observed in brain white matter volume or in quantitative measures of regional cerebral water content, thereby providing strong evidence that the observed increases in gray matter content are due to neurotrophic effects and not to any possible cell swelling and/or osmotic effects associated with lithium treatment. Most recently, to investigate the clinical significance of these findings, a longitudinal study was performed exploring neurotrophic effects of the mood stabi-

lizer lithium via high-resolution volumetric MRI in well-characterized bipolar depressed subjects ($n=28$) at baseline (medication-free) and following chronic lithium administration (4 weeks) (Moore et al., 2006). Total brain gray matter, prefrontal gray matter, and left subgenual prefrontal gray matter were determined by means of validated semi-automated segmentation and region-of-interest methodology. Significant increases in total brain gray matter in bipolar subjects were observed following chronic lithium administration, confirming the previous preliminary study. Regional analyses in the bipolar subjects revealed significant differences between responders (greater than 50 percent decrease in HAM-D) and nonresponders; only responders showed increases in gray matter in the prefrontal cortex and left subgenual prefrontal cortex (Moore et al., 2006). The increase in gray matter in these areas that are specifically implicated in the neuropathophysiology of bipolar disorder in various neuroimaging and postmortem neuropathology investigations suggests that the observed effects may be linked to clinical response. The findings also support the notion that future development of treatments more directly targeting molecules in critical CNS pathways regulating cellular plasticity hold promise as novel, improved long-term treatments for mood disorders (see Fig. 14–28).

It is striking that lithium has such robust effects on the cytoprotective protein Bcl-2, exerts neuroprotective effects in

Figure 14–26. Mechanism by which lithium may increase *N*-acetyl-aspartate (NAA) levels. Lithium, via its effects on Bcl-2 and glycogen synthase kinase 3 β (GSK-3 β), may exert major neurotrophic effects, resulting in neuropil increases, accompanied by increases in NAA levels. ERK = extracellular receptor-coupled kinase. (Source: Manji et al., 2000b. Reprinted with permission from Elsevier.)

Lithium Increases Gray Matter

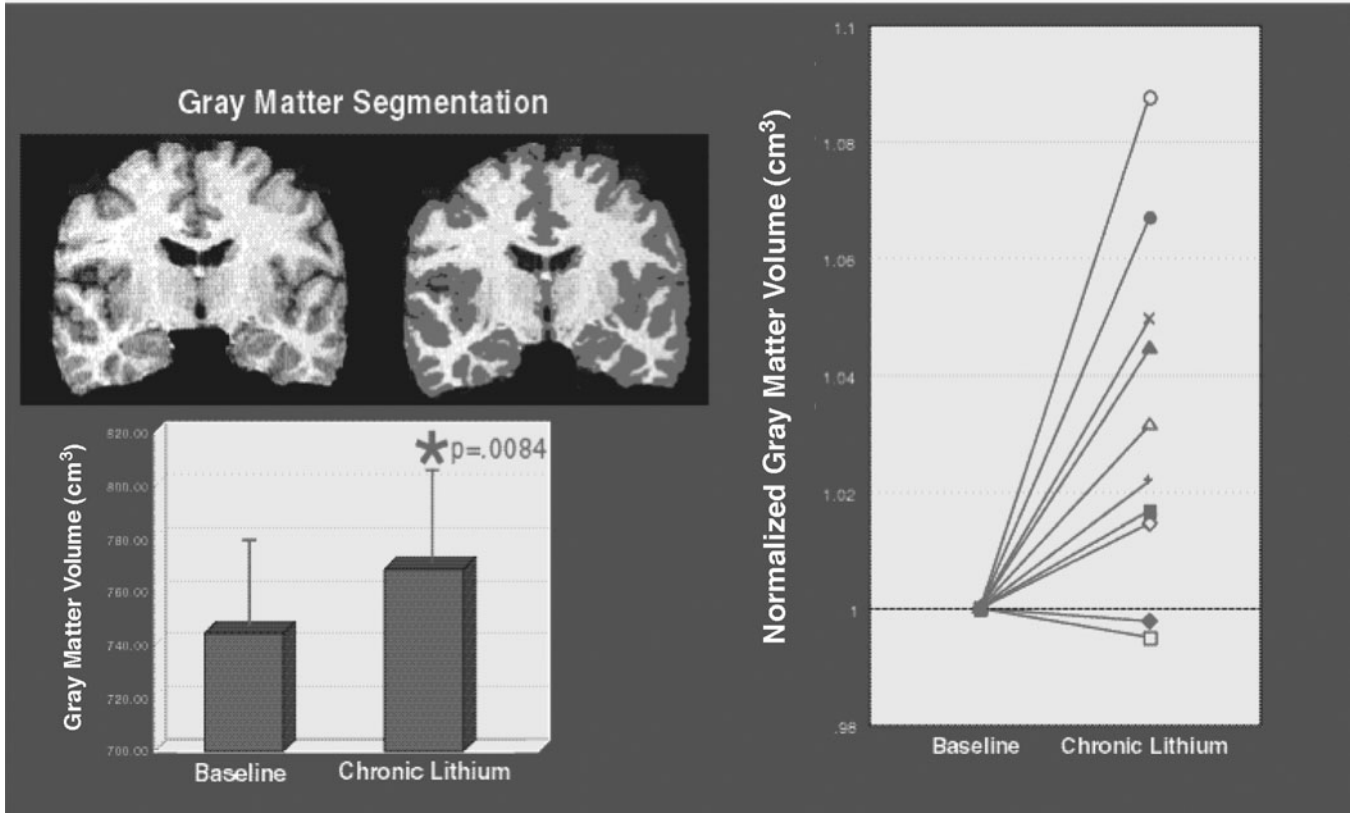

Figure 14–27. Brain gray matter volume is increased following 4 weeks of lithium administration at therapeutic levels in patients with bipolar disorder. Brain tissue volumes were examined by means of high-resolution three-dimensional MRI and validated quantitative brain tissue segmentation methodology to identify and quantify the various components by volume, including total brain white and gray matter content. Measurements were made at baseline (medication-free, after a minimum 14-day washout) and then repeated after 4 weeks of lithium at therapeutic doses. Chronic lithium significantly increases total gray matter content in the human brain of patients with bipolar disorder. No significant changes were observed in brain white matter volume or in quantitative measures of regional cerebral water. (Source: Gould and Manji, 2002b. Reprinted by permission of SAGE Publications, Inc.)

a variety of paradigms, and actually increases gray matter volume in humans. These exciting results suggest that lithium may have utility in the treatment of a variety of neuropsychiatric disorders associated with cell atrophy and loss and impairment of cellular resilience. One obvious concern, however, is lithium's tolerability, especially in patients with neurodegenerative disorders. A series of studies was therefore undertaken to determine whether the chronic administration of lithium at low doses also regulates Bcl-2 expression. These studies found that chronic lithium administration (4 weeks) at doses that produce plasma levels of approximately .35 mM (below the threshold for CNS-mediated side effects) robustly increased Bcl-2 levels in rat frontal cortex and hippocampus (see Fig. 14–29) and hippocampus. Furthermore, there is accumulating evidence suggesting that lithium exerts neuroprotective effects at low doses. Thus, 0.5 mM lithium has been shown to protect cultured cerebellar gran-

ule cells from glutamate excitotoxicity and to decrease levels of the pro-apoptotic protein p53. In middle cerebral artery occlusion, an *in vivo* model of stroke, lithium has also been shown to offer significant protection at .5 milliequivalents (mEq)/kg. Of particular interest, a recent study demonstrated that cortical neurons are even more potently protected from excitotoxicity, with significant increases in viability occurring as low as .1 mM. Overall, the data clearly suggest that lower than traditional antimanic doses of lithium have neurotrophic and neuroprotective effects, and may thus have utility as adjunctive treatment for neuropsychiatric disorders associated with cell loss and atrophy.

Regulation of Cell Survival Pathways with Antidepressants

Seminal studies from the Duman group have investigated the possibility that the factors involved in neuronal atrophy

Figure 14–28. Neurotrophic mechanisms in depression. Severe stress causes several changes in hippocampal pyramidal neurons, including a reduction in their dendritic arborizations, and a reduction in brain-derived neurotrophic factor (BDNF) expression (which could be one of the factors mediating the dendritic effects). Antidepressants increase dendritic arborizations and BDNF expression of these hippocampal neurons via growth factor cascades. By these actions, antidepressants may reverse and prevent the actions of stress on the hippocampus and ameliorate certain symptoms of depression. VPA = valproate. (Source: Adapted from Nestler et al., 2002a. Reprinted with permission from Elsevier.)

and survival could be the target of antidepressant treatment (Duman et al., 1999; D'Sa and Duman, 2002) (see Fig. 14–30). These studies demonstrated that one pathway involved in cell survival and plasticity, the cAMP–CREB cascade, is upregulated by antidepressant treatment (Duman et al., 1999).

Preclinical studies have also demonstrated that antidepressant treatment *in vivo* increases CREB phosphorylation and cAMP response element–mediated gene expression in mouse limbic brain regions (Thome et al., 2000). Upregulation of CREB and BDNF occurs in response to several different classes of antidepressant treatments, including norepinephrine- and serotonin-selective reuptake inhibitors and electroconvulsive shock, indicating that the cAMP–CREB cascade and BDNF are common postreceptor targets of these therapeutic agents (Nibuya et al., 1995, 1996) (see Fig. 14–31). In addition, upregulation of CREB and BDNF is dependent on chronic treatment, consistent with the therapeutic action of antidepressants (reviewed in

Nestler et al., 2002b; Duman, 2004; Berton and Nestler, 2006). A role for the cAMP–CREB cascade and BDNF in the actions of antidepressant treatment is also supported by studies demonstrating that upregulation of these pathways increases performance in behavioral models of depression (Duman et al., 1999). It has been observed as well that induced CREB overexpression in the dentate gyrus results in an antidepressant-like effect in the learned helplessness paradigm and the forced swim test in rats (A. Chen et al., 2001). Indirect human evidence comes from studies showing increased hippocampal BDNF expression in postmortem brain of subjects treated with antidepressants at the time of death compared with untreated subjects (B. Chen et al., 2001).

In elegant studies from the Nestler laboratory, mice were administered chronic social defeat stress followed by chronic imipramine (a tricyclic antidepressant) (Tsankova et al., 2006). Adaptations at the levels of gene expression and chromatin remodeling of five BDNF splice variant mRNAs

(I–V) and their unique promoters in the hippocampus were then studied. Defeat stress induced lasting downregulation of BDNF transcripts III and IV and robustly increased repressive histone methylation at their corresponding promoters. Chronic imipramine reversed this downregulation and increased histone acetylation at these promoters (Tsankova et al., 2006). As we discuss in greater detail later, these experiments underscore an important role for epigenetic factors in the pathophysiology of mood disorders, and they highlight the therapeutic potential for histone methylation and deacetylation inhibitors.

The data reviewed here clearly show that molecules in neurotrophic signaling cascades are regulated by both

antidepressants and mood stabilizers. Where, then, is the specificity? Are these agents simply nonspecific plasticity enhancers?

At the outset, it should be emphasized that BDNF and the ERK pathway are not synonymous. BDNF uses at least three major signaling cascades to bring about its biological effects through TrkB: ERK MAPK, PI-3-kinase/Akt, and phospholipase C; BDNF, at higher concentrations, also stimulates p75^{NTR}. The ERK MAPK pathway is regulated by several mechanisms. Thus, in addition to the neurotrophins, a variety of neurotransmitters and other neuroactive molecules also regulate the ERK pathway in stage- and other region-specific manners in the brain. It is also

Figure 14–29. Effects of low-dose lithium treatment on Bcl-2 levels in rat frontal cortex and hippocampus. Chronic lithium was shown to robustly increase the levels of the major neuroprotective protein Bcl-2 at therapeutic levels (.6–1.0mM). A series of studies was undertaken to determine if low-dose lithium also produced Bcl-2 upregulation. Inbred male Wistar Kyoto rats were treated with Li_2CO_3 at “full dose” (resulting in plasma levels of $\sim 0.8\text{mM}$) or “half dose” (resulting in plasma levels of $\sim 0.35\text{mM}$) for 3 to 4 weeks. *Left panel:* Quantification of immunoblotting of Bcl-2 in frontal cortex, which was conducted by established methods with monoclonal antibodies directed against Bcl-2. *Right panel:* Immunohistochemistry in rat hippocampus. Treatment of rats with either full-dose or half-dose lithium for 3 to 4 weeks resulted in significant increases in the levels of Bcl-2. * $p < .05$ compared with control. These results suggest that low-dose lithium may also confer neuroprotective effects, even in those patients who are intolerant of full-dose lithium because of side effects.

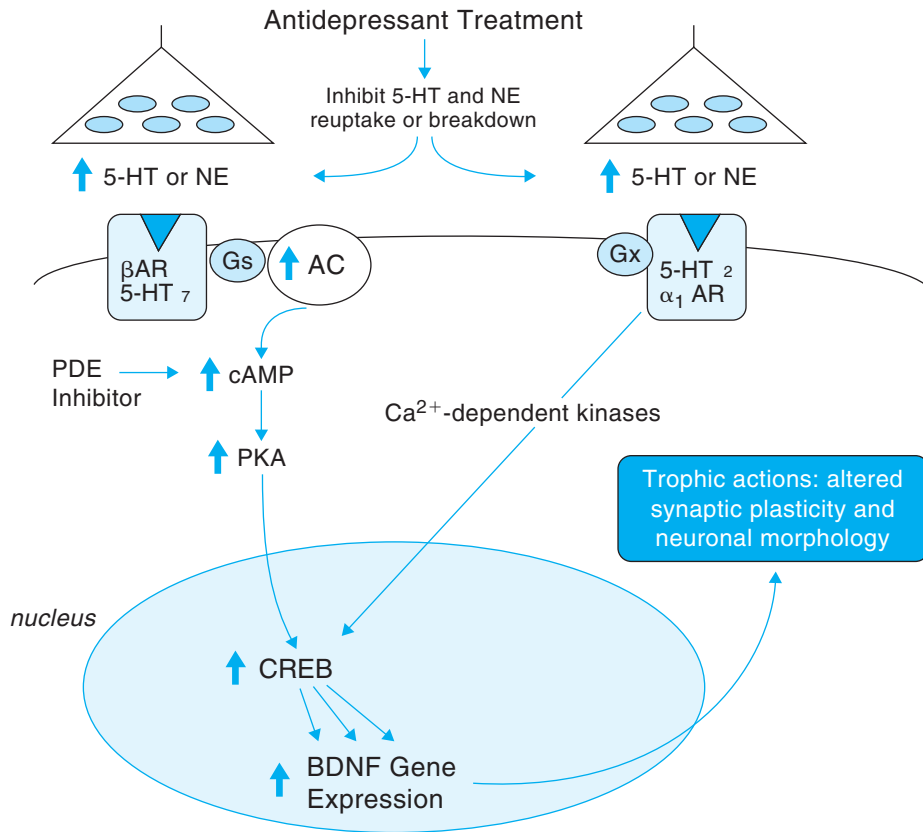

Figure 14–30. Influence of antidepressant treatment on the cAMP–CREB cascade. Antidepressant treatment increases synaptic levels of norepinephrine (NE) and 5-HT by blocking the reuptake or breakdown of these monoamines. This results in activation of intracellular signal transduction cascades, one of which is the cAMP–CREB cascade. Chronic antidepressant treatment increases Gs coupling to adenylyl cyclase (AC), particulate levels of cAMP-dependent protein kinase (PKA), and CREB. CREB can also be phosphorylated by Ca²⁺-dependent protein kinases, which can be activated by the phosphatidylinositol pathway (not shown) or by glutamate ionotropic receptors (e.g., NMDA). Glutamate receptors and Ca²⁺-dependent protein kinases are also involved in neural plasticity. One gene target of antidepressant treatment and the cAMP–CREB cascade is brain-derived neurotrophic factor (BDNF), which contributes to the cellular processes underlying neuronal plasticity and cell survival. (Source: Manji and Duman, 2001.)

likely that the stoichiometries, coupling efficiencies, and subcellular compartmentalization vary in different brain regions. Not altogether surprisingly, different behavioral effects have been reported when different brain regions were involved. It is likely that the differential effects are modulated not only by the region-specific expression of specific signaling but also by the network properties of vulnerable structures. The dynamics of the impairments of cellular plasticity and resilience are thus also likely to be determined by intrinsic properties of the affected areas.

Cellular and Neurotrophic Actions of Antidepressants

Findings of several studies support the hypothesis that antidepressant treatment produces neurotrophic-like effects (see Box 14–18). One early study found that antidepressant treatment induced regeneration of catecholamine axon

terminals in the cerebral cortex (Nakamura, 1990). Another study examined the influence of antidepressant treatment on the atrophy of hippocampal neurons in response to stress (Watanabe et al., 1992). Chronic administration of an atypical antidepressant, tianeptine, was found to block the stress-induced atrophy of CA3 pyramidal neurons, measured as a blockade of the decrease in the number and length of apical dendrite branch points. Additional studies are needed to further characterize the influence of these and other classes of typical and atypical antidepressants on the atrophy of CA3 neurons. The neurotrophic and neuroprotective effects of antidepressants in other models of cell damage or atrophy also need to be examined.

Czeh and colleagues (2001) conducted some interesting preclinical studies in which stress-induced changes in brain structure and neurochemistry were found to be counteracted

Antidepressant Treatment Increases CREB Expression in Hippocampus

Chronic Antidepressant Treatment Increases BDNF Expression in Hippocampus

Figure 14–31. Chronic antidepressant treatment increases CREB and BDNF expression in rat hippocampus. Upregulation of CREB mRNA (a) occurs in response to several different classes of antidepressant treatments, including norepinephrine- and serotonin-reuptake inhibitors, and electroconvulsive seizure, indicating that the cAMP–CREB cascade is a common postreceptor target of these therapeutic agents (Nibuya et al., 1995, 1996). Notably, CREB mRNA increases were not observed with several nonantidepressant psychoactive agents (including morphine, cocaine, or haloperidol), indicating specificity of effects. Upregulation of BDNF mRNA (b) also occurs in response to several different classes of antidepressant treatments, including a norepinephrine/NE reuptake inhibitor, SSRIs, and electroconvulsive seizure. Notably, BDNF mRNA increases were not observed with several nonantidepressant psychoactive agents (including morphine, cocaine, or haloperidol), indicating specificity of effects. In addition, upregulation of both CREB and BDNF is dependent of chronic treatment, consistent with the therapeutic action of antidepressants. As discussed in the text (not shown here), lithium and valproate have also been shown to upregulate CREB and BDNF mRNA and protein levels. Indirect human evidence comes from studies showing increased hippocampal BDNF and CREB expression in postmortem brain of subjects treated with antidepressants at the time of death compared with that of antidepressant-untreated subjects. COC = cocaine (a psychostimulant); DSP = desipramine (a noradrenergic antidepressant); ECS = electroconvulsive shock (an animal model of ECT); FLX = fluoxetine (an SSRI); HAL = haloperidol (a typical antipsychotic); MOR = morphine (an opioid); STL = sertraline (an SSRI); TCP = tranylcypromine (an MAOI); Veh = vehicle control. BOX 14–18. Summary of the Differences in Neurotrophic Properties of Antidepressants and Lithium: Evidence from Contemporary Studies

- Antidepressants exert major effects on cAMP-responsive element binding protein (CREB) and brain-derived neurotrophic factor (BDNF) expression in rat hippocampus.
- Antidepressants *may* exert modest effects on extracellular response kinase (ERK) activation in rat brain.
- Lithium exerts major effects on ERK activation in rat frontal cortex and hippocampus.
- Lithium exerts major effects on Bcl-2 in rat frontal cortex.
- Cross-sectional neuroimaging studies suggest that patients treated with chronic lithium or valproate do not show subgenual prefrontal cortex atrophy; patients treated with selective serotonin reuptake inhibitors (SSRIs) show atrophy similar to that in untreated patients.
- Longitudinal studies show that chronic lithium increases the levels of N-acetylaspartate (NAA) in areas of brain in bipolar patients; there are no similar published studies with valproate or antidepressants.
- Longitudinal studies show that chronic lithium increases gray matter volumes in bipolar patients; there are currently no similar published studies with antidepressants.

by treatment with tianeptine. In their study, male tree shrews subjected to a chronic psychosocial stress paradigm were found to have decreased NAA, a putative marker of neuronal viability (Tsai and Coyle, 1995; Moore and Galloway, 2002), measured *in vivo* by proton magnetic resonance spectroscopy (^1H -MRS); decreased granule cell proliferation in the dentate gyrus of the hippocampus; and a reduction in hippocampal volume compared with nonstressed animals. These stress-induced effects were prevented and reversed in shrews treated concomitantly with tianeptine (Czeh et al., 2001). Once again, however, the generalizability of these effects to other classes of antidepressants is unclear. (See Figure 14–32 on the neurotrophic effects of antidepressants.)

Relevance of Antidepressant Regulation of Hippocampal Neurogenesis

Recent studies have shown that chronic, but not acute, antidepressant treatment also increases the neurogenesis of dentate gyrus granule cells (Jacobs et al., 2000; Manev et al., 2001; D'Sa and Duman, 2002). These studies found that chronic administration of different classes of antidepressant treatment, including norepinephrine- and serotonin-selective reuptake inhibitors and electroconvulsive shock (the animal model of ECT), increases the prolifer-

ation and survival of new neurons. In contrast to what has been observed with mood stabilizers, increased neurogenesis is not observed in response to chronic administration of nonantidepressant psychotropic drugs. Studies demonstrating that neurogenesis is increased by conditions that stimulate neuronal activity (e.g., enriched environment, learning, exercise) suggest that this process is also positively regulated by and may even be dependent on neuronal plasticity (Kempermann, 2002).

The enhancement of hippocampal neurogenesis by antidepressants serves to highlight the degree to which these effective treatments are capable of regulating long-term neuroplastic events in the brain. In view of the opposite effects of stress and antidepressants on hippocampal neurogenesis, it is quite plausible that alterations in hippocampal neurogenesis are fundamental to the clinical syndrome of depression. To further investigate this hypothesis, Santarelli and colleagues (2003) conducted an important series of experiments. Mice were administered a variety of antidepressants or vehicle for 28 days, and their responses on a novelty-suppressed feeding were investigated. A 35 percent improvement in the speed of retrieving food or water was observed in mice taking antidepressants. In a second experiment, a 60 percent increase in BrdU-positive cells in the dentate gyrus was found after 11–28 days of treatment with fluoxetine. To test whether hippocampal neurogenesis was necessary for the antidepressants' behavioral effects, mice were exposed to x-rays directed at the hippocampus, leading to an 85 percent reduction in BrdU-positive cells in the subgranular zone. These mice were then treated with fluoxetine, imipramine, or vehicle for 28 days. The previously noted effect of antidepressants on the novelty-suppressed feeding test was not seen in irradiated mice, suggesting that these behavioral effects of chronic antidepressants may be mediated by new neuronal growth in the hippocampus (see Fig. 14–33). However, novelty-suppressed feeding behavior is generally regarded as a test of anxiety behavior and also responds to benzodiazepines (generally not regarded as having antidepressant efficacy). Thus it may be premature to infer that inhibition of the antidepressant effect of these drugs also occurs as a result of the suppression of neurogenesis; studies with genetic strategies to regulate hippocampal neurogenesis are under way and should delineate the role of hippocampal neurogenesis in the pathophysiology and treatment of mood disorders.

A problem to be addressed with the neurotrophic hypothesis of antidepressant drug action is the “tryptophan depletion conundrum.” It is now well established that patients successfully treated with SSRIs show a rapid depressive relapse following experimental procedures that deplete tryptophan and serotonin (Delgado et al., 1991, 1999; Aberg-Wistedt et al., 1998). How are such rapid effects to

Depression

Treated

Figure 14–32. Neurotrophic effects of antidepressants. *Left:* Antidepressant treatment increases synaptic levels of norepinephrine (NE) and serotonin (5-HT) by blocking the reuptake or breakdown of these monoamines. This results in activation of intracellular signal transduction cascades, one of which is the cyclic adenosine monophosphate–cAMP-responsive element-binding protein (cAMP–CREB) cascade. Chronic antidepressant treatment increases Gs coupling to adenylyl cyclase (AC), particulate levels of cAMP-dependent protein kinase (PKA), and CREB. CREB can also be phosphorylated by Ca²⁺-dependent protein kinases, which can be activated by the phosphatidylinositol pathway or by glutamate ionotropic receptors (e.g., NMDA, not shown). One gene target of antidepressant treatment and the cAMP–CREB cascade is brain-derived neurotrophic factor (BDNF), which contributes to the cellular processes underlying neuronal plasticity, and restoration/enhancement of neural connectivity mechanisms, which are essential for healthy affective functioning. *Right:* At the dendritic level, antidepressants increase synapse formation and neural outgrowth, restoring critical circuitry function. AR = adrenoceptors; DAG = diacylglycerol; IP₃, inositol monophosphate; NMDA = *N*-methyl-D-aspartate; P = phosphorylated; PIP₂ = phosphoinositide 4,5-bisphosphate; PLC, phospholipase C; TrkB, specific tyrosine kinases receptor. (Source: Manji et al., 2003b.)

be reconciled with the postulated neurotrophic actions of antidepressants? It is our contention that treatment of depression is attained by providing both trophic and neurochemical support; the trophic support restores normal synaptic connectivity, thereby allowing the chemical signal to reinstate the optimal functioning of critical circuits necessary for normal affective functioning. Thus, tryptophan depletion diets are capable of inducing a depressive relapse in SSRI-treated patients through reduced neurotransmitter synthesis and release, although they are not likely to have acute major effects on brain structure per se (see Fig. 14–34).

Long-term Clinical Implications of the Neurotrophic Effects of Mood Stabilizers and Antidepressants

As discussed earlier, there is now a considerable body of work both conceptually and experimentally suggesting that impairments in cellular plasticity and resilience may play an important role in the pathophysiology of recurrent mood disorders. Does the long-term administration of agents such as lithium and valproate actually retard disease- or affective episode-induced cell loss or atrophy? The distinction between disease progression and affective episodes per se is an important one, since it is quite possible that the neurotrophic effects of lithium or valproate may even be

independent of their ability to treat or prevent affective episodes. We are aware of no longitudinal studies that fully address this question, but it clearly represents a very important and fundamental issue worthy of investigation.

Findings that lithium administration increases brain NAA levels and gray matter volumes, as well as cross-sectional results demonstrating “normalized” subgenual prefrontal cortex volumes in patients treated with lithium and valproate, do provide indirect support for such a contention. The evidence also suggests that, somewhat akin to the treatment of conditions such as hypertension and diabetes, early and potentially sustained treatment may be necessary to adequately prevent many of the deleterious long-term sequelae associated with mood disorders.

For many refractory depressed patients, there may be a limited benefit to new drugs that simply mimic many traditional drugs that directly or indirectly alter neurotransmitter levels or bind to cell surface receptors. Such strategies implicitly assume that the target circuits are functionally

intact and that altered synaptic activity will thus be transduced to modify the postsynaptic throughput of the system. However, the evidence presented here suggests that, in addition to neurochemical changes, many patients also have pronounced structural alterations (e.g., reduced spine density, neurite retraction, overall neuropil reductions) in critical neuronal circuits. Thus, optimal treatment may be attained only by providing more direct trophic support. The trophic support would be envisioned as enhancing and maintaining normal synaptic connectivity, thereby allowing the chemical signal to reinstate the optimal functioning of critical circuits necessary for normal affective functioning.

While lithium and valproate clearly exert neurotrophic effects, they do so through indirect mechanisms—that is, many of their direct biochemical targets are considerably upstream of neuroprotective proteins such as GSK-3, ERK, and Bcl-2. Thus many patients with endogenous or acquired defects in the machinery involved in mediating the effects of mood stabilizers on neurotrophic proteins would

Figure 14–33. Antidepressant treatment increases neurogenesis in adult hippocampus. *Left panel:* A typical section of dentate gyrus that has undergone immunohistochemical analysis for bromodeoxyuridine (BrdU), the thymidine analog used to label newborn cells. The darker cells in the subgranular zone (SGZ) represent BrdU-positive cells. Chronic antidepressant treatment increases the number of BrdU-positive cells, determined 24 hours after BrdU administration. *Right panel:* Quantification of immunocytochemical data, showing antidepressant treatments increase the number of BrdU-labeled cells in dentate gyrus. Con = control; ECS = electroconvulsive shock; Fluox = fluoxetine, a 5-HT selective inhibitor; Reb = a norepinephrine selective reuptake inhibitor reboxetine; TCP = a monoamine oxidase inhibitor tranylcypromine. (Source: Gray et al., 2003; unpublished data from Ronald S. Duman, Ph.D. Professor of Psychiatry and Pharmacology, Director, Abraham Ribicoff Research Facilities, Yale University School of Medicine.)

Figure 14-34. Resolution of the tryptophan depletion conundrum of the neurotrophic hypothesis of antidepressant drug action. Treatment of depression is attained by providing both trophic and neurochemical support; the trophic support restores normal synaptic connectivity, thereby allowing the chemical signal to reinstate the optimal functioning of critical circuits necessary for normal affective functioning. Brain-derived neurotrophic factor (BDNF) also facilitates the release of neurotransmitters that act on this restored, intact circuit. Acute reduction in synaptic serotonin levels via its effects on reducing BDNF levels is capable of rapidly reducing the release of a number of neurotransmitters. Thus, tryptophan depletion diets are capable of inducing a depressive relapse in selective serotonin reuptake inhibitor-treated patients via the effects on neurotransmitter release, although likely not having major effects on structural brain changes. AC = adenylyl cyclase; cAMP = cyclic adenosine monophosphate; CREB = cAMP-responsive element-binding protein; DAG = diacylglycerol; GABA = gamma-aminobutyric acid; Glu = glutamate; IP₃ = inositolmonophosphate; NE = norepinephrine; NMDA = *N*-methyl-D-aspartate; P = phosphorylated; PIP₂ = phosphoinositide 4,5-bisphosphate; PKA = protein kinase A; PLC, phospholipase C; TrkB, specific tyrosine kinases receptor. (Source: Manji et al., 2003b.)

be expected not to display marked neurotrophic effects from the drugs. Optimal long-term treatment for refractory patients may require the early use of agents that enhance neuroplasticity and cellular resilience.

In this context, it is noteworthy that there are a number of pharmacological “plasticity-enhancing” strategies that may be of considerable utility in the treatment of mood disorders (Quiroz et al., 2004; Gould et al., 2004). Among the most immediate of these are NMDA antagonists, glutamate-release-reducing agents such as lamotrigine, AMPA potentiators, and cAMP phosphodiesterase inhibitors. An increasing number of strategies are being investigated for developing small-molecule agents to regulate the activity of growth factors, MAPK cascades, and the Bcl-2 family of proteins. This work holds much promise for the development of novel therapies for the long-term treatment of severe, refractory mood disorders. Table 14-10 summa-

rizes findings to date on potential targets for the development of new agents for the treatment of mood disorders (see Fig. 14-35).

CONCLUSIONS

The first edition of *Manic-Depressive Illness* was published in 1990; since then, there have been tremendous advances in our understanding of both the normal and abnormal functioning of the brain. Indeed, it is our firm belief that the impact of molecular and cellular biology—which has been felt in every corner of clinical medicine—will ultimately also have major repercussions for our understanding about the fundamental core pathophysiology of manic-depressive illness, and will lead to the development of improved treatments. Recent years have witnessed a more wide-ranging understanding of the neural circuits and the

TABLE 14–10. Potential Targets for the Development of New Antidepressants and Antibipolar Agents

Molecule	Hypothesized Involvement in Mood Disorders or Treatment	Function Plausibly Relevant to Mood Disorders	Findings from Animal Models	Direct or Surrogate Human Evidence	Observations from Clinical Treatment Studies
5-HT _{1A} /5-HT _{1B} antagonists	5-HT _{1A} /5-HT _{1B} antagonists may augment AD response.	Somatodendritic 5-HT _{1A} receptors regulate 5-HT neuron firing; nerve terminal 5-HT _{1B} receptors facilitate 5-HT release. Blockade increases 5-HT throughput via two mechanisms.	Coadministration of 5-HT _{1A} /5-HT _{1B} antagonists facilitates AD-induced 5-HT throughput.	Both PET and neuroendocrine studies suggest <i>reduced</i> 5-HT _{1A} levels/function in depression. However, these studies have not investigated somatodendritic receptors.	Equivocal results to date; pindolol may not be the ideal drug to test hypothesis
5-HT ₂ antagonists	5-HT ₂ antagonists may possess AD effects.	CNS distribution; may regulate DA throughput; important roles in regulating sleep and appetite	Many ADs downregulate 5-HT ₂ s (but not ECS).	Postmortem brain and PET studies are inconclusive; however, PET studies suggest that ADs reduce 5-HT ₂ binding. Elevated platelet 5-HT ₂ binding in depression	Agents with 5-HT ₂ antagonism (e.g., mirtazapine, clozapine) have AD effects; no clinical studies with selective agents
5-HT ₇ antagonists	5-HT ₇ agonists may have AD effects and/or ameliorate sleep/circadian disturbances.	CNS distribution; may regulate circadian rhythms; positively linked to cAMP generation	AD and clozapine appear to interact with and/or regulate expression of 5-HT ₇ .	None	None
α ₂ antagonists administered during REM sleep	A very investigational strategy as a rapidly acting AD	α ₂ antagonists increase firing of LC and release of NE. Enhancing NE function may have AD effects; activating central NE projections during REM sleep may allow released NE to interact with a primed, sensitized postsynaptic environment.	Agents that enhance NE throughput have AD efficacy; sleep deprivation, which has a rapid AD effect, enhances expression of plasticity molecules (e.g., CREB, BDNF) via an NE-dependent mechanism.	Sleep deprivation exerts a rapid AD effect. The LC is quiescent during REM sleep and activated by sleep deprivation.	α ₂ antagonists (idazoxan, mirtazapine) have been shown to exert AD effects. Use of an α ₂ antagonist during REM sleep is quite novel; human studies are just getting under way.

CRF antagonists	Enhanced throughput of CRF receptors may mediate some of the signs and symptoms of depression and anxiety; CRF antagonists may be effective ADs and/or anxiolytics.	Regulates NE LC firing; activated by stress; CRF receptors are well placed to regulate many of the neurovegetative symptoms of depression.	Agonists reproduce depression and anxiety-like behaviors in rodents. The orally active CRH antagonist, antalarmin, significantly reduces fear and anxiety responses in nonhuman primates.	HPA axis dysregulation in depression; CSF and postmortem brain studies in depression are supportive.	Positive effects were seen in the initial study; however, the study was stopped because of likely mechanism-unrelated side effects. Several other agents are at various stages of development.
Short-term treatment with GR antagonists	Hypercortisolemia may play an important role in the pathophysiology and/or deleterious long-term consequences of mood disorders.	Hippocampal atrophy mediated in part by hypercortisolemia. (Most studies have concentrated on the hippocampus, but other brain areas may likely show similar changes.) Diabetes, bone mineral density also affected	Injection of a GR antagonist into the dentate gyrus attenuates the acquisition of learned helpless behavior; transgenic and KO mice exhibit some symptoms of anxiety and depression. ADs exert complex effects on GR expression and function.	Abundant data demonstrating HPA axis activation in mood disorders, especially in severely ill patients	Preliminary studies of mifepristone in psychotic depression are very encouraging; larger studies are under way.
NK1 antagonists (substance P receptors)	Enhanced NK1 function in depression; NK1 antagonists may be effective treatments, but data not conclusive	Play important roles in mediating pain (? "psychic pain"); NK1 receptors reduce 5-HT neurotransmission.	Efficacy in animal models of depression; stress regulates re-distribution of NK1 receptors; NK1 KO shows reduced anxiety in certain models	No strong direct supportive evidence	Initial clinical studies positive; subsequent replications failed. Awaiting more definitive studies
NPY receptor agonists	NPY may serve as an endogenous anti-stress, anxiolytic agent. NPY agonists may be efficacious for certain symptoms of depression and anxiety.	May counter many of the deleterious effects of CRF and stress.	Efficacious in animal models of anxiety; NPY KO shows reduced anxiety in certain models. ADs and lithium may increase NPY expression.	CSF NPY may be low in depression. ECT increases CSF NPY-like immunoreactivity	No clinical studies to date

TABLE 14–10. Potential Targets for the Development of New Antidepressants and Antibipolar Agents (continued)

Molecule	Hypothesized Involvement in Mood Disorders or Treatment	Function Plausibly Relevant to Mood Disorders	Findings from Animal Models	Direct or Surrogate Human Evidence	Observations from Clinical Treatment Studies
NMDA antagonists	Enhanced throughput of the NMDA receptor may contribute to brain-regional volumetric changes observed in depression; NMDA antagonists may have antidepressant efficacy.	Key regulators of many forms of synaptic plasticity; play an important role in stress-induced hippocampal atrophy and reduction of neurogenesis; implicated in many forms of cell atrophy and death	NMDA antagonists block stress-induced cell atrophy/reduction of neurogenesis; many ADs regulate NMDA receptor subunit expression; NMDA antagonists efficacious in certain animal models of depression	Very indirect—regional volumetric reductions in mood disorders; evidence for glial and neuronal loss/atrophy in mood disorders	Amantadine and especially lamotrigine have antidepressant efficacy; preliminary results suggest that ketamine may have antidepressant efficacy. Studies with other NMDA antagonists are planned.
AMPA potentiators	AMPA receptors are known to activate MAP kinase cascades and increase plasticity.	Play important roles in neuronal functioning and plasticity	AMPA-potentiating agents have shown efficacy in animal models of depression. An ampakine (CX516) has been shown to produce a marked facilitation of performance in a memory task in rats.	Very indirect—impairment of neuronal plasticity and cellular resilience	No studies yet on mood disorders; preliminary human studies suggest a positive memory encoding effect in certain spheres; beneficial effects seen on measures of attention and memory when added to clozapine in schizophrenia
PDE4 inhibitors	Reduced throughput of cAMP signaling cascade may be involved in depression; enhancement of cAMP signaling may be AD	Enhance cAMP signaling and downstream gene expression, as well as synaptic plasticity and cell survival	PDE inhibitors effective in some models of depression; ADs enhance cAMP-mediated signaling	Postmortem brain studies suggest a potential impairment of cAMP signaling cascade in depression (but not BPD)	Preliminary early clinical studies suggested AD efficacy of rolipram; newer clinical studies with PDE inhibitors as AD adjuncts are under way

MAP kinase phosphatase inhibitors	Enhancement of neurotrophic factor signaling by inhibiting the turn-off reactions may be efficacious in treatment of depression.	MAP kinase signaling cascades are critical mediators of the effects of neurotrophic factors (e.g., BDNF) and play important roles in synaptic and structural plasticity.	ADs and lithium increase BDNF expression; valproate activates the MAP kinase cascade.	Very indirect—regional volumetric reductions in mood disorders; evidence for glial and neuronal loss/atrophy in mood disorders	No clinical studies with specific agents to date
Isozyme selective PKC inhibitors	Enhancement of PKC activity may play a role in the symptomatology of mania; PKC inhibitors may be antimanic.	Play a major role in regulating neuronal firing and neurotransmitter release; may play important roles in psychostimulant-mediated catecholamine release	Lithium and valproate, upon chronic administration, reduce levels of PKC α and ϵ ; certain biochemical and behavioral effects of psychostimulants are attenuated by PKC inhibitors.	A postmortem brain study and human platelet studies suggest activation of PKC isozymes in BPD/mania. Platelet studies also suggest normalization with lithium treatment.	A preliminary study suggests that tamoxifen (an estrogen receptor antagonist and PKC inhibitor) has antimanic efficacy. Larger clinical studies with tamoxifen are under way.
GSK-3 inhibitors, β -catenin upregulators	GSK-3 inhibitors, β -catenin upregulators may have mood-stabilizing effects.	Play important roles in structural plasticity and regulate cell death pathways	Lithium inhibits GSK-3 and upregulates β -catenin; valproate upregulates β -catenin likely via GSK-3 and non-GSK-3 mechanisms; lithium, valproate and lamotrigine protect against GSK-3 overexpression-induced cell death.	Very indirect—regional volumetric reductions in mood disorders; evidence for glial and neuronal loss/atrophy in mood disorders	Development of CNS-penetrant, selective small molecule GSK-3 inhibitors is currently under way.

TABLE 14–10. Potential Targets for the Development of New Antidepressants and Antibipolar Agents *(continued)*

Molecule	Hypothesized Involvement in Mood Disorders or Treatment	Function Plausibly Relevant to Mood Disorders	Findings from Animal Models	Direct or Surrogate Human Evidence	Observations from Clinical Treatment Studies
Bcl-2 upregulators	Upregulating Bcl-2 may exert trophic effects and enhance cellular resilience in treatment of mood disorders.	One of the major cell survival signals, and a major downstream effector of neurotrophic factors. Likely plays an important role in neurite outgrowth, neurogenesis, and other forms of neuroplasticity	Lithium and valproate, upon chronic administration, robustly upregulate Bcl-2 levels and exert neuroprotective effects.	Preliminary postmortem brain studies suggest possible involvement of Bcl-2 in mood disorders; lithium increases gray matter volumes in brain areas of reported atrophy in humans.	Lithium and valproate are effective mood stabilizers; no selective CNS Bcl-2 upregulators currently available. However, pramipexole, in addition to having dopaminergic effects, upregulates bcl-2. Positive antidepressant effects in preliminary studies; larger studies are under way

AD = antidepressant; BDNF = brain-derived neurotrophic factor; BPD = bipolar disorder; CNS = central nervous system; CRF = corticotropin-releasing factor; CRH = corticotropin-releasing hormone; CSF = cerebrospinal fluid; ECS = electroconvulsive shock; ECT = electroconvulsive therapy; GR = glucocorticoid receptor; GSK = glycogen synthase kinase; HPA = hypothalamic–pituitary–adrenal; KO = knockout; LC = locus coeruleus; MAP = mitogen activated protein; NE = norepinephrine; NK = neurokinin; NPY = neuropeptide Y; PET = positron emission tomography; PKC = protein kinase C; REM = rapid eye movement.

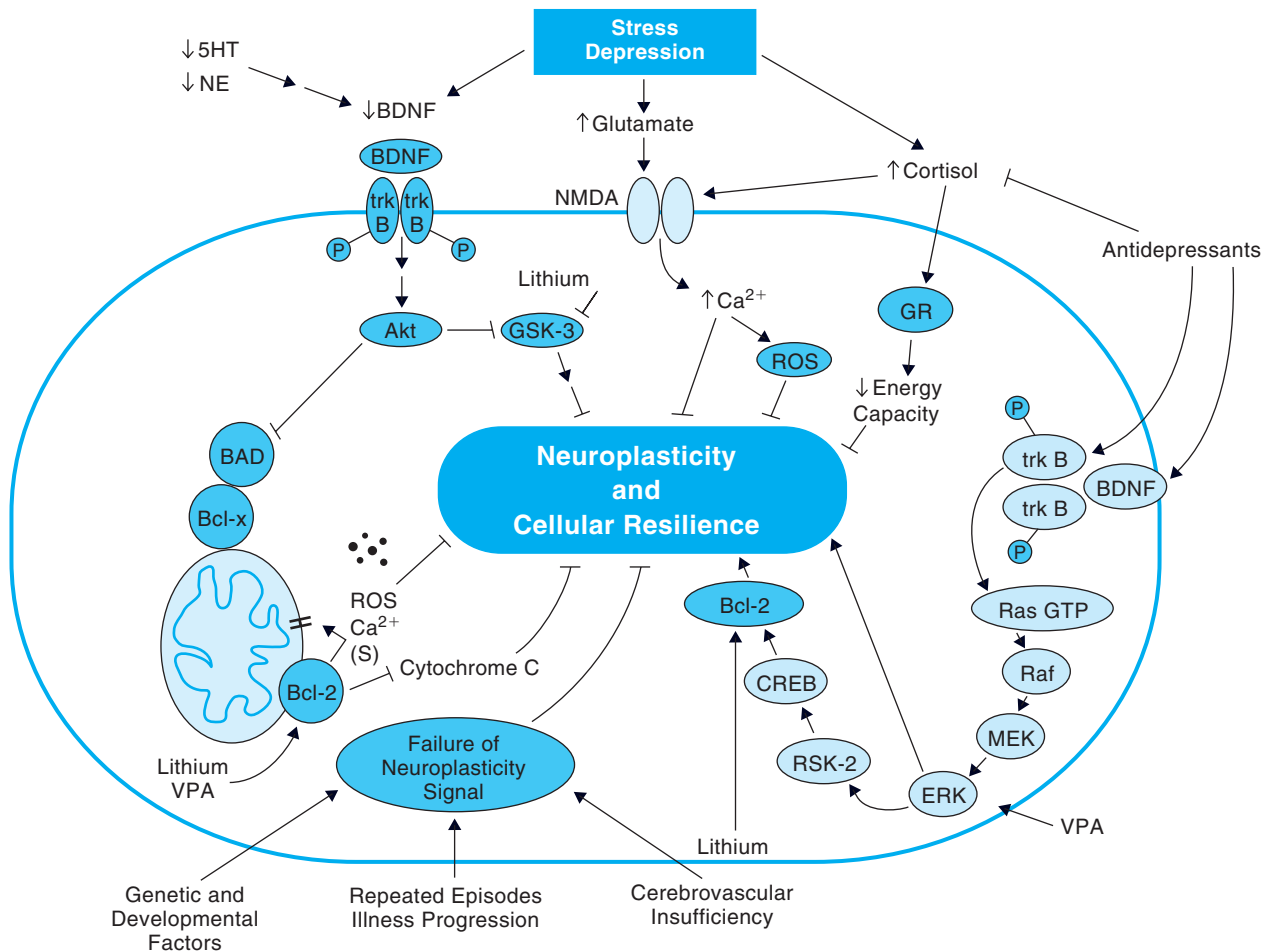

Figure 14–35. The multiple influences on neuroplasticity and cellular resilience in mood disorders. Genetic and neurodevelopmental factors, repeated affective episodes, and illness progression might all contribute to the impairments of cellular resilience, volumetric reductions, and cell death and atrophy observed in mood disorders. Stress and depression likely contribute to impairments of cellular resilience by a variety of mechanisms, including reductions in the levels of BDNF, facilitating glutamatergic transmission via NMDA and non-NMDA receptors, and reducing the cells' energy capacity. Neurotrophic factors such as BDNF enhance cell survival by activating two distinct signaling pathways: the PI_3 -kinase pathway, and the ERK–MAP kinase pathway. One of the major mechanisms by which BDNF promotes cell survival is by increasing the expression of the major cytoprotective protein, Bcl-2. Bcl-2 attenuates cell death through a variety of mechanisms, including impairment of the release of calcium and cytochrome c, sequestering of proforms of death-inducing caspase enzymes, and enhancement of mitochondrial calcium uptake. The chronic administration of a variety of antidepressants increases the expression of BDNF and its receptor TrkB. Lithium and valproate robustly upregulate the cytoprotective protein Bcl-2 and inhibit GSK-3 β , biochemical effects shown to have neuroprotective results. Valproate also activates the ERK–MAP kinase pathway, which may play a major role in producing neurotrophic effects and neurite outgrowth. BAD = pro-apoptotic members of the Bcl-2 family; Bcl-2 and Bcl-x = anti-apoptotic members of the Bcl-2 family; BDNF = brain derived neurotrophic receptor; CREB = cyclic AMP-responsive element-binding protein; GR = glucocorticoid receptor, GSK-3 = glycogen synthase kinase-3; MEK = ERK, components of the ERK–MAP kinase pathway; Ras = Raf; ROS = reactive oxygen species; RSK-2 = ribosomal S-6 kinase; TrkB = tyrosine kinase receptor for BDNF; VPA = valproate. various mechanisms of synaptic transmission, the molecular mechanisms of receptor and postreceptor signaling, and a finer understanding of the process by which genes code for specific functional proteins that in toto reduce the complexity in gene-to-behavior pathways (Gould and Manji, 2004). Here we synthesize and summarize the major advances pertaining to manic-depressive illness.

The Genetics of Bipolar Disorder

As discussed in Chapter 13, it is clear that we are on the verge of truly identifying susceptibility (and likely protective) genes for bipolar disorder. While the search for predisposing genes had traditionally tended to proceed under the assumption that schizophrenia and bipolar disorder

are separate disease entities with different underlying etiologies, emerging findings from many fields of psychiatric research do not fit well with this model (Craddock et al., 2005). Most notably, the pattern of findings emerging from genetic studies shows increasing evidence for an overlap in genetic susceptibility across the traditional classification categories. It is clear that there is not a one-to-one relationship between genes and behaviors so that different combinations of genes (and resultant changes in neurobiology) contribute to any complex behavior (normal or abnormal) (Hasler et al., 2006). It is also critically important to remember that polymorphisms in genes will very likely simply be *associated* with bipolar disorder or recurrent depression; these genes will likely not invariably determine outcome, but only lend a higher probability for the subsequent development of illness. In fact, genes will never code for abnormal behaviors per se, but rather code for proteins that make up cells, forming circuits, that in combination determine facets of both abnormal and normal behavior. These expanding levels of interaction have made the study of psychiatric diseases so difficult. The next task of psychiatric genetic research is to study how and why variations in these genes impart a greater probability to develop manic-depressive illness (to understand pathophysiology) and then to direct therapeutics at that pathophysiology (Gould and Manji, 2004). There is no doubt that knowledge of the genetics and subsequent understanding of their relevant biology will have a tremendous impact on diagnosis, classification, and treatment of psychiatric disease.

An Endophenotype Strategy

It is becoming increasingly clearer that, while the pathways beginning with genes and then expressed through simple biological processes do not necessarily have a single quantifiable endpoint (i.e. behavior), it may be possible to assay the result of aberrant genes through biologically “simpler” approaches (Hasler et al., 2006). The term *endophenotype* is described as an internal, intermediate phenotype (i.e., not obvious to the unaided eye) that fills the gap in the causal chain between genes and distal diseases (Gottesman and Shields, 1973), and therefore may help to resolve questions about etiology. The endophenotype concept assumes that the number of genes involved in the variations of endophenotypes representing more elementary phenomena (as opposed to the behavioral macros found in the DSM) are fewer than those involved in producing the full disease (Gottesman and Gould, 2003).

Will an endophenotype strategy lead to a major payoff? Endophenotypes provide a means for identifying the “upstream” traits underlying clinical phenotypes, as well as the “downstream” biological consequences of genes. The methods available to identify endophenotypes include

neuropsychological, cognitive, neurophysiological, neuroanatomical, imaging, and biochemical measures (Hasler et al., 2006). The information revised in this volume suggests that candidate brain function endophenotypes include attention deficits, deficits in verbal learning and memory, cognitive deficits following tryptophan depletion, circadian rhythm instability, and dysmodulation of motivation and reward. Moreover, reduced anterior cingulate volume and early-onset white matter abnormalities represent candidate brain structure endophenotypes. Finally, symptom provocation endophenotypes may be based on recurrent mood disorder patients’ sensitivity to sleep deprivation, psychostimulants, and cholinergic drugs (Hasler et al., 2006; see Fig. 14–36). However, it must be acknowledged that there are several potential factors that must be considered. Foremost among these is the fact that none of the suggested endophenotypes have been fully validated. Moreover, while it might seem intuitively obvious that the genetics of these candidate endophenotypes will be simpler than that of manic-depressive illness, this has yet to be clearly established. Thus, these candidate endophenotypes need to be further evaluated with respect to specificity, heritability, temporal stability, and prevalence in unaffected relatives.

Nature and Nurture

In recent years, *epigenetics*—the study of changes to the genome that, unlike mutations, do not alter the DNA sequence—has delineated just how inextricably linked nature and nurture truly are (see Petronis, 2004, for an excellent review). Epigenetics purports to define the molecular mechanisms by which different cells from different tissues of the same organism, despite their DNA sequence identity, exhibit very different cellular phenotypes and perform very different functions. It is presumed that phenotypic and functional differences are the cumulative result of a large number of developmental, environmental, and stochastic events, some of which are mediated through the epigenetic modifications of DNA and chromatin histones. Epigenetic regulation is thus one of the molecular substrates for “cellular memory” that may help us understand how environmental impact results in temporally dissociated, altered behavioral responses.

Do epigenetic factors play a major role in manic-depressive illness? It has been argued that molecular studies of manic-depressive illness would benefit significantly from adding an epigenetic perspective (Petronis, 2004). Thus, epigenetic mechanisms are consistent with various nonmendelian features of manic-depressive illness, such as the relatively high degree of discordance in monozygotic (MZ) twins, the critical age group for susceptibility to the disease, clinical differences in males and females, and fluctuation of the disease course, notably cycling between

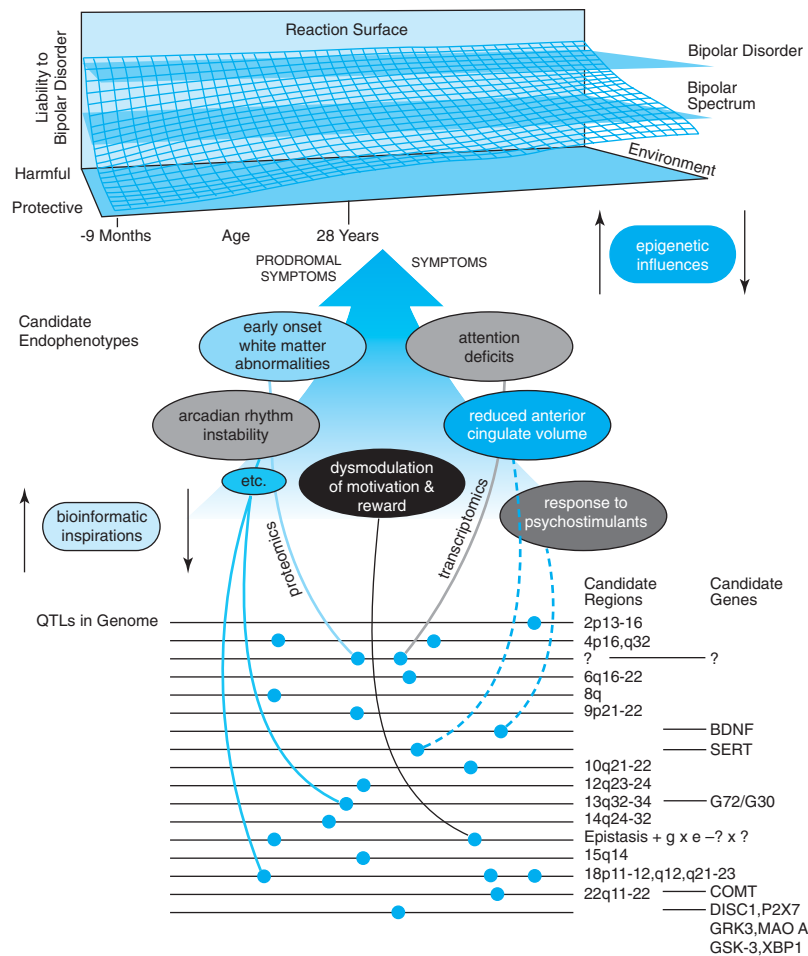

Figure 14-36. Endophenotypes in bipolar disorder. A heuristic model whereby underlying bipolar disorder gene susceptibility loci and implicated genes, modulated by environmental, epigenetic, and stochastic events, predispose to the development of bipolar disorder. Along this lengthy continuum between genes and distal phenotype lie putative bipolar endophenotypes, the identification of which will be useful for studies of the underlying neurobiology and genetics of bipolar disorders, as well as for preclinical investigations, such as the development of animal models. This figure is meant to represent a guide to future studies rather than a definitive portrait of loci, genes, and endophenotypes. QTL = quantitative trait locus. (Copyright 2005 by I.I. Gottesman. *Source:* Hasler et al., 2006. Reprinted with permission from Elsevier.)

phases (Petronis, 2003, 2004). Recent studies have shown that an epigenomic state of a gene can be established through behavioral programming, and it is potentially reversible (Weaver et al., 2004). This line of research is particularly noteworthy since early life stressors (that have been associated with later-life suicide attempts) in bipolar disorder (Leverich et al., 2003) might be amenable to treatment with agents to “undo” the epigenetic changes (e.g., histone deacetylase [HDAC] inhibitors) (Zarate et al., 2006a). In this context, recent studies have also suggested that the downregulation of reelin and GAD67 expression in cortical interneurons in schizophrenia and bipolar disorder patients may be mediated by epigenetic hypermethylation of the

respective promoters caused by the selective increase of DNA-methyltransferase 1 in GABAergic neurons (Tremolizzo et al., 2005). In sum, although considerable additional research is needed, our growing appreciation of the molecular mechanisms underlying gene–environment interactions raise the intriguing possibility that environmentally induced neurobiological changes in early life may be amenable to subsequent therapeutic strategies targeting the epigenome (Petronis 2003, 2004).

Cellular Plasticity Cascades

Overall, it should be clear from the information reviewed in this chapter that there are abnormalities in multiple systems

and at multiple levels in manic-depressive illness. It is our strong contention that manic-depressive illness arises from abnormalities in cellular plasticity cascades, leading to aberrant information processing in synapses and circuits mediating affective, cognitive, motoric, and neurovegetative function. Thus, manic-depressive illness can be best conceptualized as a disorder of *synapses and circuits*—not “too much/too little” of individual neurotransmitter or neuropeptide systems.

As discussed earlier, cellular signaling cascades form complex networks that allow the cell to receive, process, and respond to information (Bourne and Nicoll, 1993; Bhalla and Iyengar, 1999). These networks facilitate the integration of signals across multiple time scales and the generation of distinct outputs depending on input strength and duration, and regulate intricate feed-forward and feedback loops (Weng et al., 1999). These signaling cascades play a critical role as molecular switches subserving acute and long-term alterations in neuronal information processing.

As we have reviewed already, there is a considerable body of evidence in support of abnormalities in the regulation of signaling as integral to the underlying neurobiology of manic-depressive illness. The pathophysiology of this illness must account for not only the profound changes in mood but also a constellation of neurovegetative features derived from dysfunction in limbic related regions such as the hippocampus, hypothalamus, and brain stem. The highly integrated monoamine and prominent neuropeptide pathways are known to originate and project heavily within these regions of the brain, and it is thus not surprising that abnormalities have been noted in their function across clinical studies. In fact, the contribution of these pathways to the pathophysiology of manic-depressive illness must be reasonably robust, given the variability that might be expected in assessing such dynamic systems under the constraints in experimental design imposed upon such research (Manji and Lenox, 2000b). As we discuss below, the role of cellular signaling cascades offers much explanatory power for understanding the complex neurobiology of manic-depressive illness.

- Signaling cascades regulate the multiple neurotransmitter and neuropeptide systems implicated in manic-depressive illness. While dysfunction within these neurotransmitter and neuropeptide systems is likely to play an important role in mediating some facets of illness pathophysiology, it likely represents the downstream effects of other, more primary abnormalities in cellular signaling cascades. Indeed, even minor variations in ubiquitous regulators of signaling pathways can affect complex functions, yielding detrimental effects on behavior; this is clearly seen in many mouse models, where some genetic

mutations in expressed proteins have little effect on non-CNS functions, but major effects on behavior (Manji et al., 2003a).

- Abnormalities in cellular signaling cascades that regulate diverse physiologic functions likely explain the tremendous comorbidity with a variety of medical conditions (notably cardiovascular disease, diabetes mellitus, obesity, and migraine) and substance abuse. As a corollary, it is worth noting that genetic abnormalities in signaling components are often fully compatible with life, and in many instances, despite the often-ubiquitous expression of the signaling protein, one sees relatively circumscribed clinical manifestations (i.e., the abnormalities are only manifest in some physiologic systems, despite being potentially more widespread). These overt, yet relatively circumscribed, clinical manifestations are believed to ultimately arise from vastly different transcriptomes (all of the transcripts present at a particular time) in different tissues because of tissue-specific expression, haploinsufficiency, genetic imprinting, alternate splicing, varying stoichiometries of the relevant signaling partners in different tissues, and differences in the ability of diverse cell types to compensate for the abnormality (Manji et al., 2003a).
- Signaling pathways are clearly major targets for hormones that have been implicated in the pathophysiology of manic-depressive illness, including gonadal steroids, thyroid hormones, and glucocorticoids.
- Alterations in signaling pathways very likely represent the neurobiological substrates subserving the evolution of the illness over time (e.g., cycle acceleration). Thus, signaling networks play critical roles in cellular memory; cells with different histories, expressing different repertoires of signaling molecules, interacting at different levels, may respond quite differently to the same signal over time. As discussed already, experimental sensitization or kindling models have clearly shown that changes in signaling pathways play important roles in the long-term neuroplastic adaptations observed.
- Alterations in signaling pathways have major effects on circadian rhythms known to be abnormal in manic-depressive illness. It is noteworthy that although this tendency to recur is among the most distinguishing features of manic-depressive illness, in both its bipolar and its highly recurrent unipolar forms, it is poorly described and not well understood. It is noteworthy that studies have begun to uncover the molecular underpinning of circadian cycles (Chang and Reppert 2001). The core clock mechanism appears to involve a transcriptional/translational feedback loop in which gene products are involved in negative feedback of themselves and other genes in the pathway (see Chapter 16). The synchronized multioscillators system offers several advantages; notably,

interactions between neurons not only coordinate the population but decrease cycle-to-cycle variability, allowing behavioral rhythms to be more precise than individual neuronal rhythms (Herzog et al., 2004). A circadian system composed of multiple circadian oscillators can be disadvantageous, however, for the organism when internal desynchrony among circadian pacemakers results from abnormalities in signaling cascades required to provide “fine-tuning” for the system. It is our contention that, along with cyclicity, the switch process is one of the fundamental and defining characteristics of the bipolar disorder subgroup. Thus a greater understanding of the molecular and cellular underpinnings of the switch process could greatly enhance understanding of the neurobiology of the disorder. Unfortunately, the immense practical difficulties inherent in studying medication-free bipolar patients longitudinally have greatly hampered investigators’ ability to collect much-needed data on this critical facet of the illness. Nevertheless, important clues have been found, most notably with respect to the catecholaminergic systems and signaling cascades.

- Cellular signal transduction cascades are clearly the targets for our most effective treatments for manic-depressive illness. Indeed, it is likely that the identification of signaling cascades as targets for the actions of lithium and other mood stabilizers has had a profound impact on our understanding of the cellular neurobiology of manic-depressive illness (Manji and Lenox, 2000b; Bezchlibnyk and Young, 2002). While most of our drug development efforts in the past have been aimed at the treatment of the affective states of mania or depression, the unique clinical action of lithium is its ability to prophylactically stabilize the underlying disease process by effectively reducing the frequency and severity of the profound mood cycling in a majority of appropriately selected patients. There is reasonable evidence to suggest that once the disease process has been triggered and clinically manifest, long-term adaptive changes in the central nervous signaling systems predispose an individual to more frequent and severe affective episodes over time. A correction of dysregulated trans-synaptic signaling by mood stabilizers represents a physiological process able to curtail the often wild oscillations in behavioral states associated with manic-depressive illness, especially in its bipolar form. Indeed, regulation of signal transduction within critical regions of the brain by mood stabilizers affects the intracellular signal generated by multiple neurotransmitter systems; these effects undoubtedly represent targets for their therapeutic efficacy, since the behavioral and physiological manifestations of the illness are complex and are likely mediated by a network of interconnected neurotransmitter pathways.

- Abnormalities in cellular plasticity cascades likely also represent the underpinnings of the impairments of structural plasticity seen in morphometric studies of manic-depressive illness. Thus, many of these pathways play critical roles not only in “here-and-now” synaptic plasticity, but also in long-term cell growth and atrophy and cell survival and cell death. Indeed, the atrophic changes observed in multiple cell types (neurons and glia), as well as the reversibility of the changes with treatment, support a role for intracellular plasticity cascades. It is likely that the major defect is in the ability to regulate neuroplastic adaptations to perturbations (both physiological and pathophysiological)—an inability to handle “normal loads” (neurochemical, hormonal, stress-induced, pharmacologically induced, etc.) without failing or invoking compensatory adaptations that overshoot and predispose to oscillations. Indeed, the allostatic load contributes to long-term disease progression (and potentially to cycle acceleration). Many of the very same “plasticity regulators” also play a critical role in cell survival, cell death, and cellular resilience. These observations serve to explain the atrophic (perhaps degenerative) aspect of the illness in some patients, as well as the presence of stigmata normally associated with ischemic/hypoxic insults, such as white matter hyperintensities. (See Figure 14–37 for a depiction of the multiple targets by which neuroplasticity and cellular resilience can be increased in mood disorders.)

In conclusion, since publication of the first edition of this text in 1990, there have truly been tremendous advances in our understanding of the circuits, and especially of the molecular and cellular underpinnings of manic-depressive illness. Through functional brain imaging studies, affective circuits have been identified that mediate the behavioral, cognitive, and somatic manifestations of manic-depressive illness. Key areas of these circuits include the amygdala and related limbic structures, orbital and medial prefrontal cortex, anterior cingulate, medial thalamus, and related regions of the basal ganglia. Imbalance within these circuits, rather than an increase or decrease in any single region of the circuit, seems to predispose to and mediate the expression of manic-depressive illness. Moreover, studies of cellular plasticity cascades in manic-depressive illness are leading to a reconceptualization of the pathophysiology, course, and optimal long-term treatment of the illness. These data suggest that, while manic-depressive illness is clearly not a classic neurodegenerative disease, it is in fact associated with impairments of cellular plasticity and resilience. As a consequence, there is a growing appreciation that optimal long-term treatment will likely be achieved by attempting to prevent the underlying disease progression and its attendant

Figure 14-37. Targets for novel treatments. The functional interactions among monoamine neurotransmitters, glutamate, and neurotrophic signaling cascades, as well as various sites where stress affects these systems are illustrated. Genetic factors and life stress are both likely to contribute to the neurochemical alterations, impairments in cellular resilience, reductions in brain volume, and cell death and atrophy observed in depression. Targets for increasing neuroplasticity and cellular resilience and facilitating new classes of antidepressant medications include the following: (1) Phosphodiesterase inhibitors increase levels of pCREB. (2) MAPK modulators increase the expression of Bcl-2. (3) mGluR II/III receptor agonists modulate the release of excessive levels of glutamate. (4) Drugs such as riluzole and felbamate act on Na⁺ channels to attenuate glutamate release. (5) AMPA potentiators upregulate the expression of BDNF. (6) NMDA receptor antagonists such as memantine enhance plasticity and cell survival. (7) Drugs that increase glial release of trophic factors and clear excessive glutamate may have antidepressant properties. (8) CRH antagonists may reverse the anxiogenic and depressogenic effects of extrahypothalamic CRH. (9) Glucocorticoid antagonists may attenuate the deleterious effects of hypocortisolemia. (10) Agents that upregulate Bcl-2 (such as pramipexole) may have antistress and antidepressant actions. α_2 -AR = α_2 -adrenergic receptor; AC = adenylyl cyclase; AMPAR = α -amino 3-hydroxy-5-methylisoxazole propionate; BDNF = brain-derived neurotrophic factor; CREB = cAMP-responsive element-binding protein; CRH = corticotrophin-releasing hormone; G_i = family of G protein α subunits that includes G_i and G_o; G_q = family of G protein α subunits that includes G_q and G₁₁; Glu = glutamate; GR = glucocorticoid receptor; GSK-3 = glycogen synthase kinase; HDAC = histone deacetylases; MAPK = mitogen-activated protein kinase; mGluR = metabotropic glutamate receptor; NE = norepinephrine; NMDAR = N-methyl-D-aspartate receptor; PKA = protein kinase A; 5-HT = serotonin. cellular dysfunction, rather than exclusively focusing on the treatment of signs and symptoms.

There has, unfortunately, been little progress in developing truly novel drugs specifically for the treatment of manic-depressive illness, and most recent additions to the pharmacopeia are brain-penetrant drugs developed for the treatment of epilepsy or schizophrenia. This era may now

be over as there are a number of pharmacologic “plasticity-enhancing” strategies which may be of considerable utility in the treatment of manic-depressive illness. Indeed, these next-generation drugs, in addition to treating the core symptoms of bipolar and/or highly recurrent unipolar disorder, might be able to target other important aspects of the illness. They may, for example, be able to enhance cog-

nitition independent of whether mood symptoms improve, prevent, or reverse epigenetic factors that may have long-term negative impact on the course of the illness (e.g., histone deacetylase inhibitors), or reduce certain medical comorbidities such as diabetes (e.g., GSK inhibitors) (Zarate et al., 2006b).

We are optimistic that the advances outlined here will result in a dramatically different diagnostic system based on etiology, and ultimately in the discovery of new approaches to the prevention and treatment of some of humankind's most devastating and least understood illnesses. This progress holds much promise for developing novel therapeutics for the long-term treatment of severe, refractory mood disorders, and for improving the lives of millions.

NOTES

1. For example, Robbins and Sahakian, 1980; Smith and Helms, 1982; Lerer et al., 1984; Berggren, 1985; Ushijama et al., 1986.

3. Wyatt et al., 1971; Louis et al., 1975; Barnes et al., 1983; Koslow et al., 1983; Roy et al., 1985, 1987, 1988; Rudorfer et al., 1985; Veith et al., 1988, 1994; de Villiers et al., 1989. Maas et al., 1987;
4. To begin with, receptors on blood cells are by definition noninnervated, exist in a markedly different environment, and may therefore poorly reflect central, innervated, adrenergic receptors. Another major (often overlooked) consideration when interpreting studies of dynamic receptor regulation in blood cells is that white blood cell counts and the relative proportions of subsets of lymphocytes may vary. Recruitment of cells with different characteristics into the circulation may frequently explain altered receptor function. Precisely such a mechanism appears to be operative in studies demonstrating the seemingly paradoxical increase in lymphocyte beta-adrenergic receptor (β AR) density and responsiveness during short-term isoproterenol infusion, mental arithmetic, and dynamic exercise (procedures that stimulate the sympathetic nervous system) (Maisel et al., 1990; Van Tits et al., 1990). The mechanism appears to be a release of subsets of "fresh" lymphocytes from the spleen into the circulation (Van Tits et al., 1990; Werstiuk et al., 1990). These fresh, activated lymphocytes express enhanced β AR responsiveness, and this probably accounts for the exercise and catecholamine-induced increases in β AR responsiveness.

29. In a similar vein, Hong and colleagues (2000) showed that blood levels of reelin were extremely low to undetectable in children afflicted with a variant of lissencephaly. These children had various mutations involving the *RELN* gene and exhibited severe delays in neurologic and cognitive development (Hong et al., 2000). Later, Fatemi and colleagues found deficits in reelin protein in brain and blood of subjects with

- autism, another neurodevelopmental disorder characterized by significant cognitive dysfunction in association with a vulnerability to defective reelin inheritance (Fatemi et al., 2001b, 2002; Persico et al., 2001; Fatemi, 2002).

 32. Several classes of ARPs have been identified, including benzothiadiazides, such as cyclothiazide; pyrrolidones, such as piracetam and aniracetam; and benzoylpiperidines, such as CX-516. Preclinical studies have shown that modulation of AMPA receptors with the piperidine (CX-516) enhances MAPK activation and reduces the extent of synaptic and neuronal degeneration resulting from excitotoxic insults, even when infused after the insult (Bahr et al., 2002). In view of the ability of structurally dissimilar ARPs to increase BDNF expression (Hayashi et al., 1999; Lauterborn et al., 2000; Skolnick et al., 2001), studies investigating the putative efficacy of an ARP (LY392098) in animal models of depression were undertaken. These studies showed that LY392098 produced a reduction in the duration of immobility in the forced swim test similar to that produced by traditional antidepressants, suggesting that ARPs may indeed have utility as novel antidepressants.

 41. The application of the combined DEX/CRH test consists of the oral administration of 1.5 mg dexamethasone at 11:00 PM the night before an IV bolus administration of 100 µg of human CRH at 3:00 AM. Blood samples for the determination of plasma cortisol and ACTH are then drawn every 15 minutes from 2:00 to 6:00 PM. Recently, a modification of the test has been explored that involves monitoring cortisol levels in saliva, with the intent of making more routine use of the DEX/CRH test (Baghai et al., 2002).
 42. This atrophy is observed in the CA₃ pyramidal neurons, but not in other hippocampal cell groups (i.e., CA₁ pyramidal and dentate gyrus granule neurons). The stress-induced atrophy of CA₃ neurons (i.e., decreased number and length of the apical dendritic branches) occurs after 2–3 weeks of exposure to restraint stress or longer-term social stress, and has been observed in rodents and tree shrews (McEwen, 1999a; Sapolsky, 2000a). Atrophy of CA₃ pyramidal neurons also occurs upon exposure to high levels of glucocorticoids, suggesting that activation of the HPA axis likely plays a major role in mediating the stress-induced atrophy (Sapolsky 1996, 2000b; McEwen, 1999). The hippocampus has a very high concentration of glutamate and expresses both Type I and Type II corticosteroid receptors, though the latter receptors may be relatively scarce in the hippocampus of primates (Patel et al., 2000; Sanchez et al., 2000) and more abundant in cortical regions. Mineralcorticoid or Type I (MR) receptor activation in the hippocampus (CA₁) is associated with reduced calcium currents, whereas activation of glucocorticoid or Type II receptors (GR) causes increased calcium currents and enhanced responses to excitatory amino acids. Very high levels of Type II receptor activation markedly increase calcium currents and lead to greater NMDA receptor throughput that could predispose to neurotoxicity. Indeed, as we discuss in greater detail below, a growing body of data has implicated glutamatergic neurotransmission in stress-induced hippocampal atrophy and death (McEwen, 1999).
 43. Using a Golgi-Cox procedure, Wellman (2001) investigated pyramidal neurons in layers II and III of medial prefrontal cortex and quantified dendritic morphology in three dimensions. This study demonstrated a significant redistribution of apical dendrites in corticosterone-treated animals, with the amount of dendritic material proximal to the soma being increased and distal dendritic material being decreased. These findings suggest that stress may produce a significant reorganization of the apical dendritic arbor from medial prefrontal cortex in rats. Most recently, Lyons (2002) demonstrated that 4 years after a brief stressor (intermittent postnatal separations from maternal availability), young adult squirrel monkeys showed significantly larger right ventral medial prefrontal volumes. Neither overall brain volumes nor left prefrontal measures were altered, suggesting selective (rather than nonspecific) effects.
 44. CRF₁ receptors, which bind CRF with higher affinity than CRF₂ receptors, play a major role in regulating ACTH release and have been implicated in animal models of anxiety. Indeed, the central administration of CRF₁ antisense oligodeoxynucleotides has been demonstrated to have anxiolytic effects against both CRF and psychological stressors. Although CRF₂ receptors appear to act in an antagonistic manner (i.e., CRF₁ activates and CRF₂ attenuates the stress response), their precise role is still being characterized (Reul and Holsboer, 2002). Interestingly, pretreatment with a CRH antagonist also attenuates the stress-induced increases in MR levels in hippocampus, neocortex, frontal cortex, and amygdala (Gesing et al., 2001). Likewise, rats that underwent a stressor showed increased ACTH and cortisol levels following the administration of an MR antagonist, suggesting that the upregulation of MR in the stressed group was associated with increased inhibitory tone of the HPA axis.
 45. Estrogen has been shown to decrease monoamine oxidase (MAO) activity (Klaiber et al., 1971) in human plasma, while progesterone appears to enhance MAO activity (Holzbauer and Youdim, 1973). Although the exact clinical effects in humans are unclear, decreased MAO activity will ultimately increase the levels of monoamine neurotransmitters, an effect generally associated with a positive effect on mood. Preclinical studies indicate that estrogen and other gonadal hormones may facilitate downregulation of 5-HT₂ receptors during treatment with antidepressants. Thus, Kendall and colleagues (1982) showed that abrupt withdrawal of estrogen by surgical ovariectomy

- tomy in rats abolishes antidepressant-induced downregulation of 5-HT₂ receptors and that replacement of estrogen (as well as progesterone or testosterone) reverses the effect.
46. Janowsky and colleagues (1979) found that only 2 of 7 manic patients were dramatically calmed, whereas Judd and colleagues (1980) found observable decreases in manic symptoms in 4 of 12 manic patients with the same dose and route of administration. Davis and colleagues (1979) noted some apparent antimanic effects in 4 patients receiving up to 30 mg, but the changes were not sufficiently robust to reach statistical significance. Later, this same group (1980) gave 20 mg subcutaneously to 10 manic patients and reported no improvement in rated mania.
 47. In an open trial that included several depressed patients, Kline and Lehmann (1979) noted marked activation in one patient and some improvement in depression in two patients receiving IV p-endorphin. The effect occurred within minutes and lasted for several hours. Angst and colleagues (1979) found that when six depressed patients (four bipolar and two unipolar) received an IV infusion of p-endorphin, all improved in energy, mood, anxiety, and restlessness during the first 20 to 30 minutes, an effect that persisted for 2 hours. Four subsequently relapsed. Three patients switched into mania or hypomania during or soon after the trial, an outcome the authors suggest may have been caused by drug withdrawal, sleep deprivation, or stress.

In a double-blind trial, Gerner and colleagues (1980) also observed significant improvement following IV p-endorphin in 10 depressed patients, who then relapsed the day after the infusion; no hypomania was noted. Similar positive results were observed by Chazot and colleagues (1985) in a randomized placebo-controlled, double-blind trial involving 20 patients hospitalized for major depression (primarily unipolar). Two other double-blind trials were negative—one involving des-tyrosine γ -endorphin (Fink et al., 1981) and the other p-endorphin (Pickar et al., 1981). Extein and colleagues (1979a,b) administered an analog of met-enkephalin (FK 33824) to nine medication-free depressed patients (predominantly bipolar) and observed no clinical improvement. In sum, findings of initial open studies (and one double-blind study) suggest that IV p-endorphin or related endogenous opiate substances may improve depression.
 48. Terenius' group (1976) initially reported that CSF from manic and depressed patients showed alterations in binding to an opiate receptor preparation. Many of these patients were not studied under medication-free conditions, however, and it is also not clear how many of the depressed patients were bipolar. In a well-controlled study of bipolar illness, Pickar and colleagues (1982a) reported no overall relationship between manic or depressive mood state and total CSF opiate activity as measured by binding in the radioreceptor assay, although all four patients studied in both phases had significantly higher opiate receptor activity during mania than during depression. The opioid peptide precursor proopiomelanocortin (POMC) is cleaved to form various fragments, including s-endorphin, P-lipotropin, ct-MSH, ACTH, and the N-terminal fragment of POMC (N-POMC). Berrettini and colleagues (1985b, 1987) measured the five fragments in CSF and plasma in 30 normal volunteers and 40 euthymic bipolar patients (15 unmedicated, 25 lithium-treated). None of the five peptides was different in either group of well-state patients compared with controls.
 49. Lithium-induced increases in dynorphin were accompanied by an increase in the abundance of prodynorphin mRNA (Sivam et al., 1988), suggesting that the drug's effects on dynorphin levels are at least partially mediated through increased transcription and translation. Acute studies with lithium have demonstrated enhanced release of a number of opioid peptides from hypothalamic slices and have suggested an effect at the inhibitory presynaptic opioid autoreceptor (Burns et al., 1990). Chronic lithium administration did not affect the basal hypothalamic release of any of the opioids, but prevented the naloxone-stimulated release of the peptides *in vitro*, compatible with lithium-induced autoreceptor subsensitivity (Burns et al., 1990). Lithium is reported to decrease the affinity of opiate receptors *in vitro*, whereas subchronic lithium administration is reported in some but not all studies to decrease the number of opioid-binding sites in rat fore-brain structures (Goodnick and Gershon, 1984). Additional support for effects on the opioidergic system comes from behavioral studies in which lithium produced aversive states in rats that could be blocked by the depletion of central pools of endorphin or by the blockade of opioid receptors. It has also been demonstrated that chronic lithium administration abolishes both the secondary reinforcing effects of morphine and the aversive effects of the opioid antagonist naloxone (Mucha et al., 1985; Blancquaert et al., 1987; Lieblich and Yirmiya, 1987; Shippenberg et al., 1988; Shippenberg and Herz, 1991).
 50. When injected with somatostatin intracerebroventricularly, animals exhibit decreased spontaneous activity, increased appetite, decreased slow-wave and REM sleep, and decreased sensitivity to pain. Somatostatin modulates classic neurotransmitters such as NE, serotonin, and DA, and in addition is collocated with neurons containing NE, GABA, or acetylcholine. Several pieces of indirect evidence suggest its potential importance in affective illness. Somatostatin is widely distributed in the CNS, including cortical, limbic, and hypothalamic regions. It exerts inhibitory control over the HPA axis, which, as noted earlier, is often disinhibited in depression and perhaps in some manic states as well. Somatostatin is depleted in temporal cortex and CSF of patients with Alzheimer's disease. It is sometimes reduced in patients with other conditions often accompanied by cognitive impairment, including parkinsonism, multiple sclerosis, and anorexia nervosa. Somatostatin inhibits endocrine responses to a variety of hormones and alters appetite, pain, sleep, and motor activity (Rubinow et al., 1983), all of which are often abnormal in affective illness. It affects a variety of the classic neurotransmitters (NE, 5-HT, DA, GABA, and ACh) and coexists in neurons containing NE, acetylcholine, or GABA, suggesting important regulatory functions in these systems.
 51. Clinical evaluations of this hypothesis have used the measurement of CSF vasopressin, plasma vasopressin response to saline infusion challenge, and the behavioral response of depressed patients to a vasopressin analog. A number of studies have found that nonpsychotic bipolar depressed patients had significantly lower levels of vasopressin in CSF than those of manic patients, with normal control levels falling in the middle (Gold et al., 1981b; Gjerris et al., 1985; Sorensen et al., 1985). Gold's group (1984a) also found that vasopressin levels in CSF were significantly correlated with plasma vasopressin responses to hypertonic saline. There ap-

peared to be differences in vasopressin levels across manic and depressive states in the small number of patients receiving hypertonic saline infusion.

These findings suggest that there may be subtle vasopressin changes across manic and depressive mood states that are relevant to alterations in cognitive functioning. However, two studies of euthymic bipolar patients (Berrettini et al., 1982; Berrettini and Post, 1984) found no abnormalities in platelet vasopressin uptake and arginine vasopressin levels in CSF.

As noted, animal research suggests that vasopressin is important in memory processes (Weid, 1975), and several studies have found that administration of vasopressin (or its analogs) to normal volunteers, depressed patients, or amnesic subjects improved some aspects of memory and cognition (Weingartner et al., 1981). Gold and colleagues (1979) report that mood improved in two of seven hospitalized, medication-free depressed patients given l-desamino-8-D-arginine vasopressin (DDAVP); the uniformity of the memory improvement was even more significant. However, Zohar and colleagues (1985) did not find a therapeutic effect of lysine vasopressin on mood in 12 severely depressed, treatment-resistant patients in a double-blind, crossover study.

55. Clearly, caution is necessary when extrapolating from peripheral, accessible tissue in the study of complex CNS disorders. In this context, it is noteworthy that there is a growing body of evidence showing coexpression of abnormal proteins in peripheral cells in several neuropsychiatric disorders (Trottier et al., 1995; Li et al., 1999; Widner et al., 1999), thereby underscoring the potential utility of peripheral cells for such studies. More important for the present discussion, longitudinal studies have previously been undertaken with pharmacological agents known to affect signaling pathways in the brain (most notably lithium), demonstrating effects on several signaling proteins in peripheral cells from humans highly similar to those observed in rodent CNS (Manji et al., 1995a; Manji and Lenox, 1999). Furthermore, at least for some signaling molecules, studies have found a strong correlation between the treatment-induced changes in rodent brain and in platelets obtained from the same rodents (Manji and Lenox, 1999). Together, these results suggest that, with appropriate cautionary measures, peripheral cells can sometimes provide useful information about complex neuropsychiatric disorders.
56. Risby et al., 1991; Mork et al., 1992; Manji et al., 1995b; J. Wang et al., 1999; Manji and Lenox, 2000b.
57. Manji et al., 1995a,b; Stein et al., 1996; Li and El-Mallakh, 2000; Warsh et al., 2000.
58. Jope, 1999; Mork et al., 1992; Wang et al., 1997; Manji et al., 2000a.
59. Furthermore, although some studies have found modest changes in the levels of G protein subunits, the preponderance of the data suggests that the effects of chronic lithium on signal-transducing properties occur in the absence of changes in the levels of G protein subunits per se (Lenox and Manji, 1998). Chronic *in vivo* lithium treatment has been shown to produce a significant increase in pertussis toxin catalyzed [³²P]ADP-ribosylation in rat frontal cortex and human platelets. Since pertussis toxin selectively ADP-ribosylates the undissociated, inactive $\alpha\beta\gamma$ heterotrimeric form of G_i, these results suggest that lithium attenuates G_i function through stabilization of the inactive conformation. These results suggest that removal of the "inhibitory tone" by lithium may be responsible for the elevations in basal AC and the responses to agents activating the stimulatory pathway distal to the receptor.
60. The distinct actions of lithium on the AC system may explain the differing results obtained by investigators using rat membrane preparations and those using slice preparations (Manji et al., 2000a). This possibility led to an investigation of lithium's effects on the AC system *in vivo*, using microdialysis. These studies found that chronic lithium treatment produced a significant increase in basal and postreceptor-stimulated (cholera toxin or forskolin) AC activity while attenuating the β -adrenergic mediated effect (Masana et al., 1992; Manji et al., 2000a). Interestingly, chronic lithium treatment resulted in an almost absent cAMP response to pertussis toxin, suggesting a lithium-induced attenuation of G_i function. It should be noted, however, that chronic lithium exposure has also been found to increase not only cAMP levels (Wiborg et al., 1999), but also the levels of AC type I and II mRNA and protein levels in frontal cortex (Colin et al., 1991; Jensen et al., 2000). This finding suggests that lithium's complex effects on the system may represent the net effects of direct inhibition of AC, upregulation of AC subtypes, and effects on the stimulatory and inhibitory G proteins.
61. Steketee and Kalivas, 1991; Steketee et al., 1991; Giambalvo, 1992a,b; Gnegy et al., 1993; Steketee, 1993, 1994; Iwata et al., 1997a,b.
62. Lithium has also been shown to have additional potential sites of action in the PI cycle, where it has been reported to inhibit the inositol polyphosphatase that dephosphorylates I(1,3,4)P₃ and I(1,4)P₂. Because the brain has limited access to inositol other than that derived from recycling of inositol phosphates, the ability of a cell to maintain sufficient supplies of myoinositol can be crucial to the resynthesis of the PIs and the maintenance and efficiency of signaling (Sherman, 1986). Furthermore, because the mode of enzyme inhibition is uncompetitive, lithium's effects have been postulated to be most pronounced in systems undergoing the highest rate of PIP₂ hydrolysis (Berridge et al., 1989; Nahorski et al., 1991, 1992). Furthermore, because several subtypes of adrenergic (e.g., α_1), cholinergic (e.g., m₁, m₃, m₅), serotonergic (e.g., 5-HT₂, 5-HT₁), and dopaminergic (e.g., D₁) receptors are coupled to PIP₂ turnover in the CNS (Mahan et al., 1990; Rana and Hokin, 1990; Vallar et al., 1990; Fisher et al., 1992), this hypothesis offers a plausible explanation for lithium's therapeutic efficacy in treating both poles of manic-depressive disorder by the compensatory stabilization of an inherent biogenic amine imbalance in critical regions of the brain (Manji et al., 1995b).
63. Kendall and Nahorski, 1987; Casebolt and Jope, 1989; Godfrey et al., 1989; Whitworth and Kendall, 1989, discussed in Jope and Williams, 1994; Ellis and Lenox, 1990; Manji and Lenox, 1998.

64. Several lines of evidence suggest that the action of chronic lithium may not be directly manifest in receptor-mediated PI turnover. While investigators have observed that levels of inositol in brain remain reduced in rats receiving chronic lithium (Sherman et al., 1985), it has been difficult to demonstrate that this phenomenon results in reduced resynthesis of PIP₂, which is the substrate for agonist-induced PI turnover. Rather, this observation may be due to the methodological difficulties involved in accurately measuring alterations in a rapidly turning over small signal-related pool of PIP₂ and/or may be explained by recent evidence that resynthesis of inositol phospholipids may also occur through base exchange reactions from other, larger pools of phospholipids, such as phosphatidylcholine (Nishizuka, 1992; Manji and Lenox, 1994). An initial attempt to verify this hypothesis at this level of the PI cycle by examining the effects of lithium on muscarinic-stimulated accumulation of IP₁ in brain slices in the presence of exogenously added inositol were unsuccessful (Kendall and Nahorski, 1987).
- Additional support for the critical role of the PI second messenger-generating system in mediating many of lithium's effects comes from numerous biochemical, physiological, and behavioral studies showing that the coadministration of myo-inositol attenuates many of the effects of chronic lithium administration (Busa and Gimlich, 1989; Godfrey et al., 1989; Kofman and Belmaker, 1990, 1993; Pontzer and Crews, 1990; Tricklebank et al., 1991; Kofman et al., 1993; Manji et al., 1996). Thus, myo-inositol replenishment has been demonstrated to attenuate lithium's effects on agonist-stimulated PI turnover (Godfrey et al., 1989), electrophysiological effects mediated by serotonergic or muscarinic receptors (Pontzer and Crews, 1990), PKC isozymes (Manji et al., 1996), pertussis-catalyzed [³²P]ADP-ribosylation (Manji et al., 1996), and various rodent behaviors (Kofman and Belmaker, 1990, 1993; Tricklebank et al., 1991).
65. Since fluoride ion will directly activate G protein-coupled second messenger response, efforts have been made to examine the effect of lithium on NaF-stimulated PI response in brain. Although Godfrey and colleagues (1989) reported a reduction of fluoride-stimulated PI response in cortical membranes of rats treated with lithium for 3 days, no change in response was observed in cortical slices from rats administered lithium for 30 days. More recently, using labeled PI as a substrate (which should bypass any putative inositol depletion), Song and Jope (1992) found an attenuation of PI turnover in response to GTP analogs. Taken together, these results suggest that although chronic lithium administration may affect receptor-mediated phosphoinositide signaling, these effects are unlikely to be due simply to inositol depletion in the CNS (Jope, 1993; Manji and Lenox, 1994; Lenox and Manji, 1995). Through use of a yeast model, it was found that both lithium and valproate perturb regulation of the inositol biosynthetic pathway, albeit through different mechanisms (Murray and Greenberg, 2000; Vaden et al., 2001).
66. Williams and colleagues (2000) demonstrated that lithium, valproate, and carbamazepine all inhibit the collapse of sensory neuron growth cones and increase growth cone area, effects that were reversed by inositol. The authors then used the slime mold dictyostelium, which relies on IP₃ for its development, to identify mutants that confer resistance to the drugs. Null mutations of a gene with unknown intracellular function that encodes prolyl oligopeptidase confer lithium resistance and elevate intracellular levels of IP₃. The authors drew a link between their slime-mold studies and mammals by showing that prolyl oligopeptidase inhibitors abolished the effects of lithium, carbamazepine, and valproate on growth cone collapse and area in mammalian cells. Once again, if further validated in vivo, these observations would add to the body of findings identifying CNS intracellular signaling cascades as targets for mood stabilizers and could ultimately lead to the development of novel, more specific therapies for this devastating illness (Coyle and Manji, 2002).
67. Chen et al., 1994; Watson et al., 1998; Lenox and Hahn, 2000; Manji and Chen, 2000; Manji and Lenox, 2000b.
68. Interest in a putative role for ω-3 FA in bipolar disorder has arisen from the following observations: efficacy in models of kindling (antikindling properties in rat models of epilepsy) (Yehuda et al., 1994); incorporation of ω-3 FA in the membrane, thereby suppressing the phosphatidylinositol-associated signal transduction pathway (Medini et al., 1990; Sperling et al., 1993); blockade of calcium influx through L-type calcium channels (Pepe et al., 1994); and downregulation/inhibition of various protein kinases (Holian and Nelson, 1992; Slater et al., 1994). Mirnikjoo and colleagues (2001) describe a series of experiments showing that in vitro EPA and DHA significantly reduced the activity of cAMP-dependent PKA, PKC, MAPK, and calcium/calmodulin-dependent protein kinase II (CaMKII), effects not observed with similar fatty acids lacking an ω-3 double bond (e.g., arachidic acid). These preclinical observations, the absence of documented drug interaction, the lack of toxicity, and the apparent safety of use in pregnant women and children of ω-3 FA have all led to a clinical trial of ω-3 FA in bipolar disorder.
69. In an immunohistochemical study of postmortem hippocampus, region-specific reductions in SNAP-25 (an integral component of the SNARE complex) expression were found in both bipolar disorder and schizophrenia (Fatemi et al., 2001a). Likewise, reduced SNAP-25 immunoreactivity was found in Brodman's area 10 of the prefrontal cortex of schizophrenic patients (Young et al., 1998), and reduced SNAP-25 and synaptophysin immunoreactivity in the hippocampal-entorhinal projections of schizophrenic patients (Karson et al., 1999). In a related study, SNAP-25 was found to be elevated in the CSF of schizophrenic patients, and a similar but nonsignificant increase was noted in the small (n=5) number of bipolar patients included (Thompson et al., 1999). A recent study investigating the formation of the SNARE complex in anterior cingulate cortex found that SNAP-25 expression and interaction with syntaxin and synaptobrevin were significantly altered in schizophrenic and depressed suicide victims (Honer et al., 2002). Finally, reduced expression of several isoforms of synapsin was observed in the hippocampus of schizophrenic and bipolar patients (Vawter et al., 2002), and reduced synapsin II mRNA was found in the prefrontal cortex of schizophrenic patients. The authors also showed that chronic lithium or haloperidol has no effect on synapsin expression in rats, a finding confirmed for lithium and extended to valproate (unpublished observations).
70. Two of the primary presynaptic targets of CaMKII are synapsin I and synaptotagmin (Greengard et al., 1993). Synapsin is believed to regulate the movement of vesicles

- from the reserve pool to the membrane, and binds tightly to synaptic vesicles, actin, and ATP in a phosphorylation- and Ca^{2+} -dependent manner (Hilfiker et al., 1999a). Synaptotagmin is a secondary constituent of the SNARE complex, which docks vesicles to the presynaptic membrane, and is believed to act as a calcium sensor in calcium-dependent fusion (Hilfiker et al., 1999b). Both of these proteins have been shown to be phosphate enriched following treatment with antidepressants.
71. An additional effect on synapsin was recently noted: Valproate and, to a lesser extent, synapsin are reported to increase the number of synapsin-reactive clusters along neurites in primary neurons. It is unclear what these synapsin clusters represent, but they could be developing synapses or regions of increased cytoskeletal activity or axonal remodeling (a role for synapsins in developmental processes such as neurite outgrowth, branching, and synaptogenesis is hypothesized [Kao et al., 2002]). However, the observed effects on synapsin clustering and phosphorylation (discussed below) are not entirely congruent; increases in synapsin phosphorylation are believed, at least acutely, to cause dispersion of synapsin clusters (Chi et al., 2001; Angers et al., 2002).
72. GSK-3 is a highly conserved enzyme in evolution and is found in two nearly identical isoforms in mammals— α and β (Plyte et al., 1992; Cohen and Frame, 2001; Woodgett, 2001). It was first discovered (and named) on the basis of its ability to phosphorylate and thereby inactivate the enzyme glycogen synthase, an action that leads to a decrease in the synthesis of glycogen. Klein and Melton (1996) discovered that lithium inhibited the action of GSK-3, an effect that occurs through competition with magnesium for a binding site (Ryves and Harwood, 2001). GSK-3 phosphorylates—and thereby inactivates—many targets, including transcription factors and cytoskeletal proteins such as the Alzheimer's protein tau (a previous name for GSK-3 was tau kinase). Inhibition of GSK-3 thus results in the release of this inhibition and activation of multiple cellular targets.
73. GSK-3 is a serine/threonine kinase that is normally highly active in cells and is deactivated by signals originating from numerous signaling pathways (e.g., the Wnt pathway, the PI3 kinase pathway, protein kinase A, and PKC, among many others). It is found in two forms— α and β —that have similar but not always identical biological functions. Cellular targets of GSK-3 are numerous and often depend on the signaling pathway that is acting on it (because of cellular localization and regional sequestration). For example, Wnt pathway inhibition of GSK-3 activates the transcription factor β -catenin, while in the insulin/PI3 kinase signaling pathway, inhibition of GSK-3 results in activation of the enzyme glycogen synthase. Targets of GSK-3 include, among others, transcription factors (β -catenin, CREB, c-Jun), proteins bound to microtubules (tau, MAP1B, kinesin light chain), cell cycle mediators (cyclin D, human ninein), and regulators of metabolism (glycogen synthase, pyruvate dehydrogenase).
- Being a component of many signaling pathways with multiple cellular targets from which to choose allows GSK-3 to regulate a diverse array of cellular processes, such as glycogen synthesis, gene transcription, events related to synaptic plasticity, apoptosis, and the circadian cycle. While many of these functions are likely to be critically important to both cellular and organism functioning, at present GSK-3 is the subject of interest primarily as a regulator of apoptosis and cellular resilience. Generally, increased activity of GSK-3 is pro-apoptotic, whereas inhibiting GSK-3 attenuates or prevents apoptosis.
74. In addition to its possible usefulness in the treatment of bipolar disorder, inactivation of GSK-3 has been suggested as a potential therapy for a number of diseases. Diabetes and Alzheimer's disease have received the most attention. Diabetes has drawn interest because GSK-3 phosphorylates and deactivates glycogen synthase (T. Gould et al., 2003, 2004a,b). Alzheimer's disease is a target because of the role GSK-3 plays in both the phosphorylation of tau and the assembly of amyloid- β . Hyperphosphorylation of tau is associated with the formation of neurofibrillary tangles, while accumulation of amyloid- β leads to amyloid plaques. GSK-3 inhibitors may also be useful for the treatment of cardiac ischemic injury, other neurodegenerative disorders, and stroke and other neurotraumatic injuries.
- For these reasons, major efforts in industry have focused on the development of selective GSK-3 inhibitors. In 2002 it was reported that more than 45 patents for GSK-3 inhibitors had already been filed. Early-phase clinical trials (likely for Alzheimer's disease or diabetes) of GSK-3 inhibitors will probably be completed in the near future; it is expected that these compounds will also be tested for efficacy in the treatment of bipolar disorder.

77. Musselman et al., 1998; Steffens and Krishnan, 1998; Doraiswamy et al., 1999; Steffens et al., 1999.
78. BDNF has been shown to potentiate both excitatory and inhibitory transmission, albeit through different mechanisms. BDNF strengthens excitation primarily by augmenting the amplitude of AMPA receptor-mediated miniature excitatory postsynaptic currents (mEPSCs), but enhances inhibition by increasing the frequency of miniature inhibitory postsynaptic currents (mIPSCs) and increasing the size of GABAergic synaptic terminals. Furthermore, full-length TrkB receptor immunoreactivity has been found not only in glutamatergic pyramidal and granule cells but also in some interneuron axon initial segments, axon terminals forming inhibitory-type synapses onto somata and dendritic shafts, and excitatory-type terminals likely to originate extrahippocampally. Together, these results suggest that TrkB is contained in some GABAergic interneurons, neuromodulatory (e.g., cholinergic, dopaminergic, and noradrenergic) afferents, and/or glutamatergic afferents.

82. In a study that may have implications for the treatment of Alzheimer's disease, rats received ibotenic acid lesions of cholinergic basal forebrain nuclei, resulting in a 30–40 percent depletion of both cortical choline acetyltransferase (ChAT) and acetylcholinesterase (AChE) activity (Arendt

et al., 1999). Lithium as well as tetrahydroaminoacridine (THA), given separately either prior to or following the development of the lesion, had small but significant effects on the recovery of cortical ChAT and AChE activity. Intriguingly, when applied in combination, the drugs clearly showed

synergistic effects. However, considerable caution is required in the extrapolation of these results to the treatment of humans, since the coadministration of lithium and cholinesterase inhibitors has been shown to be capable of inducing seizures.

After largely regaining my reason, I had another most distinct sensation in the brain. . . . It seemed as though the refreshing breath of some kind Goddess of Wisdom were being blown gently against the surface of my brain. It was a sensation not unlike that produced by a menthol pencil rubbed ever so gently over a fevered brow. So delicate, so crisp and exhilarating was it that words fail me.

—Clifford Beers (1908, p. 73)

Converging phenomenological, neuroanatomical, and functional neuroimaging data are yielding insights into the functional neurobiology of affective processing in illness and in health. Affective processing is diverse, as it includes evaluative, experiential, and expressive components that vary in quality and intensity and can occur over differing temporal domains. One approach to these complex phenomena involves subtyping affects by temporal domains, with emotions having the briefest, moods intermediate, and temperaments the most sustained duration. These affects vary in several ways in addition to duration, however (see Table 15–1). Thus, emotions are brief experiences (lasting seconds to minutes) that often are intense, reactive to acute precipitants, and accompanied by autonomic arousal (increased heart rate and blood pressure) and lead to actions. In contrast, moods have longer duration (lasting up to hours in health or months in mood disorders), are somewhat less intense, range from reactive to spontaneous, may be accompanied by more subtle (hypothalamic–pituitary–adrenal axis [HPA] dysregulation) arousal, and tend to yield cognitions. Temperaments, the most sustained (lasting years to decades), are generally the least intense; are largely constitutional, though occasionally modified by persistent experiential factors; usually lack autonomic features; and yield integrative styles of interacting with the environment.

These affects also are related to one another, with different temperaments yielding predispositions to varying moods, which in turn result in tendencies to diverse emotions. Influences can be bidirectional, with repeated emotional experiences yielding particular moods, and chronic moods on occasion resulting in temperamental shifts. Although mood dysregulation is considered central to both bipolar disorder and unipolar major depressive disorder

(MDD), disturbances in emotion and temperament are also commonly encountered. (Recall that the focus of this book is manic-depressive illness, which includes all *recurrent* mood disorders, both bipolar and unipolar. While some of the imaging literature separates MDD into recurrent and nonrecurrent, most of it does not.) Thus, understanding the neurobiology of bipolar disorder and MDD may be facilitated by appreciating changes in the overlapping cerebral circuits mediating emotion, mood, and temperament. (Unfortunately, in the great majority of the literature relevant to this chapter, recurrent unipolar depression is not identified or analyzed as a distinct group, but represents an unknown and variable portion of the MDD category.)

Recent evidence from functional neuroimaging studies suggests that phylogenetically older anterior paralimbic structures contribute importantly to emotions. Such structures have access to motor circuits, and could thereby provide primitive, perceptually triggered, action-oriented affective processing. More recent overlying prefrontal neocortical elements appear to contribute importantly to moods and could thus provide more refined, complexly (perceptual, mnemonic, cognitive) triggered, cognition-oriented affective processing. Emerging evidence suggests that affective processing involves coordinated activity in basal ganglia–thalamocortical circuits connecting these cortical and subcortical regions.

Neuroanatomical observations dating back to the nineteenth century have suggested that deep midline cerebral structures are important contributors to emotional experiences. Broca (1878) defined the *great limbic lobe* as a midline cortical ring seen in mammals. Papez (1937) suggested corticothalamic mediation of emotion, and MacLean (1952) used the term *limbic system* to describe the limbic cortex and related brainstem structures.

TABLE 15–1. Temporal Domains and Other Characteristics of Affects

	Emotions	Moods	Temperaments
Duration	Seconds to minutes	Hours to days Weeks to months ^a	Years to decades
Relative intensity	High	Intermediate	Low
Precipitants	Acute	Variable/absent	Genetic/chronic
Autonomic arousal	Acute, robust	Variable/subtle	Absent/subtle
Products	Actions	Cognitions	Cognitive–affective interactions
Possible neural substrates	Anterior limbic/brain stem	Anterior cortical/anterior limbic	Anterior cortical/anterior limbic/brain stem

Alexander and colleagues (1990) described a series of basal ganglia–thalamocortical circuits, including *limbic* and *lateral orbitofrontal circuits* implicated in affective processes, and *dorsolateral prefrontal circuits* that may contribute to integration of such processes with higher cognitive functions (see Fig. 15–1). Dysfunction in these circuits may yield impaired thalamic gating or modulation of sensory or affective information, which in turn

could allow such input to disrupt cognitive and motor processes and thus contribute to the clinical profiles of mood disorders.

Thus, integrative aspects of emotion and mood processing may be related to activity in anterior cortical/anterior paralimbic basal ganglia–thalamocortical circuits. Clinical observations have related damage in such regions to affective changes. For example, the high prevalence of

mood disorder symptoms in patients with stroke, Huntington's disease, Parkinson's disease, traumatic brain injury, epilepsy, multiple sclerosis, and brain tumors fueled interest in a provocative but at times controversial literature concerning the neuroanatomy of secondary mood disorders.

Thus, the risk of depression may be greater after anterior compared with posterior and left compared with right strokes, while the risk of mania may be greater after right than after left strokes (Starkstein and Robinson, 1989; Stern and Bachmann, 1991). Such a laterality–valence association has been contested, however (Carson et al., 2000). Basal ganglia strokes may also be associated with secondary depression (Mendez et al., 1989). The profound basal ganglia damage noted in Huntington's and Parkinson's diseases and the high prevalence of mood symptoms in these disorders also support a role for basal ganglia dysfunction in secondary depressions.¹ Left dorsolateral prefrontal and/or left basal ganglia traumatic brain injuries may increase the risk of depression (Federoff et al., 1992), while right temporal basal polar injuries may increase the risk of mania (Jorge et al., 1993). The risk of secondary depression in patients with epilepsy may be greater with left than with right temporal lobe lesions (Altshuler et al., 1990). Temporal (Honer et al., 1987) and left frontal (George et al., 1994) lesions may also increase the risk of depression secondary to multiple sclerosis, although there are discordant data here as well (Moller et al., 1994). Finally, frontal lobe brain tumors may be associated with secondary depression (Direkze et al., 1971; Kanakarathnam and Direkze, 1976).

Primary mood disorders such as bipolar disorder and MDD may be related to the above secondary mood disorders in that similar cerebral circuits are affected by different (more subtle) processes that, although not evident with older technologies such as gross neuropathology and light microscopy, are increasingly being revealed by newer, more sensitive neurochemical, neuropathological, and functional neuroimaging methods. In this chapter, we review neuroimaging studies—first structural, then functional—in bipolar disorder and MDD. In many cases, such studies implicate the expected anterior cortical and anterior paralimbic components of basal ganglia–thalamocortical circuits. In addition, there is increasing evidence of relationships between neuroimaging findings in such regions and important clinical parameters, such as symptoms and treatment response. Emerging data from studies using neurochemically specific radiotracers, now beginning to yield insights into the nature of specific neurochemical changes in such regions, are described in Chapter 14.

STRUCTURAL NEUROIMAGING STUDIES

Computerized Tomography and Magnetic Resonance Imaging

Computed tomography (CT), also known as computer-assisted tomography (CAT), was the first modern neuroimaging method. Computerized analysis of data obtained from sensors detecting ionizing radiation transmitted through tissues yields sets of transaxial (horizontal) slices (tomograms) that reflect cerebral structures. This relatively inexpensive method is limited by the risk of ionizing radiation and limited spatial resolution. Magnetic resonance imaging (MRI) involves assessing paramagnetic (odd atomic number) elements such as hydrogen (^1H) in strong magnetic fields by exciting them into a higher-energy state with electromagnetic radiation, and then detecting energy released when these elements relax (return to a lower-energy state). Advantages of MRI over CT/CAT include the absence of ionizing radiation, better spatial resolution, enhanced gray–white matter contrast, less bone artifact, and modifiable acquisition techniques that yield a variety of images. The latter include T_1 -weighted images that better reflect neuroanatomy, T_2 -weighted images that better reflect neuropathology, diffusion tensor imaging (DTI) that detects white matter pathology, and magnetization transfer imaging (MTI) that reflects white and gray matter integrity. Moreover, magnetic resonance methods can be extended to generate functional brain images (fMRI) and measure cerebral metabolites with magnetic resonance spectroscopy (MRS), a variant of magnetic resonance methodology that allows noninvasive determination of various cerebral chemicals, some of which may be related to affective processing.

Imaging studies need to take into account the influences of age and gender. For example, in healthy volunteers there appear to be regional differences in brain development in childhood and adolescence. Data suggest nonlinear age-related patterns in both the frontal and parietal regions (maximum gray matter volume at 10–12 years, followed by a slight decline) and temporal regions (gray matter volume peak at age 16), but linear increases in the occipital region (Giedd et al., 1999). This nonlinear developmental pattern is also evident with cerebral glucose metabolism (Chugani et al., 1987) and ratios of N-acetylaspartate to choline (Horska et al., 2002). This time course corresponds to that of initial overproduction and subsequent sculpting of excessive neurons, synapses, and dendritic spines in the developing brain. In elderly patients and healthy volunteers, lateral and third ventricle enlargement and cortical sulcal and lateral (Sylvian) fissure prominence increase; in addition, hemispheric, cerebellar, frontal, temporoparietal, parieto-occipital, caudate, putamen, and thalamus size decreases

with age.² Also, compared with women, men appear to have greater age-related changes (Cowell et al., 1994; Passe et al., 1997; Coffey et al., 1998).

Studies of bipolar and MDD patients compared with one another and with healthy controls have revealed that gender, age, and other parameters can influence the findings of structural neuroimaging. In some reports, for example, increased lateral ventricular enlargement (LVE) is noted in men but not women with bipolar disorder (Andreasen et al., 1990; Swayze et al., 1990). Also, studies suggest that increased subcortical hyperintensities (SCHs) may be seen primarily in older (rather than younger) patients with MDD.³ Diagnostic subtype may also be important. Hence, some studies note increased LVE (Hauser et al., 2000) and SCHs (Altshuler et al., 1995) in bipolar-I but not bipolar-II patients.

Course of illness can affect findings as well. For example, patients with late-onset MDD may be at greater risk for SCHs than patients with early-onset MDD. Differences related to age at onset among patients with MDD can contribute to our understanding of manic-depressive illness since the more recurrent depressions that are part of the manic-depressive spectrum are very likely to have an early age at onset.⁴ Even medication status can influ-

ence structural neuroimaging findings, as lithium treatment can increase prefrontal gray matter volume in patients with bipolar disorder (C. Moore et al., 2000) (see Chapter 9).

Although structural neuroimaging methods have proven useful in detecting brain abnormalities in some secondary mood disorders, as well as differences between groups of patients with primary mood disorders and healthy controls, these techniques have lacked the necessary sensitivity or specificity to permit their use as instruments to diagnose primary mood disorders in individual patients. Below we review the findings of such studies in the areas of LVE, cortical sulcal enlargement (CSE), and third ventricular enlargement (TVE); SCHs; frontal, cerebellar, and hippocampal volume decreases; and other structural aspects salient to bipolar disorder and MDD.

Lateral Ventricular Enlargement, Cortical Sulcal Prominence, and Third Ventricular Enlargement

Taken together, 28 CT studies from the 1980s and 1990s⁵ and 29 MRI studies since the late 1980s⁶ suggest that bipolar and MDD patients compared with healthy controls have increased LVE, CSE, and TVE (see Fig. 15–2). The degree to

Right: T₂-weighted (TR 2000; TE 25, 70; slice thickness 2.5 mm) spin-echo axial MRI scan showing subcortical hyperintensities. (Source: Ketter and Wang, 2002.)

Figure 15-3. Cerebral hypoplasia/atrophy in mood disorders. Summary of 57 controlled studies of cerebral hypoplasia/atrophy in bipolar (BD) and major depressive disorder (MDD) patients compared with healthy controls. Studies with combined diagnostic groups are listed by predominant diagnosis. The graph depicts the number of studies with significant (dark blue) and nonsignificant (light blue) increases (above the horizontal axis), and nonsignificant (white) and significant (striped) decreases (below the horizontal axis) in lateral ventricular enlargement (LVE, left), cortical sulcal enlargement (CSE, middle), and third ventricular enlargement (TVE, right). Although the findings of only about half of the studies were positive, all but a few found at least nonsignificant increases, and only one found a significant decrease. Meta-analyses have confirmed findings of increased LVE and CSE in mood disorders.

which these regionally nonspecific volume deficits reflect hypoplastic developmental problems that precede the onset of affective illness as opposed to atrophic processes related to the progression of mood disorder remains to be established.

Increased LVE has frequently been reported in groups of bipolar and MDD patients compared with healthy controls. Early studies commonly used the ventricular brain ratio (percentage of the whole brain area occupied by the lateral ventricles, in the slice in which the lateral ventricles have their greatest size) as a measure of lateral ventricular size. More recent reports are based on the more accurate approach of calculating ventricular volumes.

LVE in bipolar patients compared with healthy controls has been found to be significantly increased overall in 9 studies,⁷ and in male (but not female) (Andreasen et al., 1990), psychotic (but not nonpsychotic) (Woods et al., 1995b), and bipolar-I (but not bipolar-II) (Hauser et al., 2000) patients. LVE has been found to be nonsignificantly increased in bipolar versus healthy subjects in 12 studies⁸ and nonsignificantly decreased in 4 studies⁹; 2 reports do not provide the direction of nonsignificant difference (Schlegel and Kretschmar, 1987; Woods et al., 1995a). Altogether, then, in

bipolar patients compared with controls, LVE was found to be significantly increased in 12 studies, nonsignificantly increased in 14 studies, and indeterminate or nonsignificantly decreased in 6 studies (see Fig. 15-3).

LVE in MDD patients compared with healthy controls has been found to be significantly increased overall in 13 studies,¹⁰ and in nonpsychotic (but not psychotic) patients (Woods et al., 1995b). LVE has been found to be nonsignificantly increased in MDD compared with healthy subjects in 13 studies¹¹; 2 reports do not provide the direction of the nonsignificant difference (Schlegel and Kretschmar, 1987; Greenwald et al., 1997). Thus, in MDD patients compared with controls, LVE was found to be significantly increased in 14 studies, nonsignificantly increased in 13 studies, and indeterminate in 2 studies. In the above summaries, studies with combined diagnostic groups are listed by predominant diagnosis. One additional study found nonsignificant enlargement in mood disorder patients (polarity not specified) (Weinberger et al., 1982).

In summary, about half of the studies reviewed found significantly increased LVE in bipolar and MDD patients compared with controls. It should be noted that limited

statistical power related to small sample sizes in individual studies could contribute importantly to negative findings, as all but a few of the above studies found at least nonsignificantly larger ventricles in patients compared with controls, and no study had a significant finding in the opposite direction.

Increased CSE has been reported in bipolar and MDD patients compared with healthy controls. CSE is usually assessed by rating prominence of interhemispheric or Sylvian fissures or frontal or temporal lobe sulci, or by performing volumetric assessment of cortical cerebral spinal fluid (CSF).

CSE in bipolar patients compared with healthy controls has been found to be significantly increased overall in one study (Nasrallah et al., 1982a) and in bipolar patients with (but not without) comorbid substance abuse in another (Lippmann et al., 1985), and significantly decreased in nonpsychotic (but not psychotic) bipolar patients in a study by Woods and colleagues (1995b). CSE has been found to be nonsignificantly increased in bipolar versus healthy subjects in three studies (Dewan et al., 1988a; Iacono et al., 1988; Lim et al., 1999) and nonsignificantly decreased in two studies (Harvey et al., 1994; Dupont et al., 1995b); one report does not provide the direction of the nonsignificant difference (Schlegel and Kretschmar, 1987).

CSE in MDD patients compared with healthy controls has been found to be significantly increased overall in five studies,¹² in women with endogenous depression (but not in men with endogenous depression or either gender with neurotic depression) (Baumann et al., 1997), and in nonpsychotic (but not psychotic) MDD patients (Woods et al., 1995a). CSE has been found to be nonsignificantly increased in MDD compared with healthy subjects in three studies (Abas et al., 1990; Coffey et al., 1993b; Dupont et al., 1995b), equal in one study (Iacono et al., 1988), and nonsignificantly decreased in one study (Ames et al., 1990); one report does not provide the direction of the nonsignificant difference (Schlegel and Kretschmar, 1987).

In the above summaries, studies with combined diagnostic groups are listed by predominant diagnosis. One additional study found increased CSE in mood disorder patients (polarity not specified) (Weinberger et al., 1982).

In summary, slightly fewer than half of the studies reviewed found significantly increased CSE in bipolar and MDD patients compared with controls, with the evidence being more robust for MDD patients. Again, limited statistical power related to small sample sizes in individual studies could contribute importantly to negative findings, as most of these studies found at least nonsignificantly increased CSE in patients compared with controls, and only one study had a significant finding in the opposite direction.

Thus, there has been some variability in the findings on LVE and CSE across studies of bipolar and MDD patients compared with controls. Although the direction of change is generally consistent, only about half of the studies reviewed found a statistical significance. Potentially confounding factors that could contribute to such variability include age, nutritional status, comorbid substance abuse, somatic therapies, and heterogeneity (e.g., MDD groups with different ratios of recurrent and nonrecurrent patients). Limited statistical power related to the combination of such confounding influences and small sample sizes may have contributed importantly to the negative findings of individual studies. As noted above, about half of the studies found significantly increased LVE and CSE in bipolar and MDD patients compared with healthy controls. Narrative and "vote counting" reviews (the latter defined as keeping a tally of studies with significant and nonsignificant findings) appear to yield overly conservative conclusions, as these methods unduly emphasize studies finding low statistical power (Hedges and Olkin, 1985). Consideration of the number of studies finding nonsignificant differences in the same direction may appear to offer some additional support but lacks statistical rigor. As described below, meta-analysis methods have proven valuable in confirming structural neuroimaging findings in bipolar disorder and MDD, not only for increased LVE and CSE (Raz and Raz, 1990; Elkis et al., 1995) but also for increased SCHs (Altshuler et al., 1995; Videbech, 1997). Unfortunately, such analyses are currently not available for many neuroimaging findings; in such instances, we consider findings probable if about half of the studies are positive, and no or very few studies have significant findings in the opposite direction.

Raz and Raz (1990) reported on meta-analyses indicating that mood disorder patients compared with controls had increased LVE in 18 studies and increased CSE in 7 studies. The composite sizes for increased LVE and CSE were moderate to small in magnitude (+.55 and +.42, respectively). The corresponding effect sizes for schizophrenia (+.70 and +.35, respectively) did not differ significantly from those for mood disorders.

Elkis and colleagues (1995) reported on meta-analyses likewise indicating that mood disorder patients compared with healthy controls had increased LVE (in 29 studies)¹³ and CSE (in 10 studies¹⁴) (see Table 15-2). The composite effects for increased LVE and CSE were highly significant ($p < .001$), but again moderate to small in magnitude (+.44 and +.42, respectively), and were not systematically related to gender or illness polarity. In addition, the authors noted that schizophrenic patients had greater ventricular enlargement than mood disorder patients. The composite effect size for this finding was highly significant

TABLE 15–2. Summary of Meta-Analyses of Studies of Ventricular Enlargement and Cortical Sulcal Prominence in Mood Disorders

Hypothesis	No. of Studies	Percent Unipolar	No. of Significant Studies	No. of Nonsignificant Studies	No. of Significant Not Reported	Composite Effect Size	<i>p</i> for Composite Effect Size
More ventricular enlargement in mood disorders than in healthy controls	29	58.4	11	15	3	+ .437	.001
More cortical sulcal prominence in mood disorders than in healthy controls	10	58.5	3	5	2	+ .421	.001
Less ventricular enlargement in mood disorders than in schizophrenia	11	31.3	0	11	0	– .201	.002
Less cortical sulcal prominence in mood disorders than in schizophrenia	3	—	0	3	0	Insufficient data	

Source: Reproduced from Elkis et al., 1995, with permission.

($p < .002$) but small in magnitude ($-.2$), and was not systematically related to gender or illness polarity. There are too few studies to allow conclusions regarding differences in CSE between mood disorder and schizophrenic patients. Thus, these generalized structural brain abnormalities (increased LVE and CSE) in the former patients may differ less from those in schizophrenic patients than from those in controls, consistent with a continuum model of mood and schizophrenic disorders.¹⁵

A recent meta-analysis used more robust threshold criteria for inclusion (McDonald et al., 2004). In five studies, bipolar patients compared with controls had a significant ($p = .03$) 14 percent increase in right lateral ventricular volume, but only a nonsignificant ($p = .32$) 8 percent increase in left lateral ventricular volume. In six studies, bipolar patients compared with controls tended to have ($p = .06$) a 17 percent increase in total lateral ventricular volume.

Thus, bipolar and MDD patients appear to have increased LVE and CSE. The clinical significance of these findings remains to be established, however. LVE has received more attention than CSE in this regard. As noted below, there are variable reports on the relationships between LVE and clinical phenomena, and unfortunately meta-analyses regarding such relationships are not yet available.

LVE may increase with age in bipolar patients (Pearlson and Veroff, 1981; Rieder et al., 1983), MDD patients,¹⁶ and healthy subjects.¹⁷ However, negative findings have also been reported in bipolar patients (Pearlson et al., 1984a; Dewan et al., 1988b; Brambilla et al., 2001b), MDD patients,¹⁸ and healthy subjects.¹⁹ Longitudinal studies suggest that LVE may increase with disease duration in patients with mood disorders, perhaps in excess of the increase noted with normal aging (Vita et al., 1988; Woods et al., 1990). In bipolar and MDD patients, LVE has been associated with later or late-life onset in some studies,²⁰ but not in others.²¹

One study found that multiple-episode bipolar patients compared with both first-episode patients and healthy subjects had larger lateral ventricles, with the degree of enlargement being related to number of prior manic episodes (Strakowski et al., 2002). Another study found that right LVE increased with the number of episodes (Brambilla et al., 2001b). Other studies have reported variable findings on the relationships between LVE and illness chronicity and course,²² occupational function (Pearlson et al., 1984b; Dewan et al., 1988b), and biological markers (Kellner et al., 1983; Van den Bossche et al., 1991).

LVE was found to be related to psychosis in 31 bipolar-I and 9 bipolar-II patients (Kato et al., 1994b); 66 patients with late-onset depression (Simpson et al., 2001); 22 mood

disorder patients (Luchins et al., 1984); and a mixed cohort of 33 MDD, 22 bipolar, and 5 schizoaffective patients (Schlegel and Kretzschmar, 1987). The findings of other studies, however, suggest that LVE may not be related to psychosis in bipolar disorder (Pearlson et al., 1984b; Dewan et al., 1988b; Roy-Byrne et al., 1988), and may (Targum et al., 1983; Rothschild et al., 1989; Shiraishi et al., 1992) or may not (Standish-Barry et al., 1985; Rabins et al., 1991; Hickie et al., 1995) be related to psychosis in MDD patients. LVE may (Kellner et al., 1986) or may not²³ be related to cognitive impairment in bipolar disorder, and may²⁴ or may not (Andreasen et al., 1990; Simpson et al., 2001) be related to cognitive impairment in MDD patients.

Increased LVE in bipolar (particularly male) compared with MDD patients has been reported (Andreasen et al., 1990; Swayze et al., 1990). Other groups, however, have failed to find this difference (Dolan et al., 1985; Schlegel and Kretzschmar, 1987). Likewise, as noted above, in Elkis and colleagues' (1995) meta-analysis, LVE was not found to be systematically related to polarity or gender. Investigators have also found that LVE generally fails to have a significant association with severity of mood symptoms as assessed by mood rating scales.²⁵

Most studies have indicated that LVE is unrelated to dexamethasone suppression status and post-dexamethasone cortisol,²⁶ although one study noted a trend (Rothschild et al., 1989) and another a significant relationship (Rao et al., 1989). Ventricular enlargement may (Schlegel et al., 1989b) or may not (Dewan et al., 1988b) be related to predexamethasone plasma cortisol, and may (Kellner et al., 1983) or may not (Risch et al., 1992) be related to urinary free cortisol.

Most studies have found that LVE is not related to a history of electroconvulsive therapy (ECT) in bipolar patients²⁷ or MDD patients (Dolan et al., 1985; Kolbeinsson et al., 1986). Prospectively, ECT did not cause or exacerbate LVE in MDD patients.²⁸ LVE does not appear to be related to prior treatment with lithium,²⁹ antidepressants (Dolan et al., 1985; Harvey et al., 1994; Baumann et al., 1997), antipsychotics (Rieder et al., 1983; Dolan et al., 1985; Swayze et al., 1990), or benzodiazepines (Dolan et al., 1985; Swayze et al., 1990), or with alcohol abuse (Rieder et al., 1983; Dolan et al., 1985; Swayze et al., 1990), drug abuse (Swayze et al., 1990), or substance abuse generally (Dewan et al., 1988c; Andreasen et al., 1990). Young and colleagues (1998) found LVE to be associated with poorer response to tricyclic antidepressants, but in other reports, LVE was not shown to be related to response to lithium (Dewan et al., 1988c) or other treatments.

Increased TVE has been reported in bipolar and MDD patients compared with healthy controls. In bipolar versus healthy subjects, TVE was found to be significantly increased

in three studies (Dewan et al., 1988; Strakowski et al., 1993; Pearlson et al., 1997), nonsignificantly increased in four studies,³⁰ and nonsignificantly decreased in two studies (Iacono et al., 1988; Brambilla et al., 2001b); one report does not provide the direction of the nonsignificant difference (Schlegel and Kretzschmar, 1987).

TVE was found to be significantly increased in MDD patients compared with healthy controls in five studies³¹ and in women with endogenous depression (but not in men with endogenous or in either gender with neurotic depression) (Baumann et al., 1997), and nonsignificantly increased in three studies (Tanaka et al., 1982; Iacono et al., 1988; Coffey et al., 1993b). One report does not provide the direction of the nonsignificant difference (Greenwald et al., 1997).

Thus, about half of the studies reviewed found significantly increased TVE in bipolar and MDD patients compared with healthy controls, with the evidence being more robust for the MDD patients. Once again, limited statistical power related to small sample sizes in individual studies could contribute importantly to negative findings, as all but a few of these studies found at least nonsignificantly increased TVE in patients, and no study had a significant finding in the opposite direction. A recent meta-analysis using robust threshold criteria for inclusion (McDonald et al., 2004) found that in six studies, bipolar patients compared with controls had a nonsignificant ($p=.35$) 18 percent increase in third ventricular volume.

Because the third ventricle is bounded laterally by the thalamus, TVE is consistent with a decrease in thalamic volume, which in turn supports the hypothesis that basal ganglia–thalamocortical circuit function may be disrupted in bipolar and MDD patients. TVE may (Schlegel and Kretzschmar, 1987) or may not (Dewan et al., 1988a; Brambilla et al., 2001b) be more evident in early-onset bipolar disorder, and may be associated with earlier- (Beats et al., 1991) or later- (Dahabra et al., 1998) onset MDD. There are conflicting data regarding relationships between TVE and dexamethasone suppression status and post-dexamethasone cortisol (Schlegel and Kretzschmar, 1987; Coffey et al., 1993; Mukherjee et al., 1993). TVE and neuropsychological function may not (Dewan et al., 1988) be related in bipolar disorder, and may (Beats et al., 1991) or may not (Dahabra et al., 1998) be related in MDD.

In patients with schizophrenia, LVE appears to be linked to TVE but not to CSE (Raz and Raz, 1990). This finding suggests that in schizophrenia, LVE may represent a subcortical neuropathological process related to third ventricular dilatation, yet independent of CSE. The relationships between these abnormalities in bipolar disorder and MDD remain to be determined. Rieder and colleagues (1983) found that CSE in bipolar patients was correlated

with cerebellar atrophy, but LVE was not correlated with either of these measures. Of interest, in one small study in schizophrenic and depressed patients, those with (but not without) enlarged ventricles and widened Sylvian fissures tended to have lower global metabolism than healthy controls (Kling et al., 1986).

Taken together, the above findings suggest that bipolar and MDD patients have increased LVE and CSE and probably have increased TVE as well. These findings are not anatomically or diagnostically specific, however. Moreover, the clinical significance of these findings needs to be delineated more clearly. Although the currently available data suggest that LVE may be related to age and later- or late-life onset and not to degree of depression or treatment with medications or ECT, there have been variable findings on relationships to illness chronicity, course, and polarity; to psychosis; and to HPA axis dysfunction. Unfortunately, meta-analyses regarding how LVE, CSE, and TVE are related to clinical parameters are currently not available.

Subcortical Hyperintensities

Increased SCHs have been observed in mood disorder patients compared with healthy controls. SCHs are bright areas in deep white, periventricular white, or subcortical gray matter on T2-weighted MRI images. Taken together, 41 studies since 1989 suggest that younger and older bipolar and older MDD patients compared with healthy controls have increased SCHs.³²

SCHs in bipolar patients were found to be significantly increased overall in 10 studies³³ and in bipolar-I (but not bipolar-II) patients (Altshuler et al., 1995), nonsignificantly increased in 7 studies,³⁴ and nonsignificantly decreased in 2 studies (Brown et al., 1992; Sassi et al., 2003). With the exception of 2 small pediatric studies (Botteron et al., 1995; Pillai et al., 2002), 1 small elderly adult study (McDonald et al., 1991), and 1 large study involving a broad age range (McDonald et al., 1999), these were studies of nonelderly adult bipolar patients. Altshuler and colleagues (1995) performed a meta-analysis of 8 studies³⁵ including 198 bipolar patients and 307 controls and found increased frequency of SCHs in the former, with a common odds ratio of 3.3 and 95 percent confidence interval of 1.9–5.6 ($p=.00001$). Videbech (1997) performed an expanded meta-analysis of 10 studies³⁶ including 296 bipolar patients and 516 controls and found that in all but 1 of these studies (Brown et al., 1992), the odds ratios pointed toward increased frequency of SCHs in the bipolar subjects, with a common odds ratio of 3.3 and 95 percent confidence interval of 2.1–5.1 ($p=.0000001$).

As noted above, SCHs may be more common in bipolar-I but not bipolar-II patients compared with controls (Altshuler et al., 1995), although Krabbendum and

colleagues (2000) failed to detect such a difference. In another study, there were no apparent changes in SCHs on repeat scanning 1 year later (Dupont et al., 1990). One study found that 6 of 10 unaffected relatives of patients with bipolar disorder from a loaded pedigree had subcortical gray SCHs (Ahearn et al., 1998).

SCHs in MDD patients were found to be significantly increased overall in 14 studies³⁷ and in patients with later (over age 50) but not earlier (under age 35) onset (Lesser et al., 1996), nonsignificantly increased in 12 studies,³⁸ and nonsignificantly decreased in 1 study (Sassi et al., 2003). In contrast to the studies involving bipolar patients noted above, studies involving MDD patients have assessed primarily elderly patients. Videbeck (1997) performed a meta-analysis of 7 studies³⁹ including 254 MDD patients and 511 controls and found that in nearly all of these studies, odds ratios pointed toward increased frequency of SCHs in MDD patients, with a common odds ratio of 3.3 and 95 percent confidence interval of 2.1–4.8 ($p = .00000001$).

Thus, there has been some variability in findings with regard to SCHs across studies of bipolar and MDD patients compared with controls. Although the direction of change has generally been consistent, only slightly more than half of the studies have demonstrated statistical significance.

As with the studies discussed earlier, limited statistical power related to small sample sizes in individual studies could contribute importantly to negative findings, as all but a few of these studies found at least nonsignificantly increased SCHs in patients, and no study had a significant finding in the opposite direction. Indeed, meta-analyses have confirmed increased SCHs in bipolar and MDD patients (Altshuler et al., 1995; Videbeck, 1997). This pattern of findings is similar to that for increased LVE and CSE in bipolar and MDD patients noted above. SCHs appear to occur most frequently in the frontal lobe deep white matter in both bipolar patients⁴⁰ and MDD patients.⁴¹ This observation does not hold true for all studies, however (Howard et al., 1993; Altshuler et al., 1995).

Deep white matter SCHs have been the subtype studied most frequently and found most consistently to be increased in patients compared with controls. Among 20 studies of bipolar patients, such SCHs were found to be significantly increased in 9 studies,⁴² nonsignificantly increased in 8 studies,⁴³ and equal or nonsignificantly decreased in 3 studies (Brown et al., 1992; Altshuler et al., 1995; Sassi et al., 2003) (see Fig. 15–4). Among 23 studies of MDD patients, deep white matter SCHs were found to be significantly increased in 10 studies,⁴⁴ nonsignificantly

Figure 15–4. Subcortical hyperintensities in mood disorders. Summary of 37 controlled studies of subcortical hyperintensities (SCHs) in bipolar (BD) and major depressive disorder (MDD) patients compared with healthy controls. Studies with combined diagnostic groups are shown by predominant diagnosis. The graph depicts the number of studies with significant (dark blue) and nonsignificant (light blue) increases (above the horizontal axis) and nonsignificant (white) decreases and unspecified nonsignificant findings (striped) (below the horizontal axis) in deep white (left), periventricular white (middle), and subcortical gray (right) SCHs. Although only about half of the studies yielded positive findings, all but a few found at least nonsignificant increases, and none found significant decreases. Meta-analyses have confirmed these findings.

increased in 12 studies,⁴⁵ and nonsignificantly decreased in 1 study (Greenwald et al., 1996).

Periventricular SCHs have been assessed less frequently. Among 12 studies of bipolar patients, these SCHs were found to be significantly increased in 3 studies (Altshuler et al., 1995; Woods et al., 1995a; McDonald et al., 1999), nonsignificantly increased in 2 studies (Woods et al., 1995a; Krabbendam et al., 2000), and equal or nonsignificantly decreased in 7 studies.⁴⁶ Among 15 studies of MDD patients, periventricular SCHs were found to be significantly increased in 3 studies (Coffey et al., 1990, 1993b; Iidaka et al., 1996), nonsignificantly increased in 7 studies,⁴⁷ nonsignificantly decreased in 4 studies,⁴⁸ and not significantly different (direction of nonsignificant difference not specified) in 1 study (MacFall et al., 2001).

Subcortical gray matter hyperintensities have been examined least frequently. Among 7 studies of bipolar patients, these SCHs were found to be significantly increased in 1 study (McDonald et al., 1999), nonsignificantly increased in 2 studies (Aylward et al., 1994; Altshuler et al., 1995), and equal or nonsignificantly decreased in 4 studies.⁴⁹ In contrast, among 12 studies of MDD patients, subcortical gray matter SCHs were found to be significantly increased in 6 studies,⁵⁰ nonsignificantly increased in 4 studies,⁵¹ nonsignificantly decreased in 1 study (Miller et al., 1994), and not significantly different (direction of nonsignificant difference not specified) in 1 study (MacFall et al., 2001).

Thus, SCHs appear to occur in frontal lobes (deep white matter) and in periventricular white matter in nonelderly and elderly bipolar and elderly MDD patients, and in basal ganglia (subcortical gray matter) in elderly MDD patients. The clinical significance of these findings remains to be established, however. As noted below, there are variable reports on the relationships between SCHs and clinical phenomena, and unfortunately meta-analyses in this area are not yet available.

SCHs can occur in patients with other psychiatric and neurological disorders,⁵² but lesions in the frontal lobes and basal ganglia may still be related to depressive symptoms. Moreover, SCHs are occasionally observed in clinically healthy individuals in association with ventricular enlargement, cerebral hypometabolism, higher blood pressure, and lower neuropsychological test scores (DeCarli et al., 1995).

SCHs have been reported to increase with age in bipolar patients,⁵³ MDD patients,⁵⁴ heterogeneous psychiatric patients (Deicken et al., 1991; Brown et al., 1992), and healthy volunteers.⁵⁵ However, negative findings have also been reported in bipolar patients,⁵⁶ MDD patients,⁵⁷ and healthy volunteers.⁵⁸

SCHs may be related to hypertension, carotid arteriosclerosis, arteriolar hyalinization, and dilated perivascular spaces.

They have been found to be related to cardiovascular risk factors in MDD patients (Coffey et al., 1989; Lesser et al., 1996; O'Brien et al., 1996), in healthy controls (Coffey et al., 1989; Lesser et al., 1996; O'Brien et al., 1996), and to a lesser extent in bipolar patients (Aylward, et al., 1994). The increased SCHs in bipolar and MDD patients do not, however, appear to be due solely to such risk factors,⁵⁹ although Miller and colleagues (1994) failed to find significantly increased SCHs in patients with late-life depression and without such risk factors compared with healthy controls.

Studies have reported variable findings with respect to relationships between SCHs and illness chronicity and course.⁶⁰ Among bipolar patients, SCHs may occur in late-onset illness (McDonald et al., 1991) but have also been noted in younger patients (Dupont et al., 1995a,b). Some data (Dupont et al., 1995b) but not all⁶¹ suggest that SCHs may occur preferentially in bipolar patients with later- or late-life onset. Similarly, among MDD patients, some studies⁶² but not all⁶³ indicate that SCHs may occur preferentially in patients with later- or late-life onset.

Among depressed MDD patients, psychosocial stressors have been found to be inversely related to SCHs, suggesting that stress-independent biological factors could be more relevant to these lesions (Fujikawa et al., 1997). Patients with late-onset mania had more or more widespread SCHs than did patients with early-onset mood disorders and late-onset MDD, respectively (Fujikawa et al., 1995), consistent with late-onset mania being a more biologically severe disorder (Fujikawa et al., 1996).

In healthy volunteers, white matter SCHs appear to be related to lower scores on frontal lobe-mediated neuropsychological tests (Boone et al., 1992; DeCarli et al., 1995) and decreased frontal lobe metabolism (DeCarli et al., 1995). SCHs may be related to cognitive impairment in MDD patients,⁶⁴ although some studies have failed to detect such a relationship (Zubenko et al., 1990; Dupont et al., 1995b; O'Brien et al., 1996). In bipolar patients, SCHs and cognitive impairment may (Dewan et al., 1988b; Dupont et al., 1990, 1995b) or may not (Swayze et al., 1990; Dahabra et al., 1998; Krabbendam et al., 2000) be related. In elderly individuals (mostly healthy, but some with a history of receiving antidepressants), deep white (but not periventricular) SCHs were found to be associated with depressive symptoms, especially impaired motivation, concentration, and decision making, and this relationship was especially strong in patients carrying the APOE-4 allele (Nebes et al., 2001). Another study of elderly individuals (mostly healthy, but some with a history of depression) found that subcortical and periventricular white matter SCHs were associated with depressive symptoms (de Groot et al., 2000).

SCHs do not appear to be related to severity of depression in bipolar patients (Dupont et al., 1990, 1995a; Altshuler

et al., 1995) or MDD patients,⁶⁵ although two studies detected such a relationship in the latter patients (MacFall et al., 2001; Murata et al., 2001). SCHs likewise do not appear to be related to psychosis in bipolar patients⁶⁶ or MDD patients.⁶⁷ SCHs may (Dupont et al., 1990, 1995a) or may not (Altshuler et al., 1995) be related to psychiatric hospitalizations in bipolar patients, and may not be related to psychiatric hospitalizations in MDD patients (Dupont et al., 1995a; Iidaka et al., 1996). SCHs do not appear to be related to dexamethasone suppression status or post-dexamethasone cortisol levels (Rao et al., 1989; Deicken et al., 1991; Coffey et al., 1993b).

SCHs may be more (Sassi et al., 2003) or less (Hickie et al., 1995) common in MDD patients lacking a family history of mood disorders. In contrast, SCHs in bipolar patients have been reported to be unrelated to a family history of mood disorders (Sassi et al., 2003).

Studies have found no relationship between SCHs and prior ECT in either bipolar patients (Swayze et al., 1990; Figiel et al., 1991a) or MDD patients.⁶⁸ Prospectively, ECT did not cause or exacerbate SCHs in MDD patients.⁶⁹ Basal ganglia lesions may yield patients more susceptible to ECT-induced delirium, however (Figiel et al., 1989b, 1990a,b). Limited evidence suggests that white matter SCHs may predict poorer response to ECT in MDD patients (Coffey et al., 1987; Hickie et al., 1995), perhaps because these SCHs may represent subtle vascular insufficiency (Sackeim, 1996). Other data suggest, however, that SCHs in MDD patients are not related to ECT response (Figiel et al., 1989b).

SCHs do not appear to be related to prior treatment with lithium,⁷⁰ carbamazepine (Altshuler et al., 1995), antidepressants (Altshuler et al., 1995), antipsychotics (Dupont et al., 1990; Swayze et al., 1990), or benzodiazepines (Swayze et al., 1990), or to prior alcohol abuse (Swayze et al., 1990), drug abuse (Swayze et al., 1990), or substance abuse generally (Strakowski et al., 1993b). As noted above, earlier-onset MDD patients (who have longer illness duration and greater treatment exposure) compared with later-onset patients may have fewer SCHs, an observation inconsistent with the notion that illness or treatment duration markedly affects these lesions. Moreover, it should be recalled that MDD with an early age at onset is part of the manic-depressive spectrum and as such is genetically different from later-onset MDD (see Chapter 13).

Deep white matter and basal ganglia SCHs may be associated with resistance to antidepressants (Hickie et al., 1995; Simpson et al., 1998). Basal ganglia lesions may increase the risk of antidepressant-induced delirium (Figiel et al., 1989b) and adverse effects on the central nervous system (Fujikawa et al., 1996). After 2 years of naturalistic treatment, MDD patients who had achieved and sustained

remission had attenuated increases in white matter SCH volume (11.5 percent) compared with patients who had not achieved or sustained remission (31.6 percent) (Taylor et al., 2003). Less is known about relationships between SCHs and treatment resistance in bipolar patients.

Interpretation of the significance of increased SCHs in bipolar and MDD patients is limited by sparse knowledge of the pathophysiology of these lesions. Emerging data are beginning to address this problem, however. SCHs have been associated with ventricular enlargement in healthy volunteers (DeCarli et al., 1995) and in bipolar (Dupont et al., 1995b) and MDD patients (Coffey et al., 1989; Iidaka et al., 1996), although MDD patients in one study failed to display such a relationship (Dupont et al., 1995b). SCHs have also been associated with CSE in MDD patients (Coffey et al., 1989).

SCHs have been associated with cerebral hypometabolism in healthy volunteers (DeCarli et al., 1995). Elderly patients with depression (who as a group have increased SCHs) commonly have decreased global and regional cerebral blood flow (CBF), which may persist during remission. During hypercapnea challenge, these patients can have diminished CBF responses (decreased vasodilatory reserve), a phenomenon associated with hypertension, late onset, and poor treatment response (Sackeim, 1996). In elderly depressed patients, moreover, periventricular white matter SCHs have been found to be associated with decreased temporal CBF as assessed by single-photon-emission CT using technetium-99m-hexamethylpropyleneamineoxime (99mTc-HMPAO SPECT) (Ebmeier et al., 1998).

SCHs have been found to be associated with altered cerebral metabolite ratios in phosphorous (Sappey-Marinier et al., 1992a) and proton (Sappey-Marinier et al., 1992b) MRS studies of elderly patients, and with decreased N-acetylaspartate (NAA)/creatine (Cr) in elderly MDD patients (Murata et al., 2001).

Diffusion tensor imaging (DTI) is a derivative of MRI that assesses the movement of water in axons. DTI can detect decreases in fractional anisotropy that are considered indicative of white matter pathology. DTI studies in bipolar patients compared with healthy controls found prefrontal decreased white matter fractional anisotropy (Adler et al., 2004, 2006) and increased apparent diffusion coefficient (Beyer et al., 2005). In one DTI study, SCHs compared with normal regions displayed increased apparent diffusion coefficients and lower anisotropy in both elderly depressed patients and controls, suggesting similar pathological changes (Taylor et al., 2001). Also, elderly MDD patients compared with elderly controls had lower right superior frontal gyrus white matter fractional anisotropy (Taylor et al., 2004). In another DTI study, elderly MDD patients compared with healthy controls showed more robust

declines in white matter fractional anisotropy. In patients but not controls, these declines were related to aging, consistent with emerging data suggesting that late-life depression may be associated with age-related declines in white matter integrity (Choi et al., 2002).

Taken together, the above findings suggest that bipolar and MDD patients have increased SCHs. In individuals without psychiatric disorders and in bipolar and MDD patients, these lesions increase with age. Moreover, in healthy volunteers and MDD patients (and perhaps to a lesser extent in bipolar patients), SCHs appear to be related to cardiovascular risk factors and may thus reflect decreased vascular reserve. There may also be relationships among cerebral regions, diagnosis, and age, as SCHs appear to occur in frontal lobes (deep white matter) in nonelderly and elderly bipolar and elderly MDD patients and in basal ganglia (subcortical gray matter) in elderly MDD patients, consistent with the hypothesis that anterior cortical/anterior paralimbic basal ganglia–thalamocortical circuit function may be disrupted in bipolar and MDD patients. However, the relative paucity of evidence supporting basal ganglia (subcortical gray matter) SCHs in bipolar patients could be due to these lesions being specific to older patients with bipolar disorder (McDonald et al., 1999).

There may be some disassociations between bipolar disorder and MDD in clinical correlates of SCHs. Thus in MDD (perhaps to a greater extent than in bipolar) patients, SCHs may be related to later onset, negative family history, cardiovascular risk factors, cognitive impairment, and treatment resistance. This hypothesis in turn is consistent with there being at least some disassociations between bipolar disorder and MDD in the pathophysiology of SCHs. Importantly, SCHs are not diagnostically specific, and the pathophysiology of these lesions needs to be better understood. Moreover, multiple aspects of the clinical significance of SCHs in bipolar disorder and MDD remain to be established. Although some studies suggest interesting relationships with clinical parameters, there are also multiple negative studies in this regard, and unfortunately, meta-analyses of the clinical relationships are not yet available.

Frontal, Cerebellar, and Hippocampal Volume Decreases

Bipolar and MDD patients compared with healthy controls may have cerebral volume decreases in specific regions. The frontal lobes and cerebellum in bipolar and MDD patients and the hippocampus in MDD patients have been implicated in particular.

Frontal and prefrontal volume decreases appear to occur in mood disorders. A tendency for them to occur in bipolar patients compared with healthy controls was observed in three studies (Coffman et al., 1990; Sax et al., 1999;

Strakowski et al., 1999), but they were not seen in two studies (Strakowski et al., 1993b; Zipursky et al., 1997). A recent meta-analysis using robust threshold criteria for inclusion (McDonald et al., 2004) found that in three studies, bipolar patients and controls had similar left (4 percent smaller, $p = .19$) and right (5 percent smaller, $p = .11$) prefrontal volumes. In MDD patients, these decreases were found to be present in eight studies⁷¹ and absent in only three studies (Pantel et al., 1997; Bremner et al., 2000; Janssen et al., 2004). As noted below, prefrontal CBF and metabolism are commonly decreased in depressed bipolar and MDD patients. Frontal and prefrontal volume decreases may be related to poorer performance on neuropsychological tests (Coffman et al., 1990), such as the continuous performance task (Sax et al., 1999).

Methodological advances (improved scan resolution and gray–white segmentation) have led to emerging data on gray and white matter volumes. Prefrontal gray matter may (Drevets et al., 1997; Lopez-Larson et al., 2002) or may not (Dupont et al., 1995b; Zipursky et al., 1997; Lim et al., 1999) be decreased in bipolar patients compared with healthy controls. Prefrontal gray matter density may also be decreased in bipolar disorder (Lyoo et al., 2004). Findings of a preliminary study suggest that men with bipolar-I disorder (but not men with bipolar-II or women) may be at risk for decreases in left frontal lobe gray matter that tend to correlate with decreases in NAA as assessed by MRS (Dieckmann et al., 2002). One study, however, found that dorsolateral prefrontal cortex, inferior parietal lobule, and superior temporal gyrus gray matter volumes were unchanged in bipolar patients compared with healthy controls (Schlaepfer et al., 1994), and another found that depressed adolescents compared with controls had increased frontal gray matter volumes and decreased frontal white matter volumes (Steingard et al., 2002).

Recently, voxel-based morphometry (VBM) has allowed automated voxel-wise assessments of gray and white matter volumes and densities. Studies to date in patients with bipolar disorder⁷² and MDD (Bell-McGinty et al., 2002; Pizzagalli et al., 2004) have had variable findings, perhaps as a result of confounds with respect to age, mood disorder subtype, mood state, prior pharmacotherapy (in view of the putative neurotrophic effects of lithium), current medication status, and methodological variability.

Evidence suggests that gray matter volume is decreased in the prefrontal cortex ventral to the genu of the corpus callosum in both familial bipolar disorder and familial MDD (Drevets et al., 1997), consistent with decreased CBF and metabolism (Drevets et al., 1997) and histopathological changes (Rajkowska, 1997) observed in that region. Gray matter volume decreases in the subgenual portion of the left ventral anterior cingulate cortex in bipolar and MDD patients have been demonstrated by both MRI-based

morphometric measures⁷³ and postmortem neuropathological studies of patients with a family history of bipolar disorder and MDD (Öngür et al., 1998). This reduction in volume was seen in patients with a family history of bipolar disorder (Hirayasu et al., 1999), but was notably not demonstrable in bipolar patients with no family history of mood disorders. The reduction was found early in MDD patients (Botteron et al., 2002) and may follow illness onset, as indicated by preliminary evidence in twins discordant for MDD (Botteron et al., 1999).

Coryell (2005) found decreased volume in a nearby region in patients with psychotic MDD. Kimbrell and colleagues (2002) reported that subgenual anterior cingulate metabolism was inversely correlated with the number of lifetime depressive episodes in MDD patients. Other studies, however, have failed to detect subgenual prefrontal cortical volume decreases in mood disorder patients.⁷⁴ A recent meta-analysis using robust threshold criteria for inclusion (McDonald et al., 2004) found that in four studies, bipolar patients compared with controls had nonsignificantly decreased left (20 percent, $p = .31$) and right (6 percent, $p = .36$) subgenual prefrontal volumes. Studies in MDD patients that failed to find a volume decrease in this region, however, found decreased cerebral metabolism in the region in patients with melancholia (Pizzagalli et al., 2004) and decreased gyrus rectus volumes in MDD patients compared with controls (Bremner et al., 2002). Other studies in bipolar patients that failed to detect a volume decrease in this area found more posterior and dorsal cingulate gray matter volume (Lochhead et al., 2004; Nugent et al., 2006) and density (Doris et al., 2004) decreases, as well as decreased left dorsolateral prefrontal cortical gray matter volume in pediatric patients (Dickstein et al., 2005). In addition, MTI demonstrated decreased macromolecular density in the right subgenual anterior cingulate and adjacent white matter (Bruno et al., 2004). Still other studies found that bipolar patients compared with controls had decreased gray matter density in the anterior cingulate close to subgenual prefrontal cortex (Lyo et al., 2004) and decreased left dorsal anterior cingulate volume (Sassi et al., 2004; Kaur et al., 2005). One study found decreased left cingulate, right medial frontal, and left middle frontal cortical thickness in bipolar patients compared with healthy controls (Lyo et al., 2006). Ventral prefrontal gray and white matter volumes may decline more rapidly with age in adolescents and young adults with bipolar disorder compared with healthy controls, and rapid cycling may exacerbate and pharmacotherapy may attenuate ventral prefrontal volume deficits (Blumberg et al., 2006). Of interest, decreased orbitofrontal total (Lai et al., 2000) and gray matter (Lacerda et al., 2004; Lavretsky et al., 2004) volumes have been observed in MDD patients.

Although effective treatment with selective serotonin reuptake inhibitors (SSRIs) was not found to alter subgenual prefrontal cortical volume in MDD patients (Drevets et al., 1997), this cortex appeared significantly larger in bipolar patients chronically medicated with lithium or valproate than in bipolar patients who were either unmedicated or medicated with other agents (see Fig. 15–5). These observations are compatible with evidence that chronic administration of these mood stabilizers increases expression of the neuroprotective and neurotrophic proteins in the frontal cortex of experimental animals (Manji et al., 2001). Other investigators, however, have failed to detect subgenual prefrontal cortical volume changes in familial and nonfamilial bipolar and MDD patients (regardless of whether they were taking lithium) compared with healthy controls (Brambilla et al., 2002). One report suggests that, compared with healthy controls, bipolar patients had decreased left anterior cingulate volumes when not medicated but tended to have increased left posterior and right anterior cingulate volumes when taking lithium monotherapy (Sassi et al., 2002b).

Cerebellar volume decreases appear to occur in patients with mood disorders. Compared with healthy controls, such decreases were detected in bipolar patients in six studies⁷⁵ but not in four studies,⁷⁶ and were detected in MDD patients in two studies (Shah et al., 1992; Escalona et al., 1993) but not in two other studies (Yates et al., 1987; Pillay et al., 1997). In one study, a combined group of bipolar and MDD patients compared with healthy controls tended to have vermian or cerebellar volume decreases (Weinberger et al., 1982). Vermian volume decreases were seen in bipolar patients with (but not without) a history of alcohol abuse (Lippmann et al., 1982). These decreases may tend to be related to number of episodes (DeBello et al., 1999; Brambilla et al., 2001b) and family history of bipolar disorder (Brambilla et al., 2001b), but not to lithium therapy or scores on the Hamilton Rating Scale for Depression (HAM-D) (Brambilla et al., 2001b). In MDD, fluoxetine nonresponders' (but not responders') decreased vermian volumes were found to be associated with higher pretreatment HAM-D scores (Pillay et al., 1997). Cerebellar volume decreases were not related to neuropsychological function in MDD patients, however (Greenwald et al., 1997).

Hippocampal volume decreases have been observed in MDD patients compared with healthy controls. In bipolar patients, however, findings have varied, with hippocampal volumes found to be unchanged in 13 studies,⁷⁷ decreased in 3 (Swayze et al., 1992; Noga et al., 2001; Frazier et al., 2005), tending to be decreased in 2 (Strakowski et al., 2002; Blumberg et al., 2003c), and increased in 2 (Kemmerer et al., 1994; Beyer et al., 2004). In a recent meta-analysis

Figure 15–5. Decreased subgenual prefrontal cortical (PFC) gray matter volumes in depressed patients with familial major depressive disorder and familial bipolar disorder. Decreased volumes were accompanied by reductions in cerebral activity (see Fig. 15–11 below). Reduced volumes were not evident, however, in bipolar patients taking chronic lithium or valproate. (Source: Adapted from Drevets et al., 2004.)

using robust threshold criteria for inclusion (McDonald et al., 2004), bipolar patients compared with controls were found to have similar left (6 studies, 1 percent larger, $p = .66$), right (6 studies, 1 percent smaller, $p = .60$), and total (8 studies, 1 percent smaller, $p = .24$) hippocampal volumes. One study found that, compared with controls, hippocampal shape anomalies (rounded hippocampus) occurred at a similar rate in familial bipolar disorder, but were more frequent in familial schizophrenia (Connor et al., 2004). Anzalone and colleagues observed that bipolar-I patients compared with healthy controls had right posterior (but not total) hippocampal volume decreases that were related to illness duration. In another study, however, first-episode bipolar patients compared with multiple-episode patients and healthy controls were found to have smaller hippocampal volumes (Strakowski et al., 2002). (One study yielded the curious finding of increased hippocampal volume correlating with poorer neuropsychological function [Ali et al., 2000].) The findings of some studies are consistent with hippocampal volume decreases being more evident on the right (Swayze et al., 1992; Kemmerer et al., 1994; Noga et al., 2001). In one study, however, first-episode affective psychosis patients (polarity not specified) compared with healthy controls showed decreased left (but not right) hippocampal volumes (Velakoulis et al., 1999).

As noted above, there is more consistent evidence of smaller hippocampal volumes in MDD patients. Thus, hippocampal volumes were decreased in 13 studies,⁷⁸ tended

to be decreased in 1 study (Steffens et al., 2000), but were unchanged in 5 studies.⁷⁹ Indeed, a recent meta-analysis (Campbell et al., 2004) of 12 studies⁸⁰ found that a total of 393 MDD patients compared with 303 controls had significantly smaller left and right hippocampal volumes. Significant decreases were more often detected on the left (6 of 12 studies) than on the right (3 of 12 studies). Similarly, another recent meta-analysis (Videbech and Ravnkilde, 2004) of 11 studies⁸¹ found that a total of 351 MDD patients compared with 279 controls had significantly smaller left and right hippocampal volumes. The composite effect sizes for decreased left and right hippocampal volumes were small in magnitude ($-.38$ and $-.32$, respectively). In contrast to observations in bipolar patients, the findings of some studies are consistent with the notion that volume decreases may be more likely for the left hippocampus in MDD patients,⁸² although there have been discordant observations (Janssen et al., 2004). In 4 of the 8 studies finding hippocampal volume decreases,⁸³ these decreases were related to duration of depression, consistent with the notion that chronic hypercortisolemia can lead to progressive hippocampal degeneration. However, there have been discordant observations (Janssen et al., 2004). Another study found that longer total duration of untreated (but not treated) depression was associated with a decrease in hippocampal volume (Sheline et al., 2003), consistent with the hypothesis that reduced adult hippocampal cell proliferation or neurogenesis is involved in the pathophysiology of depression, and that reversal or prevention of decreased

neurogenesis may be one way in which antidepressants exert their effects (Malberg, 2004). In a longitudinal study, although no significant hippocampal volume changes were observed in MDD patients or controls between baseline and 1-year follow-up, patients with unremitting illness at follow-up had reduced left and right hippocampal volumes at both baseline and the 1-year follow-up compared with remitting patients, and smaller right hippocampal volumes compared with healthy controls (Frodl et al., 2004). Similarly, in another study, smaller hippocampal volumes were associated with poorer response to antidepressants (Hsieh et al., 2002).

In a study of hippocampal volume, decreases were observed in multiple-episode but not first-episode MDD patients (MacQueen et al., 2003). (MDD with multiple episodes is part of the manic-depressive spectrum.) Another study, however, found hippocampal volume decreases (left-sided gray matter in men and bilateral white matter in men and women) in first-episode MDD patients and failed to detect a relationship between volume decreases and illness duration (Frodl et al., 2002b). Three studies found that greater volume decreases tended to occur with later-onset depression (Steffens et al., 2000; Lloyd et al., 2004; MacMaster and Kusumakar, 2004b), whereas other studies have failed to detect such a relationship (Ashtari et al., 1999; Frodl et al., 2002a).

In some studies, volume decreases were found to be correlated with severity of depression (Ashtari et al., 1999; Vakili et al., 2000), but other investigators have failed to detect such a relationship (Frodl et al., 2002a; MacQueen et al., 2003). One group found hippocampal volume decreases in women with MDD and a history of severe prolonged childhood physical or sexual abuse, but not in MDD patients without such histories. One study found that MDD patients compared with controls had similar hippocampal volumes, but had altered hippocampal shape (Posener et al., 2003). Janssen and colleagues (2004) failed to detect a relationship between hippocampal volumes and subcortical hyperintensities in MDD patients.

MDD patients with the homozygous L/L serotonin transporter genotype were found to have smaller hippocampal gray and white matter volumes than those of controls with this genotype, and significantly smaller hippocampal white matter volumes than those of patients with the L/S or S/S genotype (Frodl et al., 2004). No significant differences were found between patients and controls with the L/S or S/S genotype. The authors suggested that serotonergic influence on neurotrophic factors and excitatory amino acid neurotransmission could account for their findings. Some study findings are consistent with relationships between hippocampal volume loss and poorer cognitive/memory function.⁸⁴ For example, Shaw and colleagues (1998) found

that left hippocampal gray matter density was correlated with performance on a verbal memory task.

The above clinical neuroimaging findings of hippocampal volume decreases in MDD, and to a lesser extent in bipolar disorder, are consistent with basic science reports of hippocampal abnormalities in mood disorders.⁸⁵ More limited basic science evidence suggests amygdala abnormalities in these disorders (Bowley et al., 2002; Hamidi et al., 2004).

Amygdala findings have been variable in bipolar disorder and MDD. Thus in bipolar disorder, amygdala volumes may be increased,⁸⁶ unchanged,⁸⁷ tend to be decreased (Chen et al., 2004), or decreased.⁸⁸ In a recent meta-analysis using robust threshold criteria for inclusion (McDonald et al., 2004), bipolar patients compared with controls were found to have similar left (four studies, 5 percent larger, $p = .49$), right (four studies, 4 percent larger, $p = .35$), and total (five studies, 1 percent larger, $p = .91$) amygdala volumes. One study in adolescents and young adults found that with increasing age, left amygdala volumes increased in patients but decreased in healthy controls (Chen et al., 2004). These results are consistent with those of most studies including younger populations that have detected amygdala volume decreases in bipolar disorder,⁸⁹ although one study involving the very young (mean age 11 years) was negative (Frazier et al., 2005). Blumberg and colleagues (2005) found that decreased amygdala volumes in adolescents and young adults with bipolar disorder persisted 2 years later. Another study found that patients with psychotic (but not nonpsychotic) bipolar disorder compared with those with schizophrenia had increased right amygdala volumes (Strasser et al., 2002). In adults, prior number of episodes may (Altshuler et al., 2000) or may not (Strakowski et al., 1999; Brambilla et al., 2003a) be related to amygdala volume increases. Differences in age, chronicity, and treatment could account for the variation in amygdala volume findings in patients with bipolar disorder.

In MDD, amygdala volumes were found to be unchanged for the entire amygdala⁹⁰ and decreased for the entire amygdala (von Gunten et al., 2000) or core nuclei (Sheline et al., 1999), but increased in first-episode (Frodl et al., 2002b) and young female (Lange and Irle, 2004) patients. Thus, Frodl and colleagues (2002c) suggested that amygdala volumes are increased in first-episode but not recurrent MDD patients. A recent meta-analysis (Campbell et al., 2004) of six studies⁹¹ found that a total of 138 MDD patients and 121 controls had statistically similar amygdala volumes. In a longitudinal study, no significant amygdala volume changes were observed in MDD patients or controls between baseline and 1-year follow-up (Frodl et al., 2004).

Amygdala–hippocampal complex volumes appear to be unchanged in bipolar (Swayze et al., 1992) and MDD patients.⁹² A recent meta-analysis (Campbell et al., 2004) of four studies⁹³ found that a total of 126 MDD patients and 165 controls had statistically similar amygdala–hippocampal complex volumes. Thus, although hippocampal volumes appear to be decreased in the latter patients, the absence of decreases or even increases in amygdala volumes could contribute to the lack of difference in amygdala–hippocampal complex volumes.

Temporal lobe findings have been variable in bipolar and MDD patients. Thus in bipolar patients, temporal lobe size was most often found to be unchanged,⁹⁴ but in a few studies was found to be decreased (Hauser et al., 1989c; Altshuler et al., 1991) or increased (Harvey et al., 1994; Wilke et al., 2004). A recent meta-analysis using robust threshold criteria for inclusion (McDonald et al., 2004) found that in six studies, bipolar patients compared with controls had similar left (1 percent larger, $p = .63$) and right (1 percent smaller, $p = .55$) temporal lobe volumes. In MDD patients, temporal lobe size has often been found to be unchanged (Coffey et al., 1993b; Pantel et al., 1997; Bremner et al., 2000), but has been reported to tend to be decreased (Kumar et al., 1996, 2000). Decreased left temporal cortical (including hippocampus) gray matter density has been observed in chronic MDD patients (Shah et al., 1998). Later-onset compared with earlier-onset MDD patients had more left medial temporal volume decreases (Greenwald et al., 1997).

In summary, the findings of the above studies suggest that bipolar and MDD patients compared with healthy controls have decreased frontal/prefrontal and cerebellar volumes. In addition, MDD patients appear to have hippocampal volume decreases. To varying degrees, these observations are supported by clinical correlations, but meta-analyses are currently lacking. In contrast, amygdala and temporal lobe volumes have been found to be variable in mood disorders.

Other Structural Neuroimaging Findings

Caudate volumes may be unchanged,⁹⁵ decreased (in elderly manic patients) (Bocksberger et al., 1996; Lyoo et al., 2006), or increased (Aylward et al., 1994; Strakowski et al., 1999; Wilke et al., 2004) in bipolar patients; Aylward and colleagues (1994) found increased caudate volumes in men but not women with bipolar disorder. In a study of monozygotic twins with and without bipolar disorder, those with the disorder were found to have increased caudate volumes compared with their normal co-twins. (Noga et al., 2001). A recent meta-analysis using robust threshold criteria for inclusion (McDonald et al., 2004) found that in seven studies, bipolar patients compared with controls had

similar (3 percent larger, $p = .25$) total caudate volumes. Caudate volumes may be decreased in MDD patients (Krishnan et al., 1992, 1993; Greenwald et al., 1997; Parashos et al., 1998) or unchanged.⁹⁶ Later-onset compared with earlier-onset MDD patients showed greater left caudate volume decreases (Greenwald et al., 1997).

Compared with controls, putamen volumes were found to be unchanged⁹⁷ or increased (in adolescent and first-episode patients and nearly so in multiple-episode patients)⁹⁸ in bipolar disorder and unchanged (Pillay et al., 1998; Lenze and Sheline, 1999) or decreased⁹⁹ in MDD. In one study that failed to detect caudate and putamen volume differences, anterior and ventral striatal shape differences were seen in drug-naïve (but not drug-treated) bipolar patients compared with healthy controls (Lyoo et al., 2006). A recent meta-analysis using robust threshold criteria for inclusion (McDonald et al., 2004) found that in six studies, bipolar patients compared with controls had similar (2 percent larger, $p = .20$) total putamen volumes. A postmortem study found decreased bilateral external pallidum and right putamen volumes in a heterogeneous group of four MDD, two bipolar, and two schizoaffective patients compared with controls (Baumann et al., 1999).

In healthy volunteers, caudate (Jernigan et al., 1991; Krishnan et al., 1992; Murphy et al., 1992) and putamen (Husain et al., 1991) volumes were found to decrease with age; such age-related decreases were also observed in MDD patients (Husain et al., 1991; Krishnan et al., 1992). In another study, age was found to be correlated inversely with left putamen volume in bipolar patients but not healthy controls (Brambilla et al., 2001a), while in geriatric mania patients, putamen volumes failed to be correlated with age but were found to be correlated inversely with age at illness onset (Young et al., 1996). In MDD patients, left putamen volume was observed to decrease with illness duration, while left globus pallidus volume was found to increase with episode number. Illness duration was likewise found to be correlated with putamen volume decreases in bipolar patients (Brambilla et al., 2001a).

Thus basal ganglia volumes have been found to vary in bipolar and MDD patients, with some variability possibly being accounted for by age at illness onset. In contrast, 8 of 15 MRI studies in schizophrenia found enlargement of basal ganglia structures (for a review see Shenton et al., 1997). Medications may yield confounding effects, as typical antipsychotics may result in increased striatal volumes (Chakos et al., 1994).

Thalamic volumes may be unchanged¹⁰⁰ or increased (Dupont et al., 1995b; Strakowski et al., 1999) in bipolar patients. Thus Lochhead and colleagues (2004) reported increased thalamic gray matter density (but not volume) in patients with bipolar disorder, while McIntosh and

colleagues (2004) found that bipolar patients compared with controls had decreased thalamic gray matter density. Thalamic volumes may be unchanged,¹⁰¹ decreased (Dupont et al., 1995b; Kwon et al., 2002), or tend to be increased (Buchsbaum et al., 1997a) in MDD patients. A recent meta-analysis using robust threshold criteria for inclusion (McDonald et al., 2004) found that in five studies, bipolar patients compared with controls had similar (2 percent larger, $p = .54$) total thalamus volumes. Decreased thalamus volumes were seen in MRI studies of schizophrenic patients compared with controls in four of five studies (Shenton et al., 1997) and compared with bipolar patients in the study of McDonald and colleagues (2005).

Pituitary volumes in unipolar patients were found to be unchanged in two studies (Schwartz et al., 1997; Sassi et al., 2001) and increased in two studies (Krishnan et al., 1991; MacMaster and Kusumakar, 2004) (and perhaps are even related to the degree of adrenal escape from dexamethasone suppression; see Axelson et al., 1992). Pituitary volumes were observed to be decreased in patients with bipolar disorder (Sassi et al., 2001) and unchanged with seasonal affective disorder (Schwartz et al., 1997). This variability in findings may be related to differential changes in HPA function within and across disorders.

Corpus callosum size has been reported to be decreased (Coffman et al., 1990; Brambilla et al., 2003b) or unchanged (Hauser et al., 1989b) in bipolar patients, and unchanged¹⁰² or increased in the anterior and posterior subregions in MDD (Wu et al., 1993) and familial MDD patients. One MRI study found that bipolar (but not MDD) patients compared with healthy controls had decreased signal intensity in all subregions of the corpus callosum (Brambilla et al., 2004).

Healthy volunteers have cerebral asymmetry, with right wider than left frontal lobes and left wider than right occipital lobes. In schizophrenia, increased incidence of reversal of this cerebral asymmetry pattern has been reported in some but not other studies. In mood disorder patients, three studies (Weinberger et al., 1982; Tsai et al., 1983; Dewan et al., 1987) found no evidence for and one study (Tanaka et al., 1982) found a trend toward an increased incidence of reversed cerebral asymmetry.

Similar global cerebral volumes have commonly been observed in bipolar¹⁰³ and MDD¹⁰⁴ patients compared with healthy controls (see Box 15–1). However, some studies found decreased total cerebral volumes in adolescents with bipolar disorder (Blumberg et al., 2003c; DelBello et al., 2004; Lyoo et al., 2006). Another study found that late-life MDD patients compared with controls had decreased relative (total brain/total intracranial) but similar absolute (total brain) volumes (Kumar et al., 2000). A meta-analysis (Hoge et al., 1999) of seven studies,¹⁰⁵ however, found that

BOX 15–1. Structural Neuroimaging Findings in Bipolar and Major Depressive Disorder Patients Compared with Healthy Controls

- Increased lateral ventricular enlargement^a
- Increased cortical sulcal enlargement^a
- Increased third ventricular enlargement
- Increased subcortical hyperintensities (younger and older bipolar, older MDD patients)^a
- Frontal and prefrontal volume decreases
- Cerebellar volume decreases
- Hippocampal volume decreases (in MDD)^a
- Similar global cerebral volumes^a

^aConfirmed with meta-analyses.

a total of 160 bipolar patients and 215 controls had similar total cerebral volumes, with a negligible composite effect size of .04 ($p = .56$) and a 95 percent confidence interval of $-.17$ to $.25$. A recent meta-analysis using robust threshold criteria for inclusion (McDonald et al., 2004) found that in 11 studies, bipolar patients compared with controls had similar (1 percent smaller, $p = .26$) total cerebral volumes. In 5 studies, bipolar patients compared with controls had similar total gray (1 percent smaller, $p = .71$) and white (1 percent smaller, $p = .66$) matter volumes. In contrast, a meta-analysis of 27 studies revealed decreased total cerebral volumes in schizophrenic patients compared with healthy controls, with a small but significant composite effect size of $-.26$ ($p < .0001$) and a 95 percent confidence interval of $-.35$ to $-.15$ (Ward et al., 1996).

Global cortical gray matter volumes in MDD patients may be unchanged (Dupont et al., 1995b; Pillay et al., 1997), and in bipolar patients may be diffusely decreased (Lim et al., 1999) or unchanged.¹⁰⁶ In the study of Sassi and colleagues (2002b), total gray matter volumes were found to be increased in lithium-treated bipolar patients compared with untreated bipolar patients and healthy controls. Notably, lithium treatment for 4 weeks appeared to increase prefrontal gray matter volume in unmedicated depressed adult bipolar-I patients (Moore et al., 2000b). Cortical white matter volumes in bipolar patients may tend to be decreased (Strakowski et al., 1993b) or unchanged (Lim et al., 1999). In the former study, bipolar patients tended to have decreased global white and unchanged gray matter, and therefore an increased gray/white ratio (Strakowski et al., 1993b).

Thus, the above studies comparing mood disorder patients with healthy controls have yielded variable findings for caudate, putamen, and thalamus volumes, and have generally been negative for whole-brain volumes. Methodological advances allowing segmentation of gray and white

matter may enhance the detection of volumetric abnormalities in future studies.

FUNCTIONAL NEUROIMAGING STUDIES

Studies of cerebral activity reflect integrated effects of multiple neurotransmitters and thus have the strength of being able to detect *where* function is altered, even if such alteration is related to actions of multiple neurochemicals on complex networks, such as anterior cortical/anterior paralimbic basal ganglia–thalamocortical circuits. Such studies are limited in their ability to detect *what* function is altered, however. Studies of cerebral activity responses to specific neurochemical challenges can, to a limited extent, address what function is altered, as they reflect the integrated multi-neurotransmitter responses related to alterations in specific neurochemicals.

In contrast, studies of specific cerebral neurochemistry provide data regarding effects on discrete neurochemicals and thus have the strength of being able to detect more specifically *what* function is altered. They may be somewhat limited, however, in their ability to detect *where* function is altered, as they are sensitive only to effects on specific neurochemicals rather than integrated responses related to complex actions of multiple neurochemicals. Also, at least for MRS, poorer spatial resolution (compared with studies of cerebral activity) limits detection of where function is altered.

Clinical studies in mood disorder patients have detected changes in cerebral activity and alterations in specific cerebral neurochemistry in anterior cortical/anterior paralimbic basal ganglia–thalamocortical circuits. Studies of cerebral activity are reviewed in the sections below, followed by a review of studies of specific cerebral neurochemistry using MRS. Studies of specific cerebral neurochemistry using positron emission tomography (PET) and single photon emission computed tomography (SPECT) with specific neurochemical radiotracers are reviewed in Chapter 14.

Studies of cerebral activity include assessments of cerebral metabolic rate for glucose (CMRglu) and CBF. PET with fluorine-18-deoxyglucose (^{18}FDG) assesses CMRglu, and with oxygen-15 water (H_2^{15}O) measures CBF. SPECT with $^{99\text{m}}\text{Tc}$ -HMPAO, technetium-99m-exametazime ($^{99\text{m}}\text{Tc}$ -EMZ), and N-isopropyl-p- ^{123}I -iodoamphetamine (^{123}IMP) reflects CBF, and with xenon (^{133}Xe) assesses cortical CBF. In addition, fMRI studies yield neurophysiological data considered related to cerebral activity.

CMRglu and CBF generally correlate with one another,¹⁰⁷ although uncoupling can occur with some (Fox and Raichle, 1986; Hallett et al., 1994) but not other (Ginsberg et al., 1988) activation paradigms. Preliminary evidence suggests that global and regional uncoupling of CBF

(while performing a passive introspection task) and CMRglu (while performing an auditory continuous performance task) may occur in MDD patients, but not in bipolar patients or healthy volunteers (Dunn et al., 2005). In another study, MDD patients compared with healthy controls were found to have differential left basal ganglia coupling of simultaneously assessed resting CBF and CMRglu (Conca et al., 2000).

CMRglu changes with age. Thus, gray matter CMRglu is low at birth, rises rapidly to adult values by age 2 years, continues to rise to supra-adult values between ages 3 and 12, then declines to adult rates again by the latter part of the second decade (Chugani et al., 1987), similar to the nonlinear developmental patterns seen with gray matter volume (Giedd et al., 1999) and ratios of NAA to choline (Horska et al., 2002). In healthy adults, CMRglu tends to decrease with age,¹⁰⁸ but there is some variability in findings in this regard.¹⁰⁹ Differential regional effects may contribute to such variability. For example, Willis and colleagues (2002) found that in adults, increased age was correlated with decreased global and widespread cortical and increased cerebellar and focal occipital cortical CMRglu.

Although gender has not been found to be related to global CMRglu in most studies,¹¹⁰ regional differences have been reported. Thus, CMRglu in healthy women compared with men was found to be increased in widespread (Baxter et al., 1987a; Yoshii et al., 1988; Willis et al., 2002) and orbital and medial frontal, caudate, and posterior cingulate regions (Andreason et al., 1994), the thalamus (Murphy et al., 1996), and the cerebellum (Volkow et al., 1997). Compared with men, however, women were observed to have decreased anterior paralimbic (Andreason et al., 1994) and hippocampal (Murphy et al., 1996) or generally similar (Miura et al., 1990) CMRglu. Phase of menstrual cycle may contribute to this variability, as only two studies attempted to control for this parameter (Baxter et al., 1987b; Volkow et al., 1997). Indeed, healthy women during midfollicular phase (lower estradiol and progesterone) were found to have increased thalamic, prefrontal, temporoparietal, and inferior temporal CMRglu, and during midluteal phase (higher estradiol and progesterone) to have increased superior temporal, anterior temporal, occipital, cerebellar, cingulate and anterior insular CMRglu (Reiman et al., 1996).

Cerebral Activity in Affective Processing in Healthy Volunteers

Functional neuroimaging studies in healthy subjects yield important contributions to our understanding of the neural substrates of affective processing. In addition, assessments of regional cerebral function in healthy volunteers provide bases for comparison with mood disorder patients.

For example, activity in anterior compared with posterior cerebral structures is commonly relatively increased (hyperfrontality) in health and relatively decreased (hypo-frontality) in depression. Because cerebral function may vary with age and gender, it is important to match patients with healthy controls on these parameters.

The amygdala appears to be important in processing emotional stimuli, especially fear. Amygdala activation was found to be present in 10 studies of emotion evaluation of facial visual stimuli¹¹¹ and absent in only 1 (Sprenghelmeyer et al., 1998). Anterior cingulate/medial frontal gyrus/basal forebrain was implicated in 7 studies of facial emotion evaluation¹¹² and not implicated in 3 (Breiter et al., 1996; Morris et al., 1998a; Sprenghelmeyer et al., 1998). For both amygdala and anterior cingulate, laterality effects were modest. In spite of considerable variability in paradigms, these studies provide substantial support for amygdala involvement in evaluation of facial emotion, particularly for fearful expressions.

Emerging data indicate that mood disorder patients have attenuated cerebral activation while performing affective processing tasks. For example, these patients compared with healthy controls were found to have attenuated temporal and right insula activation during matching of faces for varied emotions (George et al., 1997a). In another study, adult bipolar patients (about half of whom had mood elevation) compared with healthy controls showed attenuated dorsolateral prefrontal and increased amygdala activation during fearful facial affect recognition (Yurgelun-Todd et al., 2000). In yet another study, manic patients were observed to lack the anterior cingulate and amygdala activation seen in healthy controls during sad facial affect recognition (Lennox et al., 1999). As noted below, the regions showing baseline resting deficits in depressed patients tend to fail to respond in activation studies.

Studies of induction of sadness and happiness have yielded variable findings. Restricting attention to studies using recall of sad events (some of which also used viewing faces), amygdala activation was found to be present in six sadness induction studies¹¹³ but absent in eight.¹¹⁴ On the other hand, amygdala changes were seen in only two happiness induction studies (Schneider et al., 1995, 1997) and absent in eight.¹¹⁵ There was a tendency for left-sided amygdala activation to predominate in sadness induction (four left, one bilateral, one right), and left-sided amygdala changes in happiness induction (one left increase, one left decrease). Thus, affective valence appeared to be related more to the presence or absence than to the laterality of activation. Anterior cingulate/medial frontal gyrus changes were seen in eight sadness induction studies¹¹⁶ but absent in six.¹¹⁷ These changes were present in only four happiness induction studies¹¹⁸ and absent in six.¹¹⁹ Gender may be an

important factor in sadness induction. Three studies (Pardo et al., 1993; George et al., 1996; Schneider et al., 2000) found more widespread activation in women compared with men.

Affect induction can influence cerebral activation during the performance of cognitive tasks. Thus in healthy volunteers, transient sadness induction yielded increased orbitofrontal cortical and decreased rostral medial prefrontal cortical CBF (Baker et al., 1997). Moreover, during transient sadness, subjects had attenuated verbal fluency task-induced left prefrontal, premotor, cingulate, and thalamic activation. The authors noted that the pattern of transient sadness-induced modulation of verbal fluency-induced activations overlapped with resting-state findings of decreased function in these regions in depressed patients.

Pharmacological emotion/mood induction studies have suggested variable cerebral effects across drugs, or even with the same drug across individuals. There are many potential sources of such variability, which may on occasion provide insights into affective processing. In the study of Ketter and colleagues (1996b), for example, acute intravenous procaine yielded robust transient affective experiences ranging from intense euphoria to profound dysphoria. Variability in clinical responses was accompanied by systematic variability in anterior paralimbic responses. That is, in the left amygdala, euphoria occurred with deactivation, and dysphoria was observed with activation.

Physiological and pharmacological induction of affective experiences appears to be accompanied by changes in overlapping anterior paralimbic circuits. Thus, induction of transient sadness or dysphoria by recall of sad events (George et al., 1995b) or by acute intravenous procaine (Ketter et al., 1996b) yielded overlapping anterior paralimbic CBF patterns (see Fig. 15–6).

There are fewer studies of induction of more sustained affective experiences that could perhaps provide more temporally appropriate models of moods. Ketter and colleagues (1996b) found that sustained (30-minute) self-induced sadness yielded decreased metabolism in paralimbic regions that overlapped those where increases were noted with transient sadness induction in other studies. These observations are consistent with the hypothesis that in vulnerable individuals, repeated, prolonged, or intense cerebral activations associated with negative affective experiences may deplete neurochemical substrates, diminishing cerebral metabolism and leading to clinical depression. Similarly, putative hypermetabolism in mania may eventually result in decreased metabolism and postmania depression. Additional functional neuroimaging studies are needed to explore such hypotheses.

Taken together, neuroimaging studies in healthy volunteers suggest that anterior paralimbic structures (especially

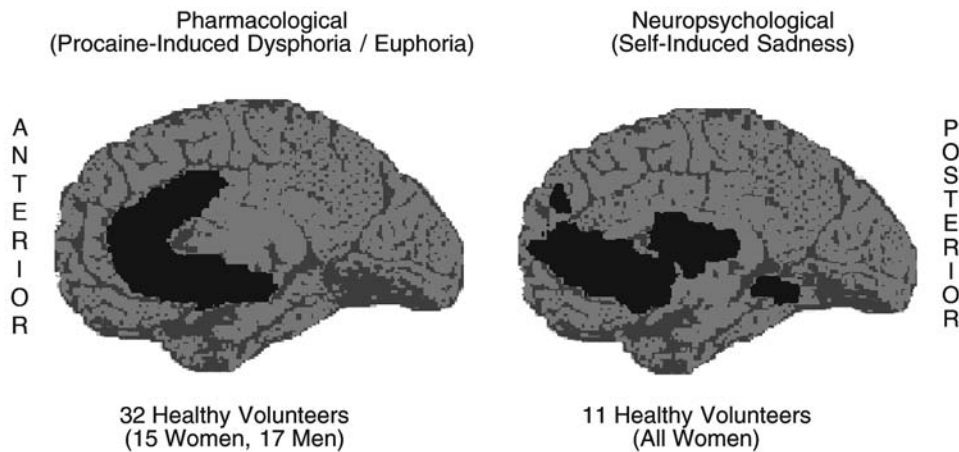

Figure 15-6. Overlapping limbic regional cerebral blood flow (rCBF) activation with transient induced emotion. Anterior paralimbic activation accompanies both neuropsychologically and pharmacologically induced acute affective changes in healthy volunteers. Images are statistical parametric maps of cerebral blood flow activation in black rendered on the mesial aspect of the left hemisphere. Left: Regions activated during transient self-induced sadness in 11 healthy women (George et al., 1995b). Right: Regions activated during acute intravenous procaine-induced affective symptoms in 32 healthy volunteers (Ketter et al., 1996b).

amygdala and anterior cingulate) contribute importantly to affective processing (particularly fear recognition and transient sadness induction). Emerging data suggest that mood disorder patients compared with healthy controls have differential activation patterns related to affective processing.

Cerebral Activity in Depression

Functional neuroimaging studies have generally implicated anterior cortical and paralimbic changes in cerebral activity in depression, not only in bipolar disorder and MDD, but also in mood disorders secondary to medical and neurological conditions.

Decreased global cerebral activity has been observed in depressed mood disorder patients compared with healthy controls. Thus, global cerebral activity in depressed bipolar patients has commonly been found to be decreased,¹²⁰ but has also been found to be unchanged (Rush et al., 1982; Buchsbaum et al., 1984; Cohen et al., 1989) or increased (Buchsbaum et al., 1986). One study found that depressed and mixed-state bipolar patients had lower global CMRglu than manic bipolar patients, euthymic bipolar patients, and depressed MDD patients (Baxter et al., 1985). In depressed MDD patients compared with controls, global activity has commonly been found to be decreased,¹²¹ but has also been observed to be unchanged¹²² or increased (Buchsbaum et al., 1986). Thus, a substantial number of studies have detected decreased global cerebral activity in depressed mood disorder patients compared with healthy controls. Findings vary, however, with about half of the

studies detecting decreased and about half similar global cerebral activity in mood disorder patients compared with healthy controls. Of importance, there has been only one report of increased global cerebral activity in depressed mood disorder patients compared with healthy controls (Buchsbaum et al., 1986).

Variability in findings relative to global cerebral activity in depressed mood disorder patients may be related to methodological or demographic differences, or to limited statistical power due to small sample sizes. Moreover, decreased global activity may be more evident in subgroups of depressed patients. Thus, two studies found that global CMRglu was or tended to be decreased in treatment-resistant moderately to severely depressed (but not relatively euthymic) bipolar (Ketter et al., 2001) and MDD (Kimbrell et al., 2002) patients. Global decreases also appeared to be more evident in depressed patients with advanced age and severe depression (Sackeim et al., 1993) or marked weight loss (Delvenne et al., 1997a). Additional factors may contribute to global changes in cerebral activity. For example, in post-thyroidectomy (for thyroid cancer) patients, global CMRglu and CBF were found to be decreased when patients were hypothyroid (with about half also having developed significant depression) after withdrawal of thyroid replacement compared with when they were euthyroid on thyroid replacement (Constant et al., 2001). Moreover, in treatment-resistant mood disorder patients, global CMRglu and CBF were found to be correlated inversely with plasma thyrotropin (Marangell et al., 1997), suggesting that even within the euthyroid range,

global cerebral activity decreases with reductions in thyroid function.

Decreased dorsolateral prefrontal activity is the most consistent regional finding in depressed bipolar patients imaged in either the resting condition or while carrying out continuous performance tasks. Thus, studies have commonly detected decreased dorsolateral prefrontal cortical activity, including CMRglu using ^{18}F FDG PET,¹²³ and CBF using H_2^{15}O PET (Ketter et al., 1996b) or $^{99\text{m}}\text{Tc}$ -HMPAO SPECT (Ebert et al., 1993; Ito et al., 1996). Nine of the above studies found bilateral, one found left lateralized (Buchsbaum et al., 1997a), and one found right lateralized (Cohen et al., 1989) decreases, and none found increases in depressed bipolar patients compared with controls. A few studies, however, failed to detect differences between depressed bipolar patients and healthy controls (Cohen et al., 1992; Goyer et al., 1992; Tutus et al., 1998b).

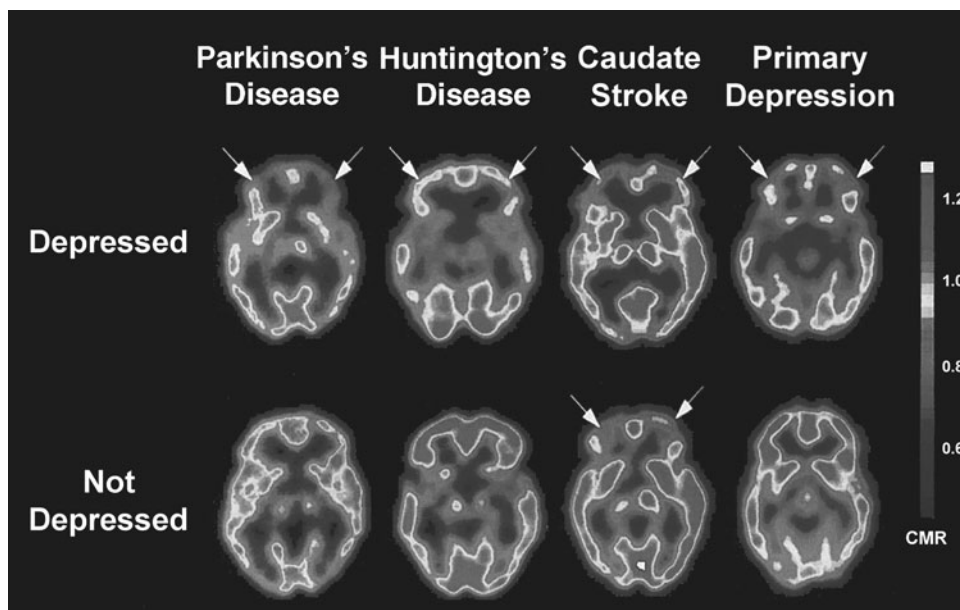

Dorsolateral prefrontal cortical activity has also commonly been found to be decreased in depressed MDD patients compared with healthy controls. These findings include CMRglu assessed with ^{18}F FDG¹²⁴ and carbon-11 glucose (^{11}C -glucose) PET (Kishimoto et al., 1987). They also include CBF assessed with oxygen-15 carbon dioxide (C^{15}O_2) PET (Bench et al., 1992, 1993; Dolan et al., 1992) and with SPECT employing $^{99\text{m}}\text{Tc}$ -HMPAO,¹²⁵ $^{99\text{m}}\text{Tc}$ -EMZ (Austin et al., 1992; Curran et al., 1993), ^{123}I MP (O'Connell et al., 1989; Kanaya and Yonekawa, 1990), and gold-195m ($^{195\text{m}}\text{Au}$)

(Schlegel et al., 1989a). Most of these studies found bilateral decreases, but six found left¹²⁶ and three found right (Lesser et al., 1994; Hurwitz et al., 1990; Kimbrell et al., 2002) lateralized decreases. However, slightly fewer than half of the studies in depressed MDD patients compared with healthy controls found similar¹²⁷ and three found increased (Buchsbaum et al., 1986; Tutus et al., 1998b; Abou-Saleh et al., 1999) dorsolateral prefrontal activity.

Hypofrontality also has commonly been reported in depression secondary to diverse neurological and medical diseases¹²⁸ or other psychiatric disorders.¹²⁹ Moreover, return of depressive symptoms induced by depletion of tryptophan (Bremner et al., 1997) and norepinephrine (Bremner et al., 2003) in MDD patients who had responded to SSRIs and desipramine, respectively, was found to be accompanied by decreased dorsolateral prefrontal and orbitofrontal metabolism. Similarly, tryptophan depletion-induced return of depressive symptoms in MDD patients was found to be accompanied by decreased ventral anterior cingulate, orbitofrontal cortex CBF (Smith et al., 1999). Taken together, the above findings suggest the possibility of hypofrontality being a common pathway contributing to depressive symptoms, to some extent independently of illness etiology (primary versus secondary) and subtype (bipolar disorder versus MDD) (see Fig. 15-7).

Anterior cerebral CBF and CMRglu decreases often have been found to be correlated with the severity of primary¹³⁰

Figure 15-7. Hypofrontality in secondary and primary depression. Transaxial images depicting cerebral metabolic rate (CMR) for glucose in patients with (top row) and without (bottom row) depression. Arrows indicate decreased frontal metabolism in patients with depression secondary to neurological disorders, as well as in those with primary (unipolar) depression. (Source: Reproduced with permission from Mayberg et al., 1994.)

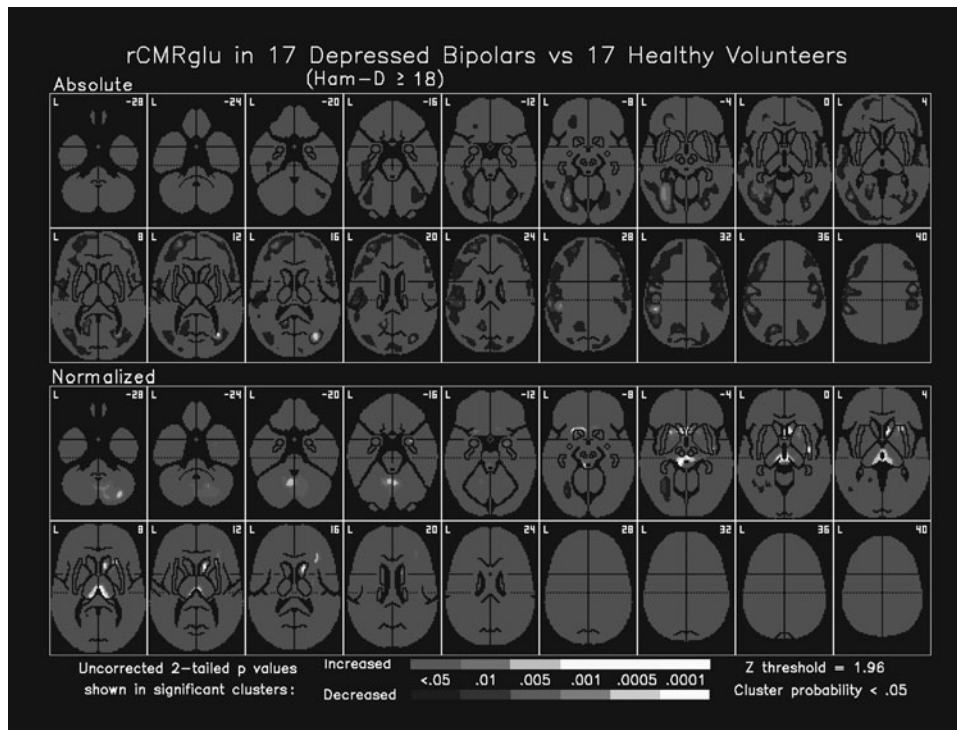

Figure 15–8. Regional cerebral metabolism in moderately to severely depressed unmedicated bipolar patients compared with healthy controls. Z-maps of differences in absolute (top) and normalized (bottom) cerebral metabolism in 17 moderately depressed unmedicated bipolar patients compared with 17 healthy controls. The legend indicates two-tailed p values. Numbers in the upper right corners indicate distances from the intercommissural plane. L = left. Absolute prefrontal and anterior paralimbic cortical metabolic decreases and normalized anterior paralimbic subcortical metabolic increases evident in these images may be state markers for depression in bipolar disorder. Decreased dorsomedial and dorsolateral prefrontal activity has commonly been reported in other studies of bipolar depression. Left (L) ventrolateral structures failed to show the absolute metabolic decreases seen in other prefrontal cortical regions in these moderately to severely depressed bipolar patients (top) or the relative metabolic increases seen in left ventrolateral structures in mildly depressed bipolar patients (Fig. 15–9, bottom). (Source: Ketter et al., 2001.)

and secondary¹³¹ depression. Some studies have failed to detect such a relationship, however.¹³²

The variability in the above findings may be related in part to differences in affective symptoms. Osuch and colleagues (2000) found depression ratings to be directly correlated with bilateral medial frontal, right anterior cingulate, and right dorsolateral prefrontal globally normalized metabolism. In contrast, anxiety ratings were found to be correlated directly with right parahippocampal and left anterior cingulate and inversely with cerebellum, left fusiform, left superior temporal, left angular gyrus, and left insula globally normalized metabolism. Another study found that parietal operculum, posterior cingulate, left parahippocampus, and ventral thalamus metabolism increased, while bilateral ventrolateral prefrontal cortical metabolism decreased, with degree of depression in MDD patients (Drevets et al., 2002c). In addition, dorsal and posterior cingulate and inferior bank of

superior temporal sulcus metabolism was found to increase with degree of dysfunctional depressive automatic thoughts.

Also of interest, depressed patients with versus those without cognitive impairment were found to have decreased anterior medial prefrontal CBF (Dolan et al., 1992). The degree of cognitive impairment was found to be correlated with the degree of decrease (Dolan et al., 1994). Ketter and colleagues (2001) found that moderately to severely (but not mildly) unmedicated depressed bipolar patients compared with controls carrying out a continuous performance task had decreased absolute prefrontal and anterior paralimbic cortical and increased normalized anterior paralimbic and subcortical metabolism (see Fig. 15–8). Moreover, the degree of depression was found to be correlated negatively with absolute prefrontal and paralimbic cortical and positively with normalized anterior paralimbic subcortical metabolism. This study also found, however, that in mildly

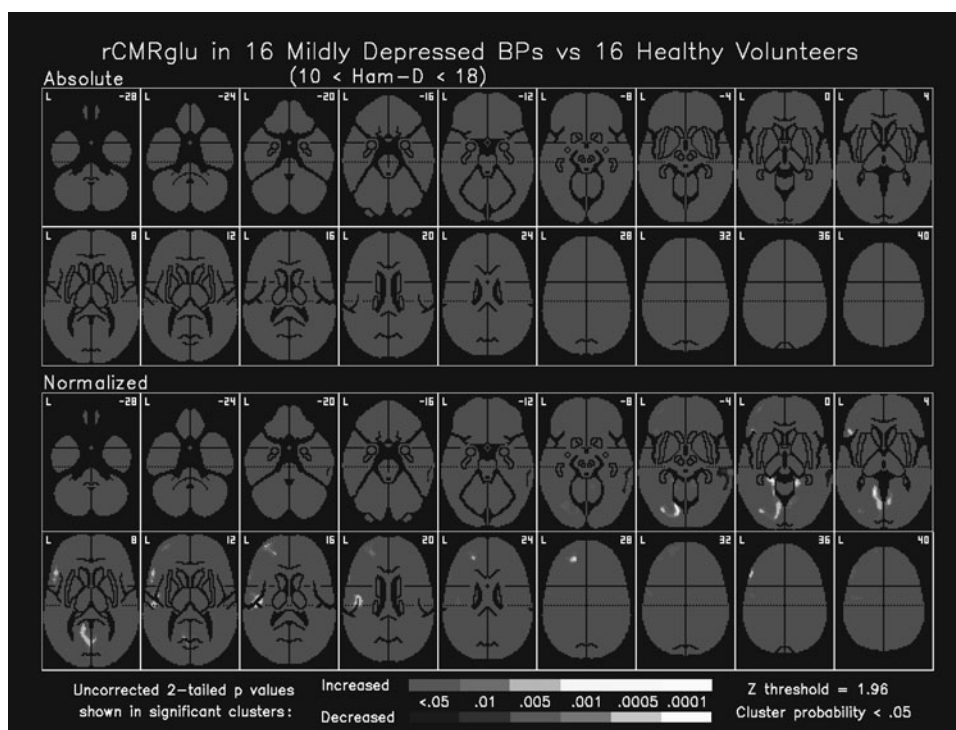

(but not moderately to severely) unmedicated depressed bipolar patients compared with healthy controls, relative (i.e., normalized to whole brain) metabolic activity was increased in the left prefrontal cortex, including ventrolateral structures such as the inferior frontal gyrus (see Fig. 15–9)—a finding reported in some studies of unmedicated depressed MDD patients imaged in the resting condition.¹³³ Of interest, left ventrolateral structures, such as the inferior frontal gyrus in moderately to severely depressed bipolar patients, failed to show the absolute metabolic decreases seen in other prefrontal cortical regions (Fig. 15–8, top) or the relative metabolic increases seen in mildly depressed bipolar patients (Fig. 15–9, bottom). Taken together, these observations are consistent with the view that the topography of cerebral functional changes may be related to the degree of depression in bipolar disorder.

Moderately to severely (but not mildly) depressed bipolar patients compared with healthy controls also were found to have increased normalized metabolism in subcortical

paralimbic structures, including ventral striatum, thalamus, and right amygdala (Fig. 15–8, bottom), consistent with a corticolimbic dysregulation model of depression positing that dorsal neocortical hypofunction may lead to ventral paralimbic overactivity or vice versa (Mayberg, 1997; Drevets, 1999, 2000) (see Fig. 15–10). Relative activation of bilateral medioposterior thalamus was also seen, consistent with altered thalamic relay and gating function with respect to communication between subcortical and cortical regions. Drevets and colleagues (1995, 2002c) confirmed the findings of elevated metabolism in the right amygdala and ventral striatum, as well as elevated metabolism in the left amygdala, in depressed bipolar patients relative to healthy controls. Increased ventral striatum and left amygdala metabolism has also been reported in depressed MDD patients meeting criteria for melancholia or familial pure depressive disease.¹³⁴

Another study found decreased CBF (by $H_2^{15}O$ PET) and CMRglu in the prefrontal cortex ventral to the genu of

Figure 15–9. Regional cerebral metabolism in mildly depressed unmedicated bipolar patients compared with healthy controls. Z-maps of differences in absolute (top) and normalized (bottom) cerebral metabolism in 16 mildly depressed unmedicated bipolar patients compared with 16 healthy controls. The legend indicates two-tailed p values. Numbers in the upper right corners indicate distances from the intercommissural plane. L = left. Increased normalized (but not absolute) metabolism was noted in left (L) inferior, middle, and superior frontal gyri; left insula and left transverse temporal gyrus; left postcentral gyrus; lingular gyrus, cuneus, and hippocampus; and bilateral cerebellum (sparsely). In contrast, decreased normalized (but not absolute) metabolism was noted in right inferior and middle temporal gyri. Ventrolateral metabolic increases have also been reported in depressed unmedicated major depressive disorder patients in the resting state. (Source: Ketter and Drevets, 2002.)

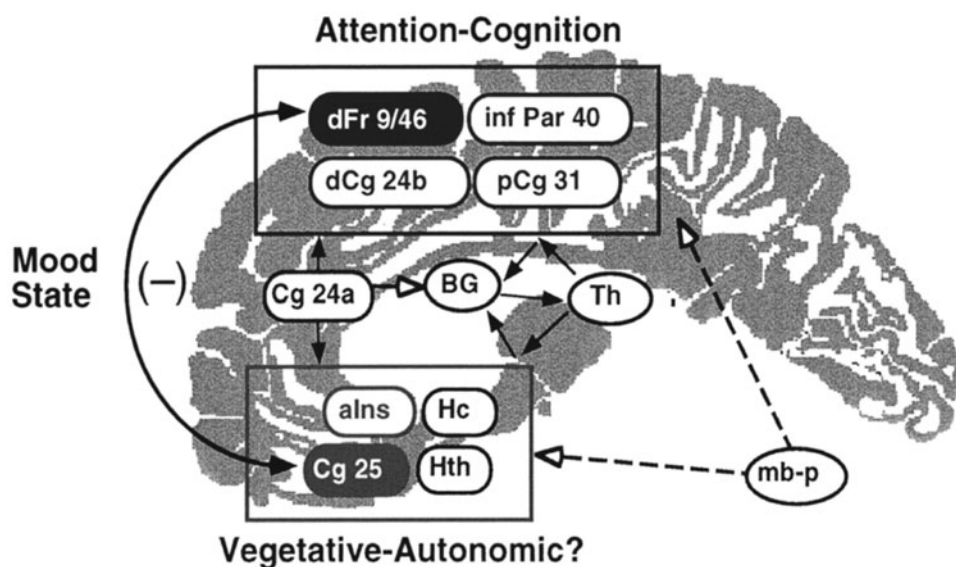

Figure 15–10. Corticolimbic dysregulation model of depression. Regions with known anatomical connections are grouped into two compartments: dorsal (black) and ventral (gray). Curved black arrows and color-filled regions emphasize inverse correlations between right dorsal prefrontal cortex (dFr 9/46, in black) and subgenual cingulate (Cg 25, in gray) seen with both transient sadness in healthy volunteers (Fr decreases, Cg increases) and mood symptom resolution in depressed patients (Fr increases, Cg decreases). Nonshaded regions are potentially critical to the schematic model. Short black arrows indicate known subcortical pathways. Numbers are Brodmann area designations. Abbreviations, from top to bottom: dFr = dorsolateral prefrontal; inf Par = inferior parietal; dCg = dorsal anterior cingulate; pCg = posterior cingulate; Cg 24a = rostral anterior cingulate; BG = basal ganglia; Th = thalamus; aIns = anterior insula; Hc = hippocampus; Cg25 = subgenual cingulate; Hth = hypothalamus; mb-p = midbrain-pons. (Source: Reproduced with permission from Mayberg et al., 1999.)

the corpus callosum (subgenual) in both depressed familial bipolar disorder and depressed familial MDD patients (Drevets et al., 1997) (see Fig. 15–11). Decreased subgenual prefrontal cortical activity was accompanied by reductions in gray matter volume (Drevets et al., 1997; Hirayasu et al., 1999), as noted above (Fig. 15–5). Of interest, Kimbrell and colleagues (2002) reported that subgenual anterior cingulate metabolism was correlated inversely with the number of lifetime depressive episodes in MDD patients. In contrast, Videbeck and colleagues (2002) found that nonfamilial depressed MDD patients compared with healthy controls had increased subgenual prefrontal cortical activity.

Drevets (1999) observed that, although baseline subgenual prefrontal cortical CBF and metabolism appeared to be abnormally decreased in PET images during depressive episodes, computer simulations that corrected the PET data for the partial volume effect of reduced gray matter volume suggested that the “actual” metabolic activity in the remaining subgenual prefrontal cortical tissue may be increased in depressive patients relative to controls and decrease to normative levels during effective treatment. This result appears to be compatible with evidence that effective antidepressant pharmacotherapy results in a decrease in metabolic activity in this region in MDD patients¹³⁵ and that during

depressive episodes, metabolism shows a positive relationship with depression severity in both depressed bipolar (Ketter et al., 2001) and depressed MDD patients.¹³⁶ This mood state dependency of subgenual prefrontal cortical metabolism is also consistent with functional neuroimaging data showing that CBF increases in this region in healthy, non-depressed individuals during sadness induced internally by contemplation of sad thoughts or memories (George et al., 1995b; Damasio et al., 1998; Mayberg et al., 1999).

Variable anterior cingulate/medial prefrontal activity has been noted in other studies of depressed bipolar patients. Some studies of such patients compared with healthy controls have detected decreased anterior cingulate/medial prefrontal metabolism assessed with ¹⁸FDG PET (Buchsbbaum et al., 1997a), and CBF assessed with H₂¹⁵O PET (Ketter et al., 1996b) and ^{99m}Tc-HMPAO SPECT (Ito et al., 1996). One study detected decreased superior but increased inferior anterior cingulate metabolism in depressed (primarily bipolar-II) patients with summer seasonal affective disorder (Goyer et al., 1992). Others, however, failed to detect differences in anterior cingulate activity in depressed bipolar patients compared with healthy controls.¹³⁷ In a study by Ketter and colleagues (2001), anterior cingulate/medial prefrontal metabolism was found to be similar in depressed

Subgenual Prefrontal Hypometabolism in Mood Disorders

Drevets WC, et al. *Nature*, 1997; 386:824-7.

Figure 15-11. Decreased subgenual prefrontal cortical metabolism in depressed patients with familial major depressive disorder and familial bipolar disorder. Coronal (31 mm anterior to the anterior commissure, or $y = 31$) and sagittal (3 mm left of midline, or $x = -3$) sections showing negative voxel t values where glucose metabolism was decreased in (7 bipolar and 10 unipolar) familial depressed patients compared with controls. Decreased activity was accompanied by reduced gray matter volume (Fig. 15-5). A = anterior, L = left, PFC = prefrontal cortex. (Source: Drevets, 2001; Drevets et al., 1997. Reprinted with permission from Macmillan Publishers Ltd: *Nature*.)

and euthymic bipolar patients and healthy controls, but correlated positively with HAM-D scores in the bipolar patients. Symptoms may be differentially related to anterior cingulate function. Thus in a combined sample of bipolar and MDD patients, HAM-D scores were found to be correlated directly with right anterior cingulate cerebral metabolism and Spielberger Anxiety-State Scale scores with left anterior cingulate cerebral metabolism (Osuch et al., 2000).

There has also been variability in findings on anterior cingulate/medial prefrontal activity in studies of depressed MDD patients. Thus these patients have been reported to have decreased anterior cingulate/medial prefrontal metabolism assessed with ^{18}F FDG PET¹³⁸ and CBF assessed with C^{15}O_2 (Bench et al., 1992, 1993; Dolan et al., 1992) and H_2^{15}O (Drevets et al., 1997) PET and with $^{99\text{m}}\text{Tc}$ -HMPAO¹³⁹ and $^{99\text{m}}\text{Tc}$ -EMZ (Curran et al., 1993) SPECT. Other studies of depressed MDD patients compared with controls, however, have found unchanged¹⁴⁰ or increased (Drevets et al., 1992; Videbech et al., 2002) anterior cingulate activity. Also, as noted below, subgroups of depressed MDD patients

may have increased anterior cingulate activity related to subsequent response to sleep deprivation¹⁴¹ or fluoxetine (Mayberg et al., 1997).

Decreased temporal cortical activity has been observed in depressed mood disorder patients compared with healthy controls. Thus several neuroimaging studies in depressed bipolar patients compared with healthy controls have found decreased temporal cortical metabolism with ^{18}F FDG PET (Post et al., 1987; Cohen et al., 1989; Ketter et al., 2001) and CBF assessed with H_2^{15}O PET (Ketter et al., 1996a) and $^{99\text{m}}\text{Tc}$ -HMPAO SPECT (Ito et al., 1996). One study detected decreased posterior but increased anterior left temporal cortical metabolism in depressed (primarily bipolar-II) patients with summer seasonal affective disorder (Goyer et al., 1992). Two of the above studies found bilateral (Ketter et al., 1996a, 2001), three found left (Cohen et al., 1989; Goyer et al., 1992; Ito et al., 1996), and one found right (Post et al., 1987) lateralized decreases. Other studies, however, found that depressed bipolar patients compared with healthy controls had increased (Buchsbaum et al., 1997b) or similar¹⁴² temporal cortical activity.

Depressed MDD patients may also have decreased temporal cortical activity. Thus these patients compared with healthy controls were found to have decreased temporal cortical metabolism with ^{18}F FDG¹⁴³ and ^{11}C -glucose PET (Kishimoto et al., 1987) and increased CBF with H_2^{15}O PET (Drevets et al., 1992) and SPECT employing $^{99\text{m}}\text{Tc}$ -HMPAO,¹⁴⁴ $^{99\text{m}}\text{Tc}$ -EMZ (Austin et al., 1992; Curran et al., 1993; Edmonstone et al., 1994), ^{123}I IMP (O'Connell et al., 1989; Kanaya and Yonekawa, 1990), and $^{195\text{m}}\text{Au}$ (Schlegel et al., 1989c). Most of the above studies found bilateral decreases, but five found left¹⁴⁵ and three found right (Hurwitz et al., 1990; Drevets et al., 1992; Edmonstone et al., 1994) lateralized decreases. One group noted possible modest lateralized increases in right more than left temporal activity in depressed MDD patients compared with medical controls (Amsterdam and Mozley, 1992), which normalized with recovery (Amsterdam et al., 1995). Other studies by this group, however, failed to detect consistent laterality differences in depressed MDD patients compared with healthy controls (Mozley et al., 1996; Hornig et al., 1997). Kowatch and colleagues (1999) found increased temporal lobe CBF in depressed adolescent MDD patients compared with healthy controls. About half of the studies, however, found that depressed MDD patients and healthy controls had similar temporal cortical activity.¹⁴⁶

Increased amygdala activity may occur in depressed mood disorder patients compared with healthy controls. Thus in comparison with healthy controls, increased amygdala activity has been noted in depressed bipolar patients through ^{18}F FDG PET (Ketter et al., 2001; Drevets et al., 2002b) and in depressed MDD patients through ^{18}F FDG (Nofzinger et al., 1999; Drevets et al., 2002c) and H_2^{15}O PET (Drevets et al., 1992; Videbech et al., 2002) and $^{99\text{m}}\text{Tc}$ -HMPAO SPECT (Kowatch et al., 1999). All of the above studies yielded lateralized findings, with four detecting left¹⁴⁷ and two right (Kowatch et al., 1999; Ketter et al., 2001) amygdala activity increases. In one of these studies, left amygdala (but not right amygdala or hippocampus) metabolism was found to be increased in both depressed bipolar and depressed MDD patients, and positively correlated with stressed (PET scan) plasma cortisol levels in both groups (Drevets et al., 2002a). This study also found that in euthymic bipolar patients, left amygdala metabolism was elevated in those patients off but not on mood stabilizers (Drevets et al., 2002c).

In an fMRI study, in a masked (outside of conscious awareness) faces paradigm, depressed MDD patients were found to have exaggerated left (but not right) amygdala activation in response to all faces that was even greater for fearful faces (Sheline et al., 2001). In another study, although depressed MDD patients and controls were found to have similar amygdala CMRglu, negative affect was

found to be correlated with right amygdala metabolism in patients (Abercrombie et al., 1998). Depressed MDD patients who later responded to sleep deprivation were found to have baseline increased left amygdala CMRglu in one study (Wu et al., 1992) and right hippocampal–amygdala complex CBF in another (Ebert et al., 1991). Hornig and colleagues (1997) found that treatment-resistant (but not non-treatment-resistant) depressed MDD patients had increased bilateral amygdala–hippocampal CBF. MDD patients who recovered on SSRIs and who had subsequent tryptophan depletion–induced (Bremner et al., 1997) or alpha-methylparatyrosine–induced (Bremner et al., 2003) relapse, but not those who failed to relapse, tended to have increased (laterality not stated) amygdala activity. In other studies, however, amygdala activity was found to be similar in depressed patients and controls.¹⁴⁸

Compared with healthy controls, depressed MDD patients have shown increased (Ebert et al., 1991; Videbech et al., 2001, 2002), decreased (Saxena et al., 2001), or unchanged (Conca et al., 2000) hippocampal activity.

Decreased basal ganglia activity in MDD patients during depression has been observed in multiple studies. Thus depressed MDD patients compared with healthy controls were found to have decreased basal ganglia metabolism with ^{18}F FDG PET¹⁴⁹ and CBF with H_2^{15}O PET (Drevets et al., 1992) and with $^{99\text{m}}\text{Tc}$ -HMPAO¹⁵⁰ and $^{99\text{m}}\text{Tc}$ -EMZ (Austin et al., 1992; Curran et al., 1993; Edmonstone et al., 1994) SPECT. However, Videbech and colleagues (2002) found increased and most studies found similar¹⁵¹ basal ganglia activity in depressed MDD patients compared with that in healthy controls.

A few studies have indicated the possibility that depressed bipolar patients have decreased basal ganglia activity. Thus compared with healthy controls, these patients were found to have decreased basal ganglia metabolism with ^{18}F FDG PET (Baxter et al., 1985; Buchsbaum et al., 1986; Cohen et al., 1989) and CBF with H_2^{15}O PET (Ketter et al., 1996a). Buchsbaum and colleagues (1997) reported that metabolism in depressed bipolar patients compared with controls was found to be decreased in the left putamen but increased in the entire striatum. In another study, moderately to severely depressed bipolar patients showed relatively increased basal ganglia metabolism compared with mildly depressed and euthymic bipolar patients and healthy controls (Ketter et al., 2001). Other studies, however, failed to detect differences in basal ganglia activity between depressed bipolar patients and healthy controls.¹⁵²

Studies have found both decreased (Baxter et al., 1985; Buchsbaum et al., 1997b) and increased (Ketter et al., 2001) thalamic metabolism assessed with ^{18}F FDG PET in depressed bipolar patients compared with healthy controls. Several other studies have failed to detect differences in thalamic

activity in depressed bipolar patients compared with healthy controls.¹⁵³

Depressed MDD patients compared with healthy controls were found to have decreased thalamic metabolism with ¹⁸F-DG PET (Hagman et al., 1990; Buchsbaum et al., 1997) and CBF with ^{99m}Tc-HMPAO (Mayberg et al., 1994; Vasile et al., 1996; Kowatch et al., 1999) and SPECT with ^{99m}Tc-EMZ (Austin et al., 1992; Curran et al., 1993). Two studies, however, found increased thalamic activity (Drevets et al., 1992; Saxena et al., 2001) and most found similar¹⁵⁴ thalamic activity in depressed MDD patients compared with healthy controls.

Increased cerebellar activity independent of mood state has been observed in treatment-resistant bipolar patients (Ketter et al., 2001). In another study, however, bipolar patients (mood state not specified) were found to have lower cerebellar blood volume than that of control subjects (Loeber et al., 1999). In the latter study, schizophrenic patients had higher cerebellar blood volume than that of control subjects. Other studies have found similar cerebellar activity in depressed bipolar patients and healthy controls (Baxter et al., 1985; Ebert et al., 1993; Ketter et al., 1996b).

Increased cerebellar activity has also been reported in depressed MDD patients with cognitive impairment (Bench et al., 1992; Dolan et al., 1992) and moderate to severe depression (Videbech et al., 2001, 2002; Kimbrell et al., 2002). However, Kumar and colleagues (1993) found decreased cerebellar metabolism in depressed patients with late-life MDD compared with healthy controls. Other studies found similar cerebellar activity in depressed MDD patients and healthy controls (Baxter et al., 1985; Wu et al., 1992; Biver et al., 1994).

In "activation" studies, mood disorder patients have also manifested altered prefrontal and anterior paralimbic responses compared with healthy controls during diverse conditions (for a more detailed review, see Malhi et al., 2004): affective processing tasks, such as facial emotion recognition (George et al., 1997a; Lennox et al., 1999; Yurgelun-Todd et al., 2000), viewing of emotionally expressive faces,¹⁵⁵ affect-inducing captioned pictures (Malhi et al., 2004), and positive (Mitterschiffthaler et al., 2003) and negative (Davidson et al., 2003; Irwin et al., 2004) affective pictures; self-induced transient sadness¹⁵⁶; and performance of an emotional version of the Stroop color-word interference test (Malhi et al., 2005). These altered responses also occurred during cognitive tasks, such as the conventional Stroop test (George et al., 1997b; Blumberg et al., 2003a,b; Kromhaus et al., 2006), complex planning (Elliott et al., 1997), planning and guessing with and without feedback (Elliott et al., 1998), word generation,¹⁵⁷ working memory (Adler et al., 2004), visuospatial working memory (Chang

et al., 2004), memory encoding (Bremner et al., 2004), and reaction time and movement velocity scaling, as well as during acute drug challenges with intravenous procaine (Ketter et al., 1993), oral amphetamine (Trivedi et al., 1995), and oral dl-fenfluramine (Mann et al., 1996). In addition, during rapid eye movement (REM) sleep versus waking, depressed MDD patients compared with healthy controls did not show increased anterior paralimbic (including anterior cingulate) metabolism and had decreased gyrus rectus metabolism, but were found to have greater tectal and left hemisphere (sensorimotor and inferior temporal cortex, uncus gyrus-amygdala, and subicular complex) metabolic increases (Nofzinger et al., 1999). Also, during non-REM sleep, depressed MDD patients compared with controls showed increased global and widespread regional (especially posterior cingulate, amygdala, hippocampus, occipital and temporal cortex, and pons) absolute metabolism and decreased prefrontal (especially medio-orbital frontal), anterior cingulate, caudate, and medial thalamus relative metabolism (Ho et al., 1996).

Activation studies may be able to detect cerebral functional differences not apparent with simpler (resting on continuous performance task) behavioral paradigms. For example, although resting and continuous performance task studies have indicated overlapping frontal deficits in schizophrenia and mood disorders, activation studies have demonstrated dissociations. Thus, during the Wisconsin Card Sorting Test, frontal activation was found to be blunted in schizophrenia but preserved in depression (Berman et al., 1993). Similarly, during word generation, frontal activation was blunted in schizophrenic but enhanced in euthymic bipolar patients (Curtis et al., 2001). Moreover, activation studies may detect additional differences between euthymic mood disorder patients and healthy controls. For example, both euthymic bipolar (Krüger et al., 2003) and euthymic MDD (Liotti et al., 2002) patients appear to have altered cerebral activation patterns with transient sadness induction.

Finally, return of depressive symptoms induced by depletion of tryptophan (Bremner et al., 1997) and norepinephrine (Bremner et al., 2003) in MDD patients who had responded to SSRIs and desipramine, respectively, was found to be accompanied by decreased dorsolateral prefrontal and orbitofrontal metabolism. Of interest, increased baseline prefrontal and limbic metabolism predicted vulnerability to such return of depressive symptoms induced by depletion of tryptophan (Bremner et al., 1997) and norepinephrine (Bremner et al., 2003).

In summary, depressed bipolar and MDD patients compared with healthy controls have commonly been found to have decreased global, dorsolateral prefrontal, and temporal cortical activity and increased amygdala activity. The

dorsolateral prefrontal finding is the most robust one and is supported by clinical correlations. Basal ganglia but not thalamus activity may also be decreased in depressed MDD patients compared with controls, but there are only sparse variable data for bipolar depression. Mood disorder patients compared with healthy controls have been found to have variable anterior cingulate/medial prefrontal activity, due perhaps in part to heterogeneity related to clinical parameters, such as symptoms and treatment response. Sparse data raise the possibility that cerebellar activity may be increased in at least some mood disorder patients. Although some studies have found lateralized effects, compelling lateralization patterns have not emerged across studies. The above observations from resting or continuous performance task studies have generally been supported by findings from activation studies.

Effects of Mood State and Treatment on Cerebral Activity

Most of the above-mentioned changes in activity in anterior cortical and subcortical components of basal ganglia–thalamocortical circuits appeared to be state related, as they were not evident in euthymic bipolar (Ketter et al., 2001) and MDD (G. Goodwin et al., 1993; Bench et al., 1995) patients. Possible exceptions include the amygdala, where Drevets and colleagues (2002b) observed that metabolism was significantly elevated in a small sample of euthymic bipolar subjects who were not taking mood-stabilizing drugs, relative both to healthy controls and to euthymic bipolar patients taking mood stabilizers. In contrast, amygdala metabolism did not differ between the bipolar subjects taking mood stabilizers and healthy controls. The cerebellum may also show normalized metabolic increases independent of mood state in treatment-resistant bipolar patients compared with healthy controls (Ketter et al., 2001).

Treatment responders compared with their depressed pretreatment baseline often show attenuation (or resolution) of pretreatment cerebral functional abnormalities with various therapies, including mood stabilizers (Ketter et al., 1999), antidepressants,¹⁵⁸ placebo (Mayberg et al., 2002), psychotherapy (Brody et al., 2001b), thyroxine (Bauer et al., 2005), phototherapy (Cohen et al., 1992; Vasile et al., 1997), sleep deprivation,¹⁵⁹ vagus nerve stimulation (Devous et al., 2002), and (nonconvulsive) transcranial magnetic stimulation (TMS) (George et al., 1995; Pascual-Leone and Pallardó, 1996). Improvements in specific symptoms may be related to normalization of activity in particular components of anterior cortical/anterior paralimbic basal ganglia–thalamocortical circuits (Brody et al., 2001b). There have been some discordant findings, however, such as antidepressants exacerbating baseline abnormalities (Nobler et al., 2000).

One report noted that in MDD patients, recovery from depression was accompanied by metabolism (assessed with ¹⁸FDG PET) increases in neocortical (right dorsolateral prefrontal, inferior parietal) structures and decreases in limbic–paralimbic (subgenual cingulate, anterior insula) regions (Mayberg et al., 1999). That is, baseline abnormalities seen in depression were attenuated or reversed. Of interest, healthy volunteers experiencing transient sadness had the reverse pattern involving the same regions, namely, neocortical increases and limbic decreases in blood flow assessed with H₂¹⁵O PET.

In contrast, successful ECT appears to exacerbate decreased anterior cerebral activity (Nobler et al., 1994; Scott et al., 1994; Henry et al., 2001), although other patterns (including normalization) have also been reported (Bonne et al., 1996b; Elizagarate et al., 2001; Mervaala et al., 2001). This apparent divergence could be related to confounding medication effects or to a different mechanism of action of ECT.

Taken together, the above findings suggest that in many instances, differences in cerebral activity in mood disorder patients compared with healthy controls are commonly state related, as they tend to be absent during euthymia and generally attenuate or reverse with successful treatment. Exceptions may occur, however, in specific regions, such as amygdala and cerebellum; in specific subgroups, such as treatment-resistant bipolar patients; and with specific therapies, such as ECT.

Baseline Cerebral Activity Markers of Treatment Response

Comparisons of baseline (pretreatment) cerebral activity in patients who later respond or fail to respond to therapy suggest possible baseline markers of treatment response. Baseline left insular hypermetabolism may be a marker for bipolar patients who are more likely to respond to carbamazepine, while hypometabolism in this region may be related to response to nimodipine (Ketter et al., 1999). Depressed bipolar patients who later respond to valproate may have low baseline rostral anterior cingulate and medial frontal gyrus cerebral glucose metabolism (Ketter et al., 2000). In contrast, depressed MDD patients who later respond to fluoxetine may have high baseline rostral anterior cingulate cerebral glucose metabolism (Mayberg et al., 1997). Thus, complementary baseline differences may be seen in depressed bipolar responders to valproate and depressed MDD responders to fluoxetine. Similarly, depressed MDD patients who later responded to venlafaxine had increased baseline anterior cingulate activation when viewing negative affective pictures (Davidson et al., 2003). Depressed MDD patients who later responded to sertraline had increased baseline gyrus rectus metabolism (Buchsbaum

et al., 1997b). In one study of depressed MDD patients compared with healthy controls, however, baseline left middle frontal gyrus, bilateral medial prefrontal, and bilateral temporal hypometabolism was seen in those who later responded to venlafaxine or bupropion, whereas baseline cerebellar hypometabolism was evident in those who later failed to respond to these agents (Little et al., 1996). Selectively, compared with control subjects, bupropion responders also had cerebellar hypermetabolism, whereas venlafaxine responders showed bilateral temporal and basal ganglia hypometabolism (Little et al., 2005). Anterior limbic hyperactivity appears to be a baseline marker for MDD patients who obtain antidepressant responses from sleep deprivation.¹⁶⁰

In MDD patients, degree of treatment resistance was found to be correlated with left orbitofrontal metabolism (Kimbrell et al., 2002). Another study found that medication-free treatment-resistant depression patients had increased hippocampal–amygdalar CBF compared with non-treatment-resistant patients and healthy controls (Hornig et al., 1997). Also, in patients with treatment-resistant mood disorders, widespread (including anterior paralimbic) baseline hypometabolism was found to be associated with better responses to high-frequency (20 Hz) TMS, while baseline hypermetabolism tended to be related to better responses to low-frequency (1 Hz) TMS (Kimbrell et al., 1999). In another study, depressed responders compared with nonresponders to (5 or 20 Hz) TMS had baseline increased inferior frontal lobe CBF (Teneback et al., 1999).

The above studies of baseline markers of treatment response offer preliminary evidence that pretreatment neuroimaging assessments of depressed mood disorder patients may have features that distinguish subsequent responders from nonresponders. Anterior paralimbic (especially anterior cingulate/medial prefrontal) regions may ultimately prove to be of special interest in assessing baseline markers of treatment response. At the same time, it should be noted that the CMRglu and CBF studies reviewed above have important limitations, including small sample sizes, varying methodology, and reliance on measures of cerebral activity rather than assessment of specific neurochemical differences.

Cerebral Activity in Mania, Hypomania, and Rapid Cycling

Because of clinical considerations, there have been relatively few studies of cerebral activity during mania. Thus, only sparse and equivocal data exist regarding changes in global cerebral activity in mania. Kishimoto and colleagues (1987) noted widespread increases in ¹¹C-glucose uptake were noted in three medication-free manic patients

compared with controls. In another study, bipolar patients in mixed (and depressed) states were found to have decreased global CMRglu compared with healthy controls and manic bipolar patients (Baxter et al., 1985). One study found that global cerebral metabolism in medication-free hypomanic or euthymic bipolar patients did not differ from that in healthy controls, but was increased compared with bipolar patients in depressed or mixed states (Schwartz et al., 1987); however, this finding was not replicated by Martinot and colleagues (1990). In other studies, manic patients and controls were observed to lack global differences (Silfverskiöld and Risberg, 1989; Rubin et al., 1995).

There have been variable regional findings in manic patients. Frontal lobe activity was found to be decreased in such patients in four studies.¹⁶¹ In one of these studies, manic patients were found to have not only decreased resting orbitofrontal CBF but also decreased right rostral prefrontal and right orbital prefrontal CBF activation during word generation (Blumberg et al., 1999). Frontal activity was found to be increased, however, in five studies,¹⁶² with the increased activity occurring in the anterior cingulate or subgenual prefrontal cortex in four of these studies.¹⁶³ Baxter and colleagues (1985, 1989) observed an increase in frontal activity in manic compared with depressed bipolar patients. Although lithium withdrawal generally led to decreased anterior cingulate activity, development of mania with lithium withdrawal was found to be associated with increased superior anterior cingulate activity (G. Goodwin et al., 1997).

Temporal lobe activity in mania was found to be decreased in one study (Migliorelli et al., 1993), increased in two studies (O'Connell et al., 1995; Gyulai et al., 1997), and mixed (decreased left amygdala and increased right temporal cortical) in one study (al-Mousawi et al., 1996). Basal ganglia activity was observed to be increased in two studies (Drevets et al., 1995; Blumberg et al., 2000) and increased in about half of patients in another study (O'Connell et al., 1995). Mania ratings were found to be correlated positively with right temporal and caudate CBF by O'Connell and colleagues (1995), but negatively correlated (a trend) with right basotemporal CBF by Migliorelli and colleagues (1993).

Cerebellar blood volume in bipolar-I patients (primarily medicated and in the manic state) compared with controls was found to be similar overall and in patients on lithium or valproate, but decreased in patients on conventional antipsychotics and increased in those on atypical antipsychotics (Loeber et al., 2002). There have also been a few functional neuroimaging studies in patients with mania secondary to medications, alcohol or drug abuse, or general medical conditions. Starkstein and colleagues

(1990) reported right temporal lobe hypometabolism in three patients (two on lithium, one unmedicated) with mania secondary to stroke (Starkstein et al., 1990).

In rapid-cycling bipolar patients, anterior temporal activity may be asymmetric when depressed, manic, or hypomanic but not when euthymic (Gyulai et al., 1997). Global cerebral metabolism (Baxter et al., 1985) and blood flow (Speer et al., 1997) may oscillate as mood state changes.

In summary, the locations of changes noted in neuroimaging studies are consistent with the broad notion that altered anterior cortical/anterior paralimbic basal ganglia–thalamocortical circuit activity may contribute importantly to the pathophysiology of mania. Unfortunately, in contrast with depression, studies of mania have been too sparse and had findings too variable (in terms of the location and direction of changes) to allow more meaningful and specific conclusions. Thus, important issues such as the degree to which the locations and directions of changes in mania compared with depression overlap or are complementary remain to be resolved. For example, the available data are insufficient to determine whether the same regions that have decreased activity in depression have increased activity in mania. Advances in research methodology are needed to make neuroimaging studies in mania more feasible so these issues can be addressed.

Assessment of Specific Cerebral Neurochemistry

Studies of specific cerebral neurochemistry complement studies of cerebral activity in that they can detect more specifically what function is altered, and they are similar in that they can detect where function is altered. Studies using PET and SPECT with specific neurochemical radiotracers to assess specific cerebral neurochemistry are discussed in Chapter 14. Below we review studies using MRS. Clinical MRS studies in patients with mood disorders have begun to detect metabolite alterations in anterior cortical/anterior paralimbic basal ganglia–thalamocortical circuits.

Proton (¹H) Magnetic Resonance Spectroscopy

Proton magnetic resonance spectroscopy (¹H-MRS) allows determination of diverse cerebral metabolites, including NAA, cytosolic choline (Cho) compounds, myoinositol (mI), compounds related to energy metabolism (creatine [Cr], phosphocreatine [PCr]), and amino acids (gamma-aminobutyric acid [GABA], glutamate). Metabolite concentrations may be assessed as absolute or relative (typically compared with Cr) measures.

N-acetylaspartate, an amino acid with putative roles in amino acid metabolism and fatty acid and protein synthesis, is found in mature neurons and may reflect neuronal density and integrity. Although findings vary, evidence is accumulating to support NAA and NAA/Cr changes in

bipolar patients. Thus in bipolar patients compared with healthy controls, NAA or NAA/Cr was found to be decreased in 8 studies,¹⁶⁴ increased in 4 studies,¹⁶⁵ and similar in 11 studies.¹⁶⁶ In contrast, MDD patients and healthy controls were found consistently to have similar NAA and NAA/Cr across 11 studies,¹⁶⁷ while only single studies found decreased caudate NAA/Cr (Vythilingam et al., 2003) and prefrontal NAA/Cr (but not NAA) (Gruber et al., 2003) in MDD patients. In the latter study, decreased prefrontal NAA/Cr in MDD appeared to be related to increased Cr (Gruber et al., 2003).

NAA and NAA/Cr findings in bipolar patients may vary on a regional basis. Thus dorsolateral prefrontal NAA or NAA/Cr in bipolar patients was found to be decreased in three studies (Winsberg et al., 2000; Chang et al., 2001; Sassi et al., 2005) and similar to that of controls in three studies (Bertolino et al., 2003; Michael et al., 2003). While studies found that bipolar patients had decreased medial prefrontal/orbitofrontal NAA (Cecil et al., 2002) and tended to have decreased cerebellar vermis NAA/Cr (Cecil, 2003), multiple other studies found that bipolar patients and controls had similar NAA or NAA/Cr in medial prefrontal (Hamakawa et al., 1999; Frye et al., 2001; Cecil et al., 2003), anterior cingulate,¹⁶⁸ and frontal/prefrontal¹⁶⁹ regions.

In bipolar patients compared with controls, hippocampal NAA (Deicken et al., 2003a) and NAA/Cr (Bertolino et al., 2003) were found to be decreased. In a post hoc analysis of the latter study, bipolar patients compared with those without a history of alcohol abuse had higher hippocampal NAA/Cr (Frye et al., 2000). In another study, however, bipolar patients and healthy controls displayed similar temporal NAA (Moore et al., 2000b). First-episode psychosis patients (46 percent of whom had bipolar disorder) were found to have decreased temporal NAA/Cr (Renshaw et al., 1995). In contrast, euthymic bipolar patients on lithium (but not valproate) showed increased temporal NAA/Cr (T. Silverstone et al., 2003). In a postmortem study, bipolar patients (most of whom had had psychotic symptoms) were found to have decreased superior temporal (but not frontal) cortex NAA, consistent with the notion that temporal lobe NAA deficits may be a common feature of psychotic disorders (Nudmamud et al., 2003).

Bipolar patients compared with controls displayed decreased (Frye et al., 2001), increased (Sharma et al., 1992), or similar¹⁷⁰ basal ganglia NAA/Cr. Medication-free depressed bipolar patients had increased left putamen NAA (Dager et al., 2004). One study found increased NAA (Deicken et al., 2001), but others found similar NAA (Dager et al., 2004) or NAA/Cr (Bertolino et al., 2003) in the thalamus in bipolar patients compared with healthy controls. Parietal and occipital regions have consistently shown similar NAA

and NAA/Cr levels in bipolar patients and healthy controls¹⁷¹ and have commonly been used as control regions. NAA has variable relationships with age.

In bipolar patients, some studies found that dorsolateral prefrontal (Winsberg et al., 2000) and basal ganglia (Kato et al., 1996a; Ohara et al., 1998) NAA/Cr decreased with age, while others found no relationship between age and dorsolateral prefrontal NAA (Brambilla et al., 2005; Sassi et al., 2005), dorsolateral prefrontal NAA/Cr in juveniles (Chang et al., 2001), medial prefrontal NAA (Hamakawa et al., 1999), hippocampal NAA/Cr (Bertolino et al., 2003), or basal ganglia NAA (Hamakawa et al., 1998). In a postmortem study of bipolar patients, superior temporal lobe and frontal NAA were not found to be related to age (Nudmamud et al., 2003). In MDD patients, age was observed to affect caudate NAA/Cr (Vythilingam et al., 2003), but not to be related to anterior cingulate NAA (Pfleiderer et al., 2003) or basal ganglia NAA or NAA/Cr (Hamakawa et al., 1998).

Variable, but most often negative, gender effects have been reported for NAA and NAA/Cr. Hamakawa and colleagues (1998) detected an overall (in euthymic and depressed bipolar and MDD patients and healthy controls) gender effect for left basal ganglia NAA (but not NAA/Cr), but the direction of the effect was not specified. In other studies, however, the same group noted no overall (in euthymic bipolar patients and healthy controls) gender effect on left basal ganglia NAA/Cr (Kato et al., 1996a) and no overall (in euthymic and depressed bipolar patients and healthy controls) gender effect on bilateral medial prefrontal NAA (Hamakawa et al., 1999). In a postmortem study of bipolar patients, superior temporal lobe and frontal NAA were not found to be related to gender (Nudmamud et al., 2003).

NAA/Cr may vary across the menstrual cycle. Thus medial prefrontal (but not occipital) NAA/Cr was found to decline from follicular to luteal phase in women with premenstrual dysphoric disorder (PMDD) by 19 percent and in healthy controls by 16 percent, and there were no statistically significant differences in NAA/Cr between these groups (Rasgon et al., 2001).

Although in one study, bipolar-I patients had bilateral dorsolateral prefrontal NAA/Cr decreases while bipolar-II patients had only unilateral (left) decreases (Winsberg et al., 2000), other researchers found that bipolar-I and -II patients had similar prefrontal (Hamakawa et al., 1999) and basal ganglia (Kato et al., 1996b; Hamakawa et al., 1998) NAA or NAA/Cr. Moreover, one of the latter studies found no basal ganglia NAA differences between bipolar and MDD patients when either depressed or euthymic (Hamakawa et al., 1998).

In bipolar patients, dorsolateral prefrontal NAA/Cr (Winsberg et al., 2000; Chang et al., 2001) and hippocampal

NAA showed a tendency to decrease with longer illness duration. However, other studies failed to detect a relationship between duration and dorsolateral prefrontal (Brambilla et al., 2005; Sassi et al., 2005), prefrontal (Hamakawa et al., 1999), basal ganglia (Hamakawa et al., 1998), or thalamus (Deicken et al., 2001) or overall gray or white matter (Dager et al., 2004) NAA or lenticular nucleus NAA/Cr (Ohara et al., 1998). In MDD patients, illness duration was found not to be related to basal ganglia NAA (Hamakawa et al., 1998).

NAA does not appear to vary with mood symptoms. Thus current mood state was not found to be related to NAA or NAA/Cr in prefrontal (Hamakawa et al., 1999; Bertolino et al., 2003), basal ganglia (Hamakawa et al., 1998; Frye et al., 2001), or hippocampal or thalamic (Bertolino et al., 2003) regions in bipolar patients, or in basal ganglia (Hamakawa et al., 1998) in MDD patients. In bipolar patients, HAM-D scores were not found to be related to prefrontal (Hamakawa et al., 1999), basal ganglia (Hamakawa et al., 1998), or overall gray or white matter (Dager et al., 2004) NAA, nor were Young Mania Rating Scale (YMRS) scores found to be related to basal ganglia NAA/Cr (Frye et al., 2001) or to overall gray or white matter NAA (Dager et al., 2004). Similarly, in MDD patients, HAM-D scores were not shown to be related to basal ganglia NAA (Hamakawa et al., 1998). In healthy volunteers, a correlation was not found between the Positive Affect Negative Affect Scale (PANAS), Positive Affect subscale, and left frontal NAA (Jung et al., 2002).

Emerging data suggest possible medication effects on NAA and NAA/Cr. Lithium, in view of its potential neurotrophic effects, is of particular interest. Acute (4-week trial) lithium monotherapy similarly increased prefrontal, temporal, parietal, and occipital NAA in depressed adult bipolar-I patients and healthy controls, but no correlation was found between cerebral NAA and blood lithium concentrations (Moore et al., 2000a). In contrast, in primarily depressed adult bipolar-I and -II patients, lithium for a mean of 3.6 months and valproate for a mean of 1.4 months failed to alter gray or white matter or regional NAA (Friedman et al., 2004). Also, in children and adolescents during manic or mixed episodes, anterior cingulate NAA/Cr showed no change with acute (1-week trial) adjunctive lithium treatment; again, no correlation was found between serum lithium concentrations and brain NAA/Cr (Davanzo et al., 2001). In addition, in adult healthy volunteers, lithium administration for 4 weeks failed to alter dorsolateral prefrontal NAA (Brambilla et al., 2004).

One study found that, compared with healthy controls, euthymic bipolar patients on chronic lithium plus other medications (but not on chronic valproate plus other medications) had increased left temporal NAA/Cr (T. Silverstone et al., 2003). Similarly, bipolar patients taking chronic

lithium had increased dorsolateral prefrontal NAA/Cr compared with unmedicated patients and healthy controls (Brambilla et al., 2005). Comparisons of bipolar patients on and not on chronic lithium, however, revealed similar anterior cingulate (Soares et al., 1999) and basal ganglia (Kato et al., 1996b; Ohara et al., 1998a) NAA/Cr and medial prefrontal NAA (Hamakawa et al., 1999); no relationship was found between serum lithium concentrations and basal ganglia or occipital NAA/Cr (Sharma et al., 1992). In euthymic adults with bipolar disorder on chronic lithium, doses were not found to be related to thalamic (Deicken et al., 2001) or hippocampal (Deicken et al., 2003a) NAA.

If lithium increases NAA or NAA/Cr, the presence or absence of chronic lithium could contribute to the variability in NAA and NAA/Cr findings in bipolar patients compared with healthy controls. In studies to date, the percentage of patients taking lithium was lower in studies detecting NAA decreases ($N = 27/111$, 24 percent)¹⁷² than in those finding no NAA differences ($N = 81/189$, 43 percent)¹⁷³ or those reporting NAA increases ($N = 23/65$, 35 percent) (Sharma et al., 1992; Deicken et al., 2001; T. Silverstone et al., 2003; Dager et al., 2004). These differences are consistent with the notion that NAA and NAA/Cr increases with chronic lithium therapy could be a confounding factor in detecting putative baseline (unmedicated) decreases in NAA and NAA/Cr in patients with bipolar disorder.

Less is known about the effects of other medications on NAA and NAA/Cr. Bipolar patients taking compared with those not taking chronic anticonvulsants were found to have increased basal ganglia NAA (Hamakawa et al., 1998), but duration of valproate treatment showed an inverse correlation with medial prefrontal NAA (Cecil et al., 2002). Bipolar patients taking compared with those not taking chronic valproate had similar medial prefrontal NAA (Hamakawa et al., 1999), and valproate doses were not found to be related to thalamus (Deicken et al., 2001) or hippocampal (Deicken et al., 2003a) NAA. Patients taking compared with those not taking chronic antipsychotics showed similar medial prefrontal NAA (Hamakawa et al., 1999) and basal ganglia NAA and NAA/Cr (Kato et al., 1996a; Hamakawa et al., 1998). Schizophrenic patients taking atypical antipsychotics compared with those taking typical antipsychotics were found to have higher cingulate NAA (Ende et al., 2000b).

In depressed MDD patients, acute nefazodone (Charles et al., 1994a) and fluoxetine (Sonawalla et al., 1999) did not alter basal ganglia NAA/Cr. The latter study also failed to detect changes when the sample was stratified by patients with sustained response to fluoxetine ("true fluoxetine response") and those with nonresponse or only transient response to the drug ("placebo pattern

response/nonresponse") (Sonawalla et al., 1999). Mood disorder patients taking compared with those not taking chronic antidepressants were found to have similar medial prefrontal NAA (Hamakawa et al., 1999) and basal ganglia NAA/Cr (Kato et al., 1996a). In depressed MDD patients, ECT did not alter parietal NAA (Felber et al., 1993), and a course of ECT did not significantly alter bilateral hippocampal NAA (Ende et al., 2000b). These observations are consistent with the notion that ECT may not result in neuronal damage.

There are very few data regarding baseline NAA or NAA/Cr markers of treatment response. In depressed MDD patients, left basal ganglia NAA/Cr was found to be similar in fluoxetine responders and nonresponders (Renshaw et al., 1997) and in those with "true fluoxetine response" and "placebo pattern response/nonresponse" (Sonawalla et al., 1999).

Choline (Cho) is an acetylcholine precursor involved in second-messenger cascades. The "cholinergic-adrenergic" hypothesis of bipolar disorder proposes that depression is related to cholinergic overactivity and adrenergic underactivity, while mania is related to cholinergic underactivity and adrenergic overactivity (Janowsky et al., 1972). In ¹H-MRS, the Cho peak represents total cellular Cho stores, the dominant component of which is believed to be from cell membranes (phospholipids) rather than acetylcholine.

Although findings vary, evidence is accumulating to support Cho and Cho/Cr changes in patients with mood disorders. Thus, Cho and Cho/Cr in bipolar patients compared with healthy controls were found to be increased in 5 studies,¹⁷⁴ to tend to be decreased in 3 studies,¹⁷⁵ to be decreased in one cohort but not a second cohort in 1 study (Wu et al., 2004), and to be similar in 17 studies.¹⁷⁶ Cho and Cho/Cr in MDD patients compared with healthy controls were found to be (or to tend to be) increased in 7 studies,¹⁷⁷ decreased in 4 studies,¹⁷⁸ and similar in 3 studies (Auer et al., 2000; Pflieger et al., 2003; Smith et al., 2003). Gruber and colleagues (2003) found decreased prefrontal Cho/Cr but not Cho in MDD patients, perhaps related to increased Cr.

Cho and Cho/Cr findings in mood disorder patients may vary on a regional basis. Thus in bipolar patients compared with healthy controls, Cho or Cho/Cr was found to be increased (Soares et al., 1999; C. Moore et al., 2000) or similar¹⁷⁹ in anterior cingulate regions, to tend to be decreased (Cecil et al., 2002) or similar (Hamakawa et al., 1999; Dager et al., 2004) in medial prefrontal regions, and to be decreased (Silverstone et al., 2004; Wu et al., 2004) or similar (Renshaw et al., 1995; Wu et al., 2004) in temporal regions. However, Cho or Cho/Cr in bipolar patients compared with healthy controls was found to be consistently similar in dorsolateral prefrontal,¹⁸⁰ frontal/prefrontal

(Castillo et al., 2000; Amaral et al., 2002; Bertolino et al., 2003), hippocampal (Bertolino et al., 2003; Deicken et al., 2003a), and temporal (Renshaw et al., 1995) regions.

Cho or Cho/Cr in bipolar patients compared with healthy controls was found to be increased,¹⁸¹ to tend to be increased (Dager et al., 2004), or to be similar (Ohara et al., 1998; Castillo et al., 2000; Bertolino et al., 2003) in basal ganglia, and similar in thalamus (Deicken et al., 2001; Bertolino et al., 2003; Dager et al., 2004). One study found that Cho tended to be increased in bipolar patients compared with controls in left caudate and right putamen, but not in other brain regions or in gray or white matter (Dager et al., 2004). Parietal and occipital regions have consistently shown similar Cho and Cho/Cr in bipolar patients and healthy controls¹⁸² and have commonly been used as control regions.

In MDD patients compared with healthy controls, basal ganglia Cho or Cho/Cr was found to be or to tend to be increased in four studies¹⁸³ but decreased in one study (Renshaw et al., 1997). Cho or Cho/Cr in MDD patients compared with healthy controls was observed to be increased in dorsolateral prefrontal (Farchione et al., 2002) and temporal lobe (Mervaala et al., 2000) regions; similar in anterior cingulate (Auer et al., 2000; Pfleiderer et al., 2003) and orbitofrontal (Steingard et al., 2000) regions; and decreased in prefrontal (Gruber et al., 2003), amygdala (Kusumakar et al., 2001), and hippocampal (Ende et al., 2000a) regions. Cho or Cho/Cr in MDD patients was similar to that in healthy controls in thalamus (Vythilingam et al., 2003) and in parietal (Auer et al., 2000) and occipital (Rosenberg et al., 2000) lobes.

In bipolar patients, no age effect was observed on basal ganglia Cho/Cr (Kato et al., 1996b; Hamakawa et al., 1998) or dorsolateral prefrontal (Brambilla et al., 2005) or prefrontal (Hamakawa et al., 1998) Cho. In MDD patients, age was found to be related to thalamic Cho/Cr (Vythilingam et al., 2003), but not orbitofrontal Cho/Cr (Steingard et al., 2000) or prefrontal Cho (Hamakawa et al., 1998).

Data vary regarding the effect of oral Cho administration on cerebral Cho. One group found that in healthy volunteers, acute administration of Cho (choline bitartrate equivalent to 50 mg/kg free Cho) increased basal ganglia Cho/Cr about two-fold by 3 hours, with no significant correlation between brain and serum Cho (Stoll et al., 1995). Another study by the same group showed that acute administration of Cho in older compared with younger healthy volunteers yielded similar (70–80 percent) increases in plasma Cho, but markedly attenuated increases in basal ganglia Cho/Cr, suggesting that uptake of acutely administered Cho may decrease with age (Cohen et al., 1995). Thus it has been proposed that development of cerebral Cho depletion underlies the deteriorating course seen

in some patients with bipolar disorder (Renshaw et al., 1996). These investigators also reported that four patients with rapid-cycling bipolar disorder who responded to 5,000–7,200 mg/day of free Cho added to lithium \pm other medications had 30–75 percent increases in basal ganglia Cho/Cr (Stoll et al., 1996). In seven patients with rapid-cycling bipolar disorder, however, Cho ingestion did not alter basal ganglia Cho/Cr after 5 weeks of administration (Demopulos et al., 1997). Also, double-blind choline bitartrate 50 mg/kg/day for 12 weeks in four lithium-treated rapid-cycling bipolar patients failed to alter left basal ganglia Cho/Cr, cerebral lithium, or clinical mood ratings, but decreased left basal ganglia purine/NAA and purine/Cho (Lyoo et al., 2003). The authors commented that decreased purine could reflect decreased adenosine triphosphate (ATP), perhaps reflecting increased ATP consumption with choline. Another group found that acute oral challenge of 50 mg/kg of choline bitartrate did not significantly alter Cho/Cr or Cho in four brain locations (Tan et al., 1998). Still another group found that in young healthy volunteers, both acute (50 mg/kg choline bitartrate single dose) and long-term (lecithin 32 g/day for 4 weeks) administration of Cho failed to alter gray matter, white matter, cerebellum, and thalamus Cho (Dechent et al., 1999b). In a more recent study in 11 healthy young men, oral choline bitartrate to yield 50 mg/kg resulted in increased left putamen Cho/Cr, with a mean peak increase of 6.2 percent approximately 2 hours after ingestion (Babb et al., 2004).

Variable, but most often negative, gender effects have been reported for Cho and Cho/Cr. Studies found no overall (in euthymic and depressed bipolar and MDD patients and healthy controls) gender effect on left basal ganglia Cho and Cho/Cr (Hamakawa et al., 1998), no overall (in euthymic bipolar patients and healthy controls) gender effect on left basal ganglia Cho/Cr (Kato et al., 1996a), and no overall (in euthymic and depressed bipolar patients and healthy controls) gender effect on bilateral medial prefrontal Cho (Hamakawa et al., 1999). In MDD patients, gender was not related to orbitofrontal Cho/Cr (Steingard et al., 2000) or hippocampal Cho (Ende et al., 2000b). Cho/Cr may vary across the menstrual cycle. Thus, occipitoparietal (but not medial prefrontal) Cho/Cr was found to have increased from follicular to luteal phase in women with PMDD by 38 percent and in healthy controls by 13 percent, and there were no statistically significant Cho/Cr differences between these groups (Rasgon et al., 2001).

In one study, bipolar-II patients compared with bipolar-I patients and healthy controls were found to have higher basal ganglia Cho/Cr (Kato et al., 1996a). Later studies by this same group failed to detect bipolar-II versus bipolar-I differences in basal ganglia (Hamakawa et al., 1998) or medial prefrontal (Hamakawa et al., 1999) Cho, but found

that depressed bipolar patients had higher basal ganglia Cho than depressed or euthymic MDD patients (Hamakawa et al., 1998). In one report, rapid-cycling compared with non-rapid-cycling bipolar patients showed a tendency to have lower basal ganglia Cho/Cr (Demopulos et al., 1996).

Cho and Cho/Cr do not appear to vary with illness duration in dorsolateral prefrontal (Brambilla et al., 2005), medial prefrontal (Hamakawa et al., 1999), or basal ganglia (Hamakawa et al., 1998; Ohara et al., 1998) regions or overall gray or white matter (Dager et al., 2004) in bipolar patients, or in basal ganglia in MDD patients (Hamakawa et al., 1998).

Cho and Cho/Cr do not appear to have consistent relationships with mood state. As noted above, Hamakawa and colleagues (1998) found that depressed compared with euthymic bipolar patients had higher basal ganglia Cho. In other studies, however, mood state in bipolar patients was not found to be related to Cho or Cho/Cr in medial prefrontal (Hamakawa et al., 1999), dorsolateral prefrontal, anterior cingulate, hippocampal, or thalamic (Bertolino et al., 2003) regions. In bipolar patients, HAM-D scores showed a positive correlation with anterior cingulate Cho/Cr (Moore et al., 2000a), but not with basal ganglia (Hamakawa et al., 1998) or overall gray or white matter (Dager et al., 2004) Cho. In MDD patients, amygdala Cho/Cr displayed a tendency to have a negative correlation with Beck Depression Inventory scores (Kusumakar et al., 2001), while no relationship was observed between HAM-D scores and anterior cingulate (Auer et al., 2000) or basal ganglia (Hamakawa et al., 1998) Cho. In healthy volunteers, however, PANAS Positive Affect subscale scores correlated with left frontal Cho (Jung et al., 2002).

Emerging data suggest possible medication effects on Cho and Cho/Cr. In depressed adult bipolar-I patients, it was found that lithium monotherapy had antidepressant effects and led to decreased prefrontal Cho (Moore et al., 1999). In contrast, in primarily depressed adult bipolar-I and -II patients, lithium for a mean of 3.6 months and valproate for a mean of 1.4 months failed to alter gray or white matter or regional Cho (Friedman et al., 2004). In children and adolescents during manic or mixed episodes, anterior cingulate Cho/Cr did not change with acute (1-week trial) adjunctive lithium treatment and showed no correlation with serum lithium concentrations (Davanzo et al., 2001). Finally, in adult healthy volunteers, lithium administration for 4 weeks failed to alter dorsolateral prefrontal Cho (Brambilla et al., 2004).

Patients taking compared with those not taking chronic lithium were found to have similar basal ganglia Cho/Cr (Lafer et al., 1994; Kato et al., 1996a; Ohara et al., 1998) and Cho (Hamakawa et al., 1998), medial prefrontal Cho (Hamakawa et al., 1999), temporal Cho/Cr (Wu et al., 2004),

and anterior cingulate Cho/Cr (Moore et al., 2000b). Serum lithium concentrations showed no relationship to basal ganglia or occipital Cho/Cr (Sharma et al., 1992).

If lithium alters Cho or Cho/Cr, the presence or absence of chronic lithium treatment could contribute to the variability in Cho and Cho/Cr findings in bipolar patients compared with healthy controls. To date, the percentage of patients taking lithium has been higher in studies finding increases in patients compared with healthy controls (46/84, 55 percent)¹⁸⁴ than in those finding no difference (N = 97/269, 36 percent).¹⁸⁵ This difference is consistent with the notion that Cho and Cho/Cr decreases with chronic lithium could be a confounding factor in detecting putative baseline (unmedicated) increases in Cho and Cho/Cr in patients with bipolar disorder.

Less is known about the effects of other medications on Cho and Cho/Cr. Bipolar patients taking compared with those not taking chronic anticonvulsants were found to have similar basal ganglia Cho (Hamakawa et al., 1998), and bipolar patients taking compared with those not taking valproate showed similar anterior cingulate Cho/Cr (C. Moore et al., 2000). Bipolar patients taking chronic antipsychotics compared with those not taking them displayed similar basal ganglia Cho (Hamakawa et al., 1998) and Cho/Cr (Kato et al., 1996b) and medial prefrontal Cho (Hamakawa et al., 1999). Also, in the study of Wu and colleagues (2004), bipolar patients taking lithium had similar temporal Cho/Cr compared with those taking valproate.

By contrast, bipolar patients taking antidepressants compared with those not taking them were found to have higher basal ganglia (Kato et al., 1996b) but not medial prefrontal (Hamakawa et al., 1999) Cho/Cr. In MDD patients, basal ganglia Cho/Cr was found to decrease in patients taking nefazodone (Charles et al., 1994a) and in those with fluoxetine "placebo pattern response/nonresponse" (Sonawalla et al., 1999) but to increase in patients with "true fluoxetine response" (Sonawalla et al., 1999). In MDD patients, depression and physical symptoms induced by SSRI (fluoxetine or paroxetine) discontinuation were observed to be associated with decreased rostral anterior cingulate Cho/Cr (but not NAA/Cr) (Kaufman et al., 2003). In MDD patients, ECT was found to increase hippocampal Cho (Ende et al., 2000b), but not to alter anterior cingulate (Pfleiderer et al., 2003) or parietal (Felber et al., 1993) Cho.

There are very few data on baseline Cho or Cho/Cr markers of treatment response. In depressed MDD patients, pretreatment basal ganglia Cho/Cr was found to be lower in fluoxetine responders than in nonresponders (Renshaw et al., 1997), but similar in patients with "true fluoxetine response" and fluoxetine "placebo pattern response/nonresponse" (Sonawalla et al., 1999).

Myoinositol (mI) is a storage form of six carbon carbohydrate inositol, an agent important in signal transduction that may have antidepressant effects (Levine et al., 1995). Inositol depletion has been proposed as a mechanism of action of lithium (Berridge et al., 1989).

Although findings vary, some evidence suggests that mI and mI/Cr may be altered in patients with mood disorders. Thus, mI and mI/Cr in bipolar patients compared with healthy controls showed a tendency to be increased in five studies,¹⁸⁶ decreased in no studies, and similar in five studies.¹⁸⁷ In MDD patients compared with healthy controls, mI and mI/Cr were found to be (or tend to be) increased in no studies, decreased in two studies (Frey et al., 1998; Gruber et al., 2003), and similar in three studies (Auer et al., 2000; Rosenberg et al., 2000; Vythilingam et al., 2003). One study found decreased prefrontal mI/Cr but not mI in MDD patients, perhaps related to increased Cr (Gruber et al., 2003).

Findings regarding mI and mI/Cr in bipolar patients may vary on a regional basis. Thus in bipolar patients compared with healthy controls, mI or mI/Cr was found to be increased in basal ganglia by Sharma and colleagues (1992), to tend to be increased by Winsberg and colleagues (2000) and Cecil and colleagues (2002), or similar to controls in dorsolateral prefrontal regions by Chang and colleagues (2001), and to tend to be increased in anterior cingulate regions by Davanzo and colleagues (2001, 2003). In multiple other studies, however, bipolar patients and controls were found to have similar mI or mI/Cr in anterior cingulate (Moore et al., 2000a), medial prefrontal (Cecil et al., 2002), frontal and temporal (Silverstone et al., 2002), parietal (Brühn et al., 1993), and occipital (Sharma et al., 1992) regions. One study found that bipolar patients had gray and white matter and regional mI similar to that of controls (Dager et al., 2004).

Two studies found that frontal mI/Cr was decreased in depressed MDD patients compared with age- and gender-matched healthy controls (Frey et al., 1998; Gruber et al., 2003). Multiple other studies, however, found that MDD patients and controls had similar mI or mI/Cr in anterior cingulate (Auer et al., 2000), basal ganglia (Rosenberg et al., 2000; Vythilingam et al., 2003), thalamus (Vythilingam et al., 2003), parietal (Auer et al., 2000), and occipital (Rosenberg et al., 2000) regions.

Oral inositol administration may transiently increase cerebral inositol. By 4 days, 12 g/day mI was found to increase occipital gray (but not parietal white) mI/Cr in healthy volunteers by 20 percent. By 8 days, however, this effect was no longer evident (Moore et al., 1999).

Variable relationships have been noted between mI and age in healthy volunteers. One study found that in depressed MDD patients, right frontal mI/Cr was correlated positively with age (Frey et al., 1998). Variable,

but most often negative, gender effects have been reported for mI and mI/Cr. One study found that in healthy controls (but not in depressed MDD patients), frontal mI/Cr tended to be lower in female than in male subjects (Frey et al., 1998). In contrast to NAA/Cr and Cho/Cr, mI/Cr may not vary across the menstrual cycle (Rasgon et al., 2001), while like these other metabolites, medial prefrontal and occipital mI/Cr was found to be similar in women with PMDD and healthy controls (Rasgon et al., 2001).

There are very few data on relationships between the clinical phenomenology of mood disorders and cerebral mI or mI/Cr. In bipolar patients during manic or mixed states, YMRS scores tended to be correlated positively with prefrontal mI (Cecil et al., 2002). In depressed MDD patients, however, HAM-D scores were not found to be related to anterior cingulate or parietal mI (Auer et al., 2000) or anterior cingulate mI/Cr (Moore et al., 2000b).

Emerging data suggest possible medication effects on mI and mI/Cr in bipolar patients. In view of its ability to inhibit inositol monophosphatase and thus deplete inositol, lithium is of particular interest. In depressed adult bipolar-I patients, lithium monotherapy was found to result in about a 30 percent decrease in prefrontal (but not temporal, parietal, or occipital) mI in patients who were generally still depressed at day 5–7; this decrease persisted until weeks 3–4, at which time patients were generally improved (Moore et al., 1999). The authors proposed that the temporal dissociation between mI decreases and clinical improvement suggests that short-term mI depletion per se is not related to lithium's antidepressant effects. In addition, in children and adolescents during manic or mixed episodes, anterior cingulate mI/Cr was found to decrease with acute (1-week trial) adjunctive lithium therapy in responders (but not in nonresponders), but no correlation was found between cerebral mI/Cr and serum lithium concentrations (Davanzo et al., 2001). Thus short-term mI depletion may be related to lithium's antimanic (rather than antidepressant) effects. In contrast, in adult healthy volunteers, lithium administration for 4 weeks failed to alter dorsolateral prefrontal mI (Brambilla et al., 2004). Also, in adult healthy volunteers, acute (1-week trial) lithium monotherapy was found not to alter temporal mI/Cr (or, as described below, phosphomonoesters, which have a limited inositol phosphate component) (Silverstone et al., 1996, 1999). Moreover, in a more sensitive paradigm in which lithium amplified amphetamine-induced phosphomonoester increases, a similar effect was not detected for mI/Cr (Silverstone et al., 1999). The authors suggested that bipolar patients (but not healthy volunteers) having altered phosphoinositol cycle function that is normalized by lithium may explain the differential effects of lithium

on mI/Cr in bipolar patients and healthy volunteers (Silverstone et al., 1999). In contrast, Friedman and colleagues (2004), studying primarily depressed adult bipolar-I and -II patients, found that lithium for a mean of 3.6 months, but not valproate for a mean of 1.4 months, increased gray but not white matter mI.

Compared with healthy controls, euthymic bipolar patients taking chronic lithium showed increased basal ganglia (Sharma et al., 1992), but similar temporal (Silverstone et al., 2002) and occipital (Sharma et al., 1992) mI/Cr and parietal mI (Brühn et al., 1993). No relationship was found between serum lithium concentrations and basal ganglia or occipital mI/Cr (Sharma et al., 1992). Also, bipolar patients taking chronic lithium or valproate compared with healthy controls showed similar anterior cingulate mI/Cr (Moore et al., 2000a). Bipolar patients taking chronic lithium compared with those taking chronic valproate were found to have similar temporal (Silverstone et al., 2002) and anterior cingulate (Moore et al., 2000a) mI/Cr.

If lithium decreases mI or mI/Cr, the presence or absence of chronic lithium could contribute to the variability in mI and mI/Cr findings in bipolar patients compared with healthy controls. In studies conducted to date, the percentage of patients taking lithium was nonsignificantly lower in studies detecting increases in mI and mI/Cr in bipolar patients compared with healthy controls (17/73, 23 percent)¹⁸⁸ than in studies finding no difference (34/100, 34 percent).¹⁸⁹ This nonsignificant difference is consistent with the notion that mI and mI/Cr decreases caused by chronic lithium could be a confounding factor in detecting putative baseline (unmedicated) increases in mI and mI/Cr in patients with bipolar disorder.

There are few data on the potential effects of other medications on mI and mI/Cr. Euthymic bipolar patients taking chronic valproate compared with healthy controls were found to have similar temporal mI and mI/Cr and frontal mI (Silverstone et al., 2002). Depressed bipolar patients taking and not taking antidepressants showed similar anterior cingulate mI/Cr (Moore et al., 2000b) that was also similar to that of healthy controls. Depressed MDD patients taking antidepressants (but not those taking antidepressants) compared with healthy controls, however, displayed decreased frontal mI (Frey et al., 1998).

The MRS *creatine* (Cr or Cr + PCr) peak consists of signals from Cr and PCr. Cr is converted to PCr, which appears to function as an intracellular energy buffer. There are limited data regarding Cr changes in patients with mood disorders. Thus in bipolar patients compared with healthy controls, Cr was found to be increased in one study (Deicken et al., 2001), to be decreased in one study (Deicken et al., 2003a), to tend to be decreased in one study (Sassi

et al., 2005), and to be similar in eight studies.¹⁹⁰ MDD patients and healthy controls have consistently shown similar Cr,¹⁹¹ with the exception of one report of increased prefrontal Cr in MDD patients (Gruber et al., 2003). The latter finding is noteworthy in that it appeared to drive decreased NAA/Cr, Cho/Cr, and mI/Cr in MDD patients, as absolute NAA, Cho, and mI in patients and healthy controls did not differ (Gruber et al., 2003).

Cr findings in bipolar patients may vary on a regional basis. One group found that bipolar patients compared with healthy controls had decreased hippocampal (Deicken et al., 2003a) and increased thalamic (Deicken et al., 2001) Cr. Another group found that dorsolateral prefrontal Cr tended to be decreased in bipolar disorder (Sassi et al., 2005). Other studies, however, found that bipolar patients and healthy controls had similar Cr in dorsolateral prefrontal (Cecil et al., 2002; Michael et al., 2003; Brambilla et al., 2005), anterior cingulate (Davanzo et al., 2003), medial prefrontal (Hamakawa et al., 1999; Cecil et al., 2002), and basal ganglia (Hamakawa et al., 1998). Dager and colleagues (2004) found that bipolar patients had gray and white matter and regional Cr that was similar to that of controls. MDD patients and healthy controls have consistently shown similar Cr in dorsolateral prefrontal (Farchione et al., 2002), anterior cingulate (Auer et al., 2000; Pflieger et al., 2003), hippocampal (Ende et al., 2000a), basal ganglia (Hamakawa et al., 1998; Rosenberg et al., 2000), parietal (Auer et al., 2000), and occipital (Rosenberg et al., 2000).

Cr has shown variable relationships with age. Studies detected no overall age effect (in euthymic and depressed bipolar patients and healthy controls) on medial prefrontal Cr (Hamakawa et al., 1999), no overall age effect (in euthymic bipolar patients) on dorsolateral prefrontal Cr (Sassi et al., 2005), and no overall age effect (in euthymic and depressed bipolar and MDD patients and healthy controls) on basal ganglia Cr (Hamakawa et al., 1998).

Gender effects on Cr have not been extensively reported. Healthy women compared with men were found to have similar Cr in frontal, parietal, occipital, insular (Pouwels and Frahm, 1998), basal ganglia (Charles et al., 1994b), and hippocampal (Ende et al., 2000a). One study (in euthymic and depressed bipolar patients and healthy controls) detected an overall gender effect on right (but not left) medial prefrontal Cr, but the direction of the effect was not specified (Hamakawa et al., 1999). However, another study by the same group (in euthymic and depressed bipolar and MDD patients and healthy controls) found no overall gender effect on left basal ganglia Cr (Hamakawa et al., 1998).

There are limited data on the effect of oral Cr administration on cerebral Cr. In healthy volunteers, Cr 20 g/day for 4 weeks was found to yield increased gray matter,

cerebellum, white matter, thalamus, and overall Cr (as well as decreased cerebellum and thalamus NAA and decreased thalamus Cho). Reversal of these changes was detected on repeat scans at least 3 months after Cr had been discontinued (Dechent et al., 1999b). In healthy volunteers, Cr 8 g/day for 5 days was found to result in attenuation of mathematical calculation task-induced mental fatigue and cerebral oxygenated hemoglobin increases (assessed with near infrared spectroscopy, consistent with increased cerebral oxygen utilization) (Watanabe et al., 2002).

Bipolar-II, bipolar-I, and MDD patients showed similar basal ganglia Cr (Hamakawa et al., 1998). Bipolar-II and bipolar-I patients were found to have similar medial prefrontal Cr (Hamakawa et al., 1999).

Cr did not appear to vary with illness duration in dorsolateral prefrontal (Brambilla et al., 2005; Sassi et al., 2005), medial prefrontal (Hamakawa et al., 1999), or basal ganglia (Hamakawa et al., 1998; Ohara et al., 1998) regions in bipolar patients, or in basal ganglia in MDD patients (Hamakawa et al., 1998).

Cr does not appear to have consistent relationships with mood state. Hamakawa and colleagues (1999) found that depressed compared with euthymic bipolar patients had lower medial prefrontal Cr (Hamakawa et al., 1999). In another study by the same group, however, basal ganglia Cr was found to be similar for both bipolar and MDD patients during depression and euthymia (Hamakawa et al., 1998). No relationship was detected between HAM-D scores and basal ganglia Cr in bipolar and MDD patients (Hamakawa et al., 1998), or anterior cingulate or parietal Cr in MDD patients (Auer et al., 2000). In healthy volunteers, no correlation was found between scores on the PANAS Positive Affect subscale and left frontal Cr (Jung et al., 2002).

There are few data regarding treatment effects on Cr. In depressed bipolar-I patients, lithium monotherapy was found to have antidepressant effects by week 3–4, but not to alter prefrontal, temporal, parietal, or occipital Cr at day 5–7 or week 3–4 (Moore et al., 1999). In primarily depressed adult bipolar-I and -II patients, lithium for a mean of 3.6 months and valproate for a mean of 1.4 months failed to alter gray or white matter or regional Cr (Friedman et al., 2004). Also, lithium, valproate, antidepressant, and benzodiazepine therapy was not found to be related to medial prefrontal Cr in bipolar patients (Hamakawa et al., 1999). Bipolar patients taking compared with those not taking antipsychotics showed increased basal ganglia (Hamakawa et al., 1998) but not medial prefrontal (Hamakawa et al., 1999) Cr. MDD patients taking compared with those not taking benzodiazepines displayed increased basal ganglia Cr (Hamakawa et al., 1998). In MDD

patients, ECT was found to modestly increase hippocampal Cr (Ende et al., 2000b), but not to alter anterior cingulate (Pfleiderer et al., 2003) or parietal (Felber et al., 1993) Cr.

Investigators commonly assume that regional Cr is stable enough within individuals and across diagnoses to be used as an internal standard, and thus report other metabolites normalized to Cr.¹⁹² Such a strategy is potentially useful because it increases statistical power by decreasing variability, but it runs the risk of yielding spurious results if Cr varies with time, environmental factors, or diagnosis. As noted above, in healthy volunteers, for example, chronic (4-week) administration of Cr monohydrate 20 g/day was found to increase paramedian parietal gray matter, parieto-occipital white matter, central cerebellum, and thalamus Cr concentrations (Dechent et al., 1999b). In this study, average (across four regions) Cr (but not NAA, Cho, or mI) increased by 8.7 percent, varying between 4.7 percent and 14.6 percent across regions. NAA (but not NAA/Cho and NAA/mI ratios) showed a decrease in cerebellum and thalamus, and Cho (but not Cho/mI ratios) a decrease in thalamus. Hence the confounding influence of referencing metabolites to Cr could be circumvented to some degree by also inspecting results referenced to other metabolites (Mervaala et al., 2000; Steingard et al., 2000; Winsberg et al., 2000).

Some investigators prefer to report metabolite concentrations in absolute units¹⁹³; to report either absolute or normalized concentrations, depending on the study (Kato et al., 1996a; Hamakawa et al., 1998, 1999); or to report both absolute and normalized concentrations.¹⁹⁴ In one such study, it appeared that increased Cr in MDD patients compared with controls drove a finding of decreased NAA/Cr, Cho/Cr, and mI/Cr in MDD, as absolute NAA, Cho, and mI in patients and healthy controls did not differ (Gruber et al., 2003).

Recent advances have allowed MRS assessment of brain GABA and glutamate, which are the main cerebral inhibitory and excitatory amino acid neurotransmitters, respectively. The ability to measure these substances in the brain is of considerable interest because plasma GABA appears to be decreased in bipolar disorder, whereas higher (nearer to normal) levels may predict antimanic (Petty et al., 1996) and possibly even antidepressant (Ketter et al., 2000) responses to the GABAergic agent valproate. Moreover, several new anticonvulsants with GABAergic and/or antiglutamatergic mechanisms appear to have potential roles in the treatment of various symptoms of bipolar disorder (Ketter and Wang, 2003; Ketter et al., 2003)

Emerging data suggest differential cerebral *gamma-aminobutyric acid* changes in depressed MDD and depressed bipolar patients. Thus depressed MDD patients compared with healthy controls were found to have

52 percent lower occipital GABA, but severity of depression (as measured by the HAM-D) showed no correlation with cerebral GABA (Sanacora et al., 1999). Preliminary data from an extension of this work indicate that depressed MDD patients compared with healthy controls and depressed bipolar patients had occipital GABA decreases of 27 percent and 23 percent, respectively, with depressed bipolar patients compared with healthy controls having only a nonsignificant (5 percent) decrease in occipital GABA (Mason et al., 2000). In contrast, euthymic bipolar patients taking GABAergic agents (valproate \pm gabapentin) may have occipital and medial prefrontal GABA levels about 50 percent higher than those of healthy controls (Wang et al., 2002).

Gender effects on GABA and GABA/Cr have not been extensively reported. Healthy women and men showed similar orbitofrontal, cingulate, insula, and thalamus GABA/Cr (Grachev and Apkarian, 2000, 2001). Women compared with men, however, showed decreased dorsolateral prefrontal GABA/Cr in young adulthood (ages 19–31) (Grachev and Apkarian, 2000), but not over a more extensive age range (ages 19–52) (Grachev and Apkarian, 2001). In another study involving both depressed MDD patients and healthy controls, women compared with men were found to have increased occipital GABA (Sanacora et al., 1999).

GABA appears to vary across the menstrual cycle. Thus, occipital GABA from follicular to luteal phase was found to decrease by 32 percent in healthy controls, but to increase by 63 percent in women with PMDD (Epperson et al., 2002). Also, PMDD patients compared with healthy controls showed lower follicular phase GABA (Epperson et al., 2002). Occipital GABA was found to be correlated with plasma estradiol and progesterone concentrations negatively in healthy women and positively in those with PMDD (Epperson et al., 2002). Occipital GABA also showed a correlation with plasma allopregnanolone concentrations negatively in healthy women, but not in those with PMDD (Epperson et al., 2002).

In depressed MDD patients, treatment with fluoxetine or citalopram \pm yohimbine was found to yield clinical improvement and a 34 percent increase in occipital GABA (Sanacora et al., 2002). Changes in occipital GABA were not correlated with improvement in depression, however. Although no correlation was detected between baseline occipital GABA and clinical improvement, subjects with the lowest and highest baseline occipital GABA showed robust increases or no change in occipital GABA, respectively. In depressed patients, treatment with ECT was found to yield clinical improvement and a 78 percent increase in occipital GABA (Sanacora et al., 2003). No correlation was found, however, between changes in occipital GABA and antidepressant or adverse (memory impairment) effects.

Thus depressed MDD patients may have low baseline cerebral GABA that normalizes with effective SSRI or ECT treatment, while depressed bipolar patients may have near-normal baseline cerebral GABA that rises to supranormal levels with effective treatment with GABAergic agents. It remains to be established whether depressed bipolar patients who obtain antidepressant responses with valproate can be differentiated from those who do not obtain such responses with respect to baseline cerebral levels of the inhibitory neurotransmitter GABA. If so, this or other applications of MRS technology may ultimately have utility in addressing questions about heterogeneity related to diagnosis (such as bipolar disorder versus MDD) and in predicting antidepressant responses to different treatments (such as valproate or SSRIs).

Interpretation of the significance of MRS-assessed cerebral *glutamate* compared with GABA assessments is more complex, as glutamate exists in both metabolic and neurotransmitter pools. In addition, the glutamine and glutamate peaks are overlapping, so that some studies report glutamine/glutamate (Glx) concentrations.

Glx and Glx/Cr in bipolar patients compared with healthy controls have been found to be increased in four studies¹⁹⁵ and similar in one (Davanzo et al., 2001). In MDD patients, they have been found to be decreased in two studies (Auer et al., 2000; Pfeleiderer et al., 2003) and increased in one (Rosenberg et al., 2000).

Glx and Glx/Cr findings in patients with mood disorders may vary on a regional basis. Thus in bipolar patients compared with healthy controls, Glx or Glx/Cr was found to be increased in prefrontal (Castillo et al., 2000; Cecil et al., 2002), dorsolateral prefrontal (Michael et al., 2003), and basal ganglia (Castillo et al., 2000) regions, but similar in anterior cingulate (Davanzo et al., 2001) and medial prefrontal (Cecil et al., 2002) regions. One study found that Glx was increased in left insula and tended to be increased in left cingulate (but not in other regions) in bipolar patients compared with controls (Dager et al., 2004). In the latter study, gray (but not white) matter Glx and lactate were increased in bipolar patients compared with controls, consistent with a shift in energy redox state from oxidative phosphorylation toward glycolysis, perhaps reflecting mitochondrial alterations. This study also found that gray and white matter Glx was increased in bipolar-I but not bipolar-II patients. In MDD patients compared with healthy controls, Glx or Glx/Cr was noted to be increased in caudate (Rosenberg et al., 2000), decreased in anterior cingulate (Auer et al., 2000; Pfeleiderer et al., 2003), and similar in parietal (Auer et al., 2000) and occipital (Rosenberg et al., 2000) regions.

There are limited data relating Glx or Glx/Cr to clinical parameters. In depressed MDD patients, no relationship

was detected between age and anterior cingulate Glx (Pfleiderer et al., 2003). Degree of depression (as measured by the HAM-D) showed no relationship to anterior cingulate or parietal Glx (Auer et al., 2000).

There are also few data relating Glx or Glx/Cr to clinical interventions. In bipolar patients, anterior cingulate Glx/Cr showed no change with acute (1-week) lithium administration and no relationship to plasma lithium concentrations (Davanzo et al., 2001). In primarily depressed adult bipolar-I and -II patients, however, longer-duration lithium (for a mean of 3.6 months) but not valproate (for a mean of 1.4 months) decreased gray but not white matter Glx, suggesting that lithium may attenuate gray matter increases observed by the same investigators in primarily depressed bipolar patients at baseline (Friedman et al., 2004). However, Cecil and colleagues (2002) found an inverse correlation between duration of valproate therapy and prefrontal Glx. In depressed MDD patients, ECT was found to increase anterior cingulate Glx in responders, but not in nonresponders (Pfleiderer et al., 2003).

Euthymic bipolar patients compared with healthy controls showed increased parietal glutamate/Cr (Glu/Cr) (Brühn et al., 1993). On the other hand, depressed MDD patients compared with healthy controls had similar parietal but decreased anterior cingulate Glu (Auer et al., 2000). In the latter study, no relationship was noted between regional Glu and degree of depression (as measured by the HAM-D).

In summary, ¹H-MRS studies suggest that patients with mood disorders compared with healthy controls may have metabolite changes in elements of anterior cortical/anterior paralimbic basal ganglia–thalamocortical circuits more than in parietal and occipital regions. Findings may differ to varying degrees with the metabolite considered, region, age, gender, phase of menstrual cycle, diagnosis, illness duration, mood state, and treatment.

Thus about half of the studies of bipolar (but not MDD) patients compared with healthy controls detected NAA or NAA/Cr decreases more than increases, in dorsolateral prefrontal and temporal more than other regions. Lithium may increase NAA or NAA/Cr, confounding efforts to detect putative baseline (unmedicated) NAA and NAA/Cr decreases in bipolar patients.

In about one-fourth of bipolar disorder and one-half of MDD studies, Cho or Cho/Cr tended to be increased compared with that in healthy controls, most often in basal ganglia. In a small number of studies, mI or mI/Cr tended to be increased, compared with that in healthy controls, in about one-half of bipolar and decreased in about one-half of MDD studies. Lithium may decrease mI and mI/Cr in bipolar patients but not in healthy controls, confounding

efforts to detect putative baseline (unmedicated) mI and mI/Cr increases in bipolar patients.

Most of the few Cr studies conducted to date have failed to detect differences between patients with mood disorders and healthy controls, and lithium may not alter Cr in bipolar patients. These negative findings address in a limited fashion concerns that the common method of referencing metabolites to Cr may confound ¹H-MRS studies comparing mood disorder patients with healthy controls.

Baseline (unmedicated) occipital GABA may be decreased in depressed MDD but not depressed bipolar patients compared with healthy controls, and increased with SSRIs, ECT, or GABAergic anticonvulsants. Emerging methodology may permit GABA and glutamate assessments in regions with greater relevance to mood disorders, such as anterior cingulate/medial prefrontal cortex.

Phosphorous (³¹P) Magnetic Resonance Spectroscopy

Phosphorous-31 magnetic resonance spectroscopy (³¹P-MRS) permits determination of cerebral phospholipids, including phosphomonoesters (PMEs), phosphodiesteres (PDEs), inorganic phosphate, high-energy phosphates, and related compounds such as PCr, as well as intracellular pH. PME's consist of phosphoethanolamine, phosphocholine, phosphoserine, and sugar phosphates such as inositol-1-monophosphate, while PDEs consist of glycerophosphocholine, glycerophosphoethanolamine, and mobile phospholipids. PME's and PDEs include cell membrane precursors and degradation products, respectively, and are of interest in view of relationships to intracellular signaling and membrane phospholipid changes proposed in bipolar disorder. PME's may to a limited extent reflect inositol-1-monophosphate concentrations, which account for about 10 percent of the PME signal (Gyulai et al., 1984), but use of PME's to indicate inositol monophosphate has been criticized (Agam and Shimon, 2000).

Decreased prefrontal phosphomonoesters have been observed in euthymic bipolar patients in clinical research. Studies have most consistently detected PME changes in bipolar-I patients. Thus, euthymic bipolar-I patients appear to have decreased prefrontal PME's consistent with abnormal membrane phospholipid metabolism, which in turn may reflect changes in signal transduction putatively related to the pathophysiology of bipolar disorder (Manji and Lenox, 2000). Kato and colleagues reported on a series of ³¹P-MRS studies in primarily medicated bipolar patients. In these studies, prefrontal PME's in euthymic bipolar-I patients compared with healthy controls were found to be significantly decreased in four studies (Kato et al., 1992b, 1993a, 1994a,b) and nonsignificantly decreased in a fifth study (Kato et al., 1991). No correlation was detected between

PMEs and brain lithium concentrations (Kato et al., 1993a). In addition, Deicken and colleagues found that euthymic medication-free bipolar-I patients had decreased PMEs compared with controls in bilateral prefrontal (Deicken et al., 1995a) and temporal (Deicken et al., 1995b) regions. Prefrontal PMEs in euthymic bipolar-I patients were also found to be significantly decreased compared with depressed bipolar-I patients (Kato et al., 1992a, 1994b), manic bipolar-I patients (Kato et al., 1991, 1993b), and euthymic MDD patients (Kato et al., 1992a). Prefrontal PMEs in manic bipolar-I patients compared with healthy controls were found to be significantly increased in one study (Kato et al., 1991) and nonsignificantly increased in another (Kato et al., 1993a). Depressed bipolar-I and depressed MDD patients showed similar prefrontal PMEs (Kato et al., 1992b).

Studies in bipolar-II patients or mixed samples of bipolar-I and -II patients have detected PME changes less consistently. Thus, euthymic bipolar-II patients were found to have prefrontal PMEs that did not differ significantly from those of healthy controls (Kato et al., 1994b,c) or across mood states (Kato et al., 1994c). Depressed and hypomanic bipolar-II patients compared with healthy controls, by contrast, showed increased prefrontal PMEs (Kato et al., 1994c). In studies of combined groups of primarily medicated bipolar-I and -II patients, prefrontal PMEs in euthymic bipolar patients compared with healthy controls were found to be nonsignificantly decreased in one study (Kato et al., 1994b) and nonsignificantly increased in another (Kato et al., 1995a), compared with depressed bipolar patients were found to be nonsignificantly decreased (Kato et al., 1995a), and compared with manic bipolar patients were found to be nonsignificantly increased (Kato et al., 1995b). Medication-free euthymic bipolar patients compared with healthy controls showed nonsignificantly increased PMEs (Kato et al., 1998). Similar occipital PMEs were detected in euthymic bipolar patients and healthy controls (Murashita et al., 2000). One study found that prefrontal PMEs in depressed bipolar patients were (significantly on the left and nonsignificantly on the right) increased compared with those of healthy controls and nonsignificantly increased compared with those of manic bipolar patients, and in manic patients were not significantly different from those of healthy controls (Kato et al., 1995a). Also, euthymic bipolar patients taking chronic lithium or valproate showed similar left temporal PMEs compared with healthy controls (Silverstone et al., 2002).

Prefrontal PMEs were found to decrease with age in euthymic bipolar patients but not in healthy controls, consistent with an illness progression effect, but the decrease was not clearly related to onset or duration of illness, psychosis, duration of lithium therapy, or LVE (Kato et al., 1994b).

Considering studies including both bipolar-I and -II patients, Yildiz and colleagues (2001b) reported on meta-analysis of eight ^{31}P -MRS studies involving 139 bipolar patients and 189 controls¹⁹⁶ that confirmed the finding of decreased prefrontal PMEs in euthymic bipolar patients. Thus across six studies, a total of 100 euthymic bipolar patients compared with 130 controls showed lower prefrontal¹⁹⁷ or temporal (Deicken et al., 1995a) PMEs ($p = .014$). Likewise, across three studies, a total of 39 euthymic bipolar patients compared with 34 depressed bipolar patients had lower prefrontal PMEs ($p = .0005$) (Kato et al., 1992a, 1994a, 1995b). In other PME comparisons, no significant differences were detected between manic and euthymic bipolar patients (Kato et al., 1991, 1993b, 1995b),¹⁹⁸ between depressed bipolar patients and controls, or between manic bipolar patients and controls. Yildiz and colleagues (2001b) thus concluded that the data suggest trait-dependent PME changes in bipolar disorder, but that there have been too few studies to permit a definitive assessment of state-dependent alterations. Of interest, prefrontal PME decreases have consistently been reported in schizophrenic patients (Pettegrew et al., 1991; Kato et al., 1995b).

There have been a few studies of PMEs in MDD patients, with varying results. Depressed MDD patients were found to have basal ganglia (Moore et al., 1997) and prefrontal (Kato et al., 1992b) PMEs similar to those of healthy controls, with the latter study also not detecting differences in euthymic MDD patients compared with depressed MDD patients or with healthy controls. In contrast, another study found that depressed MDD patients had increased prefrontal PMEs compared with those of healthy controls, but that PMEs were correlated inversely with degree of depression (Volz et al., 1998).

Because lithium inhibits inositol monophosphatase (Hallcher and Sherman, 1980), investigators have assessed its effects on PMEs, which have a limited (about 10 percent) inositol phosphate component (Gyulai et al., 1984). If lithium proved to increase PMEs, this could be related to its inhibiting the conversion of inositol-1-phosphate to inositol. Technical limitations and potential differences between the effects of lithium in patients and healthy controls may have contributed to the varied findings on this issue. In schizophrenic patients, acute lithium was found to have no overall effect on PMEs, but to tend to result in complementary biphasic longitudinal changes in the first 2 weeks of therapy in both responders and nonresponders (Keshavan et al., 1992). In six manic bipolar patients, however, lithium failed to alter prefrontal PMEs significantly (Kato et al., 1993a). In healthy volunteers, lithium administration for 1 week failed to alter left temporal PMEs significantly (Silverstone et al., 1996, 1999), but in a more sensitive paradigm, the drug was

found to amplify amphetamine-induced PME increases (Silverstone et al., 1999). Also in healthy volunteers, a study with enhanced sensitivity derived from using proton decoupling and a large (620 cc) voxel centered on the superior corpus callosum detected increased PMEs after 7 and 14 days of lithium (Yildiz et al., 2001a). Euthymic bipolar patients taking chronic lithium compared with those taking chronic valproate showed similar temporal PMEs (Silverstone et al., 2002).

Findings for *phosphodiesterases* (PDEs), in contrast to those for PMEs, are variable in bipolar patients. Thus euthymic bipolar-I patients compared with healthy controls showed similar prefrontal (Kato et al., 1992b, 1993b) and bilateral temporal PDEs (Deicken et al., 1995b) but increased bilateral prefrontal (Deicken et al., 1995a) PDEs. In a combined sample of medication-free euthymic bipolar-I and -II patients, prefrontal PDEs were found to be correlated with SCHs, but patients and healthy controls showed similar PDEs (Kato et al., 1998). One study found occipital PDEs in euthymic bipolar patients and healthy controls to be similar (Murashita et al., 2000). In a meta-analysis of four studies, Yildiz and colleagues (2001b) found that a total of 51 euthymic bipolar patients compared with 57 controls had statistically similar prefrontal (Kato et al., 1992b, 1993b; Deicken, et al., 1995b) and temporal (Deicken et al., 1995a) PDEs ($p = .597$). Other PDE comparisons across mood states and diagnoses were also negative.

Inorganic phosphate (Pi) contains PO^- and PO_4^{2-} and is seen in multiple metabolic pathways. There is little evidence of Pi changes in bipolar disorder, however. Thus medication-free euthymic bipolar-I patients and healthy controls were found to have similar bilateral prefrontal (Deicken et al., 1995a) and temporal (Deicken et al., 1995b) Pi. Also, prefrontal Pi was found to be similar to that of healthy controls in bipolar-I patients, independent of mood state (Kato et al., 1992b, 1993b), and in a combined sample of medication-free euthymic bipolar-I and -II patients (Kato et al., 1998). Likewise, similar occipital Pi was detected in euthymic bipolar patients and healthy controls (Murashita et al., 2000).

There is also little evidence of changes in *high-energy phosphates* in bipolar disorder. Thus prefrontal high-energy phosphates were found to be similar in bipolar-I patients and healthy controls, independent of mood state (Kato et al., 1992b, 1993a), and beta-adenosine triphosphate (beta-ATP) was found to be similar to that of healthy controls in medication-free euthymic bipolar-I patients in bilateral prefrontal (Deicken et al., 1995a) and temporal (Deicken et al., 1995b) regions. Also, a combined sample of medication-free euthymic bipolar-I and -II patients showed prefrontal beta-ATP similar to that of healthy controls (Kato et al., 1998). In contrast, depressed MDD patients compared with healthy

controls showed decreased beta-ATP and total nucleotide triphosphates in basal ganglia (Moore et al., 1997) and bilateral prefrontal regions (Volz et al., 1998). Of interest, decreased left basal ganglia beta-ATP has also been reported in schizophrenic patients (Deicken et al., 1995a).

Phosphocreatine is considered a high-energy phosphate buffer. Early work demonstrated decreased prefrontal PCr in bipolar-II patients (independent of mood state) compared with healthy controls (Kato et al., 1994c), but failed to detect such differences in bipolar-I patients (Kato et al., 1992b, 1993b) (aside from a decrease in severe compared with mild depression [Kato et al., 1992a]) and MDD patients (independent of mood state) (Kato et al., 1992a). The investigators suggested that decreased prefrontal PCr in bipolar-II patients may be related to decreased Cr or Cr phosphokinase activity, increased intracellular magnesium, or mitochondrial dysfunction (Kato et al., 1994c). Simultaneous consideration of prefrontal PCr and PMEs appears to allow for some discrimination between euthymic bipolar-II (low PCr) and bipolar-I (low PMEs) patients (see Fig. 15–12) (Kato et al., 1994c).

Later work revealed decreased left prefrontal PCr in depressed bipolar-I patients (correlated with degree of depression) and right prefrontal PCr in manic and euthymic bipolar-I patients (Kato et al., 1995a). Euthymic medication-free bipolar-I patients and healthy controls showed similar bilateral prefrontal and temporal lobe PCr (Deicken et al., 1995a,b). A combined sample of medication-free euthymic bipolar-I and -II patients also displayed prefrontal PCr similar to that of healthy controls (Kato et al., 1998). Euthymic medicated bipolar-I patients were found to have resting and post-photic stimulation occipital PCr similar to that of healthy controls, while lithium-resistant (but not lithium-responsive) patients showed decreased PCr for 12 minutes after photic stimulation (Murashita et al., 2000). The investigators suggested that this observation is consistent with mitochondrial dysfunction in lithium-resistant bipolar-I patients.

Some *intracellular pH* differences have been detected in bipolar disorder, perhaps reflecting altered sodium–hydrogen ion transport. Thus prefrontal intracellular pH was found to be decreased in euthymic bipolar-I patients compared with depressed (Kato et al., 1992b) and manic (Kato et al., 1993b) bipolar-I patients and healthy controls (Kato et al., 1992b, 1993b). Prefrontal intracellular pH was also found to be decreased in combined samples of euthymic bipolar-I and -II patients compared with healthy controls (Kato et al., 1994b, 1998); correlated positively with duration of lithium therapy, but not with age, illness onset, or illness duration (Kato et al., 1994b); and related to SCHs (Kato et al., 1998). On the other hand, intracellular pH was observed to be similar to that of healthy controls in

Figure 15-12. Low prefrontal phosphocreatine in euthymic bipolar-II (BP-II) patients and low phosphomonoesters in euthymic bipolar-I (BP-I) patients. Prefrontal phosphocreatine levels are shown on the vertical axis, and phosphomonoester levels on the horizontal axis. Euthymic bipolar-I patients (squares) have significantly lower phosphomonoesters and nonsignificantly higher phosphocreatine compared with euthymic bipolar-II patients (circles). These relationships allow correct classification of 18/21 patients as bipolar-I (above the diagonal line) and bipolar-II (below the broken line). HC=healthy controls. ^a $p < .05$ versus BP-I, healthy controls; ^b $p < .01$ versus BP-II, healthy controls. (Source: Reproduced with permission from Kato et al., 1994b.)

medication-free euthymic bipolar-I patients in bilateral prefrontal (Deicken et al., 1995a) and temporal (Deicken et al., 1995b) regions, in bipolar-II patients independent of mood state in prefrontal regions (Kato et al., 1994b), and in a combined sample of euthymic bipolar-I and -II patients in the occipital lobe (Murashita et al., 2000).

In summary, ³¹P-MRS studies suggest that euthymic bipolar-I patients have decreased prefrontal PME consistent with abnormal membrane phospholipid metabolism, which in turn could reflect altered signal transduction. Prefrontal PMEs in euthymic bipolar-I patients are also significantly decreased compared with those in depressed bipolar-I, manic bipolar-I, and euthymic MDD patients. Studies in bipolar-II patients and in mixed samples of bipolar-I and -II patients have detected PME changes less consistently. Nevertheless, meta-analyses of studies including both bipolar-I and -II patients confirm decreased prefrontal PMEs in euthymic bipolar patients compared with healthy controls and depressed bipolar patients. In contrast, data on PMEs in MDD patients are sparse and variable. Some data suggest that lithium may increase PMEs, but other findings fail to support this hypothesis, perhaps because of methodological and sampling differences. PDEs, in contrast to PMEs, do not appear to be systematically altered in bipolar patients. There is some evidence of pH

and PCr differences, but little evidence of Pi or high-energy phosphate changes in bipolar patients.

Lithium Magnetic Resonance Spectroscopy

Brain lithium concentrations determined by lithium-MRS are about half those seen in serum and tend to be correlated with serum lithium concentrations.¹⁹⁹ Brain/serum lithium ratios may be lower in children and adolescents than adults, suggesting that younger patients may require higher serum lithium levels than adults to achieve similar brain lithium concentrations (Moore et al., 2002). Brain (prefrontal) lithium may correlate better with serum than with red blood cell lithium levels (Kato et al., 1993). When serum lithium concentrations are restricted to therapeutic range, however, brain lithium levels can vary markedly and may be correlated only modestly with serum lithium (Sachs et al., 1995). Patients taking alternate-day compared with daily lithium therapy with similar mean 12-hour trough serum lithium levels were found to have similar brain lithium concentrations (Jensen et al., 1996). Patients taking lithium in a single bedtime dose compared with twice daily also showed similar brain lithium concentrations, but increased brain/serum lithium ratios (Soares et al., 2001). MDD and schizophrenic patients taking short-term (4–8 weeks) and long-term (over 6 months) lithium therapy

Figure 15-13. Correlation between cerebral lithium concentrations and antimanic responses. Change in Petterson Mania Rating Scale (PMRS) scores are shown on the vertical axis and brain lithium levels on the horizontal axis. The correlation coefficient is .64 ($p < .05$). The regression is shown as a dotted line. (Source: Reproduced with permission from Kato et al., 1994c.)

may have similar whole-brain/serum lithium ratios, but whole-brain lithium may be better correlated with serum lithium in long-term than in short-term treatment (Riedel et al., 1997). Relationships between mood and brain lithium concentrations remain to be established, as brain lithium has been reported to be higher when patients are both manic (Kato et al., 1992) and euthymic (Sachs et al., 1995).

Brain lithium concentrations may need to be at least .2 millimoles per liter (mmol/l) for adequate therapeutic effects (Gyulai et al., 1991; Kato et al., 1994a). Hand tremor may be related more closely to brain than to serum lithium levels (Kato et al., 1996b), as subtherapeutic prefrontal lithium levels (less than .2 mmol/l) were observed in 25 percent of patients without and only 7 percent of patients with hand tremor. Thus in patients with inadequate responses and no hand tremor, an increase in lithium dosage should be considered because of the possibility of subtherapeutic cerebral lithium levels, even if serum lithium levels appear to be within the therapeutic range.

Antimanic responses may correlate with brain (prefrontal) lithium level (Fig. 15-13) and brain/serum lithium ratio, but not serum lithium level or lithium dose/weight (Kato et al., 1994a). This observation raises the possibility that some patients may be resistant to lithium because of insufficient central nervous system lithium entry or retention, despite having therapeutic serum lithium levels.

In summary, lithium-MRS studies indicate that cerebral lithium concentrations are about half those seen in serum, tend to be correlated with serum lithium concentrations, and may be related to lithium's therapeutic and adverse effects. In

contrast, there are relatively few data regarding relationships between mood state and cerebral lithium concentrations.

CONCLUSIONS

Structural Neuroimaging

To date, structural neuroimaging cannot be used to diagnose bipolar disorder or MDD. For example, despite there being mean differences in structural parameters between groups of mood disorder patients and groups of healthy controls, the ranges overlap so that the groups are not discretely separated. Moreover, the abnormalities seen in groups of mood disorder patients compared with groups of healthy controls are nonspecific, as they can occur in other psychiatric disorders, such as schizophrenia. For example, compared with healthy controls, both schizophrenic and bipolar patients had frontal, temporoparietal, and corpus callosum white matter volume decreases, while volumes in these areas were statistically similar in the two patient groups (McDonald et al., 2005). However, the deficits in schizophrenia may be more severe and widespread than those seen in bipolar disorder. Thus, schizophrenic patients had anterior paralimbic thalamocortical (amygdala, hippocampus, insula, caudate, thalamus, lateral prefrontal and temporal cortex) gray matter volume decreases compared with both bipolar patients and healthy controls, whereas the latter two groups had statistically similar volumes in these regions (McDonald et al., 2005). This pattern of findings was also evident in first-degree relatives of patients with schizophrenia and bipolar disorder (McDonald et al., 2004). In a similar fashion, another group found that, compared with healthy controls, anterior thalamic gray matter density was decreased in both schizophrenic and bipolar patients and their relatives, with schizophrenia but not bipolar disorder also being associated with decreased middle prefrontal gyrus and dorsomedial thalamus gray matter density (McIntosh et al., 2004). Moreover, this group found that, compared with healthy controls, anterior limb of internal capsule white matter density was decreased in both schizophrenic and bipolar patients, with schizophrenia but not bipolar disorder also being associated with decreased corpus callosum and frontal subgyral white matter density (McIntosh et al., 2005).

Structural neuroimaging can be used to diagnose general medical conditions associated with secondary mood disorders. Primary (bipolar disorder and MDD) and secondary (due to substance abuse or general medical conditions) mood disorders may represent extremes of a continuum, bracketing intermediate mood syndromes with varying ratios of primary to secondary components. For example, it has been suggested that SCHs may contribute to the

development of depression in at least some patients (Alexopoulos et al., 1997; Krishnan et al., 1997; Steffens and Krishnan, 1998). Thus, these structural brain changes suggestive of mild cerebrovascular insufficiency not severe enough to merit a diagnosis of depression secondary to stroke may contribute to mood symptoms, treatment resistance, and poor prognosis in late-life or late-onset depression.

Further along the continuum, frank vascular lesions in basal ganglia–thalamocortical circuits may lead to secondary mood disorders. Thus, vascular subtypes of mania and depression have been proposed, with criteria including clinical and/or neuroimaging evidence of cerebrovascular disease (history of stroke, transient ischemic attacks, focal neurological signs, SCHs) or neuropsychological impairment (decreased cognitive processing quality or speed) (Steffens and Krishnan, 1998). Proposed supporting features include onset of or change in affective symptoms after age 50, marked anhedonia, psychomotor retardation, marked impairment in basic activities of daily living, and lack of family history of mood disorders.

Methodological advances—including new methods of image acquisition, such as DTI, and new image processing techniques, such as the ability to segment images into gray and white matter—promise to advance structural neuroimaging studies. Limited statistical power related to clinical heterogeneity and small sample sizes in individual studies needs to be addressed, however. This problem is particularly salient with respect to understanding the clinical correlates of structural imaging abnormalities in mood disorder patients. Large collaborative studies and/or standardized designs that facilitate meta-analyses may help surmount this problem.

Functional Neuroimaging

Taken together, the functional neuroimaging literature reviewed above suggests that elements of anterior cortical/anterior paralimbic basal ganglia–thalamocortical circuits may contribute importantly to affective processing in health, and can have altered function in bipolar and MDD patients (see Box 15–2).

The cerebral activity studies reviewed here have important limitations, including small sample sizes, varying methodology, and reliance on measures of patterns of activity across cerebral structures rather than assessment of specific neurochemical differences. Their findings need to be combined with emerging data from studies of specific cerebral neurochemistry using specific neurochemical radiotracers (reviewed in Chapter 14) and MRS (described above) to yield more comprehensive understanding of the nature of the neurobiology of mood disorders.

Methodological advances in MRS studies are beginning to allow in vivo assessment of specific cerebral

BOX 15–2. Functional Neuroimaging Findings in Depressed Bipolar and Major Depressive Disorder Patients Compared with Healthy Controls

- Decreased global cerebral activity (in older, more depressed patients)
- Decreased dorsolateral prefrontal activity
- Decreased temporal cortical activity
- Decreased basal ganglia activity (in MDD)
- Variable anterior cingulate and medial prefrontal activity
- Increased amygdala activity
- Decreased prefrontal phosphomonoesters (in *euthymic* bipolar patients versus healthy controls and depressed bipolar patients)^a

^aConfirmed with meta-analysis.

neurochemistry that is less invasive (no ionizing radiation) and more generally available (no need for an on-site cyclotron, radiochemistry team, or PET scanner) than PET techniques using specific neurochemical radiotracers. MRS studies are limited, however, by relatively poor spatial resolution, and by the ability to assess only a small and in some cases inadequately characterized group of metabolites.

Studies of specific cerebral neurochemistry share important limitations with those of cerebral activity, such as small sample sizes and varying methodology. Technical advances, including new methods of image acquisition (such as MRS sequences to detect GABA and glutamate with enhanced spatial and temporal resolution), promise to advance functional neuroimaging studies. As with structural neuroimaging studies, however, limited statistical power related to clinical heterogeneity and small sample sizes in individual studies remains problematic. Also as with structural neuroimaging studies, large collaborative studies and/or standardized designs that facilitate meta-analyses may help address these difficulties.

Future Directions

Despite providing substantial contributions to our understanding of which cerebral structures mediate affective processing in health and mood disorders, neuroimaging has not yet realized its potential to be a clinically relevant tool in the diagnosis and treatment of major mood disorders. Technological innovations to enhance spatial and temporal resolution, decrease or eliminate exposure to ionizing radiation, increase neurochemical specificity, increase availability, and decrease expense are needed if research is to further advance our knowledge of the neuroanatomical and neurochemical substrates of these disorders. As these technological innovations unfold, it becomes even more

important that we put considerably more effort into improved methods for diagnosis and clinical evaluation, including an agreed-upon standard for distinguishing the more recurrent forms of MDD that fall within Kraepelin's concept of manic-depressive illness. More careful differentiation between state and trait is also needed, as are consensus protocols for assessing the multiple sources of variance in these measures. Given the great promise and expense of these technologies, we can afford to do no less. While it remains to be seen whether such advances will ultimately yield clinical applications to facilitate diagnosis and target treatments more effectively in patients with mood disorders, it is clear that this potential will not be realized unless we invest more effort in standardizing the clinical characterization of the patients we study.

NOTES

Sleep and Circadian Rhythms

For our body is like a clock; if one wheel be amiss, all the rest are disordered, the whole fabric suffers: with such admirable art and harmony is a man composed.

—Robert Burton, *The Anatomy of Melancholy* (1621, p. 171)

As surely as the sun rises in the morning and bears hibernate in the winter, human functioning heeds its own innate rhythms. Body temperature rises and falls in oscillations, as do hormone secretions, cell division, heart rate, urine flow, allergic reactions, motoric activity, even mathematical finesse—and, most obvious of all, the need for sleep. Mood also fluctuates, waxing and waning, although the regularity of mood cycles is not synchronized with the clock as precisely as is the case with other biological rhythms. Indeed, abnormalities of biological rhythms have been proposed to represent endophenotypes or markers of manic-depressive illness (perhaps particularly the bipolar subgroup), presumably being present not only in patients but also in some relatives without manifest mood disorder. Sleep disruption is closely associated with recurrent affective illness. Sleep loss is a major symptom as well as a trigger of manic episodes, and when applied clinically (sleep deprivation) is one of the most effective antidepressant interventions¹—certainly the fastest acting. In addition to the diurnal, or circadian, rhythms associated with sleep, the observation that the seasons of the year influence the expression of mood disorders is as old as the classical descriptions of manic-depressive illness itself.

In this chapter we review the literature on circadian rhythms, sleep disturbances, and their relationship to affective illness. We also review the less extensive body of work on the relationship between seasonal rhythms and mood disorders. We begin by reviewing the physiology of circadian rhythms and of sleep. Next we look at the relationship between sleep and affective disorders, and that between disturbances of circadian rhythms and manic-depressive illness. We then examine the literature on experimental alterations of sleep and other biological rhythms as treatments for affective illness. Finally, we review what is

known about the relationship between seasonal rhythms and affective disorders.

PHYSIOLOGY OF CIRCADIAN RHYTHMS

As the earth rotates through its 24-hour cycle, a world of light alternates with a world of darkness. To enhance survival and conserve energy, animals have adapted their activity patterns to a diurnal, nocturnal, or crepuscular² existence, retreating at other times to a relatively protected environment where they rest and sleep. Such circadian rhythms are approximately 24-hour oscillations or alternations of biological processes that are observed in a broad spectrum of organisms. Although these rhythms are generated endogenously by internal clocks, they do not function in isolation from their surroundings; rather, they are synchronized with temporal variations of the environment by external cues, especially the light–dark cycle. Circadian rhythmicity allows organisms not only to respond to but also to anticipate regular changes in the environment, aligning their physiological and behavioral capabilities to best fit environmental demands.

A clock entrained to the natural environment has a 24-hour period, while a free-running (non-24-hour) circadian clock (in constant dark or dim–light conditions) has a slightly different period, with marked variability among species and individuals. In humans, for example, the period is slightly longer than 24 hours, while in most rodents it is slightly less. The components of a circadian system include the clock itself, which generates the biological rhythm; input pathways that transmit environmental cues to the clock; and output pathways that transmit the clock's rhythms to the rest of the organism, influencing a large number of endocrinologic, biochemical, and electrophysiological processes.

The Master Circadian Clock

Molecular analysis reveals that the master circadian clock is located in the *suprachiasmatic nuclei* (SCN), which are small, paired clusters of cells situated in the anterior hypothalamus. The SCN receive input from the retina for adjustment to the light–dark cycle and have extensive modulatory innervation from serotonergic neurons in a part of the midbrain called the *raphe*. The first indication that the master clock is located in the SCN came from ablation studies in rodents. Stephan (1983) and then Kafka and colleagues (1985) demonstrated that ablation of the SCN in rats abolishes circadian rhythms of drinking activity. Conversely, cultures of an SCN cell line that exhibit robust circadian metabolic rhythms (Earnest et al., 1999) can restore circadian rhythms of locomotor activity when transplanted into the third ventricle of SCN-lesioned rats without circadian rhythms. Thus, this cell line is sufficient to generate and drive circadian rhythmicity at the level of the whole organism. Such behavioral rescue is not trivial, since circadian rhythms *in vivo* are not restored by other cell lines, such as fibroblasts, that may show oscillatory properties.³ Is the clock function a result of the interactions of SCN neurons, i.e., a result of the neuronal network, or is it an intrinsic function of each neuronal cell? The latter possibility appears more likely at this point, based on the work of Welsh and colleagues (1995).⁴

In recent years, several genes representing components of the mammalian clock have been identified, among them *clock*, *cry*, and *per*⁵; evidence linking certain clock genes to bipolar disorder is reviewed later. How are these clock genes linked to rhythms of electrical activity in the SCN? These genes and their products are involved in interacting positive and negative feedback loops in transcription (transforming chemical information from DNA to messenger RNA [mRNA]) and translation (transforming chemical information from mRNA to proteins) of clock genes.⁶ It is from these feedback loops (which span 24 hours) that self-sustained circadian oscillations arise. The electrical activity of the clock is an output, not a necessary constituent of the clock because the clock's time-keeping function continues even if the electrical output is silenced with anesthetic agents (Reppert and Weaver, 2001). The electrical activity of the SCN is the result of activation of a related set of genes called *clock-controlled genes* (CCGs). CCGs are rhythmically regulated by the clock but are not part of the clock *per se* because their products are not essential to its functioning.⁷

To function effectively, the SCN must synchronize their approximately 20,000 neurons for a coordinated output. It appears that gamma-aminobutyric acid (GABA), the principal neurotransmitter in the SCN (and involved in the action of some of the medications used in treating bipolar

disorder), is essential for this synchronization (Liu and Reppert, 2000), although other neurotransmitters, including neuropeptides, may also be involved.⁸ In mammals, including humans, visual stimuli are required for entrainment of physiological and behavioral rhythms to the light–dark cycle (Yamazaki et al., 1999; Rugier et al., 2003).⁹ The major pathway is the retinohypothalamic tract (RHT). Its major neurotransmitter is glutamate, with additional modulation from substance P (Hamada et al., 1999) and pituitary adenylate cyclase activating peptide (Chen et al., 1999).¹⁰ In addition, abundant terminals of serotonergic neurons from the raphe modulate the activity of the SCN.

Along with neurotransmitters (the “wiring”), neurohumoral modulatory factors reach the SCN. The most important of these is melatonin, which modulates phase shifts by binding to specific melatonin receptors; melatonin also reduces the firing of SCN neurons (Liu et al., 1997a).¹¹

The output pathways (and neurohumoral mediators) from the SCN are not completely understood (Reppert and Weaver, 2001). GABA-containing axonal terminals from the SCN to the paraventricular nuclei regulate melatonin synthesis in the pineal gland (Kalsbeek et al., 1996) and thus participate in the circadian and seasonal rhythms of melatonin.¹²

The timing of several rhythms is identical in diurnal and nocturnal species relative to the day–night cycle. For example, electrical activity of the SCN and vasopressin levels in the cerebrospinal fluid are higher during the daytime, while melatonin is produced at night in all species regardless of whether they are active during the day or night. On the other hand, important physiological rhythms, such as body temperature and hypothalamic–pituitary–adrenal activity, are linked predominantly with the day–night rest–activity rhythm.

Circadian Rhythms in Humans

Evidence that human circadian rhythms are endogenous came from experiments in which people lived for weeks or months in caves, underground bunkers, or windowless, sound-proof apartments, isolated from external time cues (Chouvet et al., 1974; Siffre, 1975; Wever, 1979). Under these conditions, circadian rhythms ran according to their own intrinsic period, which, as noted above, is usually slower (i.e., longer) than one cycle every 24 hours in humans.¹³ Experimental results indicate that external time cues synchronize circadian rhythms not only with the day–night cycle but also with one another. When entrained by “zeitgebers” (see endnote 13), homeostatic mechanisms ensure that the various rhythms maintain distinct phase relationships to the environment and to one another. In humans, for instance, the temperature minimum nearly always occurs

during the last third of the night, just before dawn. Internally, circadian rhythms that are normally synchronized with each other can dissociate when one becomes disentrained from the zeitgeber. The temperature rhythm of a night shift worker, for example, may continue to be entrained to the day–night cycle but become dissociated from the sleep–wake cycle when the worker sleeps during the day. Or consider what would happen under free-running conditions (i.e., in the absence of zeitgebers). The two cycles, each following their own intrinsic periodicity, would go in and out of phase with each other (see Fig. 16–1). This internal desynchronization can create what has been called a *beat phenomenon* (such as when two peaks periodically coincide), analogous to the audible beat produced by two tuning forks of slightly different frequencies (Halberg, 1968; Kripke et al., 1978).

Proper functioning of the human circadian system depends on continuous sensory input from the environment. This feature may be particularly relevant to understanding circadian disturbances in manic-depressive illness. Equally important, behavior regulates biological rhythms by exposing a person to or shielding him or her from the entraining zeitgebers—that is, behavior serves a gating function. The depressive patient who hides under the covers is certainly less likely to be exposed to light and other zeitgebers than is the manic patient who races through the day and sleeps little at night.

The normal phase relationships between circadian oscillators and their overt rhythms can be temporarily disturbed during rapid transmeridian travel and shift work, as well as in experimental laboratory conditioning. As demonstrated in isolation experiments, the oscillators may spontaneously dissociate and oscillate with unequal periods when humans are deprived of external time cues. The

timing of circadian rhythms relative to the day–night cycle and to one another is homeostatically controlled and reflects in part the period of the intrinsic rhythm of the driving oscillators. Such a system may be altered by disease and treatment interventions. Alterations can occur in the intrinsic periods of the oscillators, in the coupling between oscillators, or between the oscillators and the external day–night cycle. Such changes may affect the phase position of circadian rhythms entrained to the day–night cycle and even their capacity to be entrained at all (Aschoff, 1981a,b).

An essential concept for understanding how light or other zeitgebers synchronize or desynchronize internal and external rhythms is the phase response curve (PRC). In short, light during midday has minimal if any phase-shifting effects, while light in the late afternoon and evening delays circadian rhythms, and late night–early morning light advances them. (It is important to note that the terms *midday*, *afternoon*, *evening*, *night*, and *morning* refer to internal time.¹⁴) In contrast to light, melatonin and behavioral arousal have a PRC that is distinct from, and even somewhat complementary to, that of light (Duncan et al., 1996). Thus, melatonin phase advances the rest–activity rhythm when administered between internal midday and early night, while producing a phase delay when administered between late night and midday. Given that the circadian period in humans is slightly longer than 24 hours, the synchronization of the circadian system in normal individuals occurs through daily phase advances.¹⁵

Biological Day and Night, Biological Dusk and Dawn

The circadian pacemaker imposes daily variation on the activity of human neuroendocrine systems. Similar to the changes in environmental light that define day, night, and twilight, these changes exhibit waveforms characterized by distinct diurnal and nocturnal periods with relatively short transitions between them (corresponding to a biological dusk and a biological dawn). In humans, for example, periods characterized by absence of melatonin secretion, low prolactin secretion, falling cortisol levels, decreasing theta activity in the electroencephalogram (EEG), and decreasing propensity to rapid eye movement (REM) (biological day) all alternate with nocturnal periods of active melatonin secretion, high prolactin secretion, rising levels of cortisol, increasing theta activity, and increasing propensity to REM sleep (biological night). In response to light, the circadian pacemaker synchronizes biological day and night so that their timing and duration are appropriately matched with the timing and duration of the external day and night.^{16,17} These processes are summarized in Figure 16–2.

Figure 16–1. The beat phenomenon. This hypothetical model shows two circadian rhythms. Oscillator A is synchronized to the day–night cycle and always peaks during the day. Oscillator B free-runs slightly faster than one cycle per 24 hours and therefore goes out of phase with A. When A and B are in phase, their ratio is stable, but when they are out of phase, the ratio of B to A may become very high. This ratio indicates the cyclic beat phenomenon that occurs every few days. (Source: Adapted from Halberg, 1968, and Kripke et al., 1978.)

Biological Dawn entrained to dawn	Biological Dusk entrained to dusk	Biological Dusk entrained to dawn
<p>BIOLOGICAL DAY</p> <p>No melatonin secretion Increasing core body temperature Decreasing sleepiness Decreasing waking EEG theta activity Decreasing REM sleep propensity</p> <p>Decreasing cortisol levels Wakefulness</p>	<p>BIOLOGICAL NIGHT</p> <p>Melatonin secretion Decreasing core body temperature Increasing sleepiness Increasing waking EEG theta activity Increasing REM sleep propensity</p> <p>Increasing cortisol levels Sleep</p>	

Figure 16–2. Temporal organization of the human circadian timing system. Profiles of a number of circadian rhythms in humans exhibit distinct diurnal and nocturnal states with abrupt switch-like transitions between them. These states and transitions can be conceptualized as a biological day and night and a biological dawn and dusk. They are generated within the organism and mirror or anticipate features of the solar day to which they correspond and with which they are synchronized. EEG = electroencephalogram; REM = rapid eye movement. (Source: Wehr et al., 2001b. Reprinted with permission from Blackwell Publishing, Ltd.)

PHYSIOLOGY OF SLEEP

Sleep is a distinct behavioral and physiological state, as defined by EEG and behavioral characteristics. In preparation for sleep, animals seek a protected environment, assume a characteristic sleep posture, and pass briefly through a drowsy state before falling asleep. Despite intense research, the function of sleep remains unknown. Nevertheless, it is well known that sleep serves a vital function, this despite its evolutionary disadvantages, such as increased vulnerability to predators. Mammals totally sleep deprived for 2–3 weeks die, as they would if deprived of food for a similar duration.¹⁸

Stages of Sleep

The discrete stages of sleep are marked by variations in EEG patterns, eye movements, and muscle tone. By convention, human sleep is divided into two major phases that alternate throughout the night: a REM phase and a non-REM (NREM) phase. On falling asleep, healthy adults go into NREM sleep, the period of rest and energy conservation, when the brain literally cools while respiration, blood pressure, heart rate, and other physiological processes slow down, eyes are still or move only slowly, and muscles are relaxed but not flaccid. This first phase comprises four stages of progressively deeper sleep. On EEG recordings, the frequency of electrical waves decreases steadily from stage 1 to stage 4, while the amplitude—the energy discharged at each impulse—increases (see Fig. 16–3). Stages 3 and 4 consist of predominant slow and ample delta waves (slow-wave sleep), the result of highly synchronized brain activity.

Following the NREM phase is REM sleep, marked by intense mental activity, vivid dreaming, and rapid and diffuse cerebral metabolism. Blood flow and most neuronal firing rates, and probably brain temperature, are higher than during either NREM or awake states, while, paradoxically, the large muscles are virtually paralyzed. Bursts of REM occur, pulse and blood pressure rise and fall, and respiration becomes irregular. EEG activity shows a sawtooth pattern, low in amplitude (voltage) and variable in frequency, similar to stage 1 NREM sleep (the brief transition period between wakefulness and sleep). Dement and Kleitman (1957) observed that in normal individuals, the distribution of REM sleep during the night was skewed, with more occurring toward the end of the night than at the beginning.

In the normal sleep of a young adult, the first period of NREM sleep (through all four stages) is followed, after an average of about 90 minutes, by a 15- to 20-minute period of REM sleep. Slow-wave sleep (stages 3 and 4, part of the NREM phase) predominates during the first part of the night, whereas REM sleep periods become progressively longer and are most concentrated in the hours before waking. While an internal self-sustaining circadian pacemaker appears to govern the propensity for REM sleep, homeostatic processes determine other sleep patterns, such as the amount of slow-wave sleep, which turns out to be proportional to the length of time the person has been awake prior to sleep.

Advances in understanding of the neurophysiological basis of the sleep EEG (Steriade, 1994; Amzica and Steriade, 1998), in conjunction with quantitative EEG analysis (Borbely et al., 1989; Aeschbach and Borbely, 1993; Achermann and Borbely, 1998), have confirmed that the EEG is

influenced by prior and ongoing individual experience. In addition, there is evidence that genetic factors contribute to sleep regulation and abnormalities (for reviews of animal research, see Franken et al., 1999; Toth, 2001). For example, EEG parameters of recovery sleep after sleep deprivation in mice are strain-specific. These differences have been linked to a locus on chromosome 5 near one of the clock genes and may reflect differences in circadian timing of sleep.¹⁹ Sleep alterations in knockout mice²⁰ are another means of evaluating genetic contributions to sleep.²¹

Neural Substrates for Sleep

A pandemic of encephalitis lethargica, a presumed viral infection, swept much of the globe during World War I, causing severe daytime sleepiness in most affected individuals. A group of individuals had the opposite problem, however—a prolonged state of insomnia. A Viennese neurologist, Baron von Economo (1930), reported that the increased sleepiness was due to injury of the posterior hypothalamus and rostral midbrain, while the severe insomnia resulted from lesions of the preoptic area and basal forebrain. On the basis of this observation, von Economo postulated that a region in the anterior hypothalamus contains sleep-promoting neurons, while a region in the posterior hypothalamus contains wakefulness-promoting neurons. Lesioning studies in animals proved his predictions correct, and

the pathways responsible for the hypothalamic regulation of wakefulness have now begun to be understood (Saper et al., 2001).²²

During REM sleep, cholinergic neurons in the caudal midbrain and rostral forebrain fire at their maximum, while the serotonergic, noradrenergic, and catecholaminergic pathways are at their minimum. These monoaminergic neurons inhibit the cholinergic REM-promoting neurons and thus terminate REM sleep.²³ NREM sleep is associated with hypersynchrony of thalamocortical rhythms, with an active inhibition of the arousal centers.²⁴ Conversely, when activated, these neurons abort sleep and induce wakefulness.²⁵ The brain structures involved in the control of NREM sleep are also involved in thermoregulation. As noted, lowering of the set point for body temperature occurs in NREM sleep. Thus, lesions that result in disruption of NREM sleep also disrupt thermoregulation. Of clinical importance, heating the body promotes NREM sleep. For example, as part of sleep hygiene, a warm bath before going to bed is recommended for patients with insomnia. In contrast to NREM sleep, more highly discrete brain areas are involved in the regulation of REM sleep. Neurons in the pontine tegmentum (the pedunculopontine tegmental nucleus and lateral dorsal tegmental nucleus) are active during REM sleep and waking and inactive during NREM sleep. Drugs that boost acetylcholine levels to these areas activate REM sleep, while

Figure 16–3. Normal sleep: electroencephalogram (EEG) patterns, distribution of non-rapid eye movement (NREM) and REM periods. EMG = electromyography; EOG = electro-oculogram. (Source: Hobson and Steriade, 1986.)

blockers of muscarinic receptors suppress REM sleep. Noradrenergic neurons in the locus ceruleus and serotonergic neurons of the dorsal raphe are active during waking, less active during NREM sleep, and inactive during REM sleep. These neurons inhibit the cholinergic neurons of the pontine tegmentum to terminate REM sleep. A less-than-active serotonergic or noradrenergic system (perhaps in depression) may result in disinhibition of REM sleep. While these discrete pontine structures are involved in REM sleep initiation, other neurons, such as those in the lateral hypothalamus, the amygdala, and other limbic structures, are involved in the maintenance of REM sleep.

In addition to GABA, histamine, acetylcholine, serotonin, norepinephrine, and orexin/hypocretin (described briefly above and in the associated notes), other neurotransmitters have an important role. For example, dopaminergic neurons promote wakefulness. In addition, cholecystikinin, prostaglandins, interleukin-1, and adenosine have a modulatory role. Adenosine in particular has been implicated in mediating the homeostatic mechanisms of sleep. Caffeine increases alertness by blocking adenosine receptors, which are widespread in the brain. Receptors on the cholinergic neurons of the basal forebrain appear to regulate adenosine's effect on sleep.²⁶

Functional Neuroimaging of Sleep

Positron emission tomography (PET) studies have used either O₁₅ water (for blood flow) or deoxyglucose-F18 (FDG) (for cerebral metabolism), each having its advantages and disadvantages.²⁷ PET studies have shown that global cerebral metabolism is similar in REM sleep and wakefulness, but regional blood flow differs. Specifically, several limbic structures, such as the cingulate gyrus, are more active during REM than waking conditions, while areas of high-order association, such as the orbitofrontal cortex, the dorsolateral prefrontal cortex, and the inferior parietal lobe, tend to be deactivated.²⁸ In contrast, slow-wave sleep is characterized by deactivation in the brain stem, thalamus, and basal forebrain (Braun et al., 1997). Compared with NREM, REM sleep is associated with higher metabolic rates in midline frontal, cingular, and dorsolateral prefrontal regions (Buchsbaum et al., 2001).

The Two-Process Model of Sleep

The timing and duration of sleep and wakefulness are the result of the interaction of circadian rhythms paced by the SCN (process *c*) and a sleep-wake-dependent (“homeostatic”) process (process *s*). *Process c* represents a circadian variation in sleep propensity that can be understood as fluctuating thresholds for falling asleep and waking up, while *process s* tracks the increase in sleep pressure during waking and a corresponding decrease during sleep (Borbely, 1982; Borbely

and Wirz-Justice, 1982). This two-process model attempts to account for the compensatory role played by the SCN with respect to process *s*. For example, as sleep appetite increases throughout the day, the SCN drives a signal of increased alertness to avoid a mandatory cessation of activity (a “wake maintenance zone”). This phenomenon can be conceptualized as an increase in the threshold for falling asleep, and sleep latency at this time is prolonged. Furthermore, as sleep appetite decreases toward early morning, the threshold for being asleep is lowered (a “sleep maintenance zone”).²⁹

Physiology of Sleep Duration

In patients with bipolar disorder, reduction of sleep duration can trigger mania. But how long do we need to sleep? Sleep duration and amount of sleep needed differ somewhat among individuals; genetic factors may play a role in determining sleep duration in humans (Partinen et al., 1983; Webb and Campbell, 1983), as well as in rodents (Franken et al., 1999; Tafti et al., 1999; Huber et al., 2000). In experimental conditions consisting of imposed rest and long artificial nights for up to 15 weeks, healthy volunteers slept almost 11 hours during their first night, interpreted as the result of “paying” the sleep debt that had accumulated from daily life before the study began. Thereafter, subjects slept progressively less on subsequent nights until reaching an average steady-state duration of 8.25 hours in the fourth week (with very little individual variation) (Wehr et al., 1991, 1993). Sleeping less than one needs results in metabolic and endocrine alterations, such as lower glucose tolerance, lower thyrotropin concentration, and elevated cortisol and sympathetic nervous system activity (Spiegel et al., 1999).^{30,31}

SLEEP IN AFFECTIVE DISORDERS

Clinical and research evidence provides tantalizing leads for understanding the connection between sleep and recurrent affective illness. Switches from depression to mania can occur after patients miss a night of sleep, for example. As noted earlier, sleep depriving a patient with depression therapeutically often results in a striking albeit temporary improvement in mood (see also Chapter 19); resuming sleep, even for a short nap, can often cause the patient to sink back into depression.

Time Course of Sleep Abnormalities in Affective Disorders

Polysomnographic abnormalities in affective disorders may be present long before the clinical onset of the disorder and continue to persist indefinitely (thus representing a “vulnerability” or “trait”). Alternatively, the abnormality may appear only with a disordered mood state; if it persists for a long time after mood has normalized, it may represent

a “scar” marker, while if it is present only during the mood episode, it is a “state” marker. Thus some researchers have found persistent REM sleep abnormalities after depressed patients have achieved remission (Rush et al., 1986; Steiger et al., 1989, 1993a,b,c). For example, in 78 unmedicated depressed patients, Thase and colleagues (1998) found that certain sleep abnormalities (sleep efficiency, REM density) were to some degree reversible with remission, while others were independent of mood state. In contrast, other researchers have found that persistent REM sleep abnormalities have a tendency to normalize after mood state has normalized,³² even to nearly complete restoration of normal sleep in remitted depressed patients (Knowles et al., 1986).

Several studies have found shortened REM latencies in healthy relatives of depressed patients (Giles et al., 1987a,b, 1988, 1989). Gillin’s group (Gillin et al., 1982; Jones and Berney, 1987) hypothesized that because euthymic individuals with a family history of affective illness have an increased response to arecholine and because relatives with affective illness have an increased REM response to arecholine relative to those without affective illness, cholinergic supersensitivity may be a vulnerability marker for affective illness. This hypothesis was confirmed by Schreiber and colleagues (1992), who found that subjects with a positive family history but negative personal history for affective illness had more frequent sleep-onset REM periods with cholinergic stimulation than did healthy controls.

Of particular relevance to the notion that recurrence is central to manic-depressive illness, some polysomnographic sleep abnormalities appear to reflect a vulnerability to recurrence of depression. Thus Thase and colleagues (1995) found more frequent REM sleep abnormalities in patients with recurrent depression than in those experiencing a single episode. Similarly, Buysse and colleagues (1997) observed that sleep abnormalities predicted future recurrence in patients with recurrent major depression. More recently, Perlman and colleagues (2006) found that a persistent sleep deficit after recovery (at least partially) from a mood episode in bipolar patients predicted depressive symptoms during a 6-month follow-up period. (Manic/hypomanic symptoms could have been undercounted because if they were brief, they were likely to have been missed in the once-a-month assessments.)

Some methodological issues tend to complicate interpretation of the state versus trait literature. These issues include variable or imprecise definitions of relapse and recurrence, an overly short interval from mood normalization to the sleep study, and uncontrolled medication effects. For example, when patients were medication-free for several years rather than for several weeks or months, sleep was more likely to normalize (Riemann and Berger, 1989; Buysse et al., 1997; Riemann et al., 2001).

Sleep in the Bipolar Subgroup

As noted above, sleep loss is often a precursor and/or precipitant of hypomania or mania in bipolar patients.³³ As we emphasized in the first edition of this text, maintaining stable sleep-wake cycles is of central importance to the maintenance of stability in bipolar illness, a point subsequently confirmed empirically (Brown et al., 1996; Frank et al., 1997). During episodes of depression, bipolar patients often report sleeping too much, although, as noted above, this hypersomnia appears predominantly in bipolar depression of mild to moderate severity. Hypersomnia is one of the symptoms of an “atypical depression syndrome,” which overlaps with many cases of bipolar depression (other symptoms being overeating, increased appetite, and weight gain). These atypical features tend to be associated with a lower incidence of the type of polysomnographic abnormalities reported in classic melancholic depression. Of relevance here is the finding that no REM sleep disinhibition or decrease in slow-wave sleep has been found³⁴ in patients with winter depression or seasonal affective disorder (SAD) (which is characterized by atypical features). Moreover, Schwartz and colleagues (2000) reported that patients with SAD, compared with controls, actually had significantly longer NREM episodes and more slow-wave sleep during NREM periods.

Sleep during Mania/Hypomania

Just as sleep loss can trigger mania in bipolar patients, reduction in sleep is a good predictor of hypomania or mania the next day in rapid-cycling bipolar patients (Leibenluft et al., 1996a). This 1-day latency is similar to observations of sleep loss triggering or intensifying mania (Wehr et al., 1987; Barbini et al., 1996) and is consistent with the recent report of Bauer and colleagues (2006), who collected longitudinal self-ratings of mood and sleep in 59 bipolar outpatients undergoing routine treatment. They found for many patients an inverse relationship between a change in sleep and a subsequent change in mood, with a usual lag period of 1 day.

But what do we know about sleep during manic/hypomanic episodes? Obviously this is a difficult question to research, especially in mania. Van Sweden (1986) studied two unmedicated severely manic patients who had been hospitalized after 2 and 3 weeks of mania. He found that, contrary to the common assumption that manic patients are unable to sleep, the EEGs of both patients showed stage 2 sleep within seconds of closing their eyes. In a study of eight unmedicated manic men, Linkowski and colleagues (1986) found that REM latency, as well as the percentage of time spent in any stage of sleep, was no different than in age-matched normal men, although the patients took longer to fall asleep and spent less time asleep. In a slightly larger study,

however, Hudson and colleagues (1988) found shorter REM latencies and higher REM densities in nine unmedicated manic patients relative to normal controls. Thus, the patients showed hypersomnia and sleep continuity disturbances very similar to those seen in bipolar depression, although to a lesser degree. Unlike patients with major depression, however, the manic patients in the Hudson group's study did not have disturbances in delta sleep (stages 3 and 4).

In a patient with rapid cycling, Gann and colleagues (1993) found that very short REM latencies, including sleep-onset REM periods, followed depressive days, and after hypomanic days, REM latency was prolonged but still shorter than normal. Feldman-Naim and colleagues (1997) described a diurnal variation in the direction of mood switch in rapid-cycling bipolar disorder. They observed an "up-switch" from depression to hypomania/mania during the daytime and a "downswitch" at night. For the great majority of bipolar patients, however, most switches into mania occur overnight (Bunney et al., 1972a,b).

Circadian abnormalities, discussed in more detail later, may underlie some sleep-wake abnormalities in patients with bipolar disorder. For example, 48- or 72-hour rhythms have been observed in rapid-cycling patients when they shift from depression to mania (Wehr et al., 1982; Mizukawa et al., 1991). This phenomenon is similar to that seen in healthy volunteers under conditions in which external time cues have been eliminated (Weitzman, 1982; Wever, 1983). Other chronobiological abnormalities in a manic state include phase advances in the nadir of the cortisol rhythms relative to the time of sleep onset, as found by Linkowski and colleagues (1994) in eight unmedicated patients in a manic state. It is possible that a phase advance of the circadian rhythms in mania is the consequence rather than the cause of sleep abnormalities, and may also reflect a previously reported supersensitivity to light (Lewy et al., 1985; Eagles, 1994). A more recent report confirmed the original finding only partially (Nurnberger et al., 2000). A plausible hypothesis is that, given the brevity of sleep in mania, such patients are exposed to bright light very early in the morning, so that under conditions of supersensitivity to light, rhythms may shift to a more advanced position.

What can be learned from bipolar patients with regard to state-trait abnormalities? Knowles and colleagues (1986) studied 10 remitted bipolar depressed patients for 5 nights. Although the patients reported more frequent arousals, no significant differences in EEG sleep parameters relative to age-matched controls were observed. Similar findings were reported by Jones and colleagues (2005). On the other hand, Harvey and colleagues (2005) showed that euthymic bipolar patients have impaired sleep efficiency, along with higher-than-normal levels of anxiety about having poor-quality sleep, and Millar and colleagues

(2004) found that sleep duration and nighttime waking were more variable in remitted bipolar patients compared with controls. Furthermore, Sitaram and colleagues (1982) found increased density and percentage of REM among bipolar patients in the well state compared with normal controls. More striking, however, was their finding that when infused with arecholine (an acetylcholine agonist that can produce a shortened REM latency), the recovered bipolar patients in the well state were more sensitive to its effects on REM latency than were the normal controls (see the discussion of cholinergic sensitivity below).

Sleep in Major Depression

Lenox and colleagues (2002) and Gould and Manji (2002a,b) proposed that circadian disturbances and disinhibition of REM sleep (such as a greater shortening of REM latency with cholinergic agents) may represent endophenotypes for recurrent unipolar depression, whereas a hypomanic or manic response to sleep deprivation may represent an endophenotype for bipolar disorder. Both unipolar and bipolar manic-depressive patients can, of course, have sleep disorders unrelated to their illness, such as sleep apnea, which may disrupt sleep and result secondarily in mood instability. In such cases, consultation with a sleep specialist may bring dramatic improvement to an occasional, apparently treatment-resistant situation while also improving overall functioning.

Initial efforts to distinguish recurrent unipolar depression from bipolar depression on the basis of sleep characteristics have been confounded by issues of overall severity and comorbid anxiety. Thus for the sake of clarity, our discussion here focuses on depression in general; where adequate data exist, we distinguish between the recurrent unipolar and bipolar forms.

In general, sleep and depression appear to be inversely related. Thus some impairment of sleep quality is reported by more than 90 percent of depressed patients (Tsuno et al., 2005), while approximately 25 percent of patients complaining of chronic insomnia suffer from major depression (Vollrath et al., 1989). Breslau and colleagues (1996) reported a relative risk of 4.0 for new onset of major depression among individuals with a history of insomnia. Insomnia also appears to be a prominent risk factor for developing major depression in the future (Pfaffenberger et al., 1994; Chang et al., 1997). Further longitudinal studies will be necessary, however, to distinguish between insomnia as a true predictor of depression and as a subclinical or prodromal symptom of depression. Conversely, timely treatment of insomnia can reduce the likelihood of a major mood episode (Weissman et al., 1997).

What is the nature of the sleep disorder in major depression? Patients with the endogenous or melancholic

form of depression tend to report global insomnia, that is, some difficulty falling asleep, frequent nocturnal awakenings, and early-morning awakenings. In contrast, hypersomnia is encountered more frequently among bipolar patients who are moderately depressed (Detre et al., 1972; Thase et al., 1989) and in patients with SAD (Rosenthal et al., 1984). Sleep abnormalities in depression have been characterized by polygraphic EEG recordings (so-called polysomnographic studies), pioneered by Snyder at the National Institute of Mental Health (NIMH) and by Kupfer's group (Kupfer and Foster, 1972; Foster et al., 1976). Kupfer's group found a decreased REM latency in depression (a shortening of the interval between sleep onset and the occurrence of the first REM period), typically accompanied by a reduction in slow-wave sleep. In addition, they found greater frequency of eye movements during REM sleep, a characteristic referred to as increased REM density. The early hypothesis that decreased REM latency may be a biological marker for primary melancholic rather than secondary depression (Kupfer, 1976; Kupfer et al., 1976) has not been confirmed by more recent studies. Rather, the phenomenon has been reported in nonmelancholic and secondary depression, in other psychiatric disorders, and even in normal aging (Benca et al., 1992; Riemann et al., 2001).

Medication Effects on Sleep in Depression

Almost all antidepressants suppress REM sleep (Sitaram et al., 1978b), an effect once considered a possible mechanism of their antidepressant activity. It is now clear, however, that suppression of REM sleep is not necessary for an antidepressant effect (Riemann et al., 2001), as some antidepressants, such as nefazodone (Sharpley et al., 1992) and bupropion (Nofzinger et al., 1995), appear to enhance rather than decrease REM sleep. There is disagreement over the time course of REM suppression, with one group reporting that it attenuated over the first 3–5 weeks of treatment (Berger et al., 1986; Riemann and Berger, 1990) and another that it persisted beyond 1 year (Kupfer et al., 1994; Reynolds et al., 1997).

Mood stabilizers have a smaller and more variable impact on REM sleep and may exert their influence mainly by increasing slow-wave sleep. Such effects have been described for lithium (Friston et al., 1989) and carbamazepine (Yang et al., 1989). Valproate decreases REM and increases slow-wave sleep (Harding et al., 1985), whereas lamotrigine and gabapentin increase rather than decrease REM sleep in patients with seizure disorders (Placidi et al., 2000a,b,c). Electroconvulsive therapy (ECT) decreases REM latency in depressed patients, and the antidepressant response is poorer in patients who continue to have sleep-onset REM periods after ECT (Grunhaus et al., 1997).

Cholinergic Sensitivity in Patients with Manic-Depressive Illness

As noted in the first edition of this text and earlier, cholinergic–adrenergic balance has been considered important for sleep regulation. According to this hypothesis as first proposed in 1972 (Janowsky et al., 1972), mania is related to decreased and depression to increased cholinergic activity. This hypothesis, although overly inclusive, did generate some useful research. Thus a cholinergic agonist such as arecholine, administered during sleep, was found to hasten the occurrence of REM sleep.³⁵ This finding may be related to the observation in patients with recurrent affective illness that REM latency is shorter than normal, although there are conflicting results as to whether this reflects a state or trait.³⁶

CIRCADIAN RHYTHM DISTURBANCES IN MANIC-DEPRESSIVE ILLNESS

Many patients with manic-depressive illness, both the bipolar and recurrent unipolar forms, lead productive lives and work late hours, work in shifts, or are engaged in transmeridian travel. In addition to the intrinsic dysregulation of sleep–wake cycles and biological rhythms in such patients, these environmental challenges strain a fragile system, especially for bipolar patients. Because of the major potential of the sleep–wake cycle to disrupt mood stability in these patients, we introduce this section with a recommendation that both clinicians and patients be aware of these risks. The psychiatrist treating individuals who work nights or travel across meridians should either be well versed and current in the principles of treating abnormalities of circadian phase, jet lag, or shift work–related complaints, or consult with or refer to colleagues who are.

As outlined in the first edition of this volume, early clinical studies of circadian rhythms in depression carried out in England in the 1950s and 1960s were inspired by Lewis and Lobban's (1957) discovery that placing a subject on unusual schedules during the Arctic summer altered the relative timing of his or her various circadian rhythms. The English clinical studies (e.g., Lobban et al., 1963; Palmai and Blackwell, 1965) were designed to explore whether early-morning awakening in depressed individuals is related to an analogous but pathological internal phase disturbance. Early studies of circadian rhythms sometimes showed dramatic phase disturbances in depressive patients, but no consensus emerged about the significance and pattern of these changes. That situation appears to be changing.

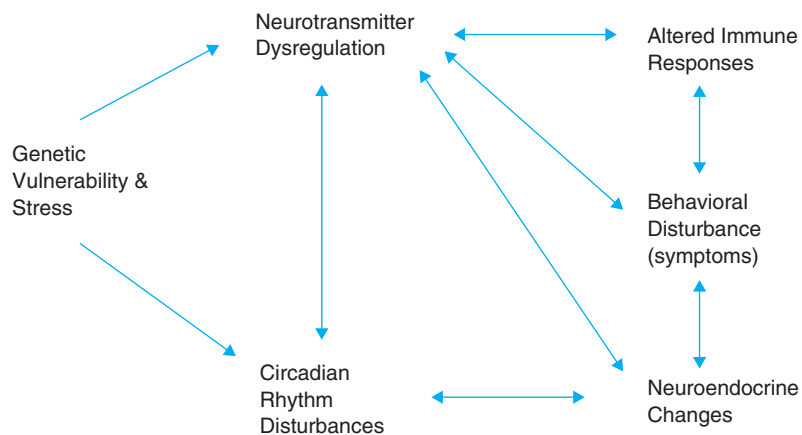

Until the 1970s, normal circadian physiology remained largely unexplored, so that no context was available in which to place findings on depression. Investigative groups studying circadian rhythms were distant from one another,

their studies widely separated in time. An initial fruitful period in the development of methodologies encompassing interactions between sleep and circadian systems in the clinical domain was followed by a period of relative stagnation (possible contributing factors are discussed later) and contradictory results. Given its complexity and cost, the gold standard, forced desynchrony,³⁷ has not been employed in this more recent work, so that some important questions about the physiology involved remain obscure. Simpler methods, such as constant routine,³⁸ raise ethical and clinical questions, as they usually involve loss of at least one night of sleep. Yet during this period of relative inactivity in the physiological realm, progress has been made in unraveling some of the molecular mechanisms underlying sleep and the circadian clock. Before discussing specific models of alterations in the timing of daily circadian rhythms and then possible homeostatic mechanisms, it is important to place circadian rhythm disturbances in a broader context. Figure 16–4 illustrates a hypothesized relationship among genetic vulnerability, stress, circadian rhythm disturbances, neurotransmitter–neuroendocrine immune dysregulation, and the symptoms of manic-depressive illness. The link between circadian rhythm disturbances and clinical symptoms (perhaps through neurotransmitter–neuroendocrine intermediaries) is, in our opinion, likely to be a closed loop, with rhythmic disturbances producing symptoms that reinforce or exacerbate abnormal rhythmic processes—or vice versa, the arrows of causation going in both directions. Also, we agree with those who have speculated that, with respect to affective disorders, the circadian biological clock provides an intriguing link between biological and psychosocial perspectives (Wehr and Goodwin 1983a; Ehlers et al., 1988, 1993).

Desynchrony and the Free-Running Hypothesis

As discussed earlier, circadian rhythms are synchronized with external zeitgebers (the most important being the light–dark cycle) and with each other. It is possible that recurrent affective illness is analogous to jet lag, with certain biological rhythms being desynchronized relative to sleep–wake cycles and to each other. Among the first hypotheses regarding abnormalities in the biological rhythms of depressed individuals was Georgi’s (1947) suggestion that the rhythms are out of synchrony. Georgi proposed that the patient’s own circadian rhythms are desynchronized either with one another (internal phase disorder) or with the entraining day–night cycle (external phase disorder). Later, Halberg (1968) formulated a more specific desynchronization hypothesis. He suggested that some circadian rhythms in affectively ill patients (particularly those with rapid cycles) may not be entrained to the 24-hour day–night cycle but free run, gradually going in and out of phase with other circadian rhythms that remain synchronized with the day–night cycle. According to Halberg, such phase disturbances leading to affective episodes (perhaps analogous to the “beat” phenomenon mentioned earlier) would occur periodically every few days or weeks. In support of Halberg’s hypothesis, Kripke and colleagues (1978; Kripke, 1983) found that five of seven rapid-cycling bipolar patients had some circadian rhythms that appeared to free run with periods shorter than the 24-hour day–night cycle. Wehr’s group (1985b) studied four patients (three bipolar, one unipolar) under free-running (isolation) conditions. One bipolar patient experienced an abnormally short intrinsic period, as predicted by the hypothesis of a fast circadian pacemaker. Unlike

Figure 16–4. Hypothesized relationship among genetic vulnerability, stress, circadian rhythm disturbances, neurotransmitter–neuroendocrine immune dysregulation, and the symptoms of manic-depressive illness.

Kripke's and Wehr's groups, Pflug and colleagues (1983) failed to detect free-running circadian rhythms in patients living on normal schedules, that is, entrained to the environment. Follow-up studies on these initial observations are lacking.

The behavioral consequences of living under conditions without zeitgebers are not well understood; anecdotal accounts suggest that mood disturbances may occur (Kripke, 1983). In contrast, the few manic-depressive patients studied in isolation have, if anything, shown amelioration of depression. Thus, one of the three bipolar patients studied by Wehr and colleagues (1985b) switched into mania, and the unipolar patient improved. As proposed by Wehr and Goodwin (1983c) and Kripke (1983), stable depression may occur in patients in whom an overly fast, intrinsic pacemaker rhythm causes circadian rhythms to become abnormally but stably advanced relative to the day–night cycle. Cyclic depression, by contrast, may result from an overly fast rhythm that escapes from entrainment and free runs, advancing repeatedly through 360 degrees relative to the day–night cycle.

The possibility of free-running circadian rhythms has far-reaching implications for research on manic-depressive illness. Not only could such a mechanism drive the dramatic cyclicality observed in some bipolar and highly recurrent unipolar patients through the beat phenomenon (Wehr and Wirz-Justice, 1982), but it could also result in epiphenomena that are misinterpreted as biological correlates of changes in the mood cycle. If, for example, a biological variable is sampled at a fixed time of day, its level appears to change cyclically as the rhythm goes in and out of phase with the sampling time, even if its mean 24-hour level never changes.

Findings of longitudinal studies with hamsters indicate that some antidepressant drugs can slow certain intrinsic rhythms of circadian oscillators, and lead to lengthening of the sleep–wake cycle and a temporary escape from the primary mode of entrainment (Wehr and Wirz-Justice, 1982). Clinically, this drug effect may lead to the frequently recurring escapes and double-length (48-hour) sleep–wake cycles found naturalistically to be associated with switches into mania (Wehr et al., 1979, 1982). Most of these patients experienced 48-hour sleep–wake cycles at the beginning of each manic phase.³⁹ Based on carefully timed sleep deprivation experiments in patients with rapid cycles, Wehr and colleagues concluded that the insomnia associated with these 48-hour cycles probably helps trigger switches into mania or exacerbates switches that have just begun. Thus, a drug-induced slowing of the intrinsic rhythm of circadian oscillators, leading to more frequent escapes from the primary mode of entrainment, may be one mechanism underlying drug-induced rapid manic-depressive cycles. Studies using constant routine and forced desynchrony procedures

would be necessary to follow up on these initial studies, but have been precluded by ongoing obstacles, including the inherent difficulties and risks of these procedures, ethical considerations, and costs and funding priorities.

Abnormalities of Phase Position: The Phase-Advance Hypothesis

Briefly, this hypothesis is based on a desynchrony between the sleep–wake cycle, which stays in a normal or phase-delayed position, and other circadian rhythms, which tend to occupy a phase-advanced position. Just as jet lag (which is a mismatch between imposed sleep–wake rhythms at the destination and circadian rhythms, which tend to remain closer to the place of origin) manifests with fatigue, mood changes, and physical malaise, so, too, the desynchrony represents a perpetuating factor in individuals predisposed to depression.

In his original formulation of the desynchronization hypothesis, Georgi (1947) linked depression to a phase disturbance.⁴⁰ One initial explanation of circadian phase abnormality was shortened REM latency, a characteristic of some affectively ill patients discussed earlier. The link between the patterns of REM sleep and nonsleep circadian processes was made in 1964 by Maron and colleagues. The following year, in one of the first EEG studies of sleep in depressed patients, Gresham and colleagues (1965) found that the normal pattern of REM sleep was altered. Depressive patients had more REM sleep than controls in the first third of the night and less REM sleep in the last third of the night. Most subsequent EEG sleep studies of depression have been variations on this theme. All the changes in the temporal distribution of REM sleep in depressed patients⁴¹ may result from a phase advance of the circadian rhythm governing the propensity for REM sleep. If the rhythm were advanced, its maximum, instead of occurring near dawn, would occur nearer to the beginning of sleep (Papoušek, 1975; Lewy et al., 1981; Wehr and Goodwin, 1981).

In addition to REM propensity, the circadian rhythms studied most extensively among nonseasonal depressed patients are those of temperature and plasma cortisol. In 1981, Wehr and Goodwin reviewed all of the studies in which the circadian pattern of a biological or physiological variable in depressed patients had been considered. They concluded that in the majority of studies, the phase position among the depressed patients (as reflected in the peak, nadir, or both) was variably advanced, generally occurring 1 to 4 hours earlier than in control subjects. In a review of the literature on circadian rhythms in nonseasonal depression, Souète (1990) found 80 studies involving a total of 1,061 patients and focusing on various measures, including cortisol, temperature, thyroid-stimulating hormone (TSH), melatonin, various neurotransmitter markers, heart rate,

and motor activity. Taken together, the results of these studies suggest that phase-advanced rhythms are quite common, although there is considerable variability among individuals and studies. It is of interest that reports of a phase delay have been strikingly less frequent than would be expected by chance. One might conclude that circadian rhythms tend to be abnormal or unstable in affective illness, with a bias toward assuming a phase-advanced position some of the time (see the review of Duncan et al., 1996). In mania, Linkowski and colleagues (1994) showed an early timing of the nadir of cortisol.

In circadian phase interpretation, age must be controlled, since circadian abnormalities associated with aging have been reported. These abnormalities consist mainly of a phase advance of sleep and delay of temperature and melatonin rhythms compared with normal sleep (Duffy et al., 1998, 2002; Dijk et al., 2000). Other important variables are diagnostic: whether patients are unipolar or bipolar, and whether the disorder is cyclic (that is, highly recurrent) or relatively noncyclic. Thus Linkowski and colleagues (1985a,b) found a significant phase advance in the cortisol nadir among unipolar patients, but only a trend among bipolar patients.

One clinical antidepressant treatment that appears to support the phase-advance hypothesis (described in more detail later) is a sleep schedule manipulation that advances the time of morning waking, producing a temporary antidepressant response in a significant proportion of patients with nonseasonal depression.⁴² Figure 16–5 illustrates how depriving patients of sleep in the second half of the night or advancing their sleep might help synchronize the abnormally advanced rhythm of REM sleep, temperature, and cortisol with the oscillator controlling sleep and wakefulness. By advancing sleep (or eliminating its second half), the abnormal phase relationship in the second half of the night would be corrected.

Figure 16–5. Hypothesized correction of an abnormally advanced oscillator by partial sleep deprivation or phase-advance treatment. (Source: Wehr and Wirz-Justice, 1981.)

It would be consistent with the phase-advance hypothesis for the antidepressant effect of light to be observed with evening administration (delaying cortisol, melatonin, and temperature rhythms and thus realigning them with the sleep–wake rhythm), coupled with a worsening of depression with morning light (which should further advance circadian rhythms). However, it has been found that the timing of light administration in nonseasonal depression is unimportant to its effect (Yamada et al., 1995; Kripke, 1998; Wirz-Justice et al., 1999a) and further, that morning light, rather than being detrimental, is as effective as evening light (Yamada et al., 1995). Light therapy is discussed in more detail later in the chapter.

Riemann and colleagues (1996) compared an experimentally advanced (from 5 PM to 12 AM) sleep period with a normal (from 11 PM to 6 AM) sleep period in patients who had responded to total sleep deprivation. Two-thirds of subjects in the latter group relapsed after one night of sleep, while two-thirds of subjects in the former group did not. Thus phase advance of the sleep–wake cycle can prolong the antidepressant effect of sleep deprivation.⁴³ In a subsequent study, Riemann and colleagues (1999) compared the ability of sleep phase advance and sleep phase delay to preserve the antidepressant effects of total sleep deprivation. They hypothesized that sleep phase advance would be more effective in preventing relapse in responders to the treatment. Among their original sample of 54 depressed patients, 77.2 percent were found to be responders to total sleep deprivation and were randomized to either the phase-advance or phase-delay experimental condition. After 7 days, 75 percent of the sleep phase–advance patients were still stabilized, compared with only 40 percent of the sleep phase–delay patients. (See also the later section on therapeutic sleep deprivation.)

Phase Instability: Evidence from Longitudinal Studies of Temperature and REM Propensity

As reviewed in the first edition of this text, findings of a few longitudinal case studies suggest a dramatic correspondence between changes in the circadian temperature rhythm and manic-depressive cycling. In two cases (Pflug et al., 1976, 1981; Wehr and Wirz-Justice, 1982), the temperature rhythm was advanced by several hours during the switch into depression. In two other cases (Pflug et al., 1981), temperature rhythms were advanced, then later delayed during the course of depressive episodes. In three cases (Kripke et al., 1978), temperature rhythms were advanced continually through all phases of the manic-depressive cycle. Only one study monitored both sleep EEG and temperature in the same patient (Wehr and Wirz-Justice, 1982). In that study, before the patient switched into depression, advances occurred in the phase position of the temperature rhythm that

were accompanied by advances in the temporal distribution of REM sleep within the sleep period. Although not inconsistent with a circadian rhythm, phase-advance model of depression, these data suggest that in cycling patients, the circadian phase position may be more related to the stage of the episode than to the state of depression or mania per se. Studying 65 inpatients with “various mental disorders” (half with major depression), Tsujimoto and colleagues (1990) found that 24-hour body temperature rhythm varied more widely in depressed and manic patients than in normal controls or schizophrenic patients.

Apparent instability of phase position may also characterize depression in noncycling patients. In studies of mixed groups of unipolar and bipolar depressed patients, Wehr and Goodwin (1983c) and Kripke (1983) found a bimodal distribution in the time of the temperature minimum, with many of the patients experiencing both modes (early and late) when sampled on different days. Thus there may be, on the one hand, a certain phase instability inherent to depression, perhaps reflecting poor entrainment by environmental zeitgebers, and, on the other hand, a phase instability linked to shifting phases of bipolar illness. Since the stability of a circadian system is positively correlated with amplitude (Aschoff and Wever, 1980; Wever, 1980), we next consider the amplitude of circadian rhythms in affective disorders.

Amplitude of Circadian Rhythms: The Temperature Dysregulation Hypothesis

As reviewed by Duncan (1996), an elevated nocturnal temperature is frequently reported in depressed patients, while increased diurnal temperature and a blunted circadian amplitude are sometimes noted. Schulz and Lund (1985, pp. 70–71) hypothesized that alterations in the timing of REM sleep could be explained by a “flattening of the arousal cycle. . . [I]ndicators of this hypothetical arousal cycle are measures of subjective sleepiness and body core temperature.” The authors based this hypothesis on their earlier finding (Schulz and Lund, 1983) that subjects with sleep-onset REM periods (perhaps reflecting phase-advanced REM) had significantly reduced amplitude of the circadian temperature curve (peak-to-trough difference) compared with those without such periods. The findings of research on the amplitude of the temperature rhythm in depressed patients are inconsistent, perhaps reflecting differences in the populations of “depressed” patients studied. Thus elevated nocturnal temperature is reported by some authors, whereas blunting of or no change in the temperature rhythm is noted by others.⁴⁴

A variety of antidepressant treatments, including tricyclic antidepressants, ECT, bright light, sleep deprivation, and phase-advance treatment, have been reported to increase

circadian amplitudes of temperature, cortisol, or TSH in patients. More recently, experimentally lengthening the duration of the dark period has been shown to increase the amplitude of circadian rhythms and been proposed as one of the plausible theoretical premises for the application of extended rest and darkness in the treatment of rapid-cycling bipolar illness (Wehr et al., 1998), as described in more detail below.

If relatively low-amplitude rhythms were somehow intrinsic to recurrent depression or bipolar illness, one would expect such rhythms to be more vulnerable to perturbation by internal or external influences, since the stability of a circadian system is positively correlated with amplitude (Aschoff and Wever, 1980; Wever, 1980). Not only do the frequency and timing of environmental zeitgebers vary considerably under normal conditions, but the dramatic behavioral shifts associated with manic-depressive illness (especially the bipolar subgroup) also multiply this variability. Thus, blunted amplitudes associated with affective disorder would be expected to be associated with phase instability. For example, using actigraphic recordings, Jones and colleagues (2005) have demonstrated that bipolar patients, even in recovery, have less stable and more variable circadian activity patterns than normal controls. This decreased stability/increased variability in activity patterns has recently been reported among individuals deemed to be at risk for bipolar disorder as defined by a threshold score on the Hypomanic Personality Scale (Meyer and Maier 2006).

One explanation for decreased circadian amplitude is poor entrainment by external zeitgebers (Aschoff and Wever, 1981), as observed in normal individuals isolated from time cues under free-running conditions. Such reduced or irregular entrainment—initially the consequence of depression (due, e.g., to loss of social zeitgebers during withdrawal)—could then feed the depression through the resulting disturbance in rhythms (Ehlers et al., 1988).

In this context, it is necessary to consider a paradox. Lewy and colleagues (1981, 1985) found that, compared with normal controls, bipolar (but apparently not unipolar) patients (Cummings et al., 1989; Lam et al., 1990) are supersensitive to light, as reflected by a lower threshold required to reduce nighttime plasma melatonin levels; moreover, this supersensitivity appears to be state independent. However in a subsequent study of euthymic bipolar patients subjected to a 500 lux light between 2 AM and 4 AM on one night and left in the dark for a comparable time period on another night, no group-level differences in melatonin suppression were found among the bipolar group, the unipolar group, and controls (Nurnberger et al., 2000). While the hypothesis that bipolar patients have an increased sensitivity to light was not confirmed, abnormalities in melatonin secretion were found in the bipolar-I subgroup.⁴⁵

If increased sensitivity to light is a trait marker of at least some bipolar patients, how can one posit decreased entrainment of zeitgebers? First, although light is indeed important to entrainment, it is hardly the only influence, since activity and temperature are important as well. Second, one could view the increased sensitivity to light as compensatory, that is, an attempt to offset the reduced entrainment due to either the compromising of other zeitgebers (e.g., activity) by the illness or an intrinsic defect in the clock mechanism. The latter possibility is particularly interesting in light of evidence that monkeys with lesions in the SCN can compensate by becoming more sensitive to certain zeitgebers (Van Cauter and Turek, 1986). The inverse relationship is also possible: that the phase instability is primary, producing the appearance of low amplitude when individual data are averaged for a group. We might refer to this as a smearing effect. In the extreme, if individuals' phase positions were randomly distributed along the time axis, the group mean would exhibit no circadian rhythm. If the group-average pattern were simply smeared by interindividual variability, the average amplitude for the group would appear to be decreased (Wehr and Goodwin, 1983c).

The preceding discussion is relevant only to phase instability. What about the apparent tendency for this instability in phase position to express itself as a phase advance? One situation that might produce both instability and a bias toward advance would be a clock with an intrinsic period length of about 24 hours—faster than the normal period of the rest–activity cycle in humans when measured under free-running conditions, which, as noted earlier, is longer than 24 hours in the majority of individuals. Findings of basic research on the factors that determine circadian phase position under conditions of entrainment (Pittendrigh and Daan, 1976; Wever, 1979) indicate that the faster the intrinsic period of the pacemaker or clock, the earlier its phase position relative to the entraining schedule—that is, it is relatively phase advanced. Furthermore, if the intrinsic period of the clock is just fast enough so that it happens to coincide with the external day–night cycle (i.e., 24 hours), it might be expected to wobble, that is, to be unstable. This is the case because under normal conditions, the intrinsic period is slower than 24 hours, a discrepancy that produces constant tension in the system: the 24-hour environmental light–dark cycle continuously pulls backward the intrinsic 25-hour clock. This constant tug of the environment on the internal circadian mechanisms would be expected to provide stability. Under conditions in which the intrinsic period of the clock is very close to the external day–night cycle, little or no tug or tension exists, and the clock is free to wobble. This mechanism would link the

evidence of a faster-than-normal clock in some patients with the findings of phase instability and the tendency toward advance.

As discussed in the first edition of this text, another possible explanation for phase advance is an increased sensitivity to zeitgebers. Given that in humans the intrinsic period of the circadian pacemaker is slower than that of the day–night cycle, environmental zeitgebers tend to pull the pacemaker closer to 24 hours, and a pacemaker that is more sensitive to zeitgebers might be expected to assume a relatively more advanced phase position (Wever, 1979). Relevant to this observation is the finding just noted—that in some studies, bipolar patients apparently have an increased sensitivity to light, which appears to be independent of the state of illness.⁴⁶ It is important to mention, however, that melatonin suppression by light is not equivalent to phase shifting by light, and future phase-shifting experiments are needed to sort this out. Obviously, the many gaps and even some apparent contradictions in the circadian literature preclude a complete synthesis. Clinical heterogeneity is a major confounding variable and may well explain apparent contradictions.

Throughout this discussion, we have referred, explicitly or implicitly, to the concept of a closed loop involving the circadian system and the phenomenology (and biochemistry) of depressive and manic episodes. We return to this subject here because it remains the most significant conceptual challenge in interpreting the circadian literature. Until we have more data from manic-depressive patients studied under forced desynchrony, we will be unable to answer the question of whether a disturbance in the function of the circadian clock is primary, and therefore driving the symptoms, or is itself simply a physiological symptom secondary to the large shifts in mood, sleep, and behavior that characterize the illness. This possibility deserves further consideration in light of evidence showing that behavioral arousal may feed back directly to the circadian pacemaker's behavior (Mrosovsky, 1988).

Mood Stabilizers and Circadian Rhythms

As reviewed in Chapter 20, lithium is effective in reducing cycling in bipolar as well as highly recurrent unipolar depression. This reduction in cycling is not immediate, nor is it immediately lost upon discontinuation of treatment. On the other hand, patients who are abruptly discontinued from lithium are at an elevated risk for increased cycling and shifting into hypomania/mania.

Lithium modifies the period and phase of circadian rhythms in species ranging from unicellular organisms to insects, mice, and humans (Klemfuss, 1992; Healy and Waterhouse, 1995; Klemfuss and Kripke, 1995). These effects, which

might be considered analogous to the effects of lithium on mood cycling, are achieved with clinically meaningful doses and do not occur immediately after initiation of the drug—as with its clinical effects, there is a lag. Most consistently, lithium lengthens the free-running circadian period across species, from single cells to whole organisms.⁴⁷ Also, there have been some reports of period-lengthening effects in normal volunteers under free-running conditions,⁴⁸ as well as phase-delayed rhythms in humans living on a 24-hour schedule (Kupfer et al., 1970; Mendels and Chernik, 1973; Kripke, 1983), which may reflect a lengthening of the period of the circadian oscillator.⁴⁹

How do mood stabilizers affect the previously discussed increased sensitivity of melatonin secretion to light in some bipolar patients? In the original studies, the increased sensitivity was reported to be greatest in patients who were medication free for at least 5 weeks, while in those taking lithium, the sensitivity was not different from that of healthy controls (Nurnberger et al., 2000). This finding is consistent with lithium's reduction of the melatonin-suppressive effect of light in healthy volunteers (Hallam et al., 2005a). Valproate has also been reported recently to reduce melatonin suppression by light in healthy volunteers (Hallam et al., 2005b). The potent mood-stabilizing effects of both lithium and valproate could, at the very least, be partially explained by their chronobiological effects, as inhibition of suppression of melatonin by light could result in an altered circadian period (specifically, a prolonged period) and thus changes in alignment between sleep–wake and biological day–night.

Clock Genes and Bipolar Disorder

As noted briefly above, certain clock genes have been associated with circadian rhythm sleep disorders⁵⁰; examples are *PER3* (Ebisawa et al., 2001; Archer et al., 2003; Pereira et al., 2005) and *CSNK1* (Takano et al., 2004) in delayed sleep-phase syndrome, and the *PER2* gene in familial advanced sleep-phase syndrome (Toh et al., 2001). Recently, linkage to and association with bipolar disorder have been examined for 10 circadian genes (*ARNTL*, *CLOCK*, *CRY2*, *CSNK1*, *DBP*, *GSK3 β* , *NPAS2*, *PER1*, *PER2*, and *PER3* (Nievergelt et al., 2005). Linkage analysis in 52 affected families revealed suggestive evidence for linkage to *CSNK1*, but this was not confirmed in an association study of 185 parent–proband triads. Through single-gene permutation tests, haplotypes in *ARNTL* and *PER3* were found to be significantly associated with bipolar disorder, the strongest association being with *PER3*. Because, as noted above, *PER3* has also been associated with circadian rhythm sleep disorder, this may represent an underlying mechanism for circadian abnormalities in bipolar disorder, as well as

overlapping features between delayed sleep disorders and bipolar disorder (Nievergelt et al., 2005). Ultimately, as Bunney and Bunney (2000) hypothesized, the circadian rhythm abnormalities in major depression and SAD may be due to altered clock genes, and genetic knowledge and technology may now be advanced enough to enable exploration of this hypothesis directly in patients. Similarly, the discovery of melatonin⁵¹ as an important molecule in circadian phototransmission is very recent, and clinical applications of this discovery can now be anticipated. (See the Web site for this volume for further information on genetic contributions to abnormalities of sleep.)

Other (Noncircadian) Mechanisms of Sleep Disturbance in Affective Disorders

The previously discussed cholinergic–aminergic hypothesis postulates that increased REM latency is secondary to increased activity of a REM excitatory cholinergic mechanism. This increased activity is accompanied by decreased activity in REM inhibitory aminergic mechanisms (including serotonin-containing raphe neurons, norepinephrine-containing neurons of the locus ceruleus, and histamine-containing neurons of the mammillary body).

Also as discussed earlier, the two-process model posits that the onset and maintenance of sleep are regulated by the interaction of process *s*, which represents a need for NREM sleep (measurable with delta power in sleep EEG), and process *c*, which reflects the circadian variation in the threshold for the onset of sleep (van den Hoofdakker and Beersma, 1985). The antidepressant effect of sleep deprivation may result from increased sleep pressure (process *s*) during prolonged wakefulness. In the future, it may be of interest to measure sleep pressure using theta waves in the waking EEG (Aeschbach et al., 1999) rather than delta waves during sleep.

EXPERIMENTAL ALTERATIONS OF SLEEP AND OTHER BIOLOGICAL RHYTHMS IN AFFECTIVE ILLNESS

One important clinical advantage of the circadian and sleep therapies listed in Table 16–1 is their shorter time lag compared with drugs or psychotherapy (Wirz-Justice et al., 2005). Box 16–1 presents the recommendations of the Committee on Chronotherapeutics in Affective Disorders of the International Society for Affective Disorders with regard to such therapies.

Despite their advantages, the current research effort on chronobiological interventions is less than what might be expected from the richness of the early findings in the field. Commenting on the relative lack of research interest even

TABLE 16–1. Circadian and Sleep Therapies for Major Depression

Therapy	Therapeutic Latency	Response Duration
Total sleep deprivation (TSD)	Hours	~1 day
Partial sleep deprivation (PSD) (2nd half of the night)	Hours	~1 day
Repeated TSD or PSD	Hours	Days/weeks
Repeated TSD or PSD with antidepressants	Hours	Weeks/months
Phase advance of the sleep–wake cycle	~3 days	1–2 weeks
TSD followed by sleep phase advance	Hours	1–2 weeks
Single or repeated TSD or PSD followed by light therapy	Hours	Weeks
Single or repeated TSD or PSD followed by phase advance and light therapy	Hours	Weeks
Single or repeated TSD or PSD combined with lithium, pindolol, or SSRIs	Hours	Months
Light therapy (winter seasonal MDD)	Days	Weeks/months
Light therapy (nonseasonal MDD)	Weeks	Weeks/months
Light therapy with SSRIs (nonseasonal MDD)	1–2 weeks	Weeks/months
Dark or rest therapy (for rapid cycling or mania)	Days	Throughout maintenance of treatment

MDD=major depressive disorder; SSRI=selective serotonin reuptake inhibitor.

in the most dramatically effective of such interventions—sleep deprivation—Wirz-Justice (2005) wrote:

In our opinion, two factors may be responsible for the current lack of interest [in sleep deprivation]. First, considerable relapses were frequently observed after recovery sleep. Second, the dominance of pharmacology and neurochemistry in research on pathogenesis and therapy of psychiatric disorders may be responsible. It is difficult to obtain funding for non-pharmacological and non-neurochemical clinical research (the same is true for another efficacious antidepressant modality, light treatment). Nevertheless, the rapidity and the magnitude of the clinical changes brought about by [sleep deprivation] and sleep still remain highly intriguing and may provide clues for understanding the pathophysiology of depression. In fact, it is surprising that no pharmaceutical company has focused on this model in the search for that

much-needed rapid-acting antidepressant; don't clinicians want a drug that works within a day?

Therapeutic Sleep Deprivation

After observing the effects of sleep on severely depressed patients, clinicians have from time to time concluded independently that sleep itself exacerbates depression. Ostefeld (1986) reported that this clinical observation was one of several that led him to try iatrogenic asomnia to treat a manic-depressive patient in 1954 at a time when ECT was the only available treatment known to be effective. Since then, investigators using sleep deprivation and many other experimental manipulations of sleep have produced a body of evidence suggesting that the dramatic changes in the timing and duration of sleep during manic and depressive episodes are not mere epiphenomena.

BOX 16-1. Recommendations of the Committee on Chronotherapeutics in Effective Disorders

The Committee on Chronotherapeutics of the International Society for Affective Disorders (ISAD) reviewed the evidence as of 2004 and made the following observations and recommendations (Wirz-Justice et al., 2005):

1. *Wake therapy* (i.e., sleep deprivation) is the most rapid antidepressant available today: approximately 60% of [depressed] patients, independent of diagnostic subtype, respond with marked improvement within hours. Treatment can be a single or repeated sleep deprivation, total (all night) or partial (second half of the night). Relapse can be prevented by daily light therapy, concomitant administration of [selective serotonin reuptake inhibitors], lithium (for bipolar patients), or a short phase advance of sleep over 3 days following a single night of wake therapy. Combinations of these interventions show great promise.
2. *Light therapy* is effective for major depression, not only for seasonal subtype. As an adjuvant to conventional antidepressants in unipolar patients, or lithium in bipolar patients, morning light hastens and potentiates the antidepressant response. Light therapy shows benefit even for patients with chronic depression of 2 years or more, outperforming their weak response to drugs. This method provides a viable alternative for patients who refuse, resist, or cannot tolerate medications, or for whom drugs may be contraindicated, as in antepartum depressive symptoms.
3. Given the urgent need for new strategies to treat patients with residual depressive symptoms, clinical trials of wake therapy and/or adjuvant light therapy, coupled with follow-up studies of long-term recurrence, are a high priority.

It is now well established that total sleep deprivation (Pflug and Tölle, 1971) and, in some studies, even partial sleep deprivation in the second half of the night (Schilgen and Tölle, 1980) can induce temporary remissions in depressed unipolar and bipolar patients.⁵² In their meta-analysis, Wu and Bunney (1990) reported that 50–60 percent of patients showed a temporary improvement in mood following total sleep deprivation, with 80 percent sinking back into depression after one night of sleep. Indeed, as noted earlier, even a nap has been found to result in relapse of depressed mood in 50 percent of patients (Wiegand et al., 1987), with morning naps being more detrimental than those in the afternoon (Weigand et al., 1993). This rapid loss of efficacy may help explain why interest in sleep deprivation in the United States has lagged behind that in Europe despite the treatment's established therapeutic

value. Wehr and Sack (1988, p. 208) emphasized the importance of sleep deprivation studies:

The single most important argument that sleep is an important factor in mental illness is the observation that sleep deprivation rapidly induces remissions in the majority of depressed patients, and induces mania in bipolar patients, and that recovery sleep after sleep deprivation rapidly induces depression in the majority of patients who have responded to sleep deprivation.

Are there differences between unipolar and bipolar patients in the efficacy and safety of response to sleep deprivation? From the occasionally dramatic mania-inducing effect of losing one night of sleep, one might presume a more intense effect in bipolar patients. Indeed, Barbini and colleagues (1998) reported that bipolar patients had a greater response than unipolar depressed patients to three cycles of total sleep deprivation and, contrary to some expectations, that no unipolar patient switched to bipolar during the treatment. It is not known, however, what proportion of the unipolar group had the more recurrent forms of unipolar depression (which in some patients may be associated with a diathesis for bipolar disorder). Another intriguing observation of this study is that subjective ratings of mood (on visual analogue scales) improved only in the bipolar group.

A large study of 206 bipolar depressed patients who underwent three nights of sleep deprivation alternated with three nights of sleep (Colombo et al., 1999) found that the risk of switch into mania was 4.85 percent and into hypomania was 5.83 percent (the rate of antidepressant response was not reported). Initial estimates suggested a risk of one in four bipolar patients, but these estimates were based on a small population of patients with a history of rapid cycling, a subgroup especially vulnerable to mood switches.

In general, there is a feed-forward relationship between sleep deprivation and mania in bipolar patients (the mania maintaining insomnia and arousal) (Wehr et al., 1987), in contrast to a feedback relationship between sleep deprivation and fatigue (causing sleepiness) in nonbipolar depressed patients. Lenox and colleagues (2002) hypothesized the response to sleep deprivation to be a genetically heritable condition and possibly an endophenotype of bipolar illness (Lenox et al., 2002).

Predictors of response to sleep deprivation include diurnal variation in mood, with spontaneous improvement in mood occurring in the afternoon and evening hours (Reinink et al., 1990); increased diurnal variation in mood independent of the direction (Reinink et al., 1993); decreased REM latency (Riemann et al., 1991), which normalizes after sleep deprivation (Duncan et al., 1980; Riemann and Berger, 1990); and “endogenous” rather than “reactive” or

“neurotic” features of depression (Wu and Bunney, 1990). Gender, age, previous hospitalizations, severity of depression, and duration of depressive episodes do not predict response to sleep deprivation (Kuhs and Tölle, 1991). The less tired (Bouhuys et al., 1995) and more aroused a patient is prior to sleep deprivation (Van Den Burg et al., 1992), the better is his or her response to the treatment. As noted earlier, some but not all studies have found a greater response in bipolar than in unipolar patients, but the clinical features just reviewed are generally not controlled for in these comparisons.

If neither placebo nor gross confounding factors account for the effects of sleep deprivation, could the explanation be as simple as the fatigue disinhibiting brain sites that modulate the expression of depressive affect or inhibiting centers that mediate depressive affect? In fact, this is the essence of a hypothesis that the influence of some subcortical areas having both an alerting and a depressogenic effect is decreased in parallel with the fatigue induced by sleep deprivation (Van Den Berg et al., 1992; Bouhuys et al., 1995).

As to the question of what underlying neuroanatomical structures are involved in the effects of sleep deprivation, brain imaging studies have indicated that increased activity is found in the orbitofrontal cortex and anterior cingulate prior to sleep deprivation in patients who respond to the treatment, but not in nonresponders,⁵³ and that improvement in mood parallels a decrease in blood flow in these areas.⁵⁴ Mayberg and colleagues (1997) found that the ventral anterior cingulate cortex was activated in association with an antidepressant response to total sleep deprivation.⁵⁵ The anterior cingulate cortex appears to play a major role in affective regulation and cognition (Devinsky et al., 1995) and in depression (Drevets et al., 1997; Drevets, 1999).

Earlier in our discussion of the regulation of sleep, we briefly considered some of the mechanisms that may underlie the antidepressant effect of sleep deprivation. First, could it simply be a placebo effect? While this possibility cannot be ruled out, it appears unlikely given that the usual expectations of the patient being deprived of sleep tend to be negative (van den Hoofdakker, 1997).⁵⁶ Numerous factors, such as light exposure, body posture, and motor activity, are confounded with sleep deprivation, but they do not appear to be major contributors to its antidepressant effect (van den Hoofdakker, 1997).

Regarding molecular mechanisms, the cholinergic hypothesis of sleep discussed earlier appears to offer an attractive explanation of the effects of sleep deprivation because the cingulate receives cholinergic projections from the basal forebrain; however, there are as yet no direct data on cholinergic mechanisms in sleep deprivation. Data do exist that suggest the involvement of both serotonergic and dopaminergic pathways in the effects of sleep deprivation.

Implicating serotonin, Benedetti and colleagues (1999b) reported better mood amelioration with sleep deprivation in subjects with the long variant of 5-HTT-linked polymorphisms, associated with increased density of the 5-HT transporter. Moreover, sleep deprivation increases brain serotonin turnover in rats (Asikainen et al., 1997) and increases firing in the serotonergic neurons in the raphe (Gardner et al., 1997). In bipolar patients, pindolol, a 5-HT_{1A} autoreceptor blocker (which blocks the receptor that puts the break on the release of serotonin, thereby enhancing serotonin release) was found to increase the antidepressant response to sleep deprivation and decrease the tendency to relapse after the procedure (Smeraldi et al., 1999). It appears that the role of serotonin in the effects of sleep deprivation is complex, and some of the data are conflicting. In one study, for example, sleep deprivation in rats resulted in reduced rather than increased serotonin and 5-HIAA in the frontal cortex (Borbely et al., 1980). And not only did Neumeister and colleagues (1998a,b,c) fail to find a hypothesized blocking of the effects of sleep deprivation with tryptophan depletion (which decreases brain serotonin), but they also noted that tryptophan depletion could actually block relapses back into depression.

Gerner and colleagues (1979) reported increased concentrations of homovallinic acid (HVA), a metabolite of dopamine, in the cerebrospinal fluid of responders to sleep deprivation, but not in nonresponders (Gerner et al., 1979). Related to this finding is that of Ebert and colleagues (1994): compared with nonresponders, responders had significantly greater displacement of a ligand for the D₂ receptor after sleep deprivation, a result suggesting dopamine receptor activation. Rigidity, bradykinesia, and gait disorder improve in patients with Parkinson's disease after therapeutic sleep deprivation (Demet et al., 1999), which could also reflect enhanced dopamine function (alternatively, it could reflect an anticholinergic effect of sleep deprivation). However, other studies have failed to find an association between sleep deprivation and dopamine enhancement. For example, Benedetti and colleagues (1996) reported that a dopamine receptor agonist (stimulant) blocks rather than enhances the effects of sleep deprivation. Thus the involvement of dopamine receptor regulation in the clinical effects of sleep deprivation is probably complex. Can sleep deprivation be considered analogous to the effect of an antidepressant drug? Given the rapidity of onset as well as the transient nature of the antidepressant effect of sleep deprivation compared with the lag and the more sustained response seen with antidepressants, a more reasonable pharmacological analogy might be with psychostimulants, whose effect on dopamine (enhancing release from presynaptic stores) is both immediate and relatively short-lived (Ebert and Berger, 1998).⁵⁷

It has been speculated that the therapeutic effect of sleep deprivation does not depend on the loss of sleep per se but is associated with not being asleep in the second half of the night. Thus Sack and colleagues (1988) compared the effects of an equivalent amount of sleep loss (4 hours) in either the first or second half of the night. Improvement was associated only with the latter. Because REM sleep is distributed predominantly in the second half of the night, this finding led to speculation that sleep deprivation may act by suppressing REM sleep.⁵⁸ Indeed, Vogel and colleagues (1980) deprived patients of REM sleep with selective nocturnal awakenings over a 3-week period and found that a 50 percent reduction in REM sleep had a significant antidepressant effect. However, REM deprivation alone cannot account for the immediate effects of sleep deprivation, since it usually requires several weeks to produce an antidepressant effect.

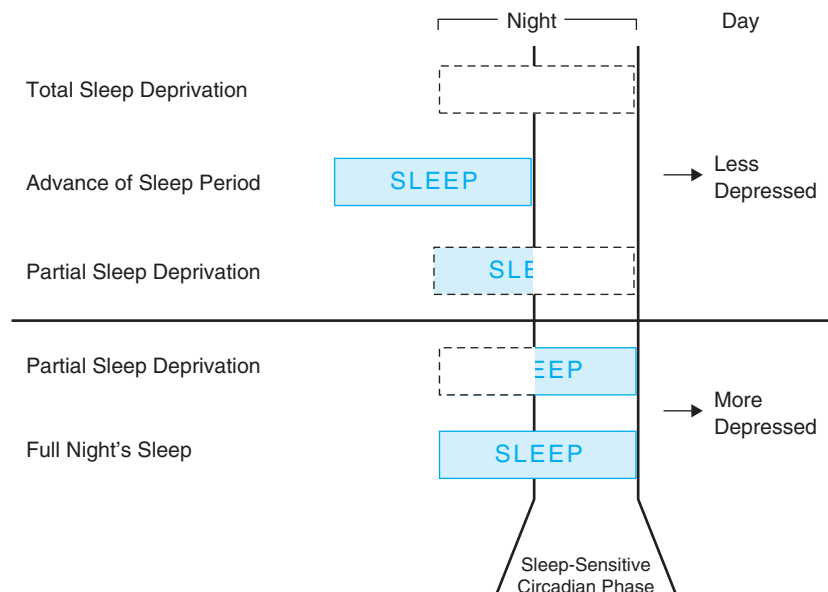

Combinations of sleep deprivation and other treatment options have been attempted to either extend the duration of mood improvement gained through sleep deprivation alone or augment or hasten the effect of the other treatments. For example, total sleep deprivation was found to hasten the effect of fluoxetine in treating major depression (Benedetti et al., 1997). Another treatment with antidepressant effects—bright light (but not dim light), discussed in more detail later—was used to maintain the beneficial effects of sleep deprivation in patients with major depression (Neumeister et al., 1996). In this context, it is of interest that response to sleep deprivation predicts response to light therapy in both seasonal and nonseasonal depression (Fritzsche

et al., 2001). In bipolar depressed patients, Colombo and colleagues (2000) found that light treatment in combination with lithium maintained the improvement in self-reported mood achieved with total sleep deprivation.⁵⁹ This finding is consistent with that of Smeraldi and colleagues (1999) that lithium successfully stabilized the antidepressant effect of sleep deprivation for 3 months in 13 of 20 bipolar patients (versus a stable antidepressant effect of sleep deprivation in only 2 of 20 patients not on lithium) (Smeraldi et al., 1999).

An obvious question is whether sleep deprivation in bipolar patients will precipitate mania or hypomania or increase mood cycling. Although the Committee on Chronotherapeutics of the International Society for Affective Disorders concluded that the rates of switch into mania or hypomania are similar to those associated with the newer antidepressants (Colombo et al., 1999; Wirz-Justice et al., 2005), we would recommend caution in the use of this treatment for bipolar-I patients, especially those with a history of rapid cycling (or an otherwise unstable course) and/or a history of psychotic mania. And, of course, sleep deprivation should not be undertaken unless and until the patient is on a mood stabilizer—the same recommendation we make with respect to the initiation of antidepressants.

As noted earlier, in addition to sleep deprivation, advancing the entire sleep period by 4–6 hours (sleep phase advance) has been shown to produce antidepressant effects, further suggesting that the effects of sleep deprivation may depend less on the amount of sleep than on its timing. These relationships are illustrated in Figure 16–6. In contrast with sleep deprivation, the improvement seen

Figure 16–6. Relationship between the timing of sleep and the antidepressant effect of sleep deprivation. (Source: Wehr and Goodwin, 1981.)

with ongoing sleep phase advance is more stable. One possible explanation for the efficacy of sleep phase advance is a realignment of the sleep–wake cycle with other circadian endogenous rhythms, such as cortisol and temperature, which tend to occupy a phase-advanced position in major depression.

Initiating sleep phase advance (Sack et al., 1985) in the evening following total sleep deprivation (as it is easier to fall asleep at 5 PM after a night without sleep) maintains the antidepressant effect of sleep deprivation in a proportion comparable to that of treatment with antidepressant medication.⁶⁰ Benedetti and colleagues (2001a) observed that, compared with unmedicated patients, those taking lithium showed greater improvement with a combination of total sleep deprivation and sleep phase advance. The authors explained their results as a double action to realign sleep–wake with other biological rhythms, the sleep phase advance bringing sleep earlier and lithium delaying the metabolic rhythms.

Extended Rest–Dark Period as a Treatment for Rapid Cycling

Given the above-noted vulnerability of bipolar patients to sleep deprivation and their apparently increased sensitivity to light (Wehr et al., 1993; Wehr, 1996), the modern use of artificial light into the nighttime may be detrimental for bipolar patients as it may modify the duration and timing of sleep, thus altering circadian rhythms. Wehr and colleagues (1998) attempted to stabilize a bipolar patient who was rapidly cycling despite being on mood stabilizers by depriving him of light for 14 hours (keeping him in the dark from 8 PM to 6 AM) each night for several weeks. His highly unstable mood and sleep cycles were stabilized (Wehr et al., 1998).⁶¹ Another group reported on a treatment-resistant rapidly cycling bipolar patient in whom extended darkness and bedrest for 10 hours resulted in immediate mood stabilization, initially in the depressed range and then, following the addition of midday light treatment, in the euthymic range (Wirz-Justice and van den Hoofdakker, 1999; Wirz-Justice et al., 1999a,b).⁶²

Interpersonal and Social Rhythm Therapy

Frank and colleagues (2000) built on the intimate relationships among mood, the circadian system, and the sleep–wake cycle, as described in the first edition of this text, to design interpersonal and social rhythm therapy (IPSRT). The central concept of IPSRT is that a manic switch is often preceded by a disruptive social event, such as death and bereavement, which may entail a combination of psychosocial challenge, threat or loss, and sleep deprivation (Wehr and Goodwin, 1983b; Malkoff-Schwartz et al., 1998; Ashman et al., 1999).⁶³ IPSRT is discussed in Chapter 22.

SEASONAL RHYTHMS AND RECURRENT AFFECTIVE DISORDERS

Melancholy occurs in autumn whereas mania in summer.

—*Posidonius, fourth century*

Repeatedly I saw in these cases moodiness set in autumn and pass over in spring, “when the sap shoots in the trees,” to excitement, corresponding in a certain sense to the emotional changes which come over even healthy individuals at the changes of the seasons.

—*Emil Kraepelin, 1921, p. 139*

[T]he gloom of the Arctic night sets in, and although the Eskimos spent their time telling stories and legends and tried hard to amuse us, I could notice a depression among ourselves, as well as among the people . . . that reached its climax at Christmas . . . we were all very blue.

—*Frederick A. Cook, M.D, Surgeon to the Peary Arctic Expedition, 1894*

The clinical lore surrounding affective disorders has alluded to their seasonal nature since ancient times. Seasonal trends emerge in the epidemiology of populations of patients, and seasonal patterns become evident in the course of manic-depressive illness in individual patients. Onsets of episodes tend to cluster in the spring and fall, especially among those prone to annual recurrences. As Wehr and Rosenthal (1989) pointed out, these patterns imply that environmental changes can both cause and ameliorate episodes of affective illness.

Nineteenth-century psychiatrists, unlike those of today, had the opportunity to observe the course of untreated manic-depressive illness for long periods (see Chapter 1). Several leading psychiatrists of the era⁶⁴ recorded many cases in which the pattern of recurrence was seasonal. In one pattern, depressions began in spring and summer. In another, the onset of depression occurred in fall or winter, while mania or hypomania appeared in the summer. These patterns also emerge in longitudinal data published by Bastrup and Schou (1967) in their now-classic lithium studies and by Kukopulos and Reginaldi (1973). Analysis of the frequency distribution of the cycle lengths of episodes drawn from a longitudinal study of 105 bipolar patients (Zis and Goodwin, 1979) shows a very large peak at 12 months, with smaller peaks at subsequent multiples of 12 (see Fig. 16–7). Although reporting bias may account for some of these findings, it is probably not sufficient to explain the magnitude of the seasonal effect.

Slater (1938) was the first to apply systematic statistical analysis to the study of seasonal patterns among manic-depressive patients. He noted that for each patient, recurrences were significantly more likely to occur at the same

Figure 16-7. Seasonal variation in the length of the photoperiod and in its rate of change: relationship to seasonal peaks in depression, mania, and suicide. (Source: Zis and Goodwin, 1979.)

time of the year than at random; that is, variability in the month of onset for any one patient was less than half the variability among patients. The study of seasonality did not resurface in the literature for nearly half a century. In the early 1980s, Goodwin's group at NIMH (Rosenthal et al., 1985) identified a specific syndrome—winter depression, one form of SAD—which since that time has been investigated extensively in the United States, Europe, Great Britain, Australia, and South America. In 1984, Rosenthal and colleagues studied recurrent winter depressions, often with summer hypomania, and published the original criteria for SAD.

Wehr and Rosenthal (1989) attributed the long hiatus in psychiatric interest in seasonality to changing fashions in theory—from the ancient humoral theories emphasizing seasonal influences to contemporary theories stressing internal psychological and biological processes. Another possible reason for the neglect may be that modern life had so shielded psychiatric observers from environmental influences that they no longer considered seasonal patterns, which in addition had become obscured by modern treatments. The authors also noted that both psychiatrists and patients may have been inclined to see episodes of affective illness as linear rather than cyclical, a shift in thinking about time that may be general in modern culture.

Physiological Mechanisms Involved in Seasonality in Mammals

Seasons are the result of the combined action of the tilted axis of the earth and its movement around the sun, which cause changes in the duration of day (photoperiod) and night (scotoperiod) with a period of 1 year. The magnitude of photoperiodic changes, as well as climatic seasonal changes (temperature, humidity, skycover, and rainfall), is directly related to latitude. Numerous species experience marked seasonal changes in physiology and behavior. Many have developed specialized neuronal circuits that detect, store, anticipate, and respond to changes in day length. Photoperiodic organisms use both absolute measures of day length and direction of day-length change to regulate their seasonal changes (see Goldman's [2001] review of mammalian photoperiodic systems). There are variations in photoperiodic responses among species, among breeding populations within species, and among individuals within single breeding populations (Goldman, 2001). This point is particularly important for understanding SAD, as individual humans differ markedly with regard to seasonality.

The SCN are not only the master circadian pacemaker (as discussed earlier) but also the central neuronal structure involved in seasonal responses (Moore, 1996a,b). Destruction of

the SCN abolishes photoperiodic responses (Schwartz et al., 2001b). SCN neurons have a higher firing rate during the daytime and less intense firing during the night, with sharp transitions around dusk and dawn, a pattern that persists in hypothalamic slices and dissociated cell cultures under constant conditions (Schwartz et al., 2001b). To understand seasonality, it is important to know that the duration of diurnal firing under constant conditions reflects the day length to which the animal has previously been exposed—shorter when the previous daylength was shorter, longer when it was longer (Mrugala et al., 2000). This suggests that the SCN cells “remember” the previous photoperiod to which they have been exposed (Jac et al., 2000a,b). Photoperiod-induced changes in melatonin secretion, as well as in SCN firing rate and other output markers of SCN activity, are ultimately determined by temporally sequenced gene expression (Hastings et al., 2001).

Pittendrigh and Daan (1976) proposed that the mammalian pacemaker consists of a morning “oscillator” (M) locking on to dawn and an evening oscillator (E) locking on to “dusk,” and that these two oscillators may be used to measure day length and adjust seasonal timing (Schwartz et al., 2001a,b). Information on day length reaches the SCN via the retinohypothalamic tract, and it modifies the duration of firing of the SCN neurons. The axons of the SCN neurons inhibit the firing of the paraventricular neurons in the hypothalamus. If uninhibited, the paraventricular neurons stimulate (via a multisynaptic pathway) the secretion of melatonin by the pineal gland.⁶⁵ Thus SCN firing ultimately results in inhibition of melatonin secretion. The duration of day length is encoded in the duration of increased SCN firing and then in the duration of time without melatonin secretion. Therefore, seasonal information starts with clock information and is then transformed into hormonal information—the duration of melatonin secretion—which in turn conveys seasonal information to other hypothalamic hormonal systems and to other organs and tissues (Malpoux et al., 1998; Morgan et al., 1999).

To what degree have these mechanisms persisted in humans? Wehr (2001) discussed this topic in detail in his review of photoperiodism in humans and other primates. He reported that neuroanatomical and physiological elements that mediate seasonality in mammals (described above) are preserved in humans. Human reproduction is not seasonal in the sense of being confined to a distinct period of the year as it is in many other mammals, including some other primates. However, it has been shown that human reproduction has a distinct seasonal variation.⁶⁶ This variation has both cultural and biological components (perhaps reflecting evolutionary forces), which would tend to shut off reproduction at certain times of the year, especially in females (Davis and Levitan, 2005).

Some humans manifest changes with season that are similar to those seen in photoperiodic mammals (animals that show marked changes in behavior in response to changes in day length, both under naturalistic conditions and in the laboratory). For example, during the late fall/winter months, some individuals become passive and less assertive, sleep more, eat more, gain weight, and have decreased interest in sex; opposite changes occur in summer (Wehr and Rosenthal, 1989; Lam and Levitt, 1999). (A summer form of SAD has also been described, as discussed further below [Wehr et al., 2001a,b]. Because the literature on summer SAD is so limited, our future references to SAD refer to the winter form unless otherwise noted.) These seasonal changes are distinct but mild in 10–20 percent of the adult U.S. population and are not associated with major depressive episodes. In 1–4 percent of the U.S. population, however, pathological changes in mood and related changes in energy, sleep, and appetite are associated with SAD. Seasonal major depression accounts for 11 percent of all major depression (Levitt et al., 2000).

Seasonality in Manic-Depressive Illness

Although there is clearly some overlap with SAD, seasonality in manic-depressive illness deserves a separate discussion. Many sources of variance confound the collection of data on seasonality in bipolar or recurrent unipolar disorder. For example, although hospital admission dates may be meaningful markers for the onset of manic episodes, they are unlikely to reflect the true onset of depressive or hypomanic episodes. In fact, hospitalizations for depression are more likely to reflect the eventual severe or suicidal phase of an evolving depressive episode than its onset. Moreover, voluntary admissions and hospital schedules (rotation of physician staff or holidays) may affect data on seasonal patterns, and diagnostic criteria vary from hospital to hospital. Despite these methodological problems, however, the consistency of findings in seasonality studies of both affective episodes and suicide is noteworthy (Eastwood and Peter, 1988). Two broad peaks are evident in the seasonal incidence of major depressive episodes: a substantial spring peak and a smaller autumn peak. This pattern tends to parallel the seasonal pattern for suicide: to date, 23 of 27 studies have reported a suicide peak in spring,⁶⁷ while many studies have also identified a suicide peak in early fall (see Chapter 8). The evidence gains further weight from the fact that virtually all the studies were carried out after the widespread use of lithium had begun, which may have dampened the natural pattern of seasonal variability. Changes in light conditions are most rapid in spring and fall, and it may be that patients with recurrent affective disorders are more susceptible to rapid changes in the photoperiod.^{68,69}

While most of the earlier studies of the seasonal incidence of depression did not differentiate bipolar and unipolar patients, some more contemporary studies, taken together, suggest that a spring peak is predominant in unipolar depression, while bipolar depression is more likely to show a (smaller) fall/winter peak.⁷⁰ A recent study of 958 consecutively admitted patients with major depression (Sato et al., 2006) found that those with “depressive mixed states” (see Chapter 1) showed a seasonal pattern similar to that of the bipolar group and different from that of the unipolar patients without such states, which is consistent with the hypothesis that these states are part of the bipolar spectrum. While the above studies employed *clinical* samples, Shin and colleagues (2005) recently confirmed the high rate of seasonality in bipolar patients compared with patients with major depression or normal controls in a large *community* sample.

Although the data on mania are somewhat more limited and therefore a bit less compelling, peak incidences tend to occur in the summer months (Takei et al., 1992). Analyzing hospital admissions, Cassidy and Carrol (2002) found that admissions for pure mania were more frequent in spring (when photoperiod increases rapidly), which coincided with the peak for total admissions for mania. However, the peak for mixed episodes was in late summer, when photoperiod starts decreasing more rapidly, and the ambient temperature is still high. Myers and Davies (1978) and Carney and colleagues (1988) showed significant correlations

between admissions for mania and total monthly hours of sunshine and average monthly day length, but not environmental temperature. Peck (1990) found that rates of mania were related to hours of sunlight in the preceding month. In England, by contrast, increased relapse of mania was not observed in any particular season, a finding that may relate to the extensive cloud cover over that country (Hunt et al., 1992; Silverstone et al., 1995).

Figure 16–8 displays these spring and fall peaks in major depression and suicide and also includes SAD, which is characterized predominantly by regularly recurring atypical depressions in winter, sometimes with hypomania in summer. The light–dark cycle shown in the figure is the principal seasonal variable of interest. Note that the overall length of the photoperiod has two extremes—longest in summer and shortest in winter—whereas the rate of change in the ratio of light to dark has two peaks—one in late winter/early spring, the other in late summer/early fall. Thus if manic-depressive patients were abnormally sensitive to seasonal light changes, this could be reflected in either opposite behavioral patterns at the two extremes (winter and summer) or behavioral disturbances in early spring or early fall, reflecting the period of rapidly increasing and rapidly decreasing light, respectively.

Moving beyond variations in photoperiod, Postolache and colleagues (2005a) hypothesized that cytokine released during seasonal inflammatory disorders may trigger decompensation/exacerbation of mood disorders in

Figure 16–8. Frequency distribution of cycle lengths among bipolar patients, showing 12-month peaks. BP-I=bipolar-I; BP-II=bipolar-II. (Source: Zis and Goodwin, 1979.)

vulnerable individuals. In a U.S.-wide epidemiological study, women showed at least a doubling of the rate of suicide during periods of high tree pollen counts (tree pollen has a massive peak in spring), after adjustment for environmental light (Postolache et al., 2005b). Consistent with a possible effect of allergens in exacerbating spring-time depression and triggering suicide in women, preliminary research found increased gene expression of cytokines to be involved in allergic reactions in the orbital cortex of female victims of suicide (Tonelli et al., 2005). Recently, moreover, in female Brown Norway rats, sensitization to tree pollen produced anxiety- and depression-like behavioral changes and activation of molecular and cellular mediators of allergy within the brain (Tonelli and Postolache 2006).

In one study on twins discordant for bipolar-I disorder in Finland, the twins with the disorder reported greater seasonality of mood and sleep length and a greater positive response to sunny days compared with their healthy co-twins (Hakkarainen et al., 2003). It is important to note that morningness–eveningness did not differ between bipolar patients and controls, an observation that argues against a circadian phase change difference underlying the greater seasonality of mood in the bipolar twins.

Diagnostic Criteria for Seasonal Affective Disorder

As noted earlier, Rosenthal and colleagues (1984) first published criteria for diagnosing SAD. By 1987, criteria for a seasonal pattern of mood disorders had been incorporated into the *Diagnostic and Statistical Manual (DSM)-III-R*. Table 16–2 compares the original criteria of Rosenthal and colleagues with the broader criteria of DSM-IV, which encompass other seasonal patterns. We consider the Rosenthal criteria to be superior to the DSM-IV criteria because they better reflect both the biological nature of the disorder and its clinical course.⁷¹

Epidemiological Studies of Seasonal Affective Disorder

Relationship between Seasonal Affective Disorder and Bipolar Disorder

At the time the first edition of this text was written, the literature indicated that on average, about half of those with SAD were bipolar, primarily bipolar-II. In the subsequent literature, which has employed the broader DSM-IV definition of SAD, estimates of the proportion of patients with SAD who also meet criteria for bipolar disorder have been lower, but no consensus has emerged. It is important to consider the extent to which the dissociation between SAD and bipolar disorder reflects nature. If most SAD is not a variant of bipolar disorder, attempts to integrate circadian

studies of SAD with those of bipolar disorder will be misleading.

Ethnicity

According to a review by Magnusson (2000), the prevalence of SAD (diagnosed using criteria based on the Seasonal Pattern Assessment Questionnaire) across 20 retrospective studies varied from 0 to 9.7 percent. Winter SAD was found to be more prevalent than summer SAD in all but four studies—three in China and Japan (Ozaki et al., 1995a; Han et al., 2000a) and a fourth in the tropics (Morrisey et al., 1996). It may be that a specific ethnic factor, genetic or environmental, protects those of Asian ethnicity from winter SAD and makes these individuals more vulnerable to summer SAD.⁷² Given the size of the Chinese population, summer SAD is not a small problem at the global level.

Latitude and Weather

Initial studies using the Seasonal Pattern Assessment Questionnaire found an effect of latitude, with winter SAD being more prevalent at higher latitudes, a finding consistent with the hypothesis that the disorder is caused by reduced light in the winter. Of three studies that examined the effect of latitude in Scandinavia, however, only one found such an effect; a latitude effect was observed in Japan, but not in Italy or Australia (Magnusson, 2000). Studies using DSM-IV criteria instead of the Seasonal Pattern Assessment Questionnaire applied to large populations found no latitude effect (Blazer et al., 1998, reviewed by Magnusson, 2000). A possible explanation may be that latitude is only a small predictor of how much sunlight people will actually receive, since meteorological conditions such as cloud cover may have an effect. Wacker and colleagues (1992), however, found no difference in the prevalence of SAD between regions that were predominantly sunny and those that were overcast in Switzerland. Similarly, a study in Iceland found no differences between those who worked outdoors and those who worked indoors (Magnusson and Stefansson, 1993). As with all studies failing to find a difference, however, the possibility of type II error (false negative) must be assessed for these studies. In sum, the literature on weather effects is mixed, with some studies reporting correlations with sunshine and/or temperature and others not (reviewed by Magnusson et al., 2000).⁷³ What these mixed findings may suggest (other than type II error) is that SAD is more likely to be related to the direction of changes in day length than to its absolute value (Wehr et al., 2001a,b).

Acclimatization

Is SAD a dysfunctional response, or is it adaptive? Over time, does longer exposure to a higher latitude result in more drastic and consolidated behavioral changes, or do

TABLE 16–2. Criteria for Seasonal Affective Disorder and Seasonal Pattern

Seasonal Affective Disorder (Rosenthal et al., 1984)	Seasonal Pattern (DSM-IV, 1994)
1. Recurrent fall–winter depressions	1. Regular temporal relationship between onset of episode of affective disorder and a particular 60-day period of the year.
2. No seasonally varying psychosocial variables that might account for the recurrent depressions	2. Do not include cases in which there is an obvious effect of seasonally related psychosocial stressors (e.g., regularly being unemployed every winter).
3. Regularly occurring nondepressed periods in the spring and summer	3. Full remissions (or a change from depression to hypomania or mania) during a characteristic time of year (e.g., depression disappears in the spring).
4. At least two of the depressions occurred during consecutive years	4. In the last 2 years, two major depressive episodes have occurred that demonstrate the temporal seasonal relationships described in previous points, and no nonseasonal major depressive episodes have occurred during the same period.
5. At least one of the depressions met Research Diagnostic Criteria (Spitzer et al., 1978a) for major depression	5. The corresponding criterion is implicit here, as “seasonal pattern” is provided as a modifier of other DSM-IV diagnoses: bipolar disorder or recurrent major depression.
6. No other Axis I psychopathology	6. Seasonal episodes of mood disturbance substantially outnumbered nonseasonal episodes.

seasonal responses habituate and decrease over time? The bulk of the data support the latter conclusion.⁷⁴

Syndromal versus Subsyndromal Seasonal Affective Disorder and the Dual-Vulnerability Hypothesis

The term *subsyndromal SAD* has two definitions. The first is based on cross-sectional epidemiological studies using a seasonality questionnaire (the Seasonal Pattern Assessment Questionnaire), which defines the syndrome according to a global seasonality score above a certain cutoff point reflecting the severity of the “problems” related to seasonal changes in mood (Kasper et al., 1989b). The second definition is based on clinical interviews, and characterizes subsyndromal SAD as reflecting winter depressive episodes that are significant but do not meet the full DSM criteria for a major depressive episode (Kasper et al., 1989a).

There are two views on the difference between SAD and subsyndromal SAD. The classic one is that the difference is

mainly quantitative (Blehar and Lewy, 1990), that is, that SAD represents the extreme of a seasonality dimension (Blehar and Lewy, 1990; Avery et al., 1998). Consistent with this view is the fact that the distribution of seasonality scores in the general population is continuous (Kasper et al., 1989b; Jang et al., 1997a,b). Others postulate separate factors for seasonality and for depression, and suggest that when this dual vulnerability obtains, SAD results (Lam et al., 2001c). The trigger for the seasonal vulnerability is said to be a decrease in photoperiod, while possible triggers for depression include a seasonal loss of energy and drive with an attendant compromised ability to meet societal demands. Depending on the relative degree of loading on these two factors, different categories emerge. For example, loading on seasonality with little or no loading on depression would be expected to result in subsyndromal SAD (which consists mainly of vegetative symptoms, such as increased appetite, weight gain, fatigue, and hypersomnia). If the degree of loading on both factors is similar, the full syndrome of SAD might be expected.⁷⁵ If one has

loading on depression with little or no loading on seasonality, a nonseasonal major depression would be expected. This dual-vulnerability hypothesis was initially proposed by Young and colleagues (1991) and further developed by Lam and colleagues (2001a,b,c). Light treatment was known to be effective for both subsyndromal SAD and SAD (Kasper et al., 1989a; Norden and Avery, 1993). Subsequently, however, Lam and colleagues (2001c) showed that subsyndromal SAD (more loading on seasonality than on depression) appears to be more responsive to the treatment. On the other hand, a meta-analysis by Kripke and colleagues (1997) found that the antidepressant effect of light treatment in nonseasonal depression is equivalent to that seen in seasonal depression.⁷⁶

Pathophysiology of Seasonal Affective Disorder

There are three levels (presumably interrelated) at which one can address the pathophysiology of SAD: genetic factors, neurotransmitter dysfunction, and chronobiological dysregulation. In addition, one must look at associations between SAD and both sensitivity to light and other, non-light factors. Here we look briefly at each of these associations. An excellent, balanced review of SAD pathophysiology is that of Lam and colleagues (2000). A more detailed review of genetic and neurobiological (including chronobiological) associations in SAD, along with discussion of sensitivity to both light and nonlight factors in SAD, is provided on the Web site for this volume.

Genetic Factors

A large study involving 4,639 adult twins pairs from Australia found that genetic factors accounted for 29 percent of the variance in seasonality (Madden et al., 1996). The heritability of seasonality was associated with a preponderance of the vegetative symptoms of depression, such as increased appetite, weight gain, and increased sleep, which are also good predictors of response to light therapy (Lam et al., 1993; Sher et al., 2001). This latter association also provides circumstantial support for a dual-vulnerability model, as seasonality in appetite, weight, and sleep is associated with loading on vulnerability for seasonality as opposed to dysphoria and anhedonia, which result from loading on vulnerability for depression. Another twin study involving 339 twin pairs (Jang et al., 1997b) found a more substantial genetic contribution than that found in the study by Madden and colleagues (1996). The authors also reported that heritability accounted for more variance in seasonality in men (69 percent) than in women (45 percent). Linkage studies have reported genetic associations between SAD and the serotonin 5-HT_{2A} promoter polymorphism—1438G/A (Enoch et al., 1999)—as well as the 218C allele of tryptophan hydroxylase (Levitan et al., 1999a,b). An association between seasonality as a trait and the short allele

of the serotonin transporter promoter gene has also been reported (Postolache et al., 1998; Rosenthal et al., 1998). Replications in larger samples are awaited.

Neurotransmitter Dysfunction

It is important to note that the subjects for the studies discussed below were patients with SAD. Therefore, the degree to which the study findings are related to seasonality in manic-depressive illness, either bipolar or recurrent depression, is unknown (see the earlier discussion of the overlap between SAD and bipolar disorder).

Serotonin. Certain indirect measures of serotonin activity, such as levels of precursors and metabolites, fluctuate markedly with the seasons. For example, plasma L-tryptophan, the precursor of serotonin, is at its highest levels in spring, declining in late (Wirz-Justice and Richter, 1979) or early (Wirz-Justice et al., 1979; Swade and Coppen, 1980) fall. In a recent study of 101 healthy men in which serotonin metabolites in the jugular vein were measured, turnover of serotonin by the brain was found to be lowest in winter ($p = .013$). In addition, the rate of production of serotonin by the brain was correlated positively with the level of ambient light, and the strongest correlation was with the day of testing (i.e., the relationship was not particularly lagged) (Lambert et al., 2002). Results of animal studies indicate that serotonin content in the hypothalamus shows a marked seasonal variation, with a minimum in the winter (Carlsson et al., 1980). The major metabolite of serotonin, 5-HIAA, measured in the cerebrospinal fluid, has its trough in springtime, which may reflect low serotonergic activity during winter (Brewerton et al., 1988). Neumeister and colleagues (2001) reported reduced serotonin transporter availability in the hypothalamic/thalamic area in winter compared with summer in healthy subjects.

Because dietary carbohydrates enhance serotonin synthesis and transmission through increased tryptophan uptake into the brain (Fernstorm and Wurtman, 1971), the observation that patients with SAD feel activated following high-carbohydrate meals whereas normal controls feel more sedated (Rosenthal et al., 1989) may suggest altered serotonin metabolism in SAD. Several studies have shown that treatment with tryptophan can improve mood in patients with SAD to a degree similar to that achieved with light treatment (Ghadirian et al., 1998; McGrath et al., 1990). Tryptophan may also augment light treatment, one study finding that it converted 9 of 14 patients from nonresponders to responders (Lam et al., 1997).

The hypothesis that SAD may involve serotonin has also been examined using tryptophan depletion, by which central serotonin synthesis can be reduced. Tryptophan depletion results in a relapse of depressive symptoms in SAD

patients who formerly responded to light treatment in winter, as shown in three different studies (Lam et al., 1996; Neumeister et al., 1997, 1998a). Tryptophan depletion in summer resulted in relapse in one study (Neumeister et al., 1998a) but not in another (Lam and Levitan, 1996). The association of tryptophan depletion with depressive relapse is not specific to seasonal depression, also being seen in non-seasonal cases (Bremner et al., 1997), which suggests that the phenomenon is related more to depression than to seasonality per se. Preliminary data suggest that D-fenfluramine, a serotonin-releasing agent, may benefit SAD patients (O'Rourke et al., 1987). Selective serotonin reuptake inhibitors (SSRIs) are also effective in the treatment of SAD, as reported for fluoxetine (Lam et al., 1995) and sertraline (Moscovitch et al., 1995). When added to light treatment, citalopram improves the efficacy of the treatment in the long run, but not in the short run (Thorell et al., 1999).

One serotonergic finding appears to be specific to SAD. Whereas patients with nonseasonal major depression do not show altered hormonal or abnormal behavioral responses to the 5-HT_{2C} agonist m-chlorophenylpiperazine (m-CPP) (Anand et al., 1994), patients with SAD show blunted hormonal responses and experience "activation euphoria"—a consistent finding in both uncontrolled (Joseph-Vanderpool et al., 1993; Jacobsen et al., 1994; Garcia-Borreguero et al., 1995) and controlled (Schwartz et al., 1997; Levitan et al., 1998) studies. These changes are normalized after successful light therapy, suggesting that the response to m-CPP is a state marker in SAD.

In conclusion, there is convincing evidence that serotonergic dysfunction plays a role in SAD. Some of these abnormalities, involving either 5-HT_{2C} or 5-HT₇, may be specific to the state of winter depression rather than being associated with depression in general.

Dopamine. There is some evidence, mostly indirect, suggesting dopamine involvement in SAD. Low resting prolactin levels independent of season have been reported in SAD patients (suggesting a trait marker), a finding interpreted as reflecting upregulation of D2 receptors secondary to reduced presynaptic dopamine (Depue et al., 1989, 1990). Another presumed indicator of altered dopamine function is blunted thermoregulatory heat loss in the winter in patients with SAD compared with normal controls (Arbisi et al., 1989, 1994), which is reversed by successful light treatment. A more direct test of the dopamine hypothesis failed when a double-blind, placebo-controlled trial of L-dopa/carbidopa yielded negative results (Oren et al., 1994b). On the other hand, the antidepressant bupropion,⁷⁷ whose mechanism of action is thought to involve enhanced dopamine (and norepinephrine) function, was found to be effective in one placebo-controlled study of SAD (Modell

et al., 2005). Perhaps also consistent with dopamine involvement in SAD, findings of a recent study indicate that adults with residual attention deficit disorder may have high seasonality scores (Levitan et al., 1999a).

Norepinephrine. An inverse relationship between depression scores in patients with SAD and levels of norepinephrine metabolites in cerebral spinal fluid has been reported (Rudorfer et al., 1993). Results of other studies, however, suggest a lower plasma norepinephrine concentration in untreated SAD patients relative to controls and in untreated versus light-treated conditions (Schwartz et al., 1997). Also after light treatment, plasma norepinephrine levels (Skwerer et al., 1988), as well as norepinephrine turnover, were found to increase (Anderson et al., 1992); both of these findings are consistent with the effectiveness of bupropion, as cited above.

Neumeister and colleagues (1998c) subjected SAD patients to both tryptophan and catecholamine depletion⁷⁸ (i.e., both dopamine and norepinephrine) and sham depletion with an active placebo (benztropine). A temporary relapse in depressive symptoms resulted from both interventions, leading the authors to conclude that catecholamines, not just serotonin, are involved in the effect of light treatment on SAD.

Chronobiological Dysregulation

There are two hypotheses regarding dysregulation of seasonal rhythms in patients with SAD. The first is based on a different duration (specifically, the duration of melatonin secretion) of the internal night between winter and summer. The second is based on a shift of the phase of the circadian rhythms.

Melatonin Duration Hypothesis. According to this hypothesis, inspired by the animal literature, a longer internal night in patients with SAD matches a longer external night in winter, and this winter–summer difference in the duration of the internal (biological) night is what drives seasonal changes in behavior. This hypothesis found additional support in initial findings of an increased prevalence of SAD with a more northern latitude characterized by more drastic changes in photoperiod, although these findings were not confirmed in studies in clinical populations (reviewed by Magnusson, 2000). A consequence of this hypothesis was the administration of light in early morning (6 AM to 9 AM) and late afternoon (4 PM to 7 PM), designed to reduce the duration of winter darkness to a level similar to that in the summer.

Because in many mammals the photoperiod signal is encoded in the duration of melatonin secretion and because light suppresses melatonin secretion, it was hypothesized that light in the morning and evening reduces the duration

of melatonin secretion, bringing it to summer levels. However, suppression of melatonin secretion is not sufficient to produce an antidepressant effect (Wehr et al., 1986). Specifically, more drastic suppression, as with atenolol, a long-acting beta-blocker, did not result in improvement (Rosenthal et al., 1988). On the other hand, a short-acting beta-blocker administered in early morning resulted in maintenance of improvement in SAD patients (Schlager, 1994). A problem in the study, however, was that propranolol was administered at a time when it may have been too late to suppress the melatonin secretion in most patients, so that the study may not represent a valid test for the melatonin duration hypothesis.

A strong argument against the melatonin duration hypothesis is the effectiveness of a late-afternoon dose of melatonin (Lewy et al., 1998, 2006).⁷⁹ According to the theory, the presence of melatonin in the blood for an increased duration would make patients more depressed. The findings of two other studies are also inconsistent with the melatonin duration hypothesis. Winton and colleagues (1989) measured melatonin profiles in SAD patients receiving two schedules of combined morning and evening light treatment. Although both treatments resulted in an equivalent shortening of melatonin secretion, the antidepressant effect was greater in the treatment group with more exposure to light. Wehr and colleagues (1986) found that two regimens of light treatment were equally effective even though only one of them was expected to shorten the photoperiod. This study cannot be considered conclusive, however, because melatonin profiles were not obtained, sample sizes were small, and patients were exposed to room lighting from 7 AM to 11 PM, which could have diminished the contrast between the two conditions.

Interest in the melatonin duration hypothesis was revived after Wehr's group (Wehr, 1991a,b; Wehr et al., 1991, 1993) showed that in humans, as previously described in rodents, the duration of nocturnal melatonin secretion reflects the extent of light exposure in the immediately preceding photoperiod. Because no changes in normal volunteers were found between winter and summer, it was suggested that artificial light suppresses melatonin and thus the hormone's response to changes in photoperiod (Wehr et al., 1995). Young and colleagues (1991, 1997) found that photoperiod may be related to the onset of vegetative symptoms in SAD, symptoms that, according to the dual-vulnerability hypothesis, are an expression of seasonality more than of depression per se. Wehr and colleagues (2001a,b) found that SAD patients, but not controls, had a winter–summer difference in the duration of active melatonin secretion. This study showed for the first time that patients with SAD generate a signal of change in season similar to that used by nonhuman mammals to regulate seasonal behavior.

Circadian Phase-Shift Hypothesis. As previously described in the section on physiology of circadian rhythms, light is a potent synchronizer and shifter of these rhythms. Building on the phase-advance hypothesis of nonseasonal depression (Kripke et al., 1978; Wehr et al., 1979), Lewy and colleagues (2003, 2006) and Burgess and colleagues (2004) suggested that a phase shift in circadian rhythms is conducive to SAD. In short, the theory posits that for most SAD patients, the internal clock is phase delayed relative to the external day–night cycle. (On the other hand, Murray and colleagues [2006] could not confirm this at a statistically significant level, although trends in their data were consistent with the phase-shift hypothesis.)

An elaboration of the phase-shift hypothesis is the hypothesized misalignment between the sleep–wake cycle and other biological rhythms (such as cortisol and melatonin secretion and body temperature) and the notion that light will realign these rhythms (Lewy et al., 1987; Lewy and Sack, 1989). According to this theory, evening light should further delay the internal clock and thus be less antidepressant than morning light. Another study (Sack et al., 1990) did indeed find delayed melatonin rhythms, consistent with the phase-shift hypothesis. The authors also found that morning light resulted in a phase advance.

A subsequent study by Terman and colleagues (2001) found no relationship between dim-light melatonin onset (DLMO), a marker of circadian phase, and severity of depression; between baseline DLMO and treatment response; or between post–light treatment DLMO and depression rating (but a type II error cannot be ruled out). Moreover, after evening light, patients with larger delays were not more depressed than those with smaller delays. In support of the phase-shift hypothesis, however, the authors found a correlation between the magnitude of the phase advance to morning light and improvement in depression scores (consistent with the findings of Lewy et al., 1987b, 1998; Sack et al., 1990).

Another strength of the Terman et al. (2001) study is that it addressed the phase-angle difference between sleep and other circadian rhythms as involved in SAD (rather than the phase shift alone), requiring that the correction in phase angle by light treatment be involved in the antidepressant response (Lewy and Sack, 1988). However, Terman and colleagues (2001) found that changes in phase-angle difference between sleep onset and melatonin onset did not predict response to treatment. In fact, morning light increased the gap between sleep and melatonin onset, having a greater phase-advancing effect on melatonin rhythms than on the sleep–wake cycle. The authors wrote, “one would conclude that phase advance is neither necessary nor sufficient for the therapeutic effect” (Terman et al., 2001). The ideal scheduling for light treatment, according to the authors, would be based

on circadian time and not sleep time, and would commence 8.5 hours after melatonin onset.

The phase-shift hypothesis in SAD has received significant support from the reported improvement in depression resulting from melatonin administered in the late afternoon, at a time when it results in a phase advance (Lewy et al., 1998, 2006). Moreover, the antidepressant effect of melatonin administration was found to be correlated with normalizing circadian alignment (Lewy et al., 2006). Other support for the phase-shift hypothesis in SAD comes from constant routine studies. Because waveforms of circadian rhythms are distorted by such factors as sleep, activity, natural and artificial light exposure, and feeding, constant routine (as compared with forced desynchrony) is a relatively simple and reliable way to unmask circadian rhythms. In short, subjects are studied for 36 hours, awake in dim light and with no time cues. In constant routine conditions, patients with SAD showed phase-delayed DLMO, core temperature, and cortisol rhythm, with these abnormalities being corrected by light treatment (Avery et al., 1993; Dahl et al., 1993). Again, however, the improvement in depression was not related to the degree of phase advance.

Results of other studies, however, fail to support a phase-shift hypothesis and the phase-advance mechanism of action of light. A number of studies did not find circadian markers (body temperature, cortisol, prolactin, thyrotropin) to be phase delayed in SAD patients (Rosenthal et al., 1990; Eastman et al., 1993; Oren et al., 1996). Many tests of the phase-shift hypothesis have assessed the antidepressant response of different timings of bright light administration. To support the phase-delay hypothesis, according to the previously described phase response curve, morning light would have to improve and evening light to worsen depression. It is true that morning light is a more potent antidepressant than evening light, as shown by direct comparisons (Lewy et al., 1998; Terman et al., 1998) and by most meta-analyses (Terman et al., 1989a; Thomson et al., 1999; Vitaterna et al., 1999). However, some studies have found evening light to be as effective as morning light (Wirz-Justice et al., 1993a,b) or nearly so (Eastman et al., 1998). Most important, even as evening light was less effective than morning light, it was more effective than placebo and certainly not detrimental, as the phase-shift theory would predict. However, the large placebo component of light that varies among subjects and studies would mitigate depressant effects of shifting the clock in the wrong direction.

Several factors may account for the somewhat conflicting results of the various circadian studies addressing SAD (reviewed by Lam and Levitan, 2000). These include small sample sizes; selection of patients not always representative of the entire SAD group (e.g., including only hypersomnic patients, excluding patients with severe phase abnormality);

and masking of effects of environmental factors, sleep, activity, and social cues. Light administered at a constant external clock time may vary greatly according to individual circadian time, by up to several hours. Thus the magnitude of a phase shift will vary considerably among individuals. According to Terman and colleagues (2001), the ideal timing of light treatment is related to a circadian marker and not to clock time. However, Terman appears to have assumed that all SAD patients are phase delayed, whereas Lewy and colleagues (2006) recently confirmed that a subgroup of patients are phase advanced and should be treated with evening bright light and/or morning low-dose melatonin administration. Lewy also cautioned against overshifting across the therapeutic window (DLMO = 6 hours before midsleep).

Seasonal Affective Disorder Patients and Sensitivity to Light

A parsimonious explanation of SAD might be that light exposure in winter compared with that in summer is significantly lower in patients with SAD relative to controls. This explanation does not hold, however, as similar light exposures have been reported in normal controls and in SAD (Oren et al., 1994a) or subsyndromal SAD (Guillemette et al., 1998) patients. If light exposure does not differ between SAD patients and controls, perhaps differences in sensitivity to light may explain the behavioral differences between individuals with and without SAD. Experiments with albino rats have shown that the retina of these animals adapts to variations in ambient light, with increased sensitivity in dim light (Schremser and Williams, 1995a,b), a phenomenon termed *photostasis*. This phenomenon is believed to have evolved for adaptation to seasonal changes in illuminance (Penn and Williams, 1986). Both a hyperphotostatic (increased sensitivity) (Beersma, 1990) and a hypophotostatic (decreased sensitivity) (Reme et al., 1990) adjustment to light have been proposed as potential etiologies for SAD (although there is no evidence that photostasis exists in humans).

Measuring retinal sensitivity indirectly with an electrooculogram (EOG), Ozaki and colleagues (1995b) found a higher sensitivity in winter than in summer in normal subjects (interpreted as a compensatory mechanism triggered by a decrease in natural sunlight), whereas in SAD patients, retinal sensitivity remained constant across the two seasons. With a more accurate technique, the electroretinogram (ERG), Lam and colleagues (1992a) found lower-than-normal amplitudes (using a mixed cone-rod response) in females with SAD and higher-than-normal amplitudes in males with SAD compared with matched controls (Lam et al., 1992a). In another study, Hebert and colleagues (2002), opting to use a stimulus for the rod

system exclusively (because photostasis was described for that system), with subsyndromal SAD patients (who are less likely to have been exposed to light treatment) as subjects, found lower sensitivities to light in these patients, with a positive correlation between their global seasonality scores and a winter decrease in rod sensitivity (Hebert et al., 2002).

It is far from clear whether alterations in sensitivity to light are contributory to SAD, a consequence of neurotransmitter dysregulation in the central nervous system, or a consequence of aberrant behaviors of SAD patients. If neurotransmitter dysfunction were the cause, one would expect that light treatment, correcting the dysfunction, would normalize the patients' retinal sensitivity. However, the persistence of those abnormalities after light therapy (Ozaki et al., 1993) argues against that alternative. Finally, higher cone sensitivity (and rod adaptation) was found in SAD patients in winter than in controls in a study using self-reported dim-light detection (Terman and Terman, 1999).

Factors Other Than Light

Light treatment, although effective, does not completely shift patients with SAD from a winter to a summer state (Postolache et al., 1988). Consequently, factors other than light may be involved in seasonal changes in behavior. Two studies found a correlation between SAD symptoms and atmospheric temperature (Molin et al., 1996; Okawa et al., 1996). This finding is consistent with the animal literature showing that low ambient temperature accelerates short-day responses in seasonal animals (Larkin et al., 2001).

Findings of other studies on seasonal behavior in animals suggest that olfaction could be involved in seasonality (Nelson and Zucker, 1981; Nelson, 1990; Schilling and Perret, 1993). Postolache and colleagues (2002d) hypothesized that patients with SAD would differ from normal controls with regard to olfactory acuity. They compared olfactory detection thresholds in patients and normal controls in both winter and summer and found that patients with SAD had an ability to detect odors greatly exceeding that of the controls. The difference was statistically significant across seasons, although there was a trend for it to be more apparent in the summer.

CONCLUSIONS

Sleep reflects a critical phase of a core circadian rhythm in humans, and thus our coverage of sleep and biological rhythms belongs in the same chapter. Sleep disturbances are central to the pathophysiology of manic-depressive illness; they are not only a key symptom of both mania and depression, but also the earliest indication of major

switches in mood state. Moreover, a manipulation of sleep—sleep deprivation—while the fastest-acting antidepressant known, can all too readily switch bipolar patients into mania. And because the clinical course of manic-depressive illness, particularly the bipolar subgroup, is cyclic, the illness is itself an abnormal rhythm. Yet despite centuries-old observations of seasonal and circadian patterns of symptoms in manic-depressive illness, the physiology of these rhythms has been explored systematically only in the last two or three decades. Further, since the publication of the first edition of this text in 1990, new research on the physiology of rhythms in manic-depressive illness has been sparse, while pharmacological and basic neurobiological research has flourished. Although such physiological research is painstaking and time-consuming, it is all the more necessary today because of rapid advances in understanding the molecular biology and genetics of the circadian clock. Without a sophisticated understanding of the phenomenology and physiology of the specific rhythmic disturbances in manic-depressive patients, the full potential of the new genetic and molecular discoveries in the field will not be realized.

Heritability of circadian disturbances has been demonstrated in both humans and animals.⁸⁰ An important focus for future research would be the prevalence of these disturbances in patients with manic-depressive illness versus normal controls, as well as the prevalence of affective illness in subjects with familial circadian disturbances. The integrity of clock genes in patients with manic-depressive illness is another potentially fruitful subject for research, as is the relationship between central and peripheral oscillators, especially the amplitude, phase, synchronization, and stability of molecular rhythms in patients with bipolar and highly recurrent unipolar disorders.

Research on the melatonin receptor agonists (one, ramelteon, recently approved by the U.S. Food and Drug Administration for treatment of insomnia) represents an advance in chronobiology. Having a greater affinity for melatonin receptors and a more favorable and predictable pharmacokinetic profile, as well as lacking contaminants, the melatonin receptor agonists might be used for synchronization and shifting in placebo-control paradigms.⁸¹ Continuing work in this area is a priority for future research on the relationship between sleep and circadian rhythms and manic-depressive illness.

NOTES

1. In the United States, however, sleep deprivation remains little known and seldom used, perhaps because of its loss of efficacy after even a short nap and a society that has become increasingly concerned about the consequences of sleep loss.

2. Active at and around dawn or dusk.
3. Earnest and colleagues (1999) noted that the difference between an oscillator and a pacemaker is the ability to orchestrate and direct rhythmicity in other cells, resulting in behavioral changes at the organismic level. A diffusible substance from these SCN cells is able to induce and is also necessary to maintain rhythmicity in cocultured fibroblasts (Allen et al., 2001).
4. Welsh and colleagues (1995) showed that a spontaneous action potential could be recorded from individual SCN cells weeks after they had been dispersed and cultured. When the same method was used with SCN neurons from *tau* mutant hamsters (Liu et al., 1997b) and *clock* mutant mice (Herzog et al., 1998), which have altered circadian cycle lengths, it was shown that alterations in cycle length are present in the electric potential of individual cells. Moreover, variation in sensitivity to circadian phase-shifting agents is a property not only of the SCN but also of individual cells (Liu and Reppert, 2000). Thus as the clock was identified inside each cell, its molecular components were not merely supportive elements of the clock; rather, they made up the clock itself.
5. *Clock* was the first gene cloned in mammals. In heterozygous mutant mice with the *clock* mutation, the circadian period is abnormally long. In homozygous *clock* mutants, complete arrhythmicity follows after the animals are placed in constant darkness (Vitaterna et al., 1994).

The products of *Cryptochrome* genes (*mcry1* and *mcry2*), the mCRY proteins, are the negative regulators in the clock. The identification of *cry* as a clock gene in mammals came as a surprise, given that the cryptochromes function as circadian blue-light photoreceptors in plants and insects. The importance of *mcry* to the clock was demonstrated using targeted deletions: deletion of *mcry1* alone lengthens circadian period, deletion of *mcry2* alone lengthens circadian period, and deletion of both results in complete arrhythmicity in constant darkness (van der Horst et al., 1999; Vitaterna et al., 1999). Three mammalian *period* genes have been identified: *per1*, *per2*, and *per3*. Although these genes were identified by homology with *Drosophila per*, the functions of the mammalian *per* appear to be very different from those of its insect counterpart. While the *Drosophila per* has an autoinhibitory effect, *mPER* proteins in mammals have little effect on the negative regulation of the clock; on the contrary, *mPER2* appears to have a positive regulatory function (Zheng et al., 1999). The role of *mPER1* and *mPER2* is not yet known.

A putative mammalian *timeless* gene has been identified (Zylka et al., 1998). While in *Drosophila*, the *tim* gene is essential for the entrainment of the clock to light, its function is unclear in mammals, as its SCN levels are not rhythmic and not altered by light pulses (Field et al., 2000). *Mtim* may be more related to the newly discovered insect gene *Timeout* and may have a developmental rather than a circadian role in mammals (Benna et al., 2000). The *cry* genes assumed in mammals the role of *tim* genes in insects.

6. See Shearman and colleagues (2000a). For recent reviews, see Reppert and Weaver (2001) and Herzog and Schwartz (2002).
7. An example is vasopressin preprorepressophysin protein, which is highly rhythmic in the SCN and augments the SCN's electrical firing.
8. Because some of the medications used in treating bipolar patients are GABAergic, it is important to note that GABA may

have a different effect on SCN neurons during subjective daytime—when in fact it appears to be excitatory—than at night, when it may be inhibitory as in the rest of the central nervous system (Wagner et al., 1997). In isolated neurons, GABA remains characteristically inhibitory, with inhibition causing phase shifts (Liu and Reppert, 2000). Many medications used for bipolar disorder enhance GABA activity, and thus may consolidate circadian rhythms through an increased excitatory role during the daytime and inhibitory role at night.

9. Despite one report that extraocular light may shift melatonin rhythms in humans (Campbell and Murphy, 1998), melatonin secretion cannot be suppressed by light in blindfolded or bilaterally enucleated subjects (Czeisler et al., 1995; Lockley et al., 1998). Moreover, only free-running (non-24-hour) cycles have been observed in bilaterally enucleated individuals (Lockley et al., 1998; Skene et al., 1999).
10. Two additional indirect pathways have been described. The first originates from the same retinal cells whose axons compose the RHT, but instead of projecting to the SCN, synapses in the intergeniculate leaflet of the lateral geniculate nucleus; then a geniculohypothalamic tract, most likely using GABA, neuropeptide Y, and enkephalin as neuromodulators, projects to the same neurons in the SCN where the retinohypothalamic tract projects. The second detour from the retina to the SCN, through the raphe nuclei, imparts a large serotonergic innervation to the SCN. These alternative pathways may play a role in nonphotic phase shifts—significantly in manic-depressive illness—including phase shifts caused by behavioral arousal (Mistlberger and Holmes, 2000).
11. Illumination of the retina induces release of glutamate at the level of the SCN. Remarkably, however, what happens after that depends on the subjective time (internal, biological, circadian) at which the stimulus is applied, similar to the behavioral effects of light. In the late night, light or, in vitro, glutamate receptor activation induces phase advances; glutamate stimulates nitric oxide production, increases cyclic guanosine monophosphate (cGMP), activates cGMP-dependent protein kinase, and phosphorylates cyclic adenosine monophosphate (cAMP)-response element binding protein (CREB) (Ding et al., 1997, 1998). In contrast, during early night, light-induced glutamate release acts via *N*-methyl-D-aspartate receptors, with release of calcium, activation of several kinases, phosphorylation of CREB, and induction of gene expression. Light or glutamate receptor activation can phosphorylate CREB only during the zone of sensitivity in the biological night or, in cardiology terms, the “vulnerable” period. That ability is absent during the subjective daytime, which is a refractory period for phase shift.
12. These efferents work by turning off a stimulatory signal from the paraventricular nucleus to the pineal via multisynaptic pathways.
13. It had been reported that the period of the free-running body temperature rhythm ranged from 24.2 to 25.1 hours (Campbell et al., 1993; Middleton et al., 1996). However, a number of factors may affect the generalizability of these findings, including knowledge of the time of day, activity, and exposure to ordinary room light. In a “forced desynchrony” protocol (Czeisler et al., 1999) involving a “28-hour day,” with bedtime scheduled to occur 4 hours later each day for more than 3 weeks under constant low light, the average circadian period was 24.18 hours, in contrast with the previously reported

period of 24.7 hours (Campbell et al., 1993). Thus the duration of the circadian period in humans is longer than 24 hours, but only slightly. In normal everyday life, the intrinsic human circadian period adjusts to 24 hours to synchronize with the environment as a result of periodic factors that serve as 24-hour time cues, or “zeitgebers.” Light is probably the principal zeitgeber.

14. For example, the PRC to light in a subject who is flown to a geographic location with a 12-hour difference from the point of departure (e.g., 2 PM is equivalent to 2 AM) will accord with the time of origin rather than that of destination.
15. Prior to the cloning of the *clock* genes, the retina was considered the only structure other than the SCN to contain a circadian clock. With the cloning of these genes, it became apparent that the *clock* genes are widely expressed, both in the brain and in many peripheral tissues, and that they oscillate independently in these tissues (Reppert and Weaver, 2001).
16. The rhythms of cortisol and sleep onset are delayed approximately 1 to 3 hours as compared with melatonin, temperature, prolactin, EEG theta waves, and REM sleep propensity rhythms (Wehr et al., 2001a).
17. In the Pittendrigh and Daan (1976) model of the rodent circadian system and in the elaboration of that model by Illnerova and Vanecek (1982), it is proposed that the circadian pacemaker consists of two component oscillators. One is entrained to dusk and controls an evening bout of locomotor activity and the onset of melatonin secretion in nocturnal rodents. The other is entrained to dawn and controls a morning bout of locomotor activity and the offset of melatonin secretion. Separate entrainment of the oscillators to dawn and dusk makes it possible for the pacemaker to adjust the duration of nocturnal periods of activity and melatonin secretion to conform to seasonal changes in night length. As applied to humans, the dusk-and dawn-entrained components of the complex circadian pacemaker could be considered to control evening and morning transitions in melatonin secretion, core body temperature, sleepiness, EEG theta activity, sleep propensity, REM sleep propensity, cortisol secretion, and sleep–awake state. The pacemaker also adjusts the timing of these transitions in response to seasonal changes in day length.
18. A major argument that sleep is vital for survival comes from marine mammals, which must be awake constantly to surface for air. Instead of being permanently alert, they sleep with one cerebral hemisphere at a time.
19. With regard to REM sleep distribution in mice, associations were found with loci on chromosomes 2, 17, and 19 (Tafti et al., 1999).
20. Knockout mice—those missing a single gene that has been knocked out—are used in biomedical research.
21. Induced mutations in serotonin receptors, somnogenic cytokines (such as interleukin 1β and tumor necrosis factor α), and the prion protein gene, implicated in the human condition of fatal familial insomnia (Chapman et al., 1996), result in alterations of sleep (for a review and a note of caution in interpreting these data, see Toth, 2001).
22. Transections of the brain stem at the midpons or below do not reduce wakefulness, while transections at or above a midcollicular level cause an acute loss of wakefulness. The tissue at the rostral pontine–caudal midbrain interface is thus essential for maintaining wakefulness. One set of neurons is located in a group of nuclei that have been identified as the

pedunculopontine and laterodorsal tegmental nuclei (PPT–LDT). These neurons project to the thalamus, intralaminar nuclei, thalamic relay nuclei, and reticular nucleus of the thalamus. The cholinergic input from these neurons to the thalamus has a major role in regulating thalamocortical transmission.

There is another group of neurons, also situated in the midbrain and pons, that ascend toward the hypothalamus and not the thalamus, among them neurons from the noradrenergic locus ceruleus and dorsal and median raphe nucleus. Their axons run through the lateral hypothalamus, where they are joined by cholinergic axons from basal forebrain cholinergic neurons and histaminergic axons from the tuberomammillary nucleus of the hypothalamus. These axons project diffusely to the cerebral hemispheres.

The PPT–LDT cholinergic neurons fire rapidly during wakefulness and even more so during REM sleep (REM-on neurons), and are inhibited during NREM sleep. The monoaminergic nuclei (raphe, ceruleus, and tuberomammillary), by contrast, are almost silent during REM sleep (REM-off neurons), while firing actively during wakefulness and slowing down during NREM sleep.

23. Just as there are ascendant axons, there are also important descendent axons that have an important role in the switch between sleep and wakefulness. One source of these fibers is the ventrolateral preoptic nucleus (VLPO), located in the anterior hypothalamus. The VLPO neurons innervate the tuberomammillary, raphe, and serotonin neurons, and their terminals contain GABA and galanin and have an inhibitory nature. The VLPO neurons fire twice as fast during sleep as during wakefulness, and twice as fast during sleep preceded by sleep deprivation as during sleep not preceded by sleep deprivation.

The VLPO appears to contain subregions specific to REM versus NREM regulation. Specifically, more peripheral areas of the VLPO inhibit the monoaminergic neurons and stimulate the PPT–LDT neurons to produce REM sleep.

The VLPO has a reciprocal inhibiting relationship with the monoaminergic neurons. During sleep, the VLPO’s rapid firing inhibits the monoamine neurons and thus disinhibits its own firing. During wakefulness, the monoamine neurons’ firing inhibits the VLPO and thus disinhibits their own firing. The overall large influences of the circadian and homeostatic processes may shift the relative balance of mutual inhibition; the pattern of firing and inhibition is reversed rapidly toward a new steady state. This is called a “flip-flop mechanism,” intended to maintain the stability of sleep and wakefulness in the face of transient fluctuations in the input to the SCN and to avoid intermediate states and frequent fluctuations in behavioral states (Saper et al., 2001).

Other important descending fibers that have a similar flip-flop stabilizing role are the axons of the hypocretin-orexin-containing neurons in the lateral hypothalamus, which innervate and stimulate all the components of the ascending arousal system. Orexin-containing neurons stabilize and promote wakefulness and decrease both REM and NREM sleep.

24. Specifically, cells in the preoptic anterior hypothalamic nucleus (POAH) send GABAergic projections to reduce the activity of the histaminergic neurons in the tuberomammillary nucleus of the posterior hypothalamus.
25. In the absence of alerting stimuli from the tuberomammillary nucleus and the ascending reticular activating system

(cholinergic neurons located in the pons in the vicinity of the midbrain), higher-frequency firing oscillations disappear, and synchronous firing of thalamocortical neurons occurs. This phenomenon is responsible for the slowing and increased amplitude of the NREM EEG.

26. The contributions of hypocretin/orexin to sleep regulation represent some of the most novel findings on sleep regulation and dysregulation, as well as one of the most fascinating examples of recent scientific history.
27. For a review see Buchsbaum and colleagues (2001). The FDG PET allows for a more “naturalistic” setting (i.e., the patient sleeps in bed, not in the scanner). In addition, the spatial resolution is better with FDG; however, the temporal resolution is better with O₁₅ water (this being important for events that follow in succession).
28. Maquet and colleagues (1996) reported an activation of amygdala during REM sleep that is potentially responsible for the affective components of dreams. Nofzinger and colleagues (1997, 2000) noted widespread activation during REM sleep, encompassing midline limbic and paralimbic structures. They suggested that one function of REM is to integrate neocortical activity with that of limbic motivational and regulatory centers (Buchsbaum et al., 2001).
29. EEG changes observed during sleep were instrumental in crystalizing the two-process model, with delta waves representing the accumulation of process *s*. Conversely, in the waking EEG, theta waves reflect both the wake-dependent homeostatic process and the circadian process and are related to sleepiness, while high-frequency alpha waves have little wake-dependent variation but significant circadian variation and are related to alertness.
30. Because these changes are related to cardiovascular morbidity and mortality, having a sleep debt may decrease longevity (see, however, Kripke and colleagues’ [2002] counterargument). We suggest that sleep debt is best defined in relative terms. Thus a long sleeper needing to sleep 10 hours a night and sleeping 8 would accumulate 2 hours of sleep debt daily, while a short sleeper needing and sleeping 6 hours daily would accumulate no sleep debt.

Besides reporting less sleepiness on the Stanford Sleepiness Scale during extended wakefulness—congruent with EEG data suggesting a higher tolerance in long sleepers to sleep pressure as compared with short sleepers (Aeschbach et al., 2001a)—long sleepers have a longer biological night (see below) than that of short sleepers (Aeschbach et al., 2003).

31. As previously discussed, the two-process model posits that the timing and duration of sleep have two determinants: the SCN (the internal, subjective clock time) and a sleep–wake-dependent process, which can be understood as the time since one was awake or asleep (Dijk et al., 1992). Monk and colleagues (1992), using a constant routine protocol, found that mood in normal subjects also reaches its lowest values around body temperature minimum. Totterdell and colleagues (1994) confirmed through sleep displacement studies that the timing of sleep significantly influences mood. In these studies, prior duration of wakefulness and endogenous rhythms were shown to be confounded. Bolvin and colleagues (1977) were the first to use a forced desynchrony to study circadian and homeostatic influences on mood in normal subjects. They found that mood was related to the interaction between the internal clock and the time awake; the

influence of the former exceeded that of the latter. Not only how long but also when one sleeps and when one stays awake influence one’s mood (see below), as well as cognitive and psychomotor functioning.

33. Wehr, 1989, 1991a, 1992a,b; Hudson et al., 1992; Barbini et al., 1996; Benedetti et al., 1996.
34. Rosenthal et al., 1989; Partonen and Lonnqvist, 1993; Partonen et al., 1993b; Anderson et al., 1994; Brunner et al., 1996.
35. Sitaram et al., 1976, 1978b; Gillin et al., 1978.
36. Gillin et al., 1979a; Sitaram et al., 1980, 1982; Berger et al., 1989; Nurnberger et al., 1989.
37. Forced desynchrony is the current gold standard in chronobiological research. It separates the sleep–wake cycle from the circadian rhythm without changing the ratio between sleep and wakefulness and without depriving patients of sleep. The principle is that while the circadian pacemaker is able to alter the duration of internal night or day to match changes in photoperiod or scotoperiod that would occur naturally, it is unable to match drastically reduced or extended periods of imposed light–dark and rest–activity cycles. Consequently, while subjects sleep and are awake on these very short (e.g., 20 hours) or very long (28- to 30-hour) days, the SCN continues to “pace” with a period of approximately 24 hours. The intent behind the procedure is to have the subjects sleep and be awake at different circadian periods, while the ratio of 33 percent sleep duration to 66 percent wakefulness duration is maintained.
38. Constant routine is an experimental procedure designed to eliminate the confounding influence of sleep. It is used to establish circadian markers, such as temperature minimum, onset and offset of melatonin secretion, cortisol and prolactin rhythms, rhythms in subjective sleepiness, cognitive and psychomotor performance rhythms, and electroencephalographic circadian parameters (e.g., EEG theta and alpha rhythms and REM sleep propensity). It consists of prolonged wakefulness of 30–50 hours, often of 40 hours, enforced by a technician present in the room, with dim light and with the patient in a semirecumbent position. Food and water are distributed throughout day and night, at equal short intervals. If patients are used, their medications must be divided into q2 hour doses. The effects of process *s*, a consequence of the time-awake interval, are eliminated using mathematical models before process *c* is analyzed by fitting a cosine function. The major limitation of constant routine in mood research is that it modifies the studied phenomenon. As discussed earlier, sleep deprivation improves mood in patients with depression, and in bipolar patients may precipitate mania. Thus, the patient’s mood state is expected to change as the procedure progresses. Moreover, several assumptions may not hold up to severe scrutiny. First, the cosine function assumes that studied parameters change as a continuous undulation rather than discontinuous alternation (see below). Second, processes *s* and *c* are assumed to have an additive interaction, whereas it is possible that at times synergistic or less-than-additive interactions are possible. Nevertheless, there is no procedure as good as constant routine for determining important markers for the timing of light interventions, such as circadian temperature minimum. Validation work is needed to find models that can eliminate the need for extended wakefulness in patients with affective illness, especially bipolar patients.

39. Wehr's group (Wehr and Wirz-Justice, 1982; Wehr et al., 1982) found that most patients who had rapid (1- to 6-week) manic-depressive cycles experienced one or more double-length (48-hour) sleep-wake cycles at the onset of each manic phase of their mood cycle. Upon switching from the depressed to the manic phase, they often had alternate nights of total insomnia. Conceivably, these recurring escapes of the sleep-wake cycle from its primary (1:1) mode to its secondary (1:2) mode of coupling to the day-night cycle result from its driving oscillator having an overly long intrinsic period. Because the sleep-wake oscillator is weak, its oscillations remain relatively well coordinated with the day-night cycle and other circadian rhythms. Thus, the dissociation of its oscillations is expressed only in the periodic 24-hour phase jumps associated with double-length sleep-wake cycles. In free-running circadian rhythm experiments in which all external time cues have been eliminated, normal individuals sometimes experience similar 48-hour sleep-wake cycles (Wever, 1979, 1983; Wehr and Wirz-Justice, 1982; Wehr et al., 1982; Weitzman, 1982). Thus, 48-hour sleep-wake cycles in manic patients may resemble the behavior of normal sleep-regulating mechanisms under free-running conditions, perhaps associated with uncoupling of oscillators that are normally linked.
40. According to Georgi (1947, p. 1267), "In the true endogenous depressive we see a shift in the 24-hour rhythm, a phase shift, that can express itself from a slight phase shift to a complete reversal—the night becomes day. Anyone knowing the material would look for the CNS origin in the midbrain, where the entire vegetative nervous system is controlled by a central clock whose rhythmicity . . . regulates and balances the biological system."
41. The literature on circadian rhythms in depression has focused on nonseasonal depression. Seasonal (winter) depression (described later in the chapter) may involve a circadian phase delay.
42. Wehr et al., 1979; Sack et al., 1985; Souétre et al., 1985; Vollmann and Berger, 1993; Berger et al., 1997; Albert et al., 1998; Riemann et al., 1999.
43. Contrary to expectations, REM latency was not different between the two groups, and the REM density was decreased to a greater degree in the "normal" sleep period group. It is thus unlikely that phase advance combined with sleep deprivation acts by reducing REM disinhibition.
44. von Zerssen et al., 1985; Souétre et al., 1988, 1989; Nagayama et al., 1992; Dietzel and Ciullo, 1996.
45. These abnormalities included a trend to increased dark-adjusted melatonin suppression compared with matched controls, significantly lower baseline melatonin levels and nadir levels on the light night, a trend to greater amplitude of variation in melatonin secretion compared with matched controls on the dark night, and significantly later peak time (Nurnberger et al., 2000).
46. This increased sensitivity is also present in offspring of bipolar patients more commonly than in healthy controls (Nurnberger et al., 1988), making it a candidate for an endophenotype for bipolar disorder.
47. Kavaliers and Ralph, 1981; Welsh and Moore-Ede, 1990; Klemfuss and Kripke, 1995; Kripke, 1995; Abe et al., 2000.
48. Johnsson et al., 1979, 1980, 1983; Klemfuss, 1992.
49. As described in Chapter 14, the enzyme glycogen synthase kinase 3-beta (GSK-3 β) appears to be a target of lithium action (Phiel and Klein, 2001). GSK is a highly conserved enzyme in evolution (Plyte et al., 1992; Cohen and Frame, 2001; Woodgett, 2001). The basic amino acid sequence and substrate specificity are common among species from unicellular organisms to *Drosophila* and humans. Of possible relevance to the circadian actions of lithium, GSK-3 β has a *Drosophila* orthologue called SHAGGY, which happens to phosphorylate the timeless protein, a component of the *Drosophila* molecular clock mechanism (Martinek et al., 2001).
- Overexpression of SHAGGY results in shortening of the free-running circadian period, while a decrease in SHAGGY activity has the opposite effect of increasing the free-running circadian period (Martinek et al., 2001). Given the participation of GSK-3 β in the circadian clock of *Drosophila* and the well-known effects of lithium in inhibiting GSK-3 β while prolonging the circadian period, Gould and Manji (2002a) have raised the possibility that GSK-3 β represents a putative cellular mechanism for altering circadian physiology in very diverse organisms, from unicellular to complex (Klemfuss, 1992), and represents a molecular target for the circadian action of lithium.
50. Sleep disruption leading to excessive sleepiness or insomnia that is due to a mismatch between the sleep-wake schedule required by a person's environment and his or her circadian sleep-wake pattern.

55. This concept was confirmed and advanced using a new technology called low-resolution electromagnetic tomography (LORETA), which computes the three-dimensional intracerebral distributions of current density for specific EEG frequency bands. Pizzagalli and colleagues (2001) reported that increased EEG theta activity in the anterior cingulate during the pretreatment period predicted antidepressant response to nortriptyline. In that study, pretreatment theta activity in the medial frontal region extending to the anterior cingulate gyrus correlated positively with percent improvement in depression after treatment. Of interest, it was only the theta band activity in the pretreatment condition that correlated with depression in the study by Pizzagalli and colleagues (2001), because theta activity in the waking EEG reflects accumulation of both process *s* and process *c* (Aeschbach et al., 1999). Moreover, the rostral anterior cingulate may be an important generator for theta activity in the human brain (Asada et al., 1999; Ishii et al., 1999). In the future, it would be interesting to correlate response to sleep deprivation with midfrontal theta wave dynamics and cingulate activity using neuroimaging.
56. It is possible, however, that after an initial dramatic response, a particular patient would respond even better to sleep deprivation in the future, given that an expectation factor may add to any biological effect.
57. Payne and colleagues (2002) suggested that sleep deprivation may act by imposing a temporal coincidence on normally

dissociated events (maintaining the activity of noradrenergic neurons of the locus ceruleus at a time when tissues innervated by the locus ceruleus show the highest sensitivity).

58. It is only during REM sleep, and not during NREM sleep or wakefulness, that neurons in the locus ceruleus, the main source of noradrenergic stimulation of the brain, are inactive and noradrenergic receptors have their highest sensitivity (Siegel and Rogawski, 1988). Thus the hypothesis that REM sleep deprivation is the mechanism of action of sleep deprivation implicates noradrenergic mechanisms.
59. In this study, adding both lithium and light treatment to total sleep deprivation did not result in further improvement, suggesting a ceiling effect.
60. Vollmann and Berger, 1993; Berger et al., 1997; Albert et al., 1998; Riemann et al., 1999.
61. In fact, the periods with greatest mood instability were those when his circadian rhythms in sleep, melatonin, and rectal temperature appeared to lose their entrainment to the 24-hour sleep-wake cycle and free run around the clock with a period longer than 24 hours. The therapeutic premise was to increase the number of hours available for sleep, overriding sleep deprivation-induced mania. Because animal research showed that a reduction in scotoperiod (duration of darkness) may decrease the ability of the circadian pacemaker to reset the response to light (Goldman and Elliott, 1988), a therapeutic increase in scotoperiod would result in increased amplitude of biological rhythms and thus decreased ability of the circadian pacemaker to synchronize downstream rhythms with the light-dark cycle.
62. The authors chose to use midday light on the basis of the preliminary observations of Leibenluft and colleagues (1995)—who followed 13 patients with rapid-cycling bipolar disorder on light therapy for 3 months—that morning light could result in increased cycling and hypomania; that evening light was largely ineffective; and that midday light, thought initially to be a placebo intervention, appeared to be the most effective (indeed, it has since been interpreted as a stabilizing, entraining stimulus for a process underlying hypomania). Kusumi and colleagues (1994) found a similar effect with morning administration of light combined with vitamin B12, without increased cycling or hypomania. Unfortunately, to our knowledge, no controlled study has followed up on these observations.
63. The purpose of IPSRT is on the one hand to regulate circadian rhythms and sleep-wake cycles (with a major intended impact on hypomania, mania, and cycling) and on the other hand to address losses, stresses, and interpersonal tensions and difficulties (with a major intended impact on depression). An example of how the social domain can interact with the circadian domain is a new baby's disrupting parents' sleep at night. Besides resulting in sleep deprivation and thus possibly in a manic switch, such disruption may expose the circadian system to light at a time of increased potential for large switches (around temperature minimum). These switches may result in depression or inadequate social functioning (e.g., falling asleep or feeling sleepy in the late afternoon in the case of phase advance) and may further contribute to deterioration of the sleep-wake cycle (inability to fall asleep and to wake up in the case of phase delay).

While the interpersonal component of the therapy focuses on four "traditional" aspects of treatment—grief, role

disputes, role transitions, and interpersonal deficits—the circadian and sleep-wake component focuses on the disruption of social zeitgebers (e.g., personal relationships and social demands and tasks) that entrain biological rhythms and the occurrence of zeitstörers (time disrupters) that may be physical (e.g., exposure to light as in transmeridian travel), chemical (e.g., medications), or psychosocial (e.g., a new baby or work deadlines). Monk and colleagues (1990) designed the Social Rhythm Metric (SRM) that is used in IPSRT. The patient and therapist review the first 3–4 weeks of SRM measures to find rhythms that are particularly unstable, such as variation in the time of going to bed from day to day or from weekday to weekend days. The therapist encourages stabilization of such social rhythms, searching for rhythm disrupters, especially ongoing environmental stressors, and making recommendations for life changes to enhance protection of circadian rhythms and the sleep-wake cycle. A slightly more regular day job, even if less lucrative, is highly desirable for some patients. Difficulty may arise with certain patients (analogous to medication nonadherence; see Chapter 24) as a very stable lifestyle may appear unappealing, and some patients may mourn their lost hypomanias. The therapist works toward achieving a healthy balance between stability and spontaneity. Another area of focus is the anticipation of changes in routines with changes in one's social climate (e.g., breakup with a partner, divorce or separation, death of a spouse, leaving for college), resulting in the loss of social zeitgebers.

An analogy with alcohol may be appropriate. Many individuals can use small amounts of alcohol intermittently with no apparent detrimental effect, but there is some consensus that a recommendation for its intermittent use is not okay for alcoholics. Similarly, while some degree of instability in social rhythms is likely okay for a majority of individuals, it is highly detrimental for bipolar patients. Even in recovered individuals, craving persists. Just as alcoholics may continue to crave alcohol, bipolar patients may continue to crave the roller coaster, the spontaneity of living, and hypomania. Ongoing therapy (e.g., Alcoholics Anonymous for the alcoholic, the preventive phase of IPRST for the bipolar patient) helps reduce the risk of relapse.

64. Baillarger, 1854; Griesinger, 1867; Falret, 1890; Kraepelin, 1921.
65. The enzyme responsible for the conversion of serotonin to melatonin is pineal N-acetyltransferase.
66. Two peaks have been identified in human conceptions—one in fall and one in spring. Usually the spring peak is dominant, although a shift toward the fall peak has been noted in the United States over the last several decades. Seasonal variation in conception has decreased in amplitude over the last 100–200 years, possibly as a result of the advent of artificial lighting and indoor temperature control. An alternative explanation is changes in nutrition. In female rats, for example, ad libitum feeding renders the pituitary-ovarian axis insensitive to melatonin, while restricted feeding sensitizes it to the effects of melatonin (Wilamowska et al., 1992). Since subsistence-level feeding may have been prevalent in earlier periods of human history (Wehr, 2001), it may have contributed to greater seasonality of reproduction. (For further support see *Journal of Biological Rhythms*, June 2004.)
67. Among them Petridou and colleagues (2002) in the United States, Rasanen and colleagues (2002b) in Finland, Morken

and colleagues (2002) in Norway, van Houwelingen and Beersma (2001a,b) in the Netherlands, and C. Cantor and colleagues (2000) in Australia.

68. Increased levels of potentially depressogenic interleukins have been found in bipolar patients with SAD (Leu et al., 2001), as well as in patients with bipolar disorder in general (Tsai et al., 2001). Nelson (2004), who brought immunology to the forefront of seasonality, suggested that immune functions are activated during winter to enhance survival in the “bottleneck” created by high-energy thermoregulatory demands at a time of reduced availability of nutrients. While preparing to defend the body from infections, the immune cells communicate via cytokines to the brain and the rest of the body that a behavioral inhibition may be necessary to conserve energy.
69. Studies aimed at distinguishing effects of depression and seasonality may produce more consistent results if SAD patients are compared not with controls but with patients experiencing nonseasonal recurrent depression. According to the vulnerability hypothesis, one could also compare subsyndromal SAD patients with normal controls.

The melatonin hypothesis could be further tested with improved designs involving either administration of light at a time when it would suppress early-morning versus later melatonin secretion or pharmacologic manipulations. Antidepressant interventions might include a bedtime delayed-release preparation of propranolol or selective melatonin receptor antagonists. On the other hand, loss of the antidepressant effect of light or the induction of a winter state during summer may result from appropriately timed administration of melatonin, a melatonin receptor agonist, or a serotonin receptor antagonist (5-HT_{1B} receptors mediate the inhibitory effect of the serotonergic system on retinohypothalamic axons).

An important contribution to our understanding of seasonality in humans, as well as to optimal treatment of SAD, may result from examining the potential role in seasonality of factors other than light, such as other physical, chemical, and biological factors, as well as interventions such as immunological, olfactory, and temperature manipulations in addition to light treatment. Also valuable would be research on melanopsin-based photoreception in patients with SAD versus controls and on retinal sensitivity to the narrow spectrum that would have maximum effect on melatonin suppression and shifting. The most important directions for future research may involve focusing at the molecular level to explore the underlying mechanisms of heterogeneity in seasonality, such as mutations in clock genes or genes that code for melatonin receptors, as well as the numeric and topographic distribution of those receptors in individuals with versus without seasonal changes in mood, level of energy, sleepiness and sleep, weight and appetite, and interest in socialization and sex.

70. Wehr and colleagues (1987) also hypothesized that summer SAD may involve a specific abnormality in thermoregulation that increases the individual’s sensitivity to heat.
71. For example, the DSM-IV criterion of two major depressive episodes occurring in the last 2 years is rarely fulfilled because approximately half of SAD patients do not become depressed each winter and, most important, because many SAD patients today treat themselves with light before experiencing a full-blown episode of major depression, thereby aborting the episode.

72. One study showed that aborigines from Northern Scandinavia have less variation in mood than other Scandinavians (Saarijarvi et al., 1997). SAD is less common in the Icelandic population (which has lived in virtual isolation during the past 1,000 years) (Magnusson and Stefansson, 1993) and its descendants in Canada (Magnusson and Axelsson, 1993) than on the eastern coast of the United States (Magnusson, 2000). This difference may be due to environmental factors—most likely “portable” environmental factors associated with lifestyle, such as diet or activity schedule, rather than “fixed” environmental factors, such as climate—or to genetic factors.
73. Young and colleagues (1997) hypothesized that weather may explain the year-to-year variation in the onset of depressive symptoms in SAD. After careful adjustment for photoperiod, however, they found no significant effect of weather on the onset of depressive symptoms in SAD.
74. In a recent study by Postolache’s group (Yousuffi et al., 2003), African college students living in the Washington, D.C., metropolitan area for at least 3 years reported more problems with changes in season than their African American colleagues, a finding consistent with a habituation hypothesis. Results of only one study, however, support the sensitization hypothesis: Murase and colleagues (1995) reported increased prevalence of winter-type SAD in long-staying as compared with short-staying Japanese residents of Sweden. In contrast, Murase and colleagues (1995) reported increased prevalence of winter-type SAD in long-staying as compared with short-staying Japanese residents of Sweden.
75. If the loading on seasonality exceeds that on depression, one would expect SAD with full remission in the summer; on the other hand, if the loading on depression exceeds that on SAD, summer remissions would be incomplete.
76. The term “hypophyseal insufficiency associated with lack of light” (first used by Marx, a German physiologist, in 1946) represents the first scientific description of SAD. Marx also hypothesized that light affected patients’ behavior via the retino-hypothalamic tract, which he termed “the hypothalamic root of the optic nerve.”

Animal seasonal rhythms provided the analogies and the impetus for SAD research. In photoperiodic animals, seasonal changes they experience are mediated by the duration of melatonin secretion. The report of Lewy and colleagues (1980) that melatonin is suppressed by bright light in humans was followed somewhat logically and somewhat serendipitously by the description of the first SAD patient and his treatment with light (Lewy et al., 1982), and then a more complete description of the syndrome and a preliminary evaluation of light treatment (Rosenthal et al., 1984). Light treatment was proven effective in a double-blind, placebo-controlled paradigm (Eastman et al., 1998; Terman et al., 1998). Wehr and colleagues (2001b) showed that patients with SAD, and not matched controls, have a longer duration of active melatonin secretion in winter than in summer, similar to changes in melatonin duration in animals. Individual variability is high in humans, but even in species with more drastic and uniform behavioral changes in response to photoperiodic changes than those experienced by humans, some individual animals do not respond at all to changes in photoperiod (Puchalski and Lynch, 1986; Gorman and Zucker, 1997).

77. Bupropion was used prophylactically to prevent the onset of winter depression in SAD.
78. Administration of the tyrosine hydroxylase inhibitor alpha-methyl-paratyrosine was used to deplete catecholamines.
79. Rather than describing phase position relative to external time, describing it relative to wake–sleep time may be more clinically relevant. Thus in a recent study (Lewy et al., 2006), the duration of the interval between melatonin onset and sleep onset (the melatonin–sleep interval, or MSI) predicted depression scores in patients with SAD. The ideal MSI is 2 hours; the more MSI deviated in either direction from 2 hours, the higher were the depression scores. Moreover, with specifically timed administration of physiological doses of melatonin, changes in depression scores were correlated with the movement toward or away from the 2-hour standard. Thus defining phase advance as MSIs greater than 2 hours and phase delay as MSIs less than 2 hours (rather than relative to astronomical time) may help guide treatment, that is, the use of timed administration of melatonin and/or light to shift abnormal phase positions.
80. Jones et al., 1999; Lowrey et al., 2000; Allada et al., 2001; Toh et al., 2001.
81. In fact, agomelatine, another melatonin receptor agonist with additional 5-HT_{2C} receptor antagonist properties, was shown in 711 depressed patients to be effective and well tolerated, with a higher efficacy than placebo and a faster response than paroxetine (Loo et al., 2002). In addition, agomelatine, in contrast to paroxetine, was not associated with a discontinuation syndrome (Montgomery et al., 2004).

PART V

TREATMENT

This page intentionally left blank

Of all our conversations, I remember most vividly [Robert Lowell's] words about the new drug, lithium carbonate, which had such good results and gave him reason to believe he was cured: "It's terrible, Bob, to think that all I've suffered, and all the suffering I've caused, might have arisen from the lack of a little salt in my brain."

—Robert Giroux, 1967

Until the middle of the twentieth century, manic-depressive illness had remained intractable, frustrating the best efforts of clinical practitioners and their forebears to treat it. This long history ended abruptly with the discovery of lithium's therapeutic benefits. The impact of the discovery of lithium has been profound and long-lasting (Goodwin and Ghaemi, 1999; Bauer et al., 2006). Not only did it reaffirm psychiatry as a medical specialty in an era when the ideology behind "the myth of mental illness" and "mental illness as a normal response to a crazy world" was in ascendancy (particularly in the United States and the United Kingdom), but the fact that lithium's effects were specific to a particular diagnosis reinforced the importance of nosology at a time when many in the mental health field were deriding the very concept of a diagnosis as "labeling." The benefits of lithium established beyond rational dispute that a major mental illness did indeed have a strong biological component with which a chemical treatment was obviously interacting; this, in turn, initiated what has become a sea change in the public's perception of the mentally ill and of mental health professionals.¹ In an ironic turn of events, moreover, the psychopharmacology revolution set in motion by lithium eventually mobilized a renaissance in the psychotherapy of manic-depressive patients. Substantially freed of the severe disruptions of mania and the profound withdrawals of depression, patients and therapists could sustain their focus on the many psychological issues related to the illness, and also confront basic developmental tasks. Most important, lithium has saved the lives of hundreds and thousands of patients and immeasurably changed for the better the course and outcome of manic-depressive illness for millions more.

For the research community and, more broadly, the mental health community, lithium and the psychopharmacology revolution it launched can be said to have led to the

development of today's formal diagnostic systems, the *Diagnostic Statistical Manual (DSM)-IV* and the *International Classification of Diseases (ICD)-10*. Because the early psychopharmacology researchers required reliable diagnoses to define their study populations, the Research Diagnostic Criteria were developed and subsequently became the basis for today's diagnostic systems. Moreover, lithium and the drugs that followed gave substantial impetus to modern neuroscience. Prior to the discovery of the clinical effects of lithium, the phenothiazines, and the antidepressants, basic and clinical scientists focused largely on neuroanatomy. Efforts to understand how these new drugs were exerting their powerful and often specific effects required a shift from a predominantly structural to a functional neuroscience focused on neurotransmitters, neuromodulators, receptors, and, more recently, mechanisms of postsynaptic signal transduction and gene induction. Today, of course, the cutting edge of neuroscience reflects the integration of functional and anatomical approaches. Here, too, the mechanisms of action of lithium continue to be a major emphasis (see Chapter 14).

THE HUMAN AND ECONOMIC COSTS OF MANIC-DEPRESSIVE ILLNESS

We have chosen here to discuss the impact of manic-depressive illness (its human and economic costs) first, followed by a brief review of "real-world" patterns of medication use and their effectiveness. In reality these issues are intertwined: contemporary data on the impact of the illness involve patient populations receiving various levels of treatment, from none to high-quality combinations of medications and psychotherapy delivered by specialists. The literature on the impact of manic-depressive illness and

the application and effectiveness of treatments has focused on the bipolar subgroup; while there is a robust literature on depressive disorders, to our knowledge recurrent depression has not been analyzed separately in these studies.

The impact of bipolar disorder on individual lives starts with its usual age at onset—adolescence and the twenties—precisely the time when individuals must navigate the critical developmental transition from childhood to adulthood (Calabrese et al., 2003; Post, 2005). In Chapter 4 we review the evidence suggesting that earlier ages at onset are associated with a less favorable course of illness. The extent to which interference with developmental processes (including interrupted educational and career trajectories) accounts for this association is not clear. What is clear is that in the aggregate, bipolar illness is associated with major functional impairment, include physical disability. Indeed, the World Health Organization (WHO) has estimated that bipolar disorder is the sixth-leading cause of disability for those in the age range most associated with the onset of the disorder—15 to 44 (Murray and Lopez, 1996). The WHO data and results of other epidemiological surveys related to the disability associated with bipolar disorder are reviewed in Chapter 5. A relationship between early age at onset and disability is suggested by the striking finding of Gillberg and colleagues (1993) that 89 percent of adolescents with bipolar disorder were receiving full disability benefits in the United States by age 30 despite treatment (primarily lithium).

As reviewed in Chapter 4, among patients receiving treatment in the community (see below), considerable functional impairment often persists even in the face of full symptomatic or syndromal recovery.² For example, Dion and colleagues (1988) found that while 80 percent of their bipolar patients hospitalized for mania were symptom-free or only mildly symptomatic 6 months after discharge, only 43 percent were employed, and only 21 percent were working at their pre-illness level. Employment status was better following a first hospital admission: 64 percent of such patients were employed versus only 33 percent of those with previous admissions.³ Conus and colleagues (2006) examined symptomatic and functional outcomes following a first episode of psychotic mania in a catchment area sample, that is, a sample broadly representative of the community. They found that at 1 year, while 90 percent of the patients had achieved syndromal recovery, 61 percent had failed to return to their previous level of functioning. Predictors of functional outcome were substance abuse, earlier age at onset, and a family history of affective disorder. Particularly striking was the impact of substance abuse: patients with this comorbidity were 19 times less likely to return to their previous level of functioning.⁴ In addition, the families of recovered euthymic

bipolar patients can still experience considerable caregiver burden (Reinares et al., 2006).

It is the extent of depressive, not manic, symptoms that predicts⁵ poor functional outcome during follow-up (Bauer et al., 2001; Judd et al., 2005; Altshuler et al., 2006); it is also depressive morbidity that explains why bipolar disorder compared with unipolar depression is associated with more than twice the number of days lost from work according to the U.S. National Comorbidity Survey (Kessler et al., 2006). In the three chapters that follow, we note the imbalance between the impressive number of medications developed for the treatment of mania and the paucity of agents developed for the treatment of bipolar or highly recurrent unipolar depression. Given that depressive symptoms are primarily responsible for the burden of illness, any continuation of this imbalance is unacceptable. It should be noted that in the Bauer and colleagues (2001) Veterans Health Administration study, clinical status (primarily the extent of depression) predicted only about half of the variance in functional outcome, the remainder being associated with individual patient factors, such as the ability to engage in treatment and to manage life tasks despite the illness.

Functional impairment and disability associated with bipolar disorder incur considerable financial costs—for the patient, the family, and society at large. Estimates of such costs vary according to the assumptions used. One of the most widely cited figures is that of Wyatt and Henter (1995), who estimated the direct and indirect costs of bipolar disorder in the United States at \$45 billion, 84 percent of which comprised indirect costs, such as lost productivity, unemployment compensation, disability payments, and law enforcement. More recently, Begley and colleagues (2001) estimated the lifetime cost for new cases of bipolar disorder in the United States during 1998 at \$24 billion, with a lifetime cost per case of up to \$625,000 for those with chronic, treatment-resistant symptoms. Yearly cost estimates globally range from \$12,000 to \$18,000 per patient, 80 percent of which consists of indirect costs (Kleinman et al., 2003; Dardennes et al., 2006). The very high ratio of indirect to direct costs suggests it should be possible to demonstrate that clinically effective treatments can be cost-effective as well (Chisholm et al., 2005). Perhaps especially relevant to policy makers today is the increased cost of medical care among bipolar patients (Kupfer, 2006; McIntyre et al., 2006; Gardner et al., 2006), which exceeds that for diabetes (Simon and Unutzer, 1999). More effective treatments would be expected to reduce these medical costs. And since mental health care generally accounts for only 6 to 7 percent of total health care costs, it has been argued that cutting back on psychiatric care for bipolar patients in an attempt to reduce health care costs is penny wise and pound foolish (Hyman et al., 2006).

“REAL-WORLD” PHARMACOTHERAPY AND ITS EFFECTIVENESS

In the three chapters that follow, we review the *efficacy* of various drugs in treating mania and depression and in preventing recurrences; the knowledge base for these chapters comes almost entirely from controlled studies of single drugs, and substantially from patients not only without comorbidities but also well enough to give informed consent for research. To understand this growing knowledge base in a larger context, it is useful first to understand the reality of how medications are actually being used in the community and how *effective* they are, that is, how well they work under circumstances in which the “average” patient has both physical and psychiatric comorbidities and is taking more than one drug. Obviously, patterns of use and effectiveness are inexorably intertwined with the illness’s human and economic costs as discussed above. While available treatments could allow many manic-depressive patients to lead relatively normal lives—lives less painfully interrupted by illness and less often ended prematurely by suicide—the reality falls far short of meeting this modest expectation. One has only to recall the naturalistic follow-up studies of the modern era (see Chapter 4), during which contemporary treatments have been available, to find support for this conclusion. Myriad interrelated factors contribute to this therapeutic shortfall, including long delays in seeking and receiving treatment and differences in health care delivery systems, in patients’ attitudes toward treatment, in clinicians’ skills and training, in the availability of family and social supports, in comorbid conditions, and so on. Before briefly examining some of these factors (many of which are also covered in the individual treatment chapters that follow), we must restate the fundamental reality emphasized in the first edition of this text: we simply do not yet have an adequate understanding of the illness in all of its various forms and complexities, including its interactions with *individual differences* that is, differences in environment and in the patient’s character and psychological and physical resilience. By thus citing the limits of our knowledge, we in no way intend to diminish the very substantial progress that has been made since the first edition was published. On the contrary, it is most encouraging that this progress has occurred on virtually all fronts, not the least of which is the development of new pharmacological and psychosocial treatments, as described in the following chapters.

In their recent review of epidemiological studies from around the world, Schaffer and colleagues (2006) concluded that anywhere from one-fourth to nearly two-thirds of individuals with bipolar disorder have never sought any sort of treatment for a mental disorder. For those who do seek

treatment, there is often a lengthy delay (approximately 10 years) before a correct diagnosis is made and appropriate pharmacotherapy initiated.⁶ This delay contributes substantially to worse long-term outcomes and to reduced effectiveness of treatments once they are started.^{7,8} More often than not, delay in the initiation of appropriate treatment means inappropriate treatment rather than simply the absence of treatment. This is the case because about half of bipolar patients are initially diagnosed as unipolar and treated with antidepressants (Ghaemi et al., 2000; Blanco et al., 2002; Perlis et al., 2006). As discussed in Chapter 19, such inappropriate treatment can have major negative consequences for the illness, including increased costs of care (Li et al., 2002; Matza et al., 2005). Whatever factors contribute to the absence of appropriate treatment in an individual patient, results of studies in nonacademic community settings indicate that half or more of all bipolar patients are not taking a mood stabilizer (see, e.g., Lim et al., 2001; Wang et al., 2005; Schaffer et al., 2006).

What does the literature tell us about the effectiveness of contemporary pharmacotherapy? It is difficult to develop an estimate of effectiveness for the “average” bipolar patient. Most studies are from academic centers, which on the one hand are likely to deliver high-quality care, but on the other are dealing with the kinds of patients who tend to end up in tertiary referral centers, that is, those with more severe and treatment-resistant illness. For example, 2-year data from the largest treatment study of bipolar disorder ever undertaken—the National Institute of Mental Health’s (NIMH) Systematic Treatment Enhancement Program for Bipolar Disorder (STEP-BD) (involving academic centers) (Perlis et al., 2006)—indicate that the “best treatment available” was associated with full remission in just over half of the bipolar patients, and that nearly half of the recovered patients relapsed at least once during the 2-year study (see Chapter 20). Similarly, a Stanley Foundation Bipolar Network academic center follow-up study (Levine et al., 2000) found that fewer than half of the patients were able to live independently or be employed, and more than half made at least one suicide attempt during the study. Results from another academic tertiary referral center (Gitlin et al., 1995) are similar: 73 percent of bipolar patients receiving “aggressive maintenance treatment” relapsed during the 5-year follow-up period, and two-thirds of those who relapsed did so more than once.

Combining the studies reviewed in this and the previous section (as well as in Chapter 4) reveals a picture suggesting that, with respect to syndromal recovery, treatment effectiveness in community samples is better than that in referral centers, but with respect to functional recovery, results in neither setting are encouraging. Perhaps functional

disabilities derive substantially from the psychological and social scars of having had episodes, rather than primarily from the severity of symptoms during episodes. It is perhaps for this reason that pharmacological treatments appear to be more effective against syndromes and symptoms than against dysfunction and disability. Obviously, the importance of psychosocial rehabilitation can hardly be overstated.

STRUCTURE AND RATIONALE OF THE TREATMENT CHAPTERS

This part of the book departs from earlier parts in its emphasis on the application of accumulated knowledge to the pragmatic business of treating individual patients. As one medical sociologist and historian has observed, “While the aim of all sciences is the maximum of generality, that of medicine ought always to be action aimed at the maximum welfare of the individual” (Wightman, 1971, p. 14). It is this principle that has guided the writing of these chapters. The chapters that follow address practical therapeutic choices faced by the clinician and summarize the clinical research on the efficacy and effectiveness of available treatments. Application of the medication strategies outlined in the next three chapters requires a psychiatrist skilled in psychopharmacology, but not necessarily a highly specialized background in manic-depressive illness. However, consultation may be necessary in some situations, such as when the diagnosis is uncertain, when the decision to hospitalize is difficult, when the response to initial treatment is poor, when the patient fails to adhere to a prescribed regimen, or, especially, when there is a danger of suicide. Although bipolar illness remains the primary focus in these chapters, highly recurrent unipolar illness and its management are considered, especially in our discussions of prophylactic treatment.

We have chosen a somewhat unconventional organization for these chapters, with clinical recommendations preceding the evidence that supports them. There are two reasons for this choice. First, our treatment recommendations represent more than a distillation of research findings. They are drawn from our reading of the literature and, we believe, represent the essential core of the evidence. Where we find the literature to be incomplete or equivocal, we supplement it with the seasoned judgments of our colleagues and opinions based on our own clinical experience. Our second reason for organizing these chapters as we did is our belief that the formal literature has more meaning when framed by clinical treatment issues. Although future research certainly will alter and supplement any of our specific recommendations, it is our hope that the fundamental principles outlined here will have lasting value for the clinical care of patients with manic-depressive illness.

Following this chapter (which includes a review of the basic pharmacology of the major classes of drugs used in treating manic-depressive illness) are three chapters devoted to medical treatment of adults, including medication, electroconvulsive therapy, novel central nervous system (CNS) stimulation techniques, and manipulation of sleep and light. The treatment of manic episodes is covered in Chapter 18 and that of depressive episodes in Chapter 19. Long-term prophylactic treatment is discussed in Chapter 20, as is the issue of side effects, which in our experience becomes most salient during prophylactic treatment. Chapter 21 focuses on the special issue of adherence to medical treatments, while Chapter 22 deals with psychotherapy and related issues. Chapter 23 addresses the pharmacological and psychological treatment of children and adolescents. Chapters 24 and 25, respectively, are focused on two special and important populations: those with comorbid conditions and those at risk for suicide. The presence of comorbid conditions, both psychiatric and medical, is increasingly recognized as a complicating and limiting factor in the treatment of manic-depressive illness; successful management of the illness depends on the clinician’s ability to recognize and treat these comorbid conditions, especially anxiety and substance abuse/dependence. Finally, far too many manic-depressive patients kill themselves, and clinicians must be astute not only in assessing suicide potential but also in knowing how to manage it, both pharmacologically and psychologically.

Stages of Treatment

In reading this section, it is important to keep in mind the natural course of manic-depressive illness, described in Chapter 4. Although many treatments can alter acute symptoms dramatically, the nature and logic of planning treatment should be shaped by respect for the course of the illness: its inherently, insidiously recurrent nature, as well as its tendency to worsen over time. Throughout these chapters, we use several terms to describe stages of medical and psychotherapeutic treatment that are linked conceptually to aspects of the illness’s natural course:

- *Acute treatment* is treatment administered during the period from the beginning of a manic or depressive episode to a clinical response—ideally, remission. This phase usually lasts from 6 to 12 weeks.
- *Continuation treatment* is the ongoing treatment of a depressive or manic episode from the point of clinical response to the point at which spontaneous recovery would be expected to occur in untreated patients. Although overt clinical symptoms of illness may remit within a few weeks, an underlying “tail” of vulnerability can remain for some time. The duration of continuation

treatment is determined by the natural course of the illness. In nonrecurrent unipolar patients, antidepressants are usually recommended for a period of 9 to 12 months after remission, but the natural course of bipolar disorder suggests a somewhat shorter continuation phase after a depressive episode—approximately 6 months. While the natural course of mania would suggest a continuation phase of about 4 months, clinically it can be longer, involving the management of a postmania depression or a sometimes protracted period of mood instability dominated by dysphoria as the patient attempts to repair the external and internal damage wrought by the manic episode.

- *Maintenance treatment* is intended to prevent or attenuate future mood episodes in patients with bipolar or recurrent unipolar illness, and it is used somewhat more selectively than are acute and continuation treatment. A word of clarification is in order, however. Although commonly used, the term *maintenance treatment* is less precise than *long-term prophylactic treatment*, or *prophylaxis*, in referring to the effects of treatment on the long-term course of manic-depressive illness. The concept of maintenance overlaps both the continuation and prophylactic phases of treatment, whereas prophylactic effects range from prevention of future episodes to attenuation of their frequency, duration and/or severity. Thus while we use the common term *maintenance treatment* throughout the volume, particularly in Chapter 20, we intend it to refer specifically to prophylaxis.

General Clinical Considerations

Psychiatric Evaluation and Diagnosis

Evaluation of the patient before treatment is the most important stage in managing the illness. As extensively as the patient's clinical condition permits, the evaluation should cover the pattern and duration of symptoms, exposure to possibly stressful life events, suicide potential, substance abuse, and personal and family history. If at all possible, the patient's spouse or a close family member should participate; clinicians evaluating depressed patients without the participation of a family member will miss prior manic (and especially hypomanic) episodes half of the time. Screening instruments can help, but a form of the screening questions for the family member to fill out should be employed as well, since the patient's response to such questions depends on (1) the individual's memory of manic/hypomanic behaviors and feelings, and (2) sufficient insight to realize the states were not normal. Also, the presence of family members serves as an opportunity for the clinician to assess their attitudes about such issues as medications and hospitalization. The situation provides an occasion as well for

evaluating the family's ability and willingness to participate further in treatment and follow-up. This ongoing involvement can be especially helpful in the early detection of prodromal symptoms (Jackson et al., 2003), such as decreased sleep; detection of prodromal signs has been shown to prolong time to manic relapse and improve social functioning significantly (Perry et al., 1999).

Differential diagnosis, discussed fully in Chapter 3, often involves:

- Patients who are in a hyperactive psychotic state and whose personal or family history is not available. In these cases, acute schizophrenia and organic and drug-induced psychoses must be ruled out.
- Patients with mild manic-like symptoms. Normal elevated mood must be differentiated from clinical hypomania.
- Patients with severe depressive symptoms whose history is unknown. The most important alternative diagnosis to consider is unipolar depression. Schizophrenia and schizoaffective illness, drug-induced states, and dementia also must be ruled out.
- Patients with moderate depressive symptoms. Major depressive illness, either unipolar or bipolar, must be distinguished from milder forms. Manic-depressive illness (bipolar or highly recurrent unipolar) should be considered whenever recurrent, discrete episodes are present.

Medical Evaluation

The medical evaluation preceding treatment, like the psychiatric evaluation, should be shaped by the clinical situation. When lithium treatment is being considered, emphasis must be given to thyroid and renal function; for carbamazepine and valproate, hepatic and hematopoietic function, and for valproate, gonadal hormone function in females; for lamotrigine, prior sensitivity to rashes; and for some atypical antipsychotics, risk factors for weight gain, metabolic syndrome, and diabetes. Since pretreatment medical evaluation is most critical for long-term treatment, specific recommendations for laboratory tests are discussed in Chapter 20. Finally, clinicians often discover previously undiagnosed medical problems in the course of their routine pretreatment evaluations. This potential dividend provides a further reason to exercise care in the initial phase of treatment.

The Therapeutic Alliance in Drug Treatment

Chapters 21 and 22 deal extensively with the relationship between psychotherapy and medication. Here we pause briefly to underscore a fundamental truth in psychopharmacology: to achieve its full potential, any drug should be given in the context of a solid and positive clinician–patient

relationship. Unfortunately, a working therapeutic alliance is not always achieved in the context of a busy practice, especially given the constraints imposed by managed care.⁹ Today most formal psychotherapy is the responsibility of nonmedical mental health professionals. The challenge is how to ensure coordination between the psychopharmacologist and the psychotherapist given that there is no reimbursement for the time professionals devote to coordinating care. Since the psychotherapist spends more time with the patient, he or she is generally in a better position to know more about side effects and quality-of-life issues. The importance of coordination of care was recently demonstrated by Simon and colleagues (2005, 2006), who randomized 441 bipolar patients in a staff model health maintenance organization (HMO) to treatment as usual or to a multicomponent intervention (initially described by Bauer et al., 2001). The latter intervention involved case monitoring by nurses, structured group psychoeducation, and monthly telephone monitoring of mood and adherence, followed by feedback to the treating professionals and facilitation of needed follow-up care, including outreach and crisis intervention. The coordinated care group had significantly fewer manic symptoms and time spent manic. While the incremental mental health cost of the intervention was \$1,251, one would expect that extra cost to be offset by a decrease in the high cost of medical care associated with bipolar disorder. Unfortunately, medical care costs were not reported, but on the basis of earlier studies, it appears reasonable to assume that cost savings associated with the reduction in frequency and severity of mania achieved would more than offset this modest incremental direct cost of mental health care. In a concurrent 3-year trial involving bipolar patients in 11 Veterans Affairs hospitals (who were generally sicker and more frequently hospitalized than the HMO patients in the above study), Bauer and colleagues (2006a,b) randomized 306 subjects to a similar collaborative care program or to usual care. Their results were strikingly similar to those achieved in the HMO population: there was a significant 6.2-week reduction in time spent in an affective episode (primarily manic), as well as improvements in social role functioning and quality-of-life measures. The intervention was slightly and nonsignificantly less costly than usual care, with increases in outpatient costs being more than offset by reductions in inpatient costs, both psychiatric and medical-surgical.

There is no substitute for clinical experience in applying the general principles listed in Box 17-1 and research knowledge to the treatment of manic-depressive illness with drugs. One cannot predict with complete certainty that a given patient will tolerate and benefit from a particular drug, nor can one predict the safest and most effective dose. Experimentation and adjustment are required when treatment

BOX 17-1. Some General Principles for the Management of Manic-Depressive Illness

- Include a family member in the initial evaluation and (on occasion and where appropriate) in the ongoing evaluation of treatment.
- Use a life chart to record the patient's history and to monitor the course of the illness.
- Aim for "balanced effectiveness"; that is, give equal weight to a drug's tolerability, efficacy, and safety. Among agents with evidence of efficacy, it is generally better to start with the most tolerable one. The side effects of most concern to patients are weight gain, neurocognitive impairment, and sedation.
- Treat breakthrough symptoms, substance abuse, comorbid anxiety and side effects vigorously. Bipolar-II patients may be more sensitive to side effects than bipolar-I patients.
- Focus psychotherapy on adherence, psychoeducation, and circadian integrity.
- Watch for suicidal behavior and persistent suicidal ideation, especially if the patient has a specific plan.
- If antidepressants are needed for the acute treatment of bipolar depression, include a mood stabilizer. Do not maintain antidepressants in bipolar patients unless attempts to taper off repeatedly fail; watch for early signs of a hypomanic/manic switch and/or increased cycling.
- When mood stabilizer monotherapy proves inadequate, use combinations in modest doses. Lithium may interact synergistically with some anticonvulsants.

begins, and the patient should be advised accordingly. The patient is most likely to cooperate if the clinician approaches drug treatment as an investigative undertaking—one depending on active collaboration. Controlled double-blind studies of antidepressant drugs not infrequently have shown success rates below those reported in some open trials. Some of this difference certainly can be attributed to the positive expectations of the clinicians in the open trials, but much of it is probably due to better adherence and the positive and reinforcing effects of the therapeutic alliance.

Clinicians are in the best position to help a depressed or manic patient when they convey an attitude of serious concern for the individual's suffering, while at the same time communicating confidence in their own ability and measured optimism about the ultimate outcome of treatment. It is important not to oversell a treatment. If the first approach fails without the patient's having been advised about the possibility of failure, not only is the patient's trust eroded, but the clinician can feel defeated and discredited—feelings that, in turn, may be subtly conveyed back to the

patient. When both clinician and patient view a treatment as an experiment, even a poor response can be seen as an important piece of new information that can contribute substantially to the rational choice of subsequent treatments. Patients who are prescribed drugs should be told that if they fail to respond to one class of drugs, they may, by that very fact, be more likely to respond to an alternative class.

The Role of Lifestyle Changes in Optimizing Treatment

Another key component of treatment is education of the patient about the importance of regular exercise and a good diet. The patient should be made aware of studies supporting an antidepressant effect of vigorous aerobic exercise, as well as evidence that exercise, when done roughly at the same time every day, helps synchronize the circadian clock (which tends to be less stable in manic-depressive illness, particularly the bipolar subgroup; see Chapter 16). Equally important is a good diet, particularly one in which simple carbohydrates are kept to a minimum. It is helpful to explain how bipolar patients tend to have a pattern of reactive hypoglycemia, in which simple carbohydrates in the morning can produce an excessive increase in blood sugar, followed by an excessive decrease; this reactive hypoglycemia is associated with symptoms patients assume are related to their mood disorder or medication, such as feeling tired, “fuzzy-headed,” or irritable. To relieve these symptoms, patients often ingest more carbohydrates (in effect “chasing” their blood sugar throughout the day), and in the process take in many additional calories. The fact that a number of the medications patients take can cause both carbohydrate craving and weight gain further supports the importance of diet and exercise in the comprehensive management of manic-depressive illness.

The clinician should also be familiar with the benefits of stress reduction techniques, such as meditation and yoga, and be able to make referrals to professionals who understand the application of these techniques to patients taking medication for mood disorders. For many patients, moreover, religious faith is not only an important part of their identity but also a source of considerable support and comfort. The clinician should be alert for clues to and always be respectful of the patient’s religious or spiritual life (Griffith and Griffith, 2002; Josephson and Peteet, 2004).

To optimize recovery and reintegration, self-help groups can be invaluable. All clinicians should be familiar with the principal support groups in their area (either patient-run, such as local chapters of the Depression and Bipolar Support Alliance [DBSA], or family-focused, such as the National Alliance for the Mentally Ill [NAMI]), and be

prepared to direct their patients to those groups. Given the importance of such groups to patients’ recovery, we encourage clinicians to support them, not only financially but also through direct participation, such as by giving talks at local meetings or volunteering as a consultant.

Finally, there is perhaps nothing more important to the stability of the bipolar patient than good sleep management. Indeed, disturbances of sleep/circadian rhythms are so central to the pathophysiology of recurrent mood disorders that we have devoted a separate chapter to the topic. As noted above, regularity of the circadian clock is especially critical to the bipolar patient. This means a stable sleep cycle. Patients with difficulty falling asleep should be educated about the importance of having a quiet, low-stimulation environment to prepare for sleep. For example, they should avoid going to sleep with the television on and avoid arguments late at night, avoid the use of stimulants such as coffee and caffeine-based cola beverages, and for most patients, it is best not to read oneself to sleep especially if it involves a computer screen. When reading in bed use a dim (25 watt) bulb. Patients should also be made aware of the importance of avoiding alcohol just before bed; while it may help with the onset of sleep, it will make the patient more likely to awaken later. For most patients, 8 hours of sleep is optimal; less than that over time produces chronic sleep deprivation, with symptoms that can be misread as depression or, when irritability predominates, as a mild mixed state. “How are you sleeping?” is therefore a question that should be part of every clinical contact. The clinician should obtain a detailed description of when sleep onset is occurring, how often and for how long the patient awakens during the night, when the patient arises, and what if any naps are taken during the day.

Summary

Competent and compassionate treatment assumes a thorough knowledge of the diagnosis, clinical description, and natural course of manic-depressive illness. In addition, it assumes an understanding of the pharmacological and psychotherapeutic options available and the lifestyle changes that can optimize treatment, as well as the ability to establish a good therapeutic relationship and a willingness to communicate clearly with patients, their families, and the other professionals involved in patient care. The healing role of the clinician and the potentially life-saving influence of competent and compassionate psychotherapy are too often overlooked in an era of increasingly sophisticated psychopharmacology. The extraordinarily important role of the therapeutic relationship in treatment and recovery was described thus by Morag Coate (1964, p. 214) in *Beyond All Reason*:

Because the doctors cared, and because one of them still believed in me when I believed in nothing, I have survived

to tell the tale. It is not only the doctors who perform hazardous operations or give life-saving drugs in obvious emergencies who hold the scales at times between life and death. To sit quietly in a consulting room and talk to someone would not appear to the general public as a heroic or dramatic thing to do. In medicine there are many different ways of saving lives. This is one of them.

UNDERSTANDING AND INTERPRETING THE TREATMENT RESEARCH LITERATURE

We now turn to the key methodological and conceptual issues one must understand to properly interpret the treatment research literature. While an extensive review of the principles of study design and analysis is beyond the scope of this discussion, we examine some common issues that arise in treatment research. Our focus is on bipolar disorder, although the principles delineated apply as well to recurrent unipolar disorder.

Observational (Naturalistic) Studies

Historically, new ideas and hypotheses have been born in the course of direct clinical observation. Unlike controlled studies, naturalistic studies, at their best, capture the richness and complexity of the seasoned clinician's observations of individual patients. Indeed, the observations of Kraepelin, the father of the study of manic-depressive illness, are continually rediscovered today. To quote Jonathan Himmelhoch (2003), himself a clinical investigator having wide direct experience with manic-depressive patients whose own novel observations have stood the test of time, "anecdotes that break new ground because of the careful clinical observation behind them have far greater sensitivity than can be produced by any instrument." We could not agree more. It has generally been assumed that observational studies report larger effects of a treatment than do randomized controlled trials. In an analysis of 136 reports on 19 various treatments in medicine, however, Benson and Hartz (2000) found little evidence to support this assumption.

On the other hand, with respect to the kind of observational study that compares groups of patients receiving different treatments, definitive conclusions are impossible because the treatments are not administered randomly; that is, the patients are treated by clinicians with particular drugs for certain reasons. This individual decision making means that confounding factors—those other than the one thought to be at issue—could explain the result observed. For example, an observational study of antidepressant discontinuation in bipolar disorder (Altshuler et al., 2003) found that after initial response to a mood stabilizer plus an antidepressant, those patients whose psychiatrist decided

to keep them on the combination stayed well longer than those whose psychiatrist decided the antidepressant should be stopped. Since the nonrandom nature of the treatment choices was not noted in the study's abstract, many readers concluded that the results obtained demonstrated better outcomes with long-term continuation of antidepressants in bipolar patients.

To assess possible confounding bias, readers must put themselves in the place of the treating clinicians: Why would one stop antidepressant use after recovery from an acute episode? There is a literature suggesting that antidepressants can indeed cause mixed states or worsen rapid cycling in patients with bipolar disorder. Thus if a patient had rapid-cycling illness, some clinicians would be inclined to stop the antidepressant after recovery from an acute episode. This might also be the case if a patient had a history of antidepressant-induced mania that was common or severe. Likewise, some clinicians would be less likely to continue antidepressant use in a patient with bipolar-I disorder than in one with bipolar-II disorder. In other words, in such a study we do not know how many patients did worse because they were taken off the antidepressant and how many were taken off the drug because they were doing (or might do) worse. In trying to interpret an observational study, then, it is necessary to know as much as possible about the characteristics of those who were treated one way versus the other. This information is often provided in an initial table of demographic and clinical characteristics so readers can see whether there are any differences, which then might be confounders. A common mistake is for researchers to compare two groups, note a *p* value above .05, and then conclude that there is "no difference" and thus no confounding effect. However, this use of *p* values is generally inappropriate, as discussed further below, because such comparisons are usually not the primary purpose of the study (which might be focused on antidepressant outcome, not age or gender differences between groups). Usually, such studies are underpowered to detect many clinical and demographic differences, and thus *p*-value comparisons are irrelevant.

Levels of Evidence and the Evidence-Based Medicine Movement

A key feature of the evidence-based medicine movement is the concept of levels of evidence (see Box 17-2). Ideally, levels of evidence should guide researchers in making consistent and justified comparisons of different studies and their findings, and enable clinicians to evaluate the validity of the research literature.

It must be borne in mind that each level of evidence has its own strengths and weaknesses, so it cannot be assumed (as those not well versed in the realities of clinical

BOX 17-2. Levels of Evidence

- Level I: Double-blind randomized trials (parallel-group or on-off designs)
 - la: Placebo-controlled monotherapy
 - lb: Non-placebo-controlled comparison trials, or placebo-controlled add-on therapy trials
- Level II: Open randomized trials
- Level III: Naturalistic studies
 - IIla: Nonrandomized controlled studies (with a comparison group)
 - IIlb: Large nonrandomized, uncontrolled studies ($N > 100$)
 - IIlc: Medium-sized nonrandomized, uncontrolled studies ($100 > N > 50$)
- Level IV: Small naturalistic studies (nonrandomized, uncontrolled) ($50 > N > 10$)
- Level V: Case series ($N < 10$), case reports ($N = 1$), expert opinion

Source: Adapted from Gray (2002). Revised in accordance with evidence regarding the validity of naturalistic studies derived from the medical literature and with types of studies frequently published in the psychiatric literature.

trials often do) that a “higher” level always trumps a “lower” one. Consider one major problem that plagues contemporary level I randomized controlled trials in bipolar disorder—the ethical difficulty of enrolling (and maintaining) very ill patients in a trial in which some will be randomized to placebo, especially if the duration of the trial is long (Vieta and Carne, 2005). Thus when a level I trial leads to the conclusion that a given treatment has not been shown to be effective, and that conclusion conflicts with much of the existing expert clinical opinion, it is wise to consider the limited generalizability of that trial’s database before dismissing the opinion of those with extensive clinical experience, including experience with the sickest patients. Many other selection factors operate (intentionally or unintentionally) to limit the generalizability of level I trials.¹⁰ Ideally, of course, the results of double-blind, placebo-controlled studies will be more valid than those of studies at the other, less rigorous levels. In reality, however, open randomized and large observational studies of bipolar disorder can be as accurate as level I studies while having the advantage of being more generalizable (Benson and Hartz, 2000).

In summary, the theory behind evidence-based medicine is not unreasonable. The problems it raises arise from the way it is applied—by the architects of guidelines, third-party payers, health care planners, and regulatory authorities, many of whom tend to overvalue level I research by minimizing its difficulties while nearly dismissing other levels of evidence, particularly if the evidence is based only on a consensus among experienced clinicians.

The Bias against Off-On, On-Off (Mirror-Image) and Crossover Designs, Even When Placebo Controlled

The seminal observation of lithium’s prophylactic effect was a within-patient comparison of episode frequency before and while taking lithium. As described in Chapter 20, the result of this much-criticized study was later confirmed by multiple level I studies. As Post and colleagues (2000) pointed out, the inherent variability and heterogeneity of individual bipolar patients can all too easily undermine the parallel-group randomized controlled trial, which, because this design is perceived to be virtually required by regulatory agencies, is the staple of industry-supported clinical trials, as well as of university institutional review boards. Crossover designs (which mirror good clinical practice) are especially suited to addressing options for those resistant to an initial monotherapy, who unfortunately represent a majority of bipolar patients. The relative strengths and limitations of the traditional parallel-group randomized controlled trial and the off-on, on-off design are outlined in Tables 17-1 and 17-2, respectively.

Challenges in Interpreting Level I Studies

A number of challenges arise in the interpretation of level 1 studies. First, *the use and misuse of p values is a major error in treatment studies*. False positive results occur when too many *p* value-based comparisons are made (type I or multiple-comparison error). The extent of this problem is often not adequately recognized. The basic idea can be understood by considering certain facts about probability. Suppose we are willing to accept a *p* value of .05, meaning that assuming the null hypothesis is true, the observed difference is likely to occur by chance 5 percent of the time. The chance of inaccurately accepting a positive finding (rejecting the null hypothesis) would be 5 percent for 1 comparison, about 10 percent for 2 comparisons, 22 percent for 5 comparisons, and 40 percent for 10 comparisons. This means that if in a randomized controlled trial, the primary analysis is negative but one of four secondary analyses is positive with $p = .05$, that *p* value actually reflects an unacceptably high (22 percent) probability of a chance positive finding. One option would be to apply a correction for multiple comparisons, such as the Bonferroni correction, which would require that the *p* value be maintained at .05 overall by being divided by the number of comparisons made. Thus for 5 comparisons, the acceptable *p* value would be $.05/5$, or .01. The other approach would be simply to accept the finding, but to give less and less interpretive weight to a positive result as more and more analyses were performed.

This is the main reason why, when a randomized controlled trial is designed, researchers should choose one or

TABLE 17–1. Strengths and Limitations of Traditional Parallel-Group Randomized Controlled Trials in Bipolar Illness

Strengths	Limitations
<ul style="list-style-type: none"> • Usually requires for approval by regulatory agencies • Standard in the literature 	<ul style="list-style-type: none"> • Cumbersome, inflexible for initial phases of drug discovery • Dose schedule usually predetermined • Confounds assessment of individual and placebo response • Requires large sample sizes, typically from many centers, increasing variance • Subject to type II errors • Placebo exposure (often lengthy) required • Homogeneous populations required, but strict entry criteria limit generalizability given that the illness is characteristically pleomorphic • Very costly and difficult to manage

Source: Adapted from Post et al., 2003.

a few primary outcome measures for which the study should be properly powered (a level of .80 or .90 [power = 1 – type II error] is a standard convention). Usually there is a main efficacy outcome measure, with one or two secondary efficacy or side-effect outcome measures. An efficacy effect or side effect to be tested can be established either a priori (which is always the case for primary and secondary outcomes) or post hoc (after the fact, which should be viewed

as exploratory but not confirmatory of any hypothesis). For example, in a randomized controlled trial of olanzapine added to standard mood stabilizers (divalproex or lithium) for prevention of mood episodes in bipolar disorder (see Chapter 20), results were reported as positive, with the group taking combined olanzapine and mood stabilizer doing better than those taking mood stabilizer alone. However, this positive finding was a secondary outcome.

TABLE 17–2. Strengths and Limitations of Off–On, On–Off Designs

Strengths	Limitations
<ul style="list-style-type: none"> • Flexible, suitable for pilot studies • Dose exploration easy • Smaller sample sizes possible • Not prone to type II error • Cost-effective • Patient serves as own control • Trial length can be individualized • Length of placebo periods is reduced • Response can be confirmed in individuals • All patients available for biological measures and response predictors • Adaptable for heterogeneous groups; broader entry criteria feasible • Amenable to drug combination studies • Causality of side effects can be established and confirmed 	<ul style="list-style-type: none"> • Traditionally not accepted • No consensus on statistical approaches or on trial length • “Off” periods still pose risk of illness exacerbation • Carryover effects may obscure results • Number of such “sample of 1” studies sufficient to demonstrate generalizable results is uncertain

Source: Adapted from Post et al., 2003.

The primary outcome was time to a new mood episode, and on this outcome, there was no difference. Among a number of secondary outcomes, there was one—defined as time to decreased ratings of mania or depression—on which the olanzapine plus mood stabilizer group did better ($p = .023$). To give the researchers the benefit of the doubt, let us assume that there were only two secondary analyses. Under these conditions, the apparent p value of .023 would represent a true likelihood above the .05 cutoff for statistical significance. Furthermore, even if valid, the outcome is generalizable only to the group of patients experiencing full acute remission with olanzapine, and the benefit was not in prevention of new episodes per se but in somewhat reduced symptomatic burden.

Second, *in presenting descriptive results (as opposed to testing hypotheses), effect-estimate statistics are generally more appropriate than t tests, since the latter can often be misleading* (increased likelihood of being falsely positive with multiple comparisons or falsely negative with underpowered comparisons). Effect-size estimates are calculated with 95 percent confidence intervals (CIs). If the CIs do not cross the null (i.e., the ratio of the numbers being compared is 1), the comparison will be statistically significant in hypothesis-testing terms. For example, in an analysis of the first 500 participants in the NIMH STEP-BD program, Ghaemi and colleagues (2006) examined medications used at baseline and reported that 43 percent of those with a history of psychosis were taking an antipsychotic, compared with only 20 percent of those without such a history; given a relative risk of 2.2 with a 95 percent CI of 1.65–2.93, one can assume that this difference is likely to be real.

A common situation in which t tests can lead to false negative results is comparison of rates of side effects with an active drug versus placebo. For example, in studies of atypical antipsychotics, rates of extrapyramidal syndrome (EPS) for most of these drugs have been reported as not significantly different from those for placebo by t test. However, these efficacy studies are not powered to detect such a difference. It is not uncommon for the risk of EPS to be three- or four-fold higher than that with placebo, but the sample size required to detect this observed difference statistically (i.e., using significance hypothesis-testing procedures) would be over 1,000. Thus absence of evidence is not evidence of absence.

Third, *if a study appears valid, the generalizability of the results should always be assessed*. After overcoming the limitations of confounding bias and chance, a reader might conclude that the results of a study are valid. The final step (noted above in our discussion of the limitations of level I studies) is to assess the generalizability of these valid results. Here the question is, given that these results are correct, to whom do they apply? One must search the methods

section of a study carefully to answer this question, usually by looking for the inclusion and exclusion criteria employed. This issue is especially relevant to maintenance studies of bipolar disorder (which may or may not represent demonstrations of true prophylaxis).

Even when samples are described as meeting diagnostic criteria, one must question whether they are truly representative with respect to treatment response. This issue is particularly relevant when one is comparing a new treatment with an older, established one. An old adage in medicine states, “the longer a successful treatment is available, the more difficult it becomes for researchers to show that it still works.” Let us assume, for example, that one is comparing a new putative mood stabilizer with lithium; it is unlikely that those patients in the community who are doing well on lithium would be interested in participating in a trial of a new drug, particularly if there were a chance that they would end up taking placebo, and their clinicians might consider it unethical to refer them. Indeed, in the initial placebo-controlled trial comparing lithium and divalproex in treating acute mania, the sample included quite a few prior lithium nonresponders. Thus in interpreting the literature, it is useful to remember that new drugs tend to have some advantage over older ones simply because of this referral bias.

Another generalizability issue in maintenance research derives from the fact that there are two basic study designs: prophylaxis and relapse prevention. In the prophylaxis design, any patient who is euthymic, regardless of how that person got well, is eligible to be randomized to drug versus placebo or a comparator. In the relapse prevention design, only those patients who respond acutely to the drug being studied are eligible to enter the maintenance phase, when they are randomized to remain on the drug or be switched (usually abruptly) to placebo and/or an active comparator. For example, the 6-month relapse prevention study of aripiprazole versus placebo started with manic or mixed patients being given the drug open label (see Chapter 20); 37 percent of the original group both tolerated the drug and met response criteria, and it was they who were then randomized to placebo or continued on aripiprazole. Obviously, the 6-month results can be generalized only to the minority who responded acutely. Thus results from a prophylactic design are generalizable, whereas those from a relapse prevention trial are not.

A further problem with the relapse prevention design is that it introduces the possibility of a withdrawal syndrome. Consider the maintenance study of olanzapine versus placebo (see Chapter 20), in which all patients who entered the placebo-controlled phase of the study had to have already responded to open-label olanzapine for acute mania (49 percent of them had). In that study, the placebo relapse

rate was very high, and for 75 percent of the patients the relapse occurred in the first 1–2 months after initiation of the study, which may represent withdrawal relapse after recent acute efficacy. Such results really reflect continuation-phase efficacy, not maintenance-phase or prophylactic efficacy, which, as noted above, is generally defined as starting 6 months to a year or longer after resolution of the acute episode.

Still another generalizability issue emerges from studies of combination therapy, often a comparison of an atypical antipsychotic plus a standard mood stabilizer with mood stabilizer monotherapy in treatment of acute mania (see the review by Zarate and Quiroz, 2003). Such studies tend routinely to show benefit with combination treatment, yet it is important to note that the patients in almost all these studies must fail to respond initially to mood stabilizer monotherapy. Indeed, the few studies of combination therapy that have started with “fresh” patients have tended to show no difference between monotherapy and combined therapy.

Fourth, *meta-analysis is an observational study, and thus cannot be accepted at face value*. Meta-analysis represents an observational study of studies; in other words, one combines the results of many different studies into one summary measure. The “apples and oranges” dilemma is, to some extent, unavoidable in that clinicians and researchers must attempt to pull different studies together into some useful summary of the state of the literature on a topic. There are different ways to go about this, with meta-analysis perhaps being the most useful, but all such reviews have their limitations.¹¹ Meta-analysis weights studies by their samples sizes, but in addition, it corrects for the variability of the data (some studies have smaller standard deviations, and thus their results are more precise and reliable). The problem still remains that studies differ from each other; this problem of heterogeneity introduces confounding bias when the actual results are combined. One option is to exclude certain confounding factors. For instance, a meta-analysis may include only women, so that gender is not a confounder, or may be limited to the elderly, thus excluding confounding by younger age. Often, meta-analyses are limited to randomized controlled trials, as in the Cochrane Collaboration, the idea being that patient samples will be less heterogeneous in the highly controlled setting of such trials than in observational studies. Nonetheless, given that meta-analysis itself is an observational study, it is important to realize that the benefits of randomization are lost. Often readers may not be aware of this, and thus it may appear that a meta-analysis of 10 randomized controlled trials is more meaningful than each trial alone. However, each large, well-conducted randomized controlled trial is basically free of confounding bias, which is never the case

for meta-analysis. The most meaningful conclusions can be reached when both the individual randomized controlled trials and the overall meta-analysis point in the same direction.

Another way to handle the confounding bias of meta-analysis, just as in single observational studies, is to use stratification or regression models, often called *meta-regression*. For instance, if 10 randomized controlled trials exist, but 5 used a crossover design and 5 a parallel design, one could create a regression model that could be used to obtain the relative risk of benefit with drug versus placebo, corrected for the variables of crossover and parallel design. Meta-regression methods are relatively new.

Besides the “apples and oranges” problem, meta-analysis has the publication bias, or “file-drawer,” problem: the published literature may not be a valid reflection of the reality of research on a topic because positive studies are published more often than negative ones. This occurs for various reasons. Editors may be more inclined to reject negative studies given the limits of publication space. Researchers may be less inclined to put effort into writing and revising manuscripts on negative studies given the relative lack of interest engendered by such reports. And, perhaps most important for treatment studies in bipolar disorder, pharmaceutical companies that conduct randomized controlled trials have a strong economic motivation not to publish negative studies of their drugs. If they did so, their competitors would likely seize upon those negative findings to malign the drugs, and the cost of preparing and producing such manuscripts would likely be difficult to justify to the top management of a publicly owned for-profit company. One possible approach to addressing this problem is to create a data registry in which all randomized controlled trials on a topic would be registered. If studies were not published, managers of the registry would obtain the actual data from negative studies and store them for systematic reviews and meta-analyses. This solution is limited, however, by its dependence on voluntary cooperation; in the case of the pharmaceutical industry, most companies refuse to provide such negative data. The patent and privacy laws in the United States protect companies on this issue, leaving definitive scientific reviews of evidence difficult to accomplish.

The potential impact of the bias toward positive findings in the publication of industry-supported studies appears to be reflected in two recent reviews. Heres and colleagues (2006) examined industry-supported studies of atypical antipsychotics and found that in 90 percent of the studies, the outcome was favorable to the sponsor’s drug. This phenomenon can be reflected in contradictory findings about the same drug studied by two different sponsors. An example is the comparison of divalproex and

olanzapine in treating acute mania, in which the results of the Lilly-sponsored study (Tohen et al., 2002) favored that company's drug (olanzapine), while in the Abbott-sponsored study (Zajacka et al., 2002), the risk/benefit analysis favored that company's drug (divalproex) (see Chapter 18). In a similar vein, Perlis (2005) compared randomized controlled trials in which the author(s) reported a financial conflict of interest and trials without such potential conflicts; the former were 4.9 times more likely to report positive results. Related to these observations is the proliferation of papers with "executive authors," in which data derived from large trials conducted by a pharmaceutical company are analyzed "in house." A manuscript is drafted by medical writers working for the company, and one or more academic opinion leaders (who may or may not have been involved as investigators when the data were initially collected) are recruited to serve as lead authors. Obviously, reviewing data already selected by company scientists and analyzed by company statisticians is not the same as selecting and analyzing one's own data de novo.

Fifth, *intent-to-treat analyses are more valid than completer analyses*. In general, in randomized controlled trials, intent-to-treat analyses are considered more valid than completer analyses because they preserve randomization. What this means is that randomization equalizes all potential confounding factors for the entire sample at the beginning of the study. If that entire sample is analyzed at the end of the study, there should be no confounding bias. However, if some of that sample is not analyzed at the end of the study (as in completer analysis, which does not include dropouts before the end of the study), one cannot be sure that the two groups are still equal at the end of the study on all potential confounding factors. If some patients drop out of one treatment arm because of less efficacy or more side effects, these nonrandom dropouts will bias the ultimate results of the study in a completer analysis. Thus in general, an intent-to-treat approach is used. From the study design perspective, this approach is called *intent to treat* because the researchers intend to treat all the patients for the entire duration of the study, regardless of whether they remain in the study until the very end. From the statistical analysis perspective, this approach is called the *last observation carried forward* because it comes down to taking the last data point available for the patient and pretending that it occurred at the very end of the study. The problem with this approach is that it assumes the last outcome for the patient in the study would have remained the same until the study's end, that is, that the patient would not have gotten any better or any worse. This is less of a problem in a short-term than in a maintenance study. Nonetheless, it is important to realize that there are assumptions built into both this and completer analyses and

that no approach fully removes all possibility of bias. The presence of some potential for bias in even the best-crafted randomized controlled trial means one can never be completely certain that the results of any such trial are valid. Thus replication with multiple randomized controlled trials is necessary to get closer to establishing causation.

Finally, *in survival analysis, one always needs to know the sample size at each time point; if there are many dropouts, the survival curve may be misleading*. Survival analysis, a statistical method commonly used in maintenance studies of bipolar or highly recurrent unipolar disorder, measures the time until an event, as opposed to simply counting the frequency of an event. The reason this approach is so prevalent is that it provides more information, and thus more statistical power, than simply assessing the number of patients who respond. In a long-term study, for instance, if one patient relapsed at 1 month and another at 1 year, both would be counted simply as patients who relapsed. Survival analysis makes it possible to take into account that one person relapsed after a much longer period of staying well compared with the other person. One can use a regression model, called *Cox regression*, for survival outcomes to provide an effect size called a *hazard ratio*, which is the survival equivalent of risk ratios or odds ratios for other outcomes.

The primary problems with survival analysis are sample size and dropouts. Sample size decreases with time in a survival analysis. This is expected because patients drop out for a variety of reasons, such as illness relapse, side effects, or having achieved the end point of the study. In general, a survival analysis is most valid for the earlier portions of the curve, where there is a larger number of patients. Thus, a treatment may appear to show a major effect after 6 months, but the sample at that point could be 10 patients in each arm, as opposed to 100 in each arm at 1 month. The results would not be statistically significant, and the effect size would not be meaningful because of the high variability of such small numbers. Nonetheless, researchers continue to rely on survival analysis, mainly because there are no other options at this time. Again, this situation highlights the need to recognize the statistical issues involved, as well as to exercise a good deal of caution in interpreting the results of even the best randomized controlled trials.

The main statistical issue is that since dropouts are unavoidably nonrandom, a survival analysis is more valid if there are few dropouts "lost to follow-up" (i.e., where one has no idea why the patient has left the study). Statisticians have tended to designate a ballpark figure of 20 percent lost to follow-up as tolerable overall so as to maintain reasonable confidence in the validity of a survival analysis.¹² In fact, the dropout rates in maintenance studies of bipolar

disorder tend to be in the 50–80 percent range, which hampers the ability to be certain of the validity of survival analysis in bipolar research. Researchers resign themselves to the fact that this population is highly nonadherent and thus difficult to study. For example, the problem of differential dropouts can be illustrated by a study comparing olanzapine and divalproex in treating bipolar disorder (see Chapter 20). Data on weight gain have been presented in a survival analysis with up to 1-year follow-up. The survival curves appear to show that olanzapine is associated with much more weight gain than divalproex in the first few months, but by 1 year, the rates of weight gain appear to converge. Although not obvious from the survival curves, by 1 year about 85 percent of the sample had dropped out, with many of the dropouts in the olanzapine arm being due to weight gain. Thus, the apparent decline in weight gain with olanzapine could reflect the fact that those who gained weight discontinued the agent earlier in follow-up.

In the above discussion, we have attempted to alert the reader to some of the methodological complexities one encounters in reading the treatment literature relevant to manic-depressive illness. The importance of emphasizing these issues in this volume is underscored by a recent methodological examination of published studies on the treatment of bipolar disorder (Soldani et al., 2005). The authors reported that of the 100 papers randomly selected from the five psychiatric journals with the highest impact ratings, only 19 percent were randomized; most of the rest were small, nonrandomized case series, relying primarily on contrasts between baseline and end point without a control group. Of the 100 papers, 53 made no reference to study design or statistical methods.

Even when considering level I randomized controlled trials, however, we emphasize the need for caution when interpreting their results—whether they indicate a difference between drug and placebo (or between two drugs) or fail to show a difference, especially when this finding is based on nonsignificant p values in the absence of effect-size estimation. The best bulwark against erroneous conclusions remains the requirement for multiple independent replications.

TREATMENT GUIDELINES AND ALGORITHMS FOR BIPOLAR DISORDER

Given the substantial increase in treatment options since the first edition of this text was published, the clinician faces what might appear to be a bewildering array of choices. Thus guidelines and algorithms have understandably been welcomed by many busy clinicians. As long as guidelines remain *advisory* to the clinician, they can be helpful to

both the professional and the patient. We become concerned when they are used by managers of care and third-party payors in an effort to enhance the cost-effectiveness of care by reducing the number of treatment options. This has already happened to those patients in Texas whose treatment is funded by the state. If the tendency to make guidelines coercive continues to grow, both quality and innovation will be threatened (G. Goodwin, 2003a). Since guidelines are, by definition, yesterday's practice of medicine, they inevitably begin going out of date even before they are published.

In their review, Fountoulakis and colleagues (2005) identified a total of 27 guidelines for the treatment of bipolar disorder published since 1994. Table 17–3 lists, in reverse chronological order, the major guidelines for the treatment of adults that have been published since 2002 from North America, Europe, Australia/New Zealand, and the World Federation of Societies of Biological Psychiatry. (Guidelines for the treatment of children and adolescents with bipolar disorder are reviewed in Chapter 23.) Direct comparisons of even the more recent guidelines are limited by the reality that each was developed in its own time frame. Obviously, the more recent guidelines are the most relevant, but even they can quickly become obsolete as new findings emerge from the research literature. Nevertheless, it is useful to examine the existing guidelines to highlight those general approaches for which there is broad consensus, and to take note of important cross-national differences.

The process by which guidelines are developed also differs in ways that may affect the recommendations made. In general, the process begins with a committee of experts who undertake an evaluation of the existing treatment research literature, ranking studies according to the levels of evidence outlined in Box 17–2. Because of the inherently limited generalizability of controlled trials, as discussed above (see also Box 17–3), guideline developers have, to varying degrees, attempted to incorporate expert opinion, thus allowing observational studies and clinical experience to fill in some of the gaps left by controlled studies, such as combined medications, the treatment of comorbid conditions, and drug–psychotherapy interactions. Developers of the Expert Consensus Guidelines in the United States (Keck et al., 2004) have assessed expert opinion most systematically, using a statistical analysis of the answers given independently by 47 experts in bipolar disorder to a series of specific questions about what they would do in particular circumstances. This approach avoids the problem associated with conclusions arising from the deliberations of a committee—that the strongly held opinions of a few members may carry more weight, given that the committee's task is to reach agreement.

TABLE 17–3. Recent Treatment Guidelines

Algorithm	Year of Publication	Reference
American Psychiatric Association Guidelines	2002	Hirschfeld et al., 2002
World Federation of Societies of Biological Psychiatry Guidelines	2002, 2003, 2004	Grunze et al., 2002, 2003, 2004
British Association for Psychopharmacology Guidelines	2003	G. Goodwin et al., 2003
Guidelines from the Danish Psychiatric Association	2003	Licht et al., 2003
Expert Consensus Guidelines (U.S.)	2004	Keck et al., 2004
Texas Medication Algorithm	2005	Suppes et al., 2005
Canadian Network for Mood and Anxiety Treatments Algorithm	2005	Yatham et al., 2005

The various guidelines differ in their level of specificity and coverage. Some, for example, such as the Texas Medication Algorithm (Suppes et al., 2005), the British Association for Psychopharmacology Guidelines (G. Goodwin, 2003b), and the World Federation of Societies of Biological Psychiatry Guidelines (Grunze et al., 2002, 2003, 2004), offer no advice on the treatment of bipolar-II patients, citing the virtual absence of level I studies, and most guidelines fail to address comorbid conditions for the same reason. As might be expected of an evolving process, the three most recent sets of guidelines—the Texas Medication Algorithm, the Canadian Network for Mood and Anxiety Treatments Algorithm (Yatham et al., 2005), and the Expert Consensus Guidelines (all of which happen to be North American in origin)—are the most comprehensive and up to date. The Canadian guidelines present the most thorough review of the literature; they also do a better job than the others of covering assessment issues, bipolar-II, mixed states, and older patients while placing relatively less emphasis on the risk/benefit ratio of different treatment options. The Texas Medication Algorithm also presents an impressive review of the literature and, in its introduction, is clear about the difference between continuation treatment and true prophylaxis. In the specific recommendations included as “maintenance” treatment, however, are two atypicals for which the bulk of the drug–placebo difference occurred in the first few months

after recovery from an acute manic episode, that is, in the continuation phase of treatment.

There are two principal differences between the North American and European guidelines. First, the Europeans place more emphasis on lithium treatment and less on valproate; in North America, the pharmaceutical industry plays a larger role, and as a result there is a great deal more exposure to the newer income-generating, patent-protected drugs, such as divalproex (valproate), and relatively less exposure to such drugs as lithium and carbamazepine (Lieberman et al., 2006; see also Box 17–4). In some European countries, antidepressants are considered first-line treatment for bipolar depression (as long as an antimanic mood stabilizer is used concurrently), whereas the North American guidelines emphasize mood stabilizers for the acute treatment of depression while acknowledging the need for adjunctive antidepressants in more severe cases. For example, the Texas Medication Algorithm considers antidepressants fourth-line treatment after mood stabilizers and combinations thereof.¹³ Another difference between the North American and European guidelines lies in recommendations for when to initiate maintenance treatment: in the North America guidelines, its initiation is clearly recommended after the first manic episode; the European guidelines recommend that maintenance treatment begin after the second manic episode, but can be “considered” after the first if that episode is severe enough (Vestergaard, 2004).

BOX 17-3. Understanding Treatment Guidelines for Bipolar Disorder

- Most guidelines are based primarily on randomized, placebo-controlled trials (RCTs), and are thus affected by the limited generalizability of such trials. For example:
 - In placebo-controlled trials, the sickest patients are under-represented because of ethical concerns about exposing them to placebo, particularly over an extended period of time.
 - Most large RCTs are of monotherapy, whereas most bipolar patients are taking combined medications.
 - Patients with comorbid conditions are excluded from most RCTs, yet most bipolar patients have comorbid diagnoses.
- The level of agreement across guidelines varies with the proportion of RCTs focused on particular states. These differences are especially pronounced between European and North American guidelines.
 - Because the majority of RCTs have been of treatments for acute mania, there is a high level of agreement across those guidelines.
 - Prophylactic treatment has been addressed by an intermediate number of RCT; accordingly, the level of agreement across those guidelines is intermediate.
 - Bipolar depression has been the subject of the fewest RCTs, and therefore the level of agreement across those guidelines is lowest.
- Guidelines follow classification systems (primarily the *Diagnostic and Statistical Manual* [DSM]-IV), and thus are affected by the limitations of those systems (see the text and Chapters 1 and 3 for discussion of these limitations).

While we refer in the chapters that follow to recommendations from various guidelines as they apply to specific treatment situations, we must pause to note that to date, there is scant evidence that guidelines are having much effect on clinical practice in the community. For example, a recent analysis of prescriptions in the community for 7,760 bipolar patients (Baldessarini et al., 2006) found that half received antidepressants, while only a quarter were prescribed a mood stabilizer.¹⁴ Turning to psychiatric settings, a survey of prescribing patterns for 1,864 bipolar-I patients in more than 100 psychiatric inpatient units in the United States (Lim et al., 2001) found that in the treatment of manic or bipolar depressed patients without psychosis, guidelines were followed only 16–17 percent of the time (the percentages were higher for those with psychosis, but still only 38 and 31 percent for mania and depression, respectively). A 1999 survey revealed that one in six psychia-

BOX 17-4. Changing U.S. Prescribing Patterns for Mood Stabilizers

In the United States between the mid-1990s and the turn of the century, a fairly marked shift occurred from lithium to valproate (principally divalproex) for the treatment of bipolar disorder, a trend not seen in most of the rest of the world (Fenn et al., 1996; Goodwin, 1999; Goodwin and Ghaemi, 1999; Blanco et al., 2002). There are many possible explanations for this change. One reason suggested is the intense marketing of divalproex to psychiatrists that occurred during the mid- to late 1990s. Given that divalproex has generated at least 20 times more sales revenue than lithium, it is no surprise that American psychiatrists have had far greater exposure to it through marketing and Abbott Laboratories–supported continuing medical education programs (Goodwin et al., 2003b; Lieberman et al., 2006). In our opinion, a clinician cannot be considered even minimally competent to treat patients with bipolar disorder unless he or she knows how to use lithium.

trists was not even aware that guidelines existed (Jaffe and Yager, 1999), and almost half had not read the guidelines for bipolar disorder. Consistent with these findings are those of Blanco and colleagues (2002), who analyzed data on psychiatrists from the National Ambulatory Medical Care Survey for the years 1992 to 1999. Over one-third of bipolar patients did not receive a mood stabilizer, whereas antidepressant use was “common”: 45 percent of office visits were associated with such a prescription, and for half of these visits there was no accompanying prescription for a mood stabilizer. Unfortunately, this apparent underuse of mood stabilizers accompanied by the apparent overuse of antidepressants was no different when data for the early and late 1990s were compared.

Not surprisingly, the correspondence between guidelines and practice is better in academic settings and in staff model HMOs (where almost all bipolar patients are pharmacologically treated by psychiatrists, and adherence to guidelines tends to be tracked). Two large U.S. datasets reflecting “real-world” open treatment as provided by psychiatrists associated with academic centers (which provide largely tertiary care) are those of the Stanley Foundation Bipolar Network and the NIMH STEP-BD program. An analysis of 457 bipolar-I patients who participated in a Stanley center voluntary registry revealed that 82 percent were taking a mood stabilizer upon entry into the registry (Levine et al., 2000); most were receiving combined treatment involving more than one mood stabilizer. Thus among the 50 percent of the total group taking lithium and the 40 percent

taking valproate, only 18 percent and 10 percent, respectively, received the mood stabilizer as monotherapy. Similarly, in an analysis of medications received just prior to the entry of the first 500 patients into the STEP-BD program (73.6 percent of whom were bipolar-I), Ghaemi and colleagues (2006) found that 72 percent were taking mood stabilizers, but only 11 percent as monotherapy. In another tertiary care setting (the NIMH Intramural Program), it was observed that the proportion of patients receiving combined medications increased sharply from the mid-1970s to the mid-1990s; the proportion of discharged bipolar patients taking three or more medications rose from 3 to 44 percent. By contrast, in two staff model HMOs (Kaiser Northern California and Group Health of Puget Sound) providing primary care psychiatry (whose guidelines for bipolar disorder reserve combined therapy for those who fail monotherapy), only 11.5 percent of patients were treated with more than one mood stabilizer (Hunkeler et al., 1995).

While the largely tertiary-care populations involved in the STEP-BD program and the Stanley centers reflected recent North American guidelines with respect to the central role of mood stabilizers in bipolar disorder, there was less correspondence with guidelines for the adjunctive use of antidepressants: 57 percent of the Stanley patients (including 55 patients not on a mood stabilizer) and 41 percent of the STEP-BD patients were taking antidepressants. The Stanley data reflected treatment patterns in the mid-1990s, whereas the STEP-BD data were collected later, in 1998 and 1999. It is possible that this difference in time frame is relevant to the modest differences reported in antidepressant use, given that the first U.S. guidelines cautioning about the use of antidepressants in bipolar disorder were published in 1994 (American Psychiatric Association, 1994) and 1996 (Frances et al., 1996). While it might be argued that the relatively high rate of antidepressant use is related to the presence of sicker patients in tertiary care settings, antidepressant use was also common in the two HMO primary psychiatric care settings referred to above: 75 percent of patients had received at least one such prescription. The primary care (HMO) data were collected from 1994 to 2001, a period that includes some time prior to the publication of the above-mentioned guidelines.

It is of interest that even though the 2003 British guidelines include antidepressants as a first-line option, the Maudsley Bipolar Project (Frangou et al., 2002) and a survey conducted in northeast England (Lloyd et al., 2003) found that only 14 and 23 percent, respectively, of bipolar patients were taking an antidepressant, whereas in both surveys the use of mood stabilizers was similar to that in the United States.

In conclusion, although there are differences among guidelines (primarily cross-national in nature), they agree on the centrality of mood stabilizers in the management of bipolar disorder and on the inappropriateness of antidepressant monotherapy. Further, all three of the most recent guidelines, to varying degrees, express caution about the use of antidepressants even when combined with a mood stabilizer. Thus far, the impact of guidelines on practice in the United States has not been obvious in the data on prescription patterns; no doubt this is due, at least in part, to the fact that prescription data are derived from all physicians, not just psychiatrists. Finally, it must be noted that guidelines are organized according to current diagnostic schema; that is, there are separate guidelines for bipolar disorder and major depression, but none for the highly recurrent unipolar group, which in effect falls between the cracks.

MEDICATIONS USED TO TREAT MANIC-DEPRESSIVE ILLNESS

Here we review the basic pharmacology of the medications used for acute, continuation, and maintenance treatment of manic-depressive illness. Clinical detail on the use of these agents, including additional findings concerning dosage and drug interactions, is presented in the chapters that follow. Since side effects and adverse events are most salient during maintenance treatment, they are covered in Chapter 20, while information on the use and side effects of the various medications related specifically to children and adolescents is presented in Chapter 23.

Lithium

Although the mechanism of lithium's action in acute treatment of mania and depression and in prophylactic therapy for bipolar disorder is unknown, several productive theories are being tested (see Chapters 18, 19, and 20, respectively, and Chapter 14). The standard oral formulation is the carbonate salt of lithium, whereas the liquid formulation uses the citrate or chloride salt. The U.S. Food and Drug Administration (FDA) has approved lithium carbonate for both the treatment of manic episodes and maintenance treatment of bipolar disorder.

Lithium carbonate is readily absorbed throughout the gastrointestinal tract. There are preparations that delay absorption somewhat (Eskalith CR, Camcolit, Priadel, and Lithobid) and to some extent reduce the peaks and valleys of serum lithium levels throughout the day. The principal advantage of these preparations is a lower frequency of initial gastrointestinal side effects, which may enhance adherence. These preparations also appear to have less of an effect on urinary osmolarity, which would be consistent

with a reduced long-term impact on renal function (although this has not yet been studied directly) (Vestergaard and Schou, 1987). Lithium is excreted primarily in urine; renal excretion is rapid under normal circumstances. The drug is passed into the glomerular filtrate and is indistinguishable from sodium in the proximal tubule, where both are reabsorbed. It is reabsorbed to a much lesser extent in the loop of Henle and is not reabsorbed at all in the distal tubule.

The half-life of lithium is initially about 12 hours, but reaches approximately 24 hours once steady-state serum levels have developed at about 5 days. The conventional trough serum lithium level occurring 12 hours after the last dose is the standard level for measurement. The dose/blood-level ratio is influenced by the individual's clinical state (manic or depressed), gender, age, weight (especially muscle mass), salt intake, extent of sweating, intrinsic renal clearance capacity for lithium, and use of other medications. A relatively higher dose/blood-level ratio is associated with being manic, younger, male, and heavier and having a higher salt intake. Although controlled studies are lacking, results of open trials suggest that therapeutic blood levels for children and adults are about the same.

To predict dosage requirements, some investigators recommend a test dose of lithium, followed 24 hours later by a plasma-level determination (Cooper and Simpson, 1976; Fava et al., 1984; Perry et al., 1984). Although this technique probably can be applied reliably when the mood state is stable, its practical value in treating acute mania is limited. Errors in the predicted dose may, for example, be due to changes in patients' sleep and activity, which cause changes in glomerular filtration rate (Perry et al., 1984). In addition, use of this method necessitates a 24-hour delay in treatment.

Because the proximal tubule reabsorbs lithium as it does sodium, it is essential for the patient to maintain normal salt and adequate fluid intake to prevent the development of lithium intoxication. Although decreased tolerance to lithium has been reported to ensue from protracted sweating, the only test of this effect in a small number of healthy long-distance runners did not find a tendency toward increased lithium levels following vigorous exercise. Nonetheless, some caution is warranted. The risk of elevation of serum lithium levels as a result of diarrhea and vomiting is undeniable. Should these conditions occur, supplemental fluid and salt should be administered, and lithium therapy may need to be stopped temporarily until fluid and salt balance can be restored.

The gap between therapeutic and toxic levels of lithium is narrow. Thus the frequency of serum monitoring of lithium should be proportional to the risks associated with particular patient profiles. When there is reason to believe

that lithium levels may be fluctuating—because of erratic adherence, a sudden change in clinical state (e.g., a switch from mania into depression),¹⁵ the presence of medical conditions that could affect renal function, concurrent medications, individual sensitivity to the effects of lithium, a low-salt diet, or excessive sweating—and whenever there is clinical suspicion of impending toxicity, serum-level monitoring must be more frequent (Goodwin and Goldstein, 2003). Serum lithium levels should be obtained whenever there is a change in dosage and at least every 6 months in stable patients. Elderly and frail patients should be tested more often.¹⁶

Anticonvulsants

Valproate

Valproate is a gamma-aminobutyric acid (GABA)-enhancing anticonvulsant approved by the FDA for the treatment of epilepsy and acute mania and for migraine prophylaxis. Preparations include capsules, elixir, rectal forms, and, most recently, an intravenous (IV) formulation; none of these forms appears to offer any particular advantage for treatment of bipolar disorder. Nor has the rapid oral loading protocol that most patients tolerate (McElroy et al., 1998) been shown to result in a faster onset of antimanic action compared with slower titration protocols. The level of gastrointestinal irritation is dramatically reduced with the sodium divalproex formulation of valproate, which has largely replaced the original formulation. Still, indigestion and nausea, along with sedation, are the most common side effects.

Valproate inhibits the enzymes that metabolize several other drugs, including, most notably, lamotrigine. The therapeutic range of this and other psychotropic drugs is difficult to define precisely, but it would appear that levels above 70 and below 120 milligrams per milliliter (mg/ml) are as close to optimal as is practical for most patients (Ellenor and Dishmon, 1995).

Carbamazepine

Carbamazepine, a tricyclic compound that is classified as an iminostilbene derivative, has been shown to be effective in the treatment of mania. Results of trials comparing its prophylactic effect with that of lithium suggest that it probably has maintenance efficacy, but it has never been submitted to the FDA for this indication.

Carbamazepine¹⁷ is reported to be absorbed slowly and erratically from the gastrointestinal tract. After chronic use, the time to peak plasma concentrations is several hours following ingestion (Pugh and Garnet, 1991). Carbamazepine is lipophilic; therefore, no parenteral forms have been developed, and different brands of the drug cannot be assumed

to produce the same blood levels. Bioavailability can be estimated at about 80 percent (Ketter et al., 1999). Although carbamazepine undergoes only modest first-pass metabolism, it is extensively metabolized in the liver. Approximately 75 percent of the drug is protein bound. Carbamazepine can induce its own metabolism such that over time, dose increments may be needed. The drug can also impact the metabolism of some other agents, most notably inducing lamotrigine metabolism such that the dose of the latter may need to be increased when the two drugs are used in combination.

Oxcarbazepine

Oxcarbazepine is a chemical derivative of carbamazepine with a similar structure and antiepileptic profile. It is rapidly and extensively converted to the 10-hydroxy metabolite, suggesting that it may be an easier drug to administer than carbamazepine, with fewer drug interactions, and easier to tolerate with less neurotoxicity. Oxcarbazepine's most common side effects are tiredness, headache, dizziness, and ataxia. Also, it has been reported to cause allergic reactions and hyponatremia, although less frequently than carbamazepine. It is also associated with a lack of effects on the hematopoietic system. Large controlled studies of its efficacy in bipolar patients is lacking.

Lamotrigine

Lamotrigine is a phenyltriazine structure; controlled trials have demonstrated its maintenance efficacy against depression in bipolar patients, for which it has an FDA indication. It is probably also effective in the acute treatment of bipolar depression. Lamotrigine inhibits the release of glutamate, which may be the basis for its anticonvulsant activity, but neither this nor the basis for its putative antidepressant action is known. It is readily absorbed in the gut and is only about 50 percent bound to plasma proteins; about 90 percent is metabolized to inactive metabolites in the liver, while 10 percent is excreted unchanged. Its half-life is about 24 hours. Birth control medications can decrease plasma levels of lamotrigine, but the converse is not true.

Gabapentin

Gabapentin is structurally related to GABA but does not bind to the GABA receptor as a GABA analogue, as was originally believed when the drug was developed in the early 1970s. It does enhance GABA function in some indirect manner. What role, if any, the drug has in the management of bipolar patients is unclear, especially after it failed to separate from placebo in controlled trials of treatment of mania. It has looked somewhat more promising as an adjunctive agent based on the results of uncontrolled studies. Gabapentin is readily absorbed, is not protein bound, is not

metabolized, and is excreted almost exclusively in its original form by the kidney. Thus it has a very short half-life of about 6 hours, indicating the need to give it in multiple daily doses. Because there is no known relationship between blood level and therapeutic response for the drug, there is no indication for therapeutic monitoring, and perhaps most difficult, a wide range of possible therapeutic doses exists (600–4500 mg/day). From a kinetic point of view, the drug would be advantageous in patients with liver function problems or those taking other drugs that affect hepatic metabolism, but there would be a corresponding need for caution in patients with impaired or unstable renal function.

Topiramate

Topiramate is described as a fructopyranose. It is an antiepileptic agent thought to increase GABA activity and to inhibit excitatory glutamate receptor activation. It is readily absorbed and largely unmetabolized, and about 70 percent is excreted in free unchanged form by the kidney; about 15 percent is protein bound. It has a serum half-life of about 21 hours. Phenytoin and carbamazepine lower its serum levels and its half-life, while topiramate can increase serum levels of those two anticonvulsants. In several controlled trials with manic patients it has not been better than placebo.

Tiagabine

Tiagabine is a nipecotic acid derivative whose mechanism of action in epilepsy is thought to be related to GABA action. There is little evidence, controlled or otherwise, for its utility in treating bipolar disorder. It is rapidly absorbed, with peak serum levels occurring within 1 hour of a first dose. It is predominantly protein bound in serum. Almost all of tiagabine is metabolized in the liver; however, other routes are also known to play some role. The mean half-life of the drug is 8 hours, but is decreased by carbamazepine and other enzyme inducers.

Antidepressants

Monoamine Oxidase Inhibitors

Monoamine oxidase inhibitors (MAOIs) inhibit enzymes responsible for the neuronal breakdown of catecholamine and indoleamine neurotransmitters. The original MAOIs were irreversible inhibitors of both types of monoamine oxidase enzyme, A and B, which are found primarily on the outer membrane of mitochondria. In the past decade, both reversible MAO-A inhibitors and a selective MAO-B inhibitor in patch form have been developed, adding the potential for greater specificity and safety to the profile of this group of antidepressants.

MAOIs are absorbed quickly when administered orally. Peak MAO inhibition occurs within several days following

the initial low dose, which is then gradually increased based on therapeutic effects and tolerability of side effects. Tranylcypromine is administered 10 mg/day; phenelzine can be given at a higher dosage of 15 mg/day. Effects of these drugs are often not observed for 2–4 weeks. Sometimes, amounts as high as 90 mg are required for an adequate response and reduction in depressive symptoms. MAOIs should be discontinued gradually, as sudden withdrawal can result in delirium and agitation.

Tricyclics

Tricyclic antidepressants—the first widely studied agents to treat depression successfully—putatively act by inhibiting the norepinephrine and serotonin uptake in nerve endings. Imipramine was the first tricyclic used and remains the most thoroughly studied (Kuhn, 1957). Amitriptyline, clomipramine, desipramine, doxepin, nortriptyline, protriptyline, and trimipramine are other widely available tricyclic preparations.

Tricyclic antidepressants are absorbed quickly and almost completely by the small bowel. Peak plasma concentrations usually occur within 2–3 hours of ingestion. The half-lives of tricyclic antidepressants are relatively long and variable, ranging from 6 to 198 hours. Protriptyline, for example, has a half-life of 80 hours. Tricyclic antidepressants are highly lipophilic and bind strongly to plasma proteins in the heart and to brain tissue.

Plasma levels have been correlated with both therapeutic (Ziegler et al., 1978) and toxic (Spiker and Pugh, 1976) effects. Wide variation in plasma levels is due largely to genetic differences in the hepatic enzymes responsible for the drugs' metabolism. Sampling should be performed 1 week following administration to ensure a steady-state level, and 10–12 hours following the last dose to ensure complete absorption and distribution. The therapeutic ranges suggested in the literature are 50–140 nanograms per milliliter (ng/ml) for nortriptyline and 110–180 ng/ml for all other tricyclic antidepressants (except protriptyline).

Selective Serotonin Reuptake Inhibitors

Selective serotonin reuptake inhibitors (SSRIs) block 5-HT reuptake from synaptic clefts, making more of this neurotransmitter available at postsynaptic receptors. Their popularity, particularly outside of psychiatry, is due primarily to their having fewer side effects, far less potential for lethal overdose, and drug interactions compared with the older antidepressants, as well as a reduced requirement for medical testing (e.g., electrocardiogram) prior to their use and the elimination of plasma monitoring. The absorption of SSRIs is generally efficient, although results of one study suggest that the concentration of sertraline in

plasma is 32 percent higher when taken with food. The metabolism of SSRIs is influenced by age, disease, gender, environmental agents, and type and amount of drug administered.

The specific SSRI dosage varies depending on the particular drug. The simplest regimens, for citalopram, fluoxetine, and paroxetine, are 20 mg/day from the initial day of treatment. Sertraline and fluvoxamine are usually titrated upward until a clinical effect is achieved. Most SSRIs have elimination half-lives ranging from 15 to 26 hours. However, norfluoxetine, the active metabolite of fluoxetine, has a half-life of 7–9 days. Because of this longer half-life, the usual 2-week “wash-out” period recommended when switching an SSRI to an MAOI should be extended (usually to 5 weeks) when a patient is being switched from fluoxetine to an MAOI.

Bupropion, Selective Norepinephrine Reuptake Inhibitors, and Other Antidepressants

Bupropion is a weak blocker of the neuronal uptake of serotonin and norepinephrine, but it does increase norepinephrine turnover by other mechanisms; it also inhibits the neuronal reuptake of dopamine to some extent. In humans, following oral administration of bupropion, peak plasma bupropion concentrations are usually achieved within 2 hours, followed by a biphasic decline. The terminal phase has a mean half-life of 14 hours, with a range of 8 to 24 hours. The distribution phase has a mean half-life of 3 to 4 hours. The mean elimination half-life (\pm standard deviation [SD]) of bupropion after chronic dosing is 21 (\pm 9) hours, and steady-state plasma concentrations of the drug are reached within 8 days. Plasma bupropion concentrations are dose-proportional following single doses of 100 to 250 mg; however, it is not known whether the proportionality between dose and plasma level is maintained in chronic use.

Venlafaxine and its major metabolite, O-desmethylvenlafaxine (ODV), are potent inhibitors of neuronal serotonin and norepinephrine reuptake and weak inhibitors of dopamine reuptake. Venlafaxine is well absorbed, with peak plasma concentrations occurring approximately 2 hours after dosing. The drug is extensively metabolized, with peak plasma levels occurring approximately 4 hours after dosing. The mean elimination half-lives for venlafaxine and its active metabolite are 5 (\pm 2) and 11 (\pm 2) hours, respectively.

Duloxetine is a balanced selective serotonin and norepinephrine reuptake inhibitor. It appears to be fairly well absorbed after oral doses; peak plasma levels occur in 6–10 hours (dose-dependent). The drug is extensively metabolized in the liver to active metabolites; most of an oral dose is excreted in the urine, only a small amount of which is

unchanged. An elimination half-life of 11–16 hours has been reported.

Reboxetine is a novel selective norepinephrine reuptake inhibitor that is well absorbed after oral administration. Its absolute bioavailability is 94.5 percent, and maximal concentrations are generally achieved within 2 to 4 hours. Food affects the rate but not the extent of absorption. The mean half-life of the drug (approximately 12 hours) is consistent with the recommendation to administer it twice daily.

Nefazodone exerts dual effects on serotonergic neurotransmission through blockade of 5-HT₂ receptors and inhibition of serotonin reuptake. These two properties combine to increase serotonergic neurotransmission through other serotonin receptors, such as the 5-HT_{1A} receptor. Nefazodone is rapidly and completely absorbed but is subject to extensive metabolism, so that its absolute bioavailability is low—about 20 percent—and variable. Peak plasma concentrations occur at about 1 hour, and the drug's half-life is 2–4 hours.

Typical Antipsychotics

In 1952, the first conventional antipsychotic, chlorpromazine, was found to be therapeutic for schizophrenia, an effect thought to be related to its blockade of dopamine D₂ receptors. Since that time, a multitude of new antipsychotic drugs have been introduced. These drugs are categorized into five distinctive classes: phenothiazines, butyrophenones, dibenzoxazepines, thioxanthenes, and dihydroindolones. All typical antipsychotics act equally to relieve psychotic symptoms, such as hallucinations, delusions, and thought disorders.

All antipsychotics are well absorbed; however, oral administration can result in less predictability in absorption, and food and antacids can affect absorption by the gastrointestinal tract. Most antipsychotics peak at approximately 3 hours following oral administration, but peak plasma levels can occur within 30 minutes or after up to 5 hours. Steady-state blood levels are reached within 3 to 5 days. Metabolism occurs mainly in the liver, but also in the intestinal wall. The bioavailability of most of the antipsychotics is relatively high, but for some is considerably lower. Haloperidol tablets, for example, have an average bioavailability of only 60 percent. The elimination half-life of typical antipsychotics can range from 1.5 hours to 26 days.¹⁸

Atypical Antipsychotics

Following oral administration of atypical antipsychotics, the gastrointestinal system absorbs the drug rapidly and almost completely. Food appears to have no effect on the rate and extent of absorption of these agents with the exception

of ziprasidone, which is absorbed to a lesser extent on an empty stomach. Peak plasma concentrations for the original compound usually occur between 1 and 6 hours. A steady-state level can be achieved within 5 to 6 days. It has been found that atypical antipsychotics have a very high bioavailability and protein binding. The elimination half-lives for all atypical antipsychotics range from 3 to 27 hours.

Benzodiazepines

Although benzodiazepines are now prescribed for a wide range of indications, they were introduced in the 1970s as powerful and rapid-acting antianxiety or hypnotic drugs. These drugs bind benzodiazepine receptors, which allosterically modulate GABA receptors, the most ubiquitous inhibitory neurotransmitter in the brain. In bipolar disorder, the high-potency benzodiazepines (clonazepam and lorazepam) are used either for their sedative properties (for example, to abort an emerging hypomanic/manic episode by aiding sleep) or as treatments for comorbid anxiety symptoms.

Following oral administration, lorazepam is absorbed rapidly and completely, whereas clonazepam is absorbed more slowly. Peak serum levels for lorazepam occur within 1–2 hours, whereas clonazepam requires several hours. All benzodiazepines exhibit first-order kinetics over the therapeutic dosage range, with metabolism occurring in the liver; they all bind to plasma proteins at levels of 70 percent or higher. Lorazepam has a relatively short half-life of 10–20 hours, whereas that of clonazepam is 18–50 hours.

NOTES

1. Indirectly, lithium also made possible the birth of the first patient-run support/advocacy group, the National Depressive and Manic Depressive Association (now the Depressive and Bipolar Support Alliance [DBSA]), by helping many patients function well enough to form and run an effective national organization.
2. Tohen et al., 1990, 1992, 2000, 2006; Coryell et al., 1993; Strakowsky et al., 1998, 2000.
3. In a recent survey in Norway, bipolar patients were more than three times as likely as controls to be unemployed and three times as likely to be on disability, despite the fact that the patients enjoyed a significantly higher educational level than that of the controls (Schoyen et al., 2006).
4. Earlier studies, largely from academic health centers, while noting the expected relationship between substance abuse and symptomatic and/or syndromal outcome, did not find such a relationship with functional outcome (reviewed in Bauer et al., 2001). The difference between these studies and that of Conus and colleagues (2006) may reflect the fact that patients in tertiary referral academic centers are generally sicker, with both high rates of substance abuse and poor functional outcome, making it more difficult to demonstrate a relationship.

5. The word *predicts* is used here in the statistical sense, reflecting an association between two variables without implying the direction of causality.
6. See, e.g., Lish et al., 1994; Ghaemi et al., 2002; Goldberg and Ernst, 2002; Hirschfeld et al., 2003.
7. Not surprisingly, the bulk of the data establishing this relationship comes from studies of lithium.
8. Prien et al., 1974; Abou-Saleh and Coppen, 1986; Gelenberg et al., 1989; O'Connell et al., 1991; Winokur et al., 1993; Lish et al., 1994; Baldessarini et al., 1999; Franchini et al., 1999; Swann et al., 1999.
9. One managed care problem that is rarely addressed is the practice of pharmacy benefit managers allowing patients to obtain only 30 days of a prescription at one time; this practice substantially increases the likelihood of patients missing medications and thus going through periods of withdrawal.
10. See, for example, Calabrese and Rapport, 1999; Baldessarini et al., 2000; Post et al., 2000; Rush et al., 2000; Licht et al., 2002; Rothwell et al., 2005.
11. The least acceptable approach to a review of the literature is the classic "selective" review, in which the reviewer selects those articles that agree with his or her opinion and ignores those that do not. In this approach, any opinion can be supported by selectively choosing among studies in the literature. Unfortunately, most reviews of the literature on bipolar disorder fall into this category. The opposite of the selective review is the systematic review. In this approach, some effort is made, usually with computerized searching, to identify all studies on a topic. Once all studies have been identified (ideally including some that may not have been published), the question is how these studies can be compared.
The simplest approach to reviewing a literature is the "box score" method: How many studies were positive and how many negative? The problem with this approach is that it fails to take into account the quality of the various studies (i.e., sample sizes, randomized or not, control of bias, adequacy of statistical testing for chance). The next-most rigorous approach is a pooled analysis. Unlike the "box score," this approach corrects for sample size, but nothing else. Other features of studies are not assessed, such as bias in design, randomization or not, and so on. Sometimes, those features can be controlled by inclusion criteria that might, for instance, limit a pooled analysis to randomized studies.
12. Sometimes a sensitivity analysis can be done, where one assumes a best-case scenario (all dropouts remain well) and a worst-case scenario (all dropouts relapse) to see whether the conclusions change. Nonetheless, a high percentage of dropouts means one cannot be certain whether results are valid.
13. The Texas Medication Algorithm does include the olanzapine-fluoxetine combination (OFC) as one third-line option, given that it was approved by the U.S. Food and Drug Administration for bipolar depression based on adequate data from randomized controlled trials. However, when comparing treatment options, it is important to note that OFC is not a drug—it is two drugs marketed as a single pill. Scientifically, it should be compared with other combinations of two drugs.
14. It should be noted that these data include all prescriptions, not just those written by psychiatrists.
15. In the lithium treatment of acute mania, the patient's clinical state is one of the factors affecting the dose/blood-level ratio. Some patients when manic retain lithium in body pools outside the plasma, possibly in bone (Greenspan et al., 1968; Almy and Taylor, 1973). In practice, more lithium may be needed to achieve a given blood level during mania than during euthymia or depression (Goodwin et al., 1969; Serry, 1969; Kukopulos et al., 1985).
16. When renal concentrating ability is substantially impaired or the patient excretes in excess of 4 liters of urine per 24 hours, careful monitoring (by the patient and the physician) of fluid balance is required to avoid dehydration and lithium intoxication (Vestergaard and Shou, 1987). Although renal concentrating ability usually improves if lithium is discontinued, the improvement can be quite delayed and incomplete if the impairment has been long-standing. Lithium discontinuation studies indicate that increases in 24-hour urine output remain the same or decrease only slightly after lithium is discontinued.
17. More sedation and ataxia occur with rapidly rising levels of carbamazepine than with most other modern anticonvulsants, and as a consequence, titration often needs to be slowed, especially when multiple drugs are being used together. Most of these cases have occurred in the elderly and within the first 4 months of treatment.
18. Serious side effects are associated with the typical antipsychotics. Common central nervous system side effects involve altered thermoregulation, extrapyramidal syndrome, neuroleptic malignant syndrome, and tardive dyskinesia. Orthostatic hypotension is also observed. Erectile dysfunction, blurred vision, constipation, and urinary retention are common anticholinergic effects. Cardiovascular effects include electrocardiogram changes, tachycardia, and torsade de pointes. Changes in the endocrine system, including amenorrhea and galactorrhea, occur as well. Occasionally the hematological system can be involved, with agranulocytosis and leucopenia occurring. Liver enzyme elevations are sometimes seen early in treatment; they usually resolve even with continued treatment, but can cause bilirubin with cholestatic jaundice to occur. Other pertinent side effects include allergic reactions and skin photosensitivity and all immune-mediated agranulocytopenia. Sedation and weight gain are observed as well. So-called low-potency antipsychotics cause more sedation and vascular side effects (orthostasis), whereas the more potent drugs are more commonly associated with extrapyramidal syndrome. The greatest concern arises for extrapyramidal syndrome, the potentially fatal neuroleptic malignant syndrome, and potentially irreversible tardive dyskinesia. These severe side effects have led to a recent trend toward the use of atypical antipsychotics, especially for patients newly diagnosed.

[Robert Lowell] showed me the bottle of lithium capsules. Another medical gift from Copenhagen. Had I heard what his trouble was? “Salt deficiency.” This had been the first year in eighteen he hadn’t had an [manic] attack. There’d been fourteen or fifteen of them in the past eighteen years. Frightful humiliation and waste. . . . His face seemed smoother, the weight of distress—attacks and anticipation both gone.

—Richard Stern (cited in Hamilton, 1982, p. 370)

Despite the availability of many effective pharmacological agents for treating mania and hypomania, the management of both states is often challenging. Unlike the depressed patient, who usually seeks out treatment, the manic patient—and especially, perhaps, the hypomanic patient—often resists treatment. Moreover, the physician treating the first manic episode in a previously untreated patient must engage the patient’s cooperation in treatment, simultaneously educate family and friends about the illness, and coordinate efforts with hospital staff and even law enforcement agencies. In many ways, the pharmacological treatment of the manic patient, the main focus of this chapter, may be the easiest part of the clinical work performed by the physician.

This chapter addresses hypomanic, manic, and mixed affective states, the latter usually characterized by a combination of the dysphoric mood of depression and the pressured agitation of mania; the management of mixed states resembles that of mania much more than that of bipolar depression (see Chapter 19). Note that this chapter focuses on medical treatment during the acute and continuation stages of these conditions, as defined in Chapter 17. Long-term maintenance (prophylactic) treatment is covered in Chapter 20, while psychotherapeutic treatment is discussed in Chapter 22. Two important related topics—medication adherence and psychotherapy—are addressed in Chapters 21 and 22, respectively. Note also that many of the drugs discussed here for acute and continuation treatment of hypomania, mania, and mixed states are used as well for patients with acute bipolar depression and for maintenance treatment, and are therefore discussed in Chapters 19 and 20 as well. The reader interested in a detailed review of the drugs themselves, including their functioning and their side effects, should refer to those chapters.

The chapter begins with a discussion of clinical management, emphasizing proven and/or widely accepted approaches to treatment. We then review the literature supporting these approaches, as well as newer and less proven but nevertheless promising interventions that may become more standard in the future. All of the drugs mentioned in the first section of the chapter are discussed in detail in the second.

CLINICAL MANAGEMENT

A patient in the throes of a manic or mixed episode can be intensely agitated, uncooperative, psychotic, aggressive, and quite dangerous. By the time the clinician is contacted, both patient and family may be confused and distraught, and the clinician may have little time to ponder available choices. Ideal treatment involves both persuasion and medication, but is the patient persuadable, and which drug is best for this patient in this situation? To what degree is there a danger to staff, accompanying family, or the patient in the manic or mixed state? Should the selected drug be offered orally, or will parenteral administration be quicker and more effective? Each decision calls for balancing the high-risk manic agitation against the consequences of intervention—a medication’s potency against its side effects, for example, or the patient’s safety against the risks and responsibilities of forced medication and possible involuntary hospitalization. Our recommendations for the selection of appropriate treatments for particular patients are presented later in the chapter.

This section addresses the key aspects of clinical management of hypomania, mania, and mixed states. Discussed in turn are evaluation of the manic, mixed-state, and hypomanic patient; hospitalization; general considerations involved in medical treatment; clinical features that modify

medication management; medication dosages and therapeutic monitoring; hypomanic symptoms; and general psychological issues related to the medical treatment of mania. Detailed discussion of special considerations in treating children and adolescents is presented in Chapter 23, and of issues involving drugs and pregnancy in Chapter 20.

Evaluation of the Manic, Mixed-State, and Hypomanic Patient

By definition, the manic or mixed-state patient is highly agitated and not easily amenable to examination. It is critical, then, to obtain the patient's history from family, friends, coworkers, law enforcement officers, or whoever may be available to give information about the course of illness and development of symptoms. A history of prior manic or depressive episodes will, of course, be very helpful in making a diagnosis, but mania should be suspected in any disorganized patient with marked psychomotor agitation (see also the discussion of diagnosis in Chapter 3). A differential diagnosis will include schizophrenia, drug-induced states, and delirium from metabolic or other medical causes, but because the emergent treatment of all these conditions is generally similar, behavioral management of the potentially dangerous patient will usually take priority over the subtleties of the usual psychiatric diagnostic process. Nevertheless, a mental status examination assessing such symptoms as euphoric or irritable mood, pressured speech, and grandiose themes should be performed when feasible. Although the usual structured cognitive examination may not be possible, it is important to rule out delirium by means of questions addressing orientation and awareness of surroundings.¹

Laboratory testing is extremely important in evaluating the agitated psychiatric patient. Even if the history obtained clearly suggests a diagnosis of mania, the patient's psychiatric condition can be exacerbated by and the clinical picture confused by drug use or medical conditions. The patient's condition may also be affected by nonadherence to treatment for concurrent medical conditions, such as diabetes and hypertension. Manic patients will frequently be dehydrated and may be at risk for rhabdomyolysis, or they may present with simultaneous alcohol or drug intoxication or withdrawal (see Chapter 7). Testing for electrolyte abnormalities, hypo- and hyperglycemia, liver and renal dysfunction, and illicit drug use is thus an essential part of the initial evaluation.

The hypomanic patient will show less psychomotor agitation than the manic patient and can often be examined in greater detail. These patients may be less than forthcoming during the exam, however, and quite unreliable when it comes to giving a medical or psychiatric history. Indeed, hypomanic patients may actively withhold information or

even prevaricate regarding symptoms and behavior if they believe doing so is necessary to avoid hospital confinement. Furthermore, mental status examination of hypomanic patients, who may evidence little more than slightly pressured speech and infectious high spirits, can belie the dangerousness of their situation. Such patients will be more likely than disorganized, agitated manic patients to enter into ruinous business deals or sexual indiscretions. Again, information from other individuals is vital for treatment planning.

Hospitalization

Patients exhibiting severe mania will need to be hospitalized, often involuntarily. When manic symptoms are still in the mild to moderate range, judging the need for and the timing of hospitalization is more difficult. In deciding whether to hospitalize a patient, the clinician must keep in mind that mild mania can progress rapidly and unexpectedly to more severe forms. The medical, social, occupational, and legal risks of such extreme behavior must be weighed against the financial, social, and personal consequences of hospitalization.

The uncomfortable affect of the mixed state, together with its disinhibition, paranoia, and behavioral activation, can be an especially dangerous combination. Such patients are at very high risk of self-harm, sometimes higher than that for patients with pure major depression (see Chapter 8). A history of serious suicide attempts, as well as of previous hospitalizations, further increases the risk of suicide. Expressions of desperation or hopelessness in a manic patient indicate the need for immediate hospitalization.

The interpretation of commitment laws and the details of the commitment process vary considerably from community to community, even within the same state. Therefore, familiarity with local commitment laws is indispensable for the clinician involved in the treatment of manic, mixed-state, or hypomanic patients. Many states require that the clinician have first-person knowledge of disturbed behavior or suicidality before a psychiatric patient is hospitalized involuntarily—knowledge sometimes not available to the clinician who is at the receiving end of a phone call from a desperate family member. The clinician may have to spend considerable time educating family members about the steps necessary to initiate involuntary commitment of their loved one. Family members may resist taking on this responsibility, regarding it as a betrayal of their relative; some may worry about future physical or psychological reprisals. First-hand knowledge of the commitment process will enable the clinician to provide the necessary guidance and support. Advance directives, executed when the patient was euthymic, can be of help (see Chapter 22).

Safety issues will frequently inform the decision whether to hospitalize the manic patient, and here the choice is often more clear-cut. Patients showing severe behavioral dyscontrol and marked psychomotor agitation will obviously need to be hospitalized. In the case of the hypomanic patient, such overt evidence of poor impulse control, potential suicidality, or imminent violence may be absent. The decision-making process then shifts from focusing on the patient's current condition to assessing the probability that this condition will deteriorate, as well as the likelihood of being able to intervene quickly should that occur. Several questions arise: How insightful is the patient about his or her condition? Has the patient shown a willingness to seek more intensive treatment in the past when asked to do so by family or physician? Is there a complicating substance abuse problem? Do patient and family have quick and easy access to the clinician, day and night if necessary? The availability and competence of the patient's community support system—family members, a reliable and available therapist or case manager, and law enforcement officials who are informed and experienced in the care of psychiatric patients—also come into play.

Medical Treatment: General Considerations

Treatment goals for management of the manic or mixed-state patient include emergency management to allow for safe care in a standard inpatient setting; initial behavioral stabilization; mood stabilization; and, finally, transition to maintenance treatment.

Emergency Management

In general, the sooner an agitated manic patient can be effectively medicated, the better. A medication that is easy to use, safe, and rapidly calming is the ideal. Haloperidol given intramuscularly (IM) is the most widely used emergency treatment for acute mania (although other high-potency typical antipsychotics, such as fluphenazine, are just as effective and slightly less likely to cause extrapyramidal syndrome [EPS]).² Three of the atypicals—olanzapine, ziprasidone, and risperidone (a depot preparation)—are now available in parenteral form. IM ziprasidone, 2–10 mg, was shown in one study to offer a short-term advantage over IM haloperidol for acute agitation and to be associated with less EPS (Brook et al., 2000). IM clonazepam (.5–1.0 mg) and IM lorazepam (1–2 mg) have also been used for short-term treatment of agitated manic states; however, they are not as effective as the high-potency antipsychotics in calming most manic patients. For example, IM olanzapine has been shown to be superior to IM lorazepam for the treatment of acute manic agitation (Meehan et al., 2001). Nevertheless, benzodiazepines can be highly effective and provide some welcome drowsiness for patients in a mixed

manic state with a moderate degree of agitation; they also are less likely to leave the patient as dysphoric as some feel after receiving antipsychotics. On the other hand, the short-term risk of disinhibition with benzodiazepines is a hazard in the already hyperactive patient, although it is uncommon after a single dose.

Initial Behavioral Stabilization

The treatments of choice in the first days of dealing with moderately severe to severe mania vary by institution and locale. Many American centers begin with valproate and/or lithium or with a typical antipsychotic, the latter remaining the most common choice for combination treatment (Chou et al., 1996; Keck et al., 1996; Tohen et al., 2001), although use of atypicals is increasing (Letmaier et al., 2006). By contrast, many centers outside the United States continue to use the typical antipsychotics as first-choice agents (Letmaier et al., 2004), either alone or in combination with lithium, valproate, or carbamazepine. Both the more sedating atypical antipsychotics, such as clozapine, olanzapine, and quetiapine, and those that tend to be less sedating—risperidone, aripiprazole, and ziprasidone—are gaining in popularity, and controlled data support their effectiveness as monotherapy or for use in combination treatments to stabilize the manic patient. In applying these controlled data on the new atypicals to clinical situations involving severe psychotic mania, however, it is important to realize that the ethics of placebo-controlled trials mean the sickest patients are less likely to be included.

The primary caution with antipsychotic combinations (especially the typical antipsychotics) relates to side effects, such as weight gain and metabolic syndrome, EPS, effects involving dopaminergic systems, and antipsychotic malignant syndrome. Moreover, concurrent administration of multiple medications makes it difficult for the clinician to determine which side effects and which beneficial effects are due to which drug. Despite substantial evidence supporting the efficacy of atypical antipsychotic monotherapy for acute mania, a sizable fraction of patients do not fully recover when these drugs are used alone, ultimately necessitating a typical antipsychotic and/or the addition of lithium or an anticonvulsant. Furthermore, because manic patients are prone to rapid shifts in mood and behavior during the early phases of recovery, those taking lithium or an anticonvulsant alone will frequently require high-potency antipsychotics or benzodiazepine medications on an as-needed basis during the first week or so of treatment. Combination therapies therefore predominate in treatment for acute mania, despite the paucity of clinical studies specifically assessing their use. More detail about individual drugs (doses, blood levels, and the like) is provided below.

If a patient fails to improve or manic behavior escalates despite the use of antipsychotics, lithium, and/or anticonvulsants, electroconvulsive therapy (ECT) is a valuable alternative. Both a randomized controlled trial (Small et al., 1988) and a large retrospective study (Black et al., 1987) found that ECT compares favorably with lithium for the treatment of acute mania or mixed states.³ ECT may also be especially useful for women in the first trimester of pregnancy, when it is preferable to avoid medications, and for those in mixed states with a high risk of suicide. Obtaining informed consent for ECT, however, can be quite difficult with acutely manic or mixed patients. Some clinical investigators believe bilateral electrode placement may be necessary to obtain the full antimanic effect of ECT (Milstein et al., 1987), whereas others find no difference between unilateral and bilateral placement (Black et al., 1987). If ECT is used, lithium dosage should be reduced or discontinued because of the risk of delirium (Rudorfer et al., 1987). Rapid transcranial magnetic stimulation (rTMS) may turn out to be a useful alternative to ECT in some patients.

In acutely manic patients who do not respond to or cannot tolerate lithium, valproate, carbamazepine, or antipsychotics, the question arises of whether newer anticonvulsants may be adequate alternatives. Topiramate had been of interest because of its potential to produce weight loss, but controlled data have failed to demonstrate its antimanic efficacy. Oxcarbazepine has also been of interest because of its relatively more benign side-effect profile, especially the fact that it lacks the hematopoietic effects of the parent compound. Yet while some open studies have found it to be helpful (perhaps especially in patients with milder manic symptoms), there have been no adequately controlled studies establishing its efficacy as monotherapy. Gabapentin has shown no antimanic efficacy in controlled trials, although its sedative or anxiolytic properties may be useful when it is combined with an antimanic agent. Phenytoin and levetiracetam appear to show some antimanic activity as adjuncts, but controlled monotherapy data are still lacking.

Mood Stabilization

The likelihood that manic symptoms will resolve rapidly or slowly often becomes apparent within the first 4 to 5 days of inpatient care. While the occasional extremely agitated and delusional patient will remain calm for days after a single IM injection of antipsychotic medication, other patients will remain manic to the point of requiring seclusion and physical restraint for a week or more despite receiving high-dose antipsychotics combined with an anticonvulsant and lithium. Most patients' response to treatment falls somewhere between these extremes, and the length of time to recovery cannot be predicted accurately.

When patients accept short-term medical management, they often do so without really understanding or accepting their diagnosis and its implications, especially in the initial stages of their recovery. With clinical improvement, however, many manic patients will develop at least partial insight into the full consequences of uncontrolled mania and sign on to the treatment plan. At this point, the physician will be able to have more meaningful though still limited discussion of the advantages and disadvantages of the various treatment options with the patient. When the patient recovers the capacity to exercise sufficient judgment, it becomes possible for patient and physician to collaborate on a plan for continued acute treatment and a strategy for remission maintenance. Day hospital is often an ideal setting for manic patients who are partially recovered and cooperative to attain adequate control of their symptoms and improved insight and judgment. When dealing with hypomanic patients in particular, it can be helpful to point out that hypomania, albeit more than pleasant at the moment, usually can be thought of as the beginning of the next depression.

Continuation Treatment and the Transition to Maintenance Therapy

Even with aggressive pharmacotherapy, severely ill manic patients can take 4 weeks or longer to attain a stable affective state with sufficient insight to permit outpatient care. With careful monitoring of the therapeutic benefits as well as the side effects of treatment, titration of the lithium, anticonvulsant, or antipsychotic dose into the therapeutic range (using blood levels where appropriate), along with a gradual decrease in the dose of any typical antipsychotic medication, can be substantially accomplished within 1–2 weeks of initiation of treatment. By the third week, some patients can be maintained on lithium, an anticonvulsant, or an atypical antipsychotic alone. Recovering manic patients should not be discharged to day hospital or outpatient care unless they are well enough to make an informed and reliable commitment to medication adherence (see Chapter 21) and regular office or clinic visits; in addition, it is helpful to enlist family members whose involvement can increase the likelihood that the treatment plan will be followed.

The danger of discharge without sufficient improvement and insight is not merely a theoretical concern. Patients who appear to be improving over the short term can rapidly relapse into manic symptoms if they do not adhere to treatment; even if they do adhere, they may cycle into the depressed phase of the illness. Moreover, many patients with bipolar disorder are at substantial risk for suicidal behavior, regardless of the polarity of the acute episode (see Chapter 8).⁴ Rucci and colleagues (2002) found that an intensive treatment program, which included closely monitoring treatment adherence and tracking down patients

who missed appointments, virtually eliminated suicide attempts in bipolar patients in the period following an acute manic episode.

Clinical Features That Modify Medication Management

Extreme Hyperactivity

Extreme hyperactivity poses substantial direct and indirect risks to manic patients; these include dehydration, cardiovascular stress, and the medically necessitated physical restraint and seclusion often associated with intense agitation. It should not be forgotten that many manic patients died of exhaustion before the advent of modern treatments (see Fig. 18–1). Typical antipsychotics are the most rapidly effective agents in controlling this set of symptoms; in these situations, they are often combined with lithium, an anticonvulsant, or an atypical antipsychotic.

Psychotic Symptoms

Approximately 50 percent of inpatient manic patients suffer from delusions, usually grandiose or paranoid in nature. Formal thought disorder and auditory hallucinations, although less common, also occur relatively frequently (see Chapter 2). Antipsychotics (both typical and atypical) are quite effective in treating these symptoms.

Euphoric versus Mixed Mania

Prior to the availability of anticonvulsants and atypical antipsychotics, a combination of lithium and typical antipsychotics was generally used for the acute treatment of mixed

Figure 18–1. Deaths from psychotic exhaustion. Mortality statistics for psychotic exhaustion, Royal Park Hospital, for the years 1946–1950, 1956–1960, 1966–1970. (Source: Cade, 1978.)

Figure 18–2. Percent response to divalproex and lithium in classic vs. mixed mania. (Source: Adapted from Bowden et al., 1994. Reprinted with permission.)

states. Some studies have shown lithium to be more effective in typical manic states than in dysphoric/mixed or rapid-cycling acute states, whereas valproate is particularly effective in mixed or acute rapid-cycling states (Juckel et al., 2000). Two separate analyses of the original divalproex registration trial showed divalproex monotherapy to be superior to lithium monotherapy for the treatment of manic states in patients with elevated depression scales and in those with multiple previous episodes. However, this is confounded by the high number of prior lithium failures in the sample. Carbamazepine may be superior to lithium for mixed states (Emilien et al., 1996).

It is important to note that in the divalproex registration trial, lithium was more effective than divalproex among patients with the “classic” manic features of euphoria and grandiosity (see Fig. 18–2). This trial is also noteworthy for finding that prior good response to lithium predicted a good response during subsequent manic episodes and a poorer response to anticonvulsants—an argument for using lithium in some patients with mixed states despite the apparent superiority of valproate in treating such states. Olanzapine, either as monotherapy or adjunctively, has been shown to be as effective in mixed mania as in pure mania. There are similar data for other atypical antipsychotics, suggesting a class effect. However, each atypical is unique in its clinical profile, and many patients do poorly on one but very well on another.

Rapid-Cycling Bipolar Disorder

A history of rapid cycling, usually defined as four or more affective episodes within 1 year, has implications for the

treatment of acute mania in that it makes sense to start medications in the short term that have proven beneficial for this subgroup of patients in the longer term. Early studies of lithium prophylaxis suggested that patients with a history of at least four affective episodes in 1 year were disproportionately overrepresented among those who failed to experience a prophylactic effect from lithium (Dunner and Fieve, 1974). However, a more recent naturalistic study of rapid-cycling and non-rapid-cycling patients found that lithium was equally effective in both groups (Baldessarini et al., 2000), a finding that may, in part, be related to the relatively conservative use of antidepressants in this particular group of patients. Another important consideration is that in the Dunner and Fieve study, the minimum criterion for treatment failure was a single new episode, whereas Baldessarini and colleagues examined the overall reduction in morbidity associated with lithium treatment in the two groups of patients; clinically, the latter is a more relevant measure. Indeed, Dunner (2000) himself advocated starting lithium acutely in patients with a history of rapid cycling and only adding an anticonvulsant later if needed. Likewise, McElroy and Keck (2000), based on their review of the literature, recommended that manic or mixed-state patients with a history of rapid cycling be started on lithium, reserving adjunctive valproate for those who fail to respond to lithium. However, contemporary North American guidelines recommend that rapid-cycling patients be started on an anticonvulsant acutely (valproate is recommended most frequently; see Sachs et al., 2000), with the option of adding lithium later depending on the response to the anticonvulsant. This recommendation may be modified in light of the recent carefully controlled trial of Calabrese and colleagues (2005) showing that lithium and divalproex monotherapy had equivalent (poor) maintenance efficacy in rapid-cycling patients who had been stabilized on the combination (see Chapter 20).

Rapid cycling has also been shown to predict an acute antimanic effect for carbamazepine (Post et al., 1986a), although results of other studies indicate that this effect does not translate into prophylaxis against mania in patients with a history of rapid cycling (Denicoff et al., 1997). In the initial studies that established olanzapine as an antimanic agent, it was equally effective among rapid and nonrapid cyclers (Tohen et al., 2004), and this appears to be true for other atypicals as well. Furthermore, among patients with a history of rapid cycling who are nonresponders to lithium or anticonvulsants, the addition of atypical antipsychotics has been shown to be effective for the treatment of acute mania (Sanger et al., 2003), although the data do not support giving an atypical to all patients with a history of rapid cycling in the absence of other indications.

Medication Dosages and Therapeutic Monitoring

Lithium

Lithium's antimanic effects correlate more closely with serum levels than with dosage. Early studies of its efficacy in mania indicate that its antimanic (as well as its prophylactic) serum level is positively correlated with blood levels. Results of several monotherapy studies suggest that levels below .8 milliequivalents per liter (mEq/l) are not as effective as those above this level. Although there is an upper limit of therapeutic benefit in serum lithium level, this limit appears to be set by toxicity rather than by loss of therapeutic benefit. Prien and Caffey's (1976) systematic search of their controlled trial data established .9 mEq/l as the lower limit for antimanic efficacy and 1.4 mEq/l as the limit above which additional benefit could not be demonstrated because of high rates of toxicity. It is important to note that when lithium is administered to an acutely manic patient, it is generally necessary to adjust the dose downward as the mania begins to subside in order to maintain the blood level in a reasonable range. As detailed in the first edition, the ratio of dose to plasma level is higher in mania than in euthymia or depression. The mechanism by which lithium excretion appears to be enhanced during manic states is unknown, but probably involves changes in aldosterone levels. Following resolution of the acute mania (that is, when shifting to the continuation phase of treatment), the blood level should gradually be reduced, if possible, to the .6–.8 mEq/l range (see Chapter 20).

Anticonvulsants

As with lithium, the therapeutic benefit of anticonvulsants in mania appears to correlate with serum levels rather than with dosage. Thus studies of valproate suggest that levels above 45 micrograms per milliliter ($\mu\text{g/ml}$) are necessary for antimanic efficacy (Bowden et al., 1996) and that side effects become increasingly problematic at levels above 125 $\mu\text{g/ml}$.

Oral medication loading strategies have been devised for speeding up the onset of the antimanic action of anticonvulsants. For valproate, the strategy is to dose at 30 milligrams per kilogram (mg/kg) of body weight for days 1 and 2 of therapy, followed by 20 mg/kg on days 3–10 (Hirschfeld et al., 1999). In one double-blind study, valproate loading was shown to be at least as rapid in reducing manic symptoms as treatment with haloperidol (McElroy et al., 1996), and in a pooled analysis of randomized, double-blind studies, the loading strategy was found to be more rapidly effective than standard-titration valproate and equivalent to olanzapine (Hirschfeld et al., 2003). Intravenous loading has also been reported to be rapidly effective and may be an option for some patients (Grunze et al., 1999a).

Serum carbamazepine levels of 8–12 mEq/ml appear to be optimal for the treatment of mania (Post et al., 1986a). Although oxcarbazepine has been studied in Europe since the early 1980s, its optimal dose and therapeutic serum level have not been established for the treatment of bipolar disorder. A dose that is 1.5 times that of carbamazepine (oxcarbazepine dose of 600–1200 mg/day) is recommended for epilepsy (Dam, 1994), and clinical experience suggests this ratio is probably appropriate for mania as well.

Typical Antipsychotic Agents

Although clinicians have frequently used larger oral doses of antipsychotics for acute mania than for schizophrenia, results of controlled studies suggest that lower doses are effective for mania as well. Haloperidol remains widely used at doses ranging from 2 mg/day up to as high as 50 mg/day (25 mg orally every 12 hours).⁵ Chlorpromazine, thioridazine, and other low-potency antipsychotic agents are now used rarely because of high rates of orthostatic hypotension and extrapyramidal side effects.⁶

Atypical Antipsychotic Agents

A major change in the treatment of mania since 1990, especially in the United States, has been the emergence of atypical antipsychotics as effective antimanic agents. Olanzapine, risperidone, quetiapine, ziprasidone, and aripiprazole have received the approval of the U.S. Food and Drug Administration (FDA) as antimanic agents, and as of this writing, the European regulatory agency has approved olanzapine, risperidone, and quetiapine. In the United States, olanzapine, quetiapine, and clozapine have largely replaced chlorpromazine and thioridazine as the favored *sedating* antipsychotics. However, it is worth noting that these new drugs are not always an adequate replacement for the typical agents, especially in cases of more severe mania and when rapid control of psychosis and hyperactivity are required, such as in an emergency room setting. As Licht and colleagues (1997) pointed out, placebo-controlled trials of atypicals have, of necessity, tended to involve more moderately ill patients in order to obtain ethically acceptable informed consent.

Olanzapine is usually begun at oral doses of 2.5–5 mg every 6 hours for treatment of mania, titrated up to 20 mg/day (although some studies suggest 2.5–5 mg/day may work as well). Quetiapine is dosed on the basis of height, weight, and clinical response, but not blood levels; the usual starting dose is 100 mg/day, with a target dose ranging from 400 to 800 mg/day and averaging 600 mg/day. Clozapine is begun at 25–50 mg every 6 hours and titrated up to 1,000 mg/day.

Use of the less sedating oral antipsychotics risperidone, aripiprazole, and ziprasidone is also increasing. Risperidone

is started at 1 mg every 6–8 hours and usually does not exceed 6–10 mg/day. Aripiprazole doses of 30 mg/day are generally recommended, with an option to decrease this dose to 15 mg/day if tolerability is a problem. Oral ziprasidone is started at 40 mg twice daily (BID) with food, increased to 60 or 80 mg BID on the second day, then adjusted in the range of 40–80 mg BID. The IM dose in acute psychotic states is usually about 10–20 mg every 4 hours, up to 40 mg/day.

It has been suggested that there may be clinically important differences among the various atypical antipsychotics in the initial onset of antimanic effects (Keck, 2005). However, such a conclusion is premature given the design differences among the various registration trials for these drugs. For the risperidone and ziprasidone trials, the first ratings were obtained at 1 or 2 days, for aripiprazole at 4 days, and for olanzapine at 7 days. The impression that ziprasidone and risperidone have a more rapid onset of action than the other drugs is probably an artifact of these design differences.

Benzodiazepines

High-potency benzodiazepines, including lorazepam and clonazepam, have been shown to have short-term benefits in the treatment of acute manic agitated states, especially in emergency room settings. IM or oral doses of 1–2 mg up to every 2 hours are most common (Lenox et al., 1992). Adjunctive oral benzodiazepines can also be useful, such as in the management of the initial activation sometimes seen with ziprasidone or aripiprazole.

Hypomanic Symptoms

Hypomanic symptoms need not always be treated aggressively, as they will often resolve with watchful waiting. However, repeated episodes of hypomania can be indicators of more general mood instability that should lead the clinician to reassess the adequacy of the maintenance strategy (see Chapter 20). The threshold for treating hypomanic symptoms in a particular patient depends on diagnostic considerations: the threshold should be lower in patients with a history of similar symptoms evolving into full-blown mania (i.e., bipolar-I disorder) than in those whose hypomanic episodes have never progressed to mania (i.e., bipolar-II). Hypomania with depressive features (dysphoric hypomania) is not uncommon (see Chapters 1 and 2), and this makes it more likely that pharmacological intervention will be sought and needed.

The decision regarding treatment can often be difficult, however; patients early in the course of illness whose diagnosis is less than clear and those who are unreliable present obvious challenges. It is important to remember that

patients with mild hypomania can be disinhibited enough to suffer substantial interpersonal, professional, or financial or legal adverse consequences from a period of even mildly elevated mood. Approaches thought to be useful for the treatment of mania have generally been extrapolated to the treatment of hypomania, as there is a paucity of clinical research data specifically on the treatment of hypomania. Finally, it is reasonable to consider the possibility that treatment of hypomania may reduce the likelihood and/or severity of subsequent depressive episodes. Indeed, as noted earlier, it can be useful to point out that a period of hypomania is often the beginning of the next depression when dealing with a hypomanic patient reluctant to be treated.

An evaluation for possible etiological factors is an initial step in deciding how to proceed. Iatrogenic causes should be investigated, specifically the recent addition to the patient's regimen of a medication, such as an antidepressant, that may precipitate hypomanic symptoms (see Chapter 19). Numerous over-the-counter preparations—including nutritional supplements such as St. Johns Wort (Nierenberg et al., 1999), dehydroepiandrosterone (DHEA) (Dean, 2000), and others—have been reported to be associated with hypomanic symptoms. Patients not infrequently supplement their prescribed medications with such preparations without informing their physicians because they fear disapproval or do not realize the potential for adverse effects. Surreptitious substance abuse is another important and all-too-common factor, as is sleep deprivation.

Lowering the dose of or discontinuing such potentially mania-inducing agents is a sensible first step in addressing hypomanic symptoms. Thereafter, a reasonable initial intervention is to optimize whatever antimanic treatment the patient is already receiving. Dosage increases need to be guided by serum drug levels when possible, while the implications for long-term management should be considered before another agent is added. The addition of an anticonvulsant to lithium or vice versa may be indicated if the current hypomanic episode is one of many and appears to signify a pattern of inadequate maintenance treatment. The addition of an atypical antipsychotic agent is frequently recommended for the short-term control of hypomanic symptoms, especially given the fairly rapid onset of benefit, which may be due to immediate improvement in sleep. Vieta and colleagues (2001) examined this strategy in an open study of 44 patients with bipolar-II disorder. In the 34 patients who completed the study, the Young Mania Rating Scale (YMRS) score dropped from a mean of 22.1 to 3.1 (essentially asymptomatic) within 2 weeks when risperidone was added to various other medications being taken, including lithium, anticonvulsants, and combinations.

Benzodiazepines also have a place in the treatment of hypomanic symptoms. The temporary use of adjunctive clonazepam often can abort the beginning of a hypomanic episode by stabilizing sleep, although systematic data on this strategy are lacking.

Figure 18–3 outlines our recommended approach to the treatment of acute mania/hypomania.

Psychological Issues Related to Medical Treatment of Mania

Many manic or mixed-state patients in acute care will undergo treatment without real insight into their condition. Although each situation is unique, some general guidelines can be offered to the clinician working with acutely manic patients whose judgment is substantially impaired.

The most extreme situation is when the patient is dangerous but will not or cannot give informed consent for treatment. In most states, commitment to a hospital is sufficient legal grounds for emergency medication against the patient's wishes, but not for routine medication, which often requires a separate administrative review. In more moderate circumstances, the patient is intermittently agreeable to treatment, or is consistently agreeable to some medication interventions but not to others. In such cases, establishing a few firm, non-negotiable limits very calmly and without rhetorical flourish or rancor can minimize a confrontation in the acute care situation.⁷ Once a degree of cooperation has been achieved, it is important to begin educating manic patients about diagnosis and treatment to the extent that they are able to comprehend these matters, while gradually negotiating a path toward a full commitment to maintenance therapy. (These issues are explored in detail in Chapter 22.) As noted in Chapter 17, the most effective approaches involve the integration of drugs and psychotherapy.

Although family members are often no more able than the treating clinician to win a manic patient's cooperation, they are in a position to strengthen the patient's resolve *against* treatment if they do not understand the disorder and the rationale for the treatment. Families can easily become frightened by the intrinsically imprecise nature of pharmacological treatment of mania; they may worry that the patient taking multiple medications is being overmedicated and become concerned about the quality of care. It is important to inform family members about the sedative effects of medications and the extent to which such effects may be unavoidable (or even welcomed). Warning family members about likely side effects (such as periods of oversedation) and options for their management will reassure them and help gain their trust in and collaboration with the treatment process.

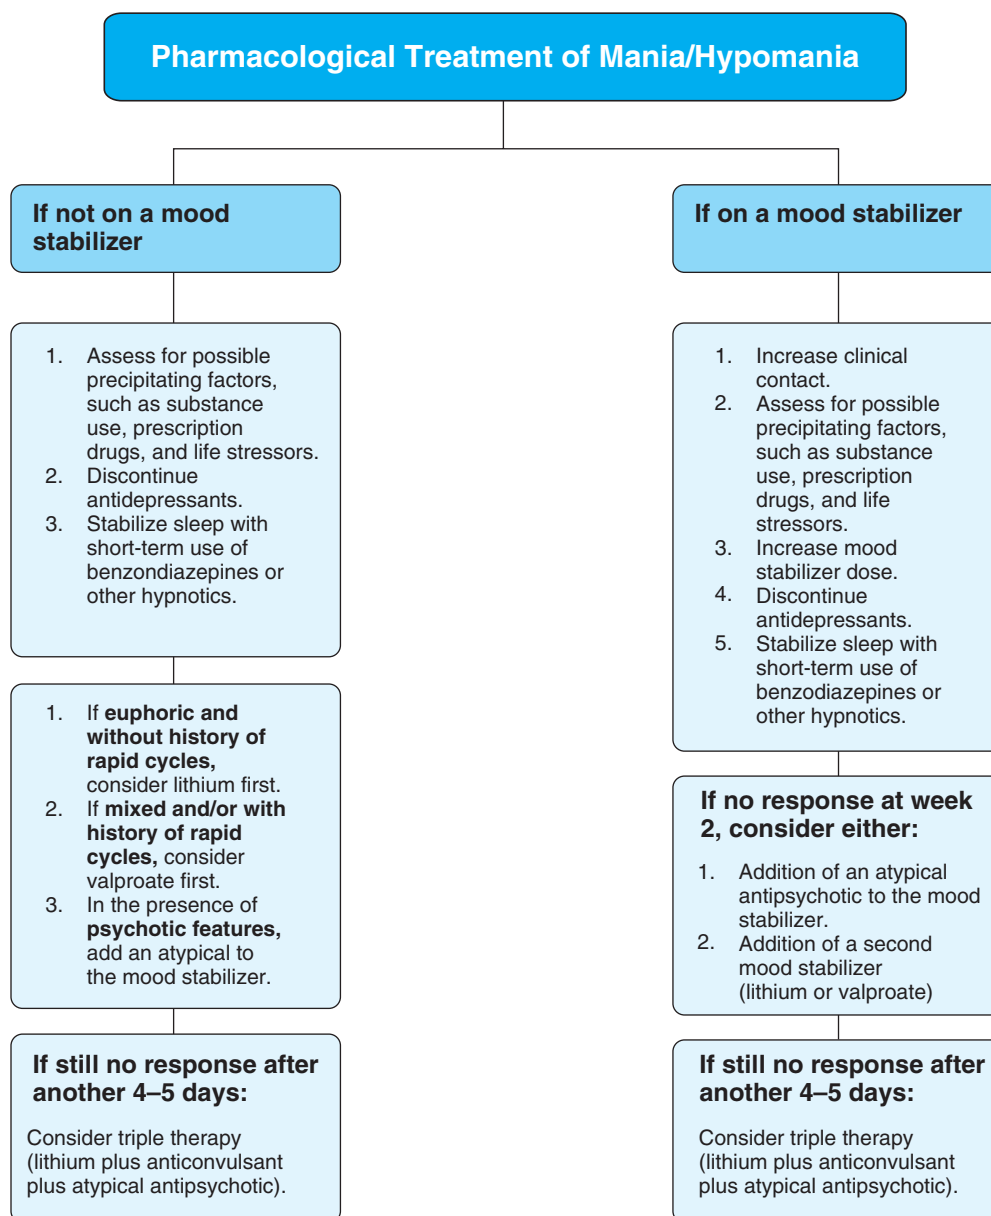

Figure 18–3. Recommendations for pharmacologic treatment of acute mania/hypomania.

REVIEW OF THE LITERATURE

In this section we review the literature on the various medications used to treat hypomania, mania, and mixed states: lithium, anticonvulsants, typical and atypical antipsychotics, and benzodiazepines. Other treatments, including ECT, TMS, calcium channel blockers, omega-3 fatty acids, and cholinergic agents, are discussed as well. Results of randomized, double-blind monotherapy trials for each of the major pharmacological agents are summarized in Table 18–1 and Figure 18–4, while results of non-placebo-controlled trials and placebo-controlled add-on trials are summarized in Table 18–2.

Lithium

Earlier controlled studies of lithium clearly established its superiority to placebo in treating acute mania. Studies conducted since 1990 were designed to compare newer medications with lithium as the reference antimanic agent (e.g., Bowden et al., 1994).

As detailed in the first edition of this volume, early placebo-controlled studies⁸ established lithium as an effective, although not rapidly acting, treatment of choice for mania.⁹ Many of these studies varied as to dosage, serum levels, and rapidity of dosage titration, making it difficult to establish the precise time to onset of lithium's antimanic

TABLE 18–1. Summary of Randomized, Double-Blind, Placebo-Controlled Monotherapy Trials That Have Demonstrated Acute Antimanic Efficacy

Drug	No. of Studies	Sample Size ^a
Lithium	5	358

^aCombined drug and placebo groups.

action. Nonetheless, there is little doubt that lithium is as effective as other antimanic agents over a 3-week period, with some studies showing a more rapid onset of action (as little as 10 days).

The largest randomized, double-blind study of lithium versus placebo in acutely manic patients was actually designed to study the benefits of divalproex (valproate) for the treatment of acute mania, with lithium- and placebo-treated

groups serving as controls (Bowden et al., 1994; Swann et al., 1997, 2002). In this study, 49 percent of the lithium-treated patients responded (i.e., had at least a 50 percent reduction in their YMRS scores) during the 3-week trial period (efficacy comparable to that seen for the valproate group). This result doubled the response rate of 25 percent in the placebo group. Nearly half of the patients had a history of poor response to lithium, which predicted the

TABLE 18–2. Drugs Demonstrating Acute Antimanic Efficacy in Non-Placebo-Controlled Comparison Trials or in Placebo-Controlled Add-On Trials

Drug	No. of Studies	Sample Size	Findings
Lithium	16	775	Equivalent to typical antipsychotics or valproate
Carbamazepine	5	230	Equivalent to typical antipsychotics
Valproate	6	620	Equivalent to lithium or typical antipsychotics
Oxcarbazepine	2	72	Equivalent to both lithium and haloperidol
Phenytoin	1	39	Modest additional benefit when added to haloperidol among partial responders
Clozapine	1	27	Open-labeled monotherapy benefit or equivalent to chlorpromazine
Chlorpromazine	8	521	More effective than or equivalent to lithium
Haloperidol	9	901	Equivalent to lithium and atypical antipsychotics
Clozapine	4	115	Open-labeled monotherapy benefit or additional benefit when added to mood stabilizers
Risperidone	6	463	Equivalent to lithium; more effective than placebo as adjunct among non- or partial responders to lithium or anticonvulsants
Olanzapine	6	1,539	Equivalent to haloperidol, lithium, and valproate; more effective than placebo as adjunct among non- or partial responders to lithium or valproate
Quetiapine	5	440	More effective than placebo as adjunct among non- or partial responders to lithium and valproate
Electroconvulsive therapy (ECT)	2	64	Equivalent to lithium; ECT + chlorpromazine more effective than ECT alone
Totals	65	5,246	

Note: Many of the individual studies comparing two active drugs without a placebo control lack sufficient statistical power to make it possible to evaluate whether the observed absence of a difference actually means equivalence.

differential response seen in this trial. Thus among the prior lithium responders who received lithium in this trial, there was a 15-point mean reduction in YMRS scores (a 60 percent improvement), compared with only a 1-point mean improvement in the previously nonresponsive group (Bowden et al., 1994). Among the prior lithium responders randomized to valproate, by contrast, there was only a 27 percent improvement, compared with the 60 percent improvement with lithium.

In another analysis of the data from this study, Swann and colleagues (1997) found evidence of some pharmacological

specificity in that patients with mixed manic-depressive symptoms had a better response to valproate than to lithium, while those with typical manic symptoms did better on lithium (Bowden et al., 1995; see Fig. 18–2). Still another analysis of the same dataset, illustrated in Figure 18–5, revealed that manic patients with more than 10 prior affective episodes (of any polarity) also had a poorer response with lithium than with valproate (Swann et al., 1999). (Details of the findings on the efficacy of valproate are discussed below.)

A 12-week trial designed to evaluate quetiapine in acute mania included 98 patients on lithium as an active control

Figure 18-5. Number of prior episodes as a predictor of acute antimanic response to lithium or divalproex. SADS=Schedule for Affective Disorders and Schizophrenia. (Source: Swann et al., 1999. Reprinted with permission from the *American Journal of Psychiatry*, copyright 1999, American Psychiatric Association.)

(mean serum lithium .77 mEq/l). The response rate among the latter patients (defined as a decrease in YMRS scores of 50 percent or more) was 53 percent—identical to the response rate among the 107 patients on quetiapine and significantly better than that among the placebo group (27 percent). Discontinuation because of adverse events was infrequent with both drugs (lithium 6.1 percent, quetiapine 6.5 percent) (Bowden et al., 2005).

The response rates to lithium in the relatively recent studies of valproate and quetiapine are somewhat lower than the rates found in earlier studies. While this difference may relate in part to the evolution of research methodologies, another explanation (noted in Chapter 17) is (unintentional) referral bias. It is an old adage in medicine that the longer a successful treatment is available to clinicians, the more difficult it becomes for investigators to show that it still works. The reasons for this are straightforward. Among the bipolar patients referred to research centers for the evaluation of a new drug, those who are already doing well on lithium would tend to be underrepresented. Neither the patients nor their physicians have much of an incentive for participation in a trial of a new agent in which they have a chance to end up taking placebo. We also refer the reader to Box 17-4 in Chapter 17, which reviews the shift in prescribing patterns in the United States away from lithium and toward valproate, and suggests a possible nonmedical explanation for part of this shift.

There has been one trial of rapid administration (loading doses) of lithium to treat acute mania, aimed at assessing the potential to reduce the delay in the drug's onset of action (Keck et al., 2001b). In this trial, 15 manic and mixed-state patients were treated with 20 mg/day of lithium given in two doses. Concomitant lorazepam up to 4 mg/day through day 6 and up to 2 mg/day through day 8 was also allowed during the study. All patients achieved lithium levels above .6 mEq/l after 1 day of treatment. Two could not tolerate the rapid titration and stopped—one because of tachycardia and the other because of tremor, fatigue, and diarrhea—and one subject did not adhere to the regimen. Among the remaining 12 subjects, 7 were well enough to be discharged before the 10-day trial was completed. The mean YMRS score for these subjects was 11. Overall, 9 of 15 patients had achieved a greater than 50 percent reduction in YMRS scores by day 10 (by definition they were “responders”).

As noted in Chapter 14, one hypothesis for the therapeutic action of lithium in mania is its inhibition of inositol monophosphatase, which by reducing brain inositol levels decreases the ability of neurons to generate certain second messengers. In a recent pilot open study, Shaldubina and colleagues (2006) evaluated the effect of an inositol-deficient diet on the clinical efficacy of lithium in a mixed group of 15 bipolar patients. Seven of these patients were in a manic episode that had not responded to lithium, and the remainder were lithium- or valproate-resistant rapid cyclers. Ten

of the patients evidenced a substantial reduction in symptom severity, beginning in the first 1–2 weeks of treatment; of the 5 who did not respond, 3 did not adhere to the diet. A controlled replication of this intriguing observation is awaited.

Anticonvulsants

The use of anticonvulsant agents for the treatment of bipolar disorder was a watershed event for psychiatry in the late twentieth century. The clear effectiveness of some anticonvulsants for patients who do not respond well to or cannot tolerate lithium has made these drugs a welcome addition to the armamentarium. Controlled trials have shown both valproate and carbamazepine (including the new extended-release formulations of each) to be more effective than placebo and, as noted above, as effective as lithium for treatment of acute mania.¹⁰ Moreover, a series of small non-placebo-controlled studies has found that oxcarbazepine, the 10-keto metabolite of carbamazepine, appears to have antimanic action similar to that of its parent compound, but requiring a higher dose. It has also become clear that not all anticonvulsants are effective antimanic agents. Thus while several case reports and open studies had suggested that topiramate might be effective for the treatment of acute mania, controlled studies have failed to show its efficacy as monotherapy for this state. Results of open studies suggest its usefulness as an adjunct, but these results need to be confirmed with placebo-controlled studies. There are also a few case reports of apparent precipitation of manic symptoms with topiramate.¹¹ One controlled study supports the efficacy of phenytoin as an adjunct, while monotherapy studies of gabapentin and the gamma-aminobutyric acid (GABA) analogue tiagabine have shown no apparent benefit in manic patients. Results of open studies suggest some efficacy for levetiracetam in treating acute mania, but there are as yet no controlled data. Other, newer anticonvulsants that have not been assessed in systematic studies of bipolar patients include losigamone, progabide, and vigabatrin.

Carbamazepine

Starting in the 1970s, a number of studies showed carbamazepine to be superior to placebo, although not necessarily equivalent to lithium, in the short-term treatment of mania.^{12,13} Okuma and colleagues (1990) conducted a double-blind, placebo-controlled study of manic patients who were undergoing treatment with antipsychotics without substantial benefit. Half of the 105 patients were given 400–1200 mg/day of carbamazepine, and the other half were given lithium in amounts sufficient to establish relatively low mean serum levels of .46; all the patients continued on haloperidol. The final assessment revealed moderate

to marked improvement in both groups of patients.¹⁴ Since no group was assigned to continue antipsychotics alone, however, it remains unclear how much of the improvement seen was due to the adjunctive mood stabilizers versus the antipsychotics themselves. Small and colleagues (1991) conducted an 8-week double-blind comparison of carbamazepine and lithium in 52 hospitalized acutely manic patients. They found that the two drugs were equally effective in reducing manic symptoms (as judged by YMRS scores),¹⁵ a conclusion supported by a later meta-analysis (Emilien et al., 1996).

Post and colleagues (1987) studied carbamazepine for the treatment of mania and concluded that rapid-cycling illness was a predictor of the drug's efficacy in treating acute mania. Subsequent investigators reported, however, that many patients with rapid cycling did not have good control of mania symptoms over the long term on carbamazepine monotherapy. For example, Denicoff and colleagues (1997) found that fewer than 20 percent of patients with rapid-cycling illness remained in remission during a 1-year study of the drug. More recently, however, two large multicenter double-blind, placebo-controlled trials of the extended-release formulation of carbamazepine showed its superiority over placebo for the acute treatment of mania or mixed states (Weisler et al., 2004, 2005). On the basis of these two trials,¹⁶ extended-release carbamazepine has been approved by the FDA for the acute treatment of mania/mixed states.

In one of the few available studies of combinations of anticonvulsants, a retrospective chart review revealed that 12 bipolar manic patients but none of 4 schizoaffective manic patients did well with a combination of valproate and carbamazepine (Tohen et al., 1994). Small and colleagues (1995) conducted an 8-week inpatient trial of carbamazepine plus lithium compared with haloperidol plus lithium in manic patients. About half of the original 60 patients dropped out of the study during the 2-week placebo washout phase, primarily because of worsening mania. Among the 33 remaining patients, 17 treated with carbamazepine plus lithium and 16 with haloperidol plus lithium showed comparable levels of improvement. However, more of the latter patients left the study prematurely because of side effects. Conversely, more of the former patients terminated the protocol because of nonadherence; this group also needed more “rescue” medications for aggressive, uncooperative behavior in the first week of therapy.

Valproate

The French psychiatrist Lambert first reported a possible role for valproate in the treatment of bipolar disorder in the course of its first clinical trials in patients with epilepsy in the 1960s (Lambert et al., 1966). Many years later, Calabrese

and Delucchi (1990) found that the drug appeared to have marked effects in treating mania, mixed states, and cycling. They also noted that most patients (63 percent) with a good response to the drug had failed to improve on lithium or carbamazepine (or both). The most striking results were seen in patients with mixed mania; for the group as a whole there was minimal evidence of any benefit during the depressive phases of illness.¹⁷ Calabrese and colleagues (1992) later suggested that the subgroup of patients for whom valproate had shown some antidepressant effect were likely to have experienced an antimanic effect as well.

Muller-Oerlinghausen and colleagues (2000) reported on a double-blind, placebo-controlled study in which valproate was added to the medications used more commonly to treat acute mania in European centers—typical antipsychotics. A total of 136 patients taking haloperidol and/or perazine or some other antipsychotic received either valproate at a fixed dose of 20 mg/kg or placebo. The patients receiving valproate experienced a more rapid remission of symptoms and required progressively lower doses of the antipsychotic relative to patients in the placebo group. (It is not clear whether the sample was all “fresh” patients or included any non- or partial responders to antipsychotic monotherapy.) Studies of the reverse—an adjunctive antipsychotic among patients not responding adequately to lithium or anticonvulsant—are reviewed in the section on antipsychotics below.

Randomized, placebo-controlled studies have compared valproate with placebo and with lithium. In the first such study (Pope et al., 1991), 17 patients were randomized to divalproex and 19 to placebo. The divalproex-treated patients showed a median improvement in YMRS scores of 54 percent, versus only 5 percent for the placebo group ($p = .003$). Similar benefit was seen on the Global Assessment of Social Scale (GAS) and the Brief Psychiatric Rating Scale (BPRS). A significant problem with this and several other studies of mania is that the completion rate for the 3-week study was only 24 percent in the divalproex group and 21 percent in the placebo group.

In the largest placebo-controlled study of acute mania conducted to date (referred to above in our review of lithium studies), 179 patients with acute mania were treated with either divalproex, lithium, or placebo for 21 days (Bowden et al., 1994) (as in the Pope et al. [1991] study, a large number of patients failed to complete this study). About half of the patients in the divalproex- and lithium-treated groups but only one-fourth of the patients in the placebo-treated group showed marked improvement. While the authors concluded that the efficacy of divalproex appeared to be independent of prior responsiveness to lithium, in fact the drug showed only a 27 percent response rate among prior lithium responders (compared with a 60 percent response rate with lithium) while having greater effi-

cacy among prior lithium nonresponders. As noted above, in a later analysis of this study, Swann and colleagues (1999) found that a history of many previous episodes (but not rapid cycling or mixed states) predicted a poor response to lithium and placebo but not to valproate.

An earlier double-blind study comparing lithium and divalproex in the treatment of acute mania found that high pretreatment depression scores (i.e., mixed-mood symptoms) predicted a favorable response to divalproex but not to lithium, although lithium had a slightly higher efficacy rate overall, with a trend toward better efficacy in patients with classic euphoric mania (Freeman et al., 1992). Several subsequent analyses have supported the preferential use of divalproex for irritable-dysphoric, mixed, and rapid-cycling states (Bowden et al., 1994; Swann et al., 2002), while lithium has shown some advantage for patients with “classic” euphoric/grandiose mania (see Fig. 18–2), although the apparent advantage of lithium in this group is not reflected in the various North American treatment guidelines. It has been suggested that manic patients treated with valproate have shorter hospital stays and lower associated costs than patients treated with lithium. One retrospective study examining this issue reported a 40 percent reduction in length of stay for patients on divalproex monotherapy compared with those on lithium monotherapy (Frye et al., 1996); however, another, similar study found no such advantage (Dalkilic et al., 2000).

Recently, high-dose intravenous valproate (20 mg/kg over 30 minutes) was evaluated in seven acute manic patients, with no benefit noted. The authors speculated that the antimanic effect of anticonvulsants requires changes in cell signaling systems over time (Phrolov et al., 2004). The new extended-release form of divalproex, which allows once-a-day dosing was recently approved by the FDA for the acute treatment of mania after it was shown to be superior to placebo in a 3-week randomized, parallel-group, multicenter study (Bowden et al., 2006).

Oxcarbazepine

Oxcarbazepine is one of two major products of the microsomal metabolism of carbamazepine. It is nearly devoid of hematological side effects, and, compared with carbamazepine causes fewer allergic skin reactions, and appears to be much less active as a hepatic enzyme inducer (i.e., causes less autoinduction). It is, however, a significant contributor to the occasional gastrointestinal, teratogenic, endocrine, and central nervous system toxicity seen with carbamazepine. Hyponatremia is the one adverse effect that may occur more frequently with this drug than with the parent compound (see the recent review by Ketter, 2005).

Several 2-week open clinical trials conducted in Germany in the 1980s indicated that relatively high doses of

oxcarbazepine had an effect equivalent to that of haloperidol (mean dose of 42 mg/day) in acutely manic patients; the oxcarbazepine was very well tolerated compared with the high-dose haloperidol regimen. Two randomized comparisons, one with valproate (Emrich et al., 1985) and one with lithium (Emrich, 1990), found that oxcarbazepine had comparable efficacy over 2 weeks, with roughly similar side-effect profiles; however, the absence of a placebo group in these studies renders their conclusions tentative. A more recent study of oxcarbazepine for treatment of mania using an on-off design had a high dropout rate that likewise makes its results difficult to interpret (Hummel et al., 2002). Nevertheless, some of these mild to moderately manic patients had a greater than 50 percent reduction in their YMRS scores, suggesting that further studies should be done to assess this agent for antimanic efficacy. A comparative study in which 23 of 42 patients with mania being treated with valproate were switched to oxcarbazepine found comparable reductions in the Clinician Administered Rating Scale for Mania (CARS-M) at 10 weeks. More of the patients who continued on valproate had a significant weight gain compared with those who switched to oxcarbazepine (Hellewell, 2002).

Given that oxcarbazepine appears to have a relatively benign side-effect profile, it has been the subject of considerable clinical interest, and some open studies have suggested its usefulness as an adjunct (Benedetti et al., 2004). To date, however, a single adequately powered placebo-controlled study of its efficacy as monotherapy in treating mania is still lacking.

Topiramate

There have been several single-case reports and open studies indicating the apparent benefits of topiramate in the treatment of mania.^{18,19} McElroy and colleagues (2000) treated more than 50 bipolar patients with topiramate in addition to other medications in an open design as part of the Stanley Foundation Bipolar Network studies. In patients with manic symptoms (N=30), the mean YMRS score was 10 at the start of the study, indicating relatively mild manic symptoms. At 10 weeks, the reduction in score was statistically significant, albeit of questionable clinical salience given the long duration of antimanic treatment and the relatively mild symptoms at the outset. The patients lost an average of 2.4 pounds in 4 weeks and remained stable in weight over 10 weeks.²⁰ However, in a recent randomized placebo controlled trial of topiramate in bipolar patients experiencing a manic/mixed episode while on lithium or valproate, the addition of topiramate (400 mg) was no more effective than placebo (Chengappa et al., 2006).

Given its failure to separate from placebo in five large randomized controlled trials (Powers et al., 2004; Kushner

et al., 2006; Chengappa et al., 2006), one cannot recommend topiramate monotherapy for the treatment of mania in adults, and indeed none of the guidelines do so. There is, however, some evidence suggestive of a beneficial effect in adolescents (see Chapter 23), although this controlled trial was unfortunately terminated early by the manufacturer after the failure of the adult trials (DeBello et al., 2005). Yet, unlike many other anticonvulsants, topiramate does not cause weight gain and actually causes weight loss in many patients. In light of this advantageous side-effect profile, it is unfortunate that the controlled attempts to demonstrate the drug's efficacy in treating adult mania failed. We can hope that the somewhat encouraging results with adolescents will spur further work in this age group, given how problematic weight gain can be in the young bipolar patient. Moreover, the drug has also shown promise as an adjunctive agent, making randomized, double-blind adjunctive trials another potentially valuable area for future work.

Lamotrigine

Lamotrigine is an anticonvulsant with sodium channel blocking activity similar to that of carbamazepine and phenytoin. Case reports and open studies have suggested some efficacy for this drug in treating mania,²¹ but this finding was not confirmed in controlled studies. A small (30 subjects) 4-week randomized controlled trial compared lamotrigine with lithium for treatment of hospitalized manic patients (Ichim et al., 2000). Patients in the lithium group received a fixed dose of 800 mg/day, achieving an average plasma level of .743 millimoles per liter (mmol/l) arguably not an adequate lithium dose for mania. The lithium and lamotrigine groups shared similarly reduced YMRS scores, but the absence of a placebo group renders the results of this underpowered study inconclusive. Other controlled studies in patients with mania/mixed states and hypomania found no significant difference between lamotrigine and placebo (Anand et al., 1999; Frye et al., 2000). An open study of patients with a history of rapid cycling found lamotrigine to be helpful in some rapid-cycling patients with mania, but not in those with the most severe manic symptoms (Bowden et al., 1999).

Gabapentin

A number of case reports and uncontrolled studies of gabapentin in patients with manic and mixed states have suggested a beneficial effect when the drug is used adjunctively.²² On the other hand, Pande and colleagues (2000) found that gabapentin was less effective than placebo as an adjunctive agent for treating mania in patients taking lithium, valproate, or both, while Frye and colleagues (2000) found that it was no different from placebo in refractory bipolar disorder. There have also been a number of reports

of mania associated with the initiation of gabapentin (Short and Cooke, 1995; Ghaemi et al., 1998).

Other Anticonvulsants

Tiagabine is a GABA uptake inhibitor used for the adjunctive treatment of partial complex seizures. One open study of patients with bipolar disorder treated with this agent indicated a possible benefit (Schaffer et al., 2002). In another open study, however, fewer than one-quarter of 13 treatment-refractory patients with bipolar disorder appeared to be helped by adjunctive tiagabine (Suppes et al., 2002). In a third study, none of 8 acutely manic patients appeared to benefit from tiagabine as either monotherapy or an adjunctive agent (Grunze et al., 1999b).

Some case reports and small open studies have indicated beneficial responses in manic patients treated with zonisamide (Kanba et al., 1994; Berigan, 2002), a drug associated with weight loss in obese bipolar patients. In an open-label trial of adjunctive zonisamide, investigators in the Stanley Network (McElroy et al., 2005) noted significant improvements in YMRS and CGI scores among 34 manic or mixed patients who had not responded to conventional treatment ($p < .001$); 14 of the 34 patients were “much” or “very much” improved after 8 weeks of treatment. In an open study, adjunctive zonisamide (300–600 mg/day) at bedtime was associated with significant weight loss in obese euthymic bipolar patients on maintenance medication (Yang et al., 2003).

Other open studies have noted antimanic and/or mood-stabilizing effects associated with levetiracetam.^{23,24} A 6-week open-label, add-on study of mexiletine (an antiarrhythmic drug with anticonvulsant properties) in “treatment-resistant” bipolar patients found that four of the five patients with manic or mixed states in the study had a “full” response and the remaining patient a “partial” response as measured by a derived scale that estimated symptom burden (Schaffer and Levitt, 2005).

Surprisingly little work has been done on one of the oldest anticonvulsants—phenytoin—in the treatment of bipolar disorder. Mishory and colleagues (2000) in Israel reported on 39 patients in whom they examined the antimanic efficacy of phenytoin given with haloperidol in a double-blind, placebo-controlled study. Significantly more improvement was observed in the manic patients who received phenytoin and haloperidol than in those who received placebo and haloperidol.

Typical Antipsychotics

As reviewed extensively in the first edition of this volume, from the 1960s through the early 1990s, typical antipsychotics, particularly haloperidol, were unchallenged as the fastest-acting treatment for acute manic agitation. They were generally considered the treatment of choice for acute mania,

and this practice was reasonably well supported by the literature of the time (Prien et al., 1972; Shopsin et al., 1975; Garfinkel et al., 1980). These studies found that antipsychotics and lithium were equally effective after 3 weeks, but that antipsychotics had a more rapid onset of antimanic action in highly active, acutely manic patients. While American studies were limited to the use of chlorpromazine and haloperidol, European studies often included zuclopenthixol and flupenthixol as well. As Schatzberg and Nemeroff (1998) concluded, “All of the traditional antipsychotic drugs are effective in reducing manic excitement. In comparison with lithium, valproic acid, and carbamazepine, antipsychotic drugs often have a more rapid onset of action.” Today, despite the relative deemphasis on typical antipsychotics in the U.S. Expert Consensus Guidelines and other recent treatment algorithms/guidelines, these agents continue to be widely used in Europe and the United States in the treatment of hospitalized manic patients.

Haloperidol, although by no means the first choice of all clinicians for treatment of acute mania, is still frequently used for this purpose, perhaps more in Europe than in the United States. A small double-blind, prospective study compared the efficacy of three different doses of haloperidol for acute mania (10, 30, and 80 mg/day) over a 6-week period and found no advantage for doses over 10 mg/day (Riflan et al., 1994). By contrast, another double-blind study compared haloperidol at doses of 5 and 25 mg/day for 21 days and found the higher dose to be more effective. Adding lithium enhanced the antimanic effect of the lower but not the higher dose (Chou et al., 1999). Typical antipsychotic medications frequently are combined with lithium in acute treatment of mania, and these combinations have been the focus of controlled studies (Small et al., 1995; Sachs et al., 2002). To our knowledge, however, there has been only one well-designed double-blind study of manic patients not selected for prior poor response to lithium, which demonstrated the superiority of such combinations over lithium monotherapy (Garfinkel et al., 1980).²⁵

In more recent studies, typical antipsychotics have been compared with atypical agents for the treatment of manic states.²⁶ Barbini and colleagues (1997) compared chlorpromazine (mean dose 3.10 mg/day) with clozapine (166 mg/day) and found a more rapid onset of antimanic action at 2 weeks in the clozapine-treated group. However, the two groups were comparable by 4 weeks of treatment. A comparison of haloperidol and olanzapine monotherapy for the treatment of acute mania found comparable symptomatic improvement with the two agents, but concluded that patients taking olanzapine had an enhanced return to normal functioning at 12 weeks as measured by scores on the Health-Related Quality of Life questionnaire and self-report work status (Shi et al., 2002). In a large randomized, double-blind

comparison of olanzapine ($n=234$) with haloperidol ($n=219$), Tohen and colleagues (2003b) found that the proportions remitting were comparable, which is in line with the conclusion of a recent Cochrane database systematic review (Cipriani et al., 2006). Similar results were found in large double-blind, randomized comparisons of risperidone with haloperidol (Smulevich et al., 2005) and quetiapine with haloperidol (McIntyre et al., 2005).²⁷

To our knowledge, there has been only one controlled study in which an atypical showed superior efficacy to a typical. This was a large randomized, double-blind comparison of aripiprazole (15–30 mg/day) and haloperidol (10 to 15 mg/day) (Vieta et al., 2005).²⁸ The advantage of the atypical agents over the typicals is generally believed to depend on their greater tolerability. On the basis of median YMRS scores at entry, studies of atypicals in acute mania were comparing typical and atypical antipsychotics in moderately manic subjects. It is possible that a comparison in a naturalistic setting involving more severely manic patients would show some advantage for the typical agent. However, in a chart review of 106 consecutively admitted manic inpatients in a routine clinical setting, Letmaier and colleagues (2006) found more improvement at 2 weeks (and less EPS) in those treated with an atypical versus a typical, even though the two groups had comparable severity on admission as measured by the CGI scale.

Atypical Antipsychotics

As noted above, during the past decade the treatment of mania has been significantly altered by the introduction of atypical antipsychotics, especially in North America. The more favorable side-effect profile of these drugs, particularly the lower incidence of extrapyramidal symptoms (at least as compared with haloperidol in controlled monotherapy trials in schizophrenia), was a significant factor prompting research into their efficacy for patients with bipolar disorder. It soon became apparent, however, that these agents also have effects on mood more specific than those of the typical antipsychotics, with antimanic and possibly some antidepressant and maintenance efficacy in bipolar patients (including those with mixed states; see Suppes et al., 1992; Benabarre et al., 2001) not shared to the same extent by their predecessor compounds.

Table 18–3 summarizes key findings from the literature on the efficacy of the various atypicals. Essentially, the controlled data indicate equivalent antimanic efficacy for each of these drugs, whether studied as monotherapy (Perlis et al., 2006a) or in combination with lithium or valproate. It is important to note that the studies of atypicals as adjunctive agents all started with patients who had already failed to have a satisfactory response to lithium or an anticonvulsant. Differences in the drugs' tolerability profiles, as outlined

briefly in the table, can affect the choice of treatment, but these differences become more important in maintenance treatment and are thus emphasized in Chapter 20.

Among the atypical antipsychotics, olanzapine and risperidone have been studied most extensively. Initially, case reports and open studies suggested that these two agents had antimanic effects, but some patients appeared to experience a worsening of manic symptoms. However, this reported worsening was not supported by subsequent controlled studies: a post hoc analysis of the results of two placebo-controlled trials of olanzapine in treatment of acute mania (Tohen et al., 1999, 2000) found that a worsening of mania occurred in 38 percent of placebo- and 21 percent of olanzapine-treated patients (Chengappa et al., 2003). Although these results do not eliminate the possibility that the atypical antipsychotics can cause a worsening of mania, they do not support the idea either.

Clozapine

Clozapine has been studied for treatment of mania only in open studies, presumably because of its side-effect profile (including sedation, hypotension, and hematological dyscrasias). In the earliest such study, Muller and Heipertz (1977) found that about half of 52 patients with mania responded quickly to clozapine treatment. Nearly 20 years later, investigators at the McLean Hospital reported a small case series of treatment-resistant bipolar patients who improved substantially on clozapine, especially in manic, mixed, and rapid-cycling states (Zarate et al., 1995). Calabrese and colleagues (1996) reported on an open trial of clozapine monotherapy in 10 bipolar and 15 schizoaffective patients who had failed to either tolerate or respond to lithium.²⁹ All but 3 of the patients completed the 13-week trial, and 18 (72 percent) showed marked improvement on the YMRS and BPRS. It was clear that the bipolar patients experienced more improvement than the schizoaffective patients, and those with rapid cycling did not respond to clozapine as well as the other patients.

An open prospective clozapine trial involving 22 psychotic manic patients who had failed other therapies found that the 14 patients who completed at least 10 weeks of the trial had a better than 50 percent improvement on the YMRS and BPRS and a 39 percent improvement on the CGI (Green et al., 2000). Barbini and colleagues (1997) found clozapine to be as effective as but more rapidly acting than chlorpromazine in a group of 27 manic patients. Suppes and colleagues (1999) compared clozapine adjunctive therapy with treatment as usual in bipolar and schizoaffective patients with a history of mania. Although their study was conducted primarily to assess outcome at 1 year, they also observed that 65 percent of the clozapine-treated patients showed at least 30 percent improvement by 3 months.³⁰

TABLE 18–3. Efficacy and Side-Effect Profiles of Various Atypical Antipsychotics for Treatment of Mania

Agent	Efficacy Summary	Side-Effect Profiles
Clozapine	Effective as adjunctive agent in open trials among non- or partial responders to lithium or anticonvulsants. Effective as monotherapy in open studies.	Sedating; weight gain +++; dyslipidemia ++; prolactin elevation +/-; hypotension common; risk of blood dyscrasias necessitates frequent white blood count determinations
Olanzapine	Effective in adjunctive trials among non- or partial responders to lithium or anticonvulsants. Monotherapy superior to placebo and comparable to lithium and valproate in randomized, double-blind trials.	Sedating; weight gain +++; dyslipidemia +++; prolactin elevation +/-; dose-related extrapyramidal syndrome (EPS) +; parenteral form rapidly effective
Risperidone	Efficacy as adjunctive agent in open and randomized, double-blind trials among non- or partial responders to lithium or anticonvulsants. Monotherapy superior to placebo in two randomized, double-blind trials; as effective as lithium or haloperidol monotherapy in randomized, double-blind trials among non- or partial responders to those drugs.	Less sedating; weight gain ++; dyslipidemia +; prolactin elevation +++; dose-related EPS ++
Quetiapine	Efficacy as adjunctive agent in open trials and one randomized, double-blind trial among non- or partial responders to lithium or anticonvulsants. Monotherapy superior to placebo in two randomized, double-blind trials.	Sedating; weight gain ++; dyslipidemia +; prolactin elevation 0; dose-related EPS +/-
Ziprasidone	Monotherapy superior to placebo in two randomized, double-blind trials	Sedating at high doses; weight gain +/-; dyslipidemia +/-; prolactin elevation +/-; dose-related EPS +; parenteral form rapidly effective
Aripiprazole	Monotherapy superior to placebo in two randomized, double-blind trials	Less sedating; weight gain +/-; dyslipidemia +/-; prolactin elevation 0; dose-related EPS +

The studies of adjunctive atypicals were conducted in patients who had failed to respond adequately to lithium or an anticonvulsant and cannot be generalized beyond that population. Number of plus signs indicates severity of side effects. For individual literature references see the text.

Olanzapine

This atypical agent has been shown to be superior to placebo in several randomized, double-blind comparisons in acutely manic patients. In the first of these studies, olanzapine at a dose of 5–20 mg/day resulted in substantially greater improvement over that seen in placebo-treated subjects in a 3-week study (Tohen et al., 1999). The olanzapine-treated patients' response rate (defined as a reduction in YMRS score) was 48 percent, compared with 24 percent for the placebo-treated group. The difference favoring olanzapine was not apparent, however, until the third week of the study. Even though twice as many patients responded to olanzapine as to placebo, it is sobering to consider that at 3 weeks, fewer than half of the patients on the atypical met response criteria, an observation that can also be made about acute mania trials with other atypical antipsychotics.

There was no significant EPS in the olanzapine-treated subjects, but several had transient elevation of liver enzymes, and the olanzapine-treated group gained an average of 3 pounds during the 3-week study. A second randomized, placebo-controlled study yielded similar results, except that the difference in efficacy between olanzapine and placebo appeared after only 1 week of treatment and was sustained throughout the remainder of the trial (Tohen et al., 2000).³¹ The olanzapine-treated subjects with mixed mania experienced improvement in depressed mood that was statistically superior to that among the placebo group. It is also worth noting that in both studies, the improvement rate for the olanzapine-treated manic subjects was equivalent for those with nonpsychotic and psychotic mania; similar findings have been reported with other atypical agents.

Taken together, these findings support the conclusion that the effect of the atypicals in treating mania is truly

antimanic, rather than nonspecifically antipsychotic or sedative (Baker et al., 2003b). Along the same lines, Baldessarini and colleagues (2003) found olanzapine response to be independent of number of prior episodes, rapid cycling, and lifetime substance abuse.³² It is likely that such findings represent a class effect for the atypicals rather than being unique to olanzapine.

In addition to the comparisons of typical and atypical antipsychotics discussed above, a number of studies have compared olanzapine with other mood stabilizers. In a randomized, double-blind comparison of lithium and olanzapine monotherapy, impressive improvements were seen in manic symptoms for both agents over the 4 weeks of the study. All but one of the four scales employed³³ showed equivalent, dramatic improvement; the fourth³⁴ indicated greater improvement among the olanzapine-treated patients. Mean lithium level was only .74 mg/L, however, which almost certainly favored the olanzapine treatment regimen (Berk et al., 1999).

In a 3-week randomized, double-blind study comparing olanzapine (5–20 mg/day, mean dose 17.4 mg/day) with divalproex (500–2,500 mg/day, mean dose 1,401 mg/day, achieving a mean blood level of 82 mg/ml) for the treatment of acute manic or mixed episodes in 248 patients, Tohen and colleagues (2002) demonstrated a slight but significant advantage for olanzapine over divalproex as measured by the percentage of patients achieving a greater than 50 percent decrease in YMRS score, by the percentage achieving remission as defined by a YMRS score of 12 or lower, and by the mean reduction in score among the two groups. A 44-week double-blind extension of this study found that only after 15 weeks of treatment was the efficacy of valproate comparable to that of olanzapine (Tohen et al., 2003b). Zajecka and colleagues (2002), by contrast, found that olanzapine and valproate had comparable efficacy in a 12-week randomized, double-blind study involving 120 patients with acute mania. The difference between the results of these two studies appears to be explained by dose: compared with the Lilly-funded Tohen et al. study, the Abbott-funded Zajecka et al. study used a lower dose of olanzapine (mean daily doses were 14.7 mg) and a higher dose of valproate (2,115 mg/day). In both studies, patients in the olanzapine group experienced significantly more side effects, especially somnolence and weight gain, than those in the valproate group. Finally, Baker and colleagues (2004) found that, for those with mixed states not responding adequately to a mood stabilizer, adjunctive olanzapine produced significantly more improvement in scores on the Hamilton Rating Scale for Depression (HAM-D) compared with the mood stabilizer alone.³⁵

Some case reports (primarily from the schizophrenia literature) have suggested that olanzapine might occasionally

exacerbate mania. This question was examined systematically by Baker and colleagues (2003a), who pooled the results of two large randomized, placebo-controlled studies of manic patients. Among the 254 patients in these studies, manic exacerbations were significantly more frequent in the placebo group (38 versus 22 percent). However, patients in controlled trials are less likely to have some of the risk factors (such as substance abuse) associated with switching, and they have just experienced a spontaneous manic episode to qualify for the trial.³⁶

To our knowledge, there has been only one comparative study of the IM formulation of olanzapine, in which it was compared with IM lorazepam and placebo as a sedating agent in acutely agitated manic patients in a randomized trial (Meehan et al., 2001). The investigators found that 10 mg of olanzapine was superior to 2 mg of lorazepam or placebo at 2 hours and remained superior to placebo in reducing manic agitation at 24 hours. Olanzapine had no more side effects than lorazepam during the acute period.

Risperidone

In open studies of manic patients, Tohen and colleagues (1996) found a 50 percent or greater reduction in manic symptoms in 10 of 12 patients when risperidone was added to lithium. Keck and colleagues (1995) studied a mixed group of patients treated with risperidone, noting that all 9 bipolar patients with mania showed moderate to marked improvement when the drug was added to a mood-stabilizing regimen consisting of lithium, valproate, or carbamazepine. Ghaemi and Sachs (1997) found that 9 of 14 bipolar patients, most with mania or mixed states, responded well to the addition of risperidone in small doses, averaging under 3 mg/day. In contrast to some early reports of antidepressant activity (Hillert et al., 1992) and even aggravation of manic symptoms (Dwight et al., 1994), Ghaemi and Sachs saw no evidence of worsening of mixed or manic symptoms, a finding consistent with those of the controlled studies described below.

Three large randomized, double-blind trials have demonstrated the superiority of risperidone over placebo in the treatment of mania/mixed states (Vieta et al., 2003; Hirschfeld et al., 2004; Khanna et al., 2005); these studies constitute the database for FDA registration of this drug as an antimanic agent. The largest of the three (Khanna et al., 2005) was conducted in India, where 144 hospitalized manic or mixed patients were randomized to placebo and 146 to a flexible dose of risperidone (1–6 mg/day) for 3 weeks; at end point, a clinical response (50 percent or greater decrease in YMRS scores) was observed in 73 percent of the risperidone patients versus 36 percent of the placebo patients ($p < .001$). The major side effect was EPS (primarily mild), in 35 percent of risperidone-treated patients versus

6 percent of placebo-treated patients. The authors noted that their patients' manias were, on average, substantially more severe than those of patients participating in controlled trials elsewhere.³⁷ This was reflected in the unusually large mean change in YMRS scores (-23.2). In the other large study, Hirschfeld and colleagues (1999) randomized 134 manic patients to risperidone (mean modal dose 4.1 mg/day) and 125 to placebo, also for 3 weeks. Again, improvement in mania (YMRS score) was significantly greater in the risperidone group, with separation from placebo evident as early as 3 days; 43 percent of those randomized to risperidone met response criteria at 3 weeks, versus 24 percent in the placebo group. Remission rates (decline in YMRS score ≤ 12) were 38 percent for risperidone versus 20 percent for placebo. The most common adverse event was somnolence; while EPS rating scale scores were significantly higher in the active treatment group in all three studies, these symptoms were generally mild.

A randomized, double-blind study of risperidone in combination with lithium, carbamazepine, or valproate showed a significantly more rapid decline in YMRS scores for patients taking risperidone in addition to their other medication. The mean modal dose in this study was 4 mg/day (Yatham et al., 2003). In another prospective double-blind, placebo-controlled trial of risperidone as adjunctive treatment for mania (added to lithium or valproate, to which the patients were not responding adequately), Sachs and colleagues (2002) noted more improvement in YMRS scores with risperidone than with placebo at the end of weeks 1, 2, and 3.³⁸ Similar findings were reported by Yatham and colleagues (2004), who randomly added risperidone ($n=75$) or placebo ($n=75$) to lithium or valproate, noting significantly more reduction in mania (YMRS scores) with the combined treatment.

What about comparisons of risperidone and other antimanic agents? In a randomized, double-blind trial of risperidone monotherapy, 45 manic patients took risperidone 6 mg/day, haloperidol 10 mg/day, or lithium 800–1,200 mg/day in a 3-week trial.³⁹ There were no differences in treatment outcomes among the three groups, all of which showed a mean improvement of about 50–60 percent on the YMRS, as well as substantial improvements on general psychopathology and functioning scales (Segal et al., 1998). The fact that lithium and risperidone showed similar efficacy in this monotherapy study appears at first glance to be at odds with the results of controlled studies reviewed above in which adjunctive risperidone was superior to lithium (or valproate). But each of these adjunctive studies started with patients already on a mood stabilizer *to which they had not had an adequate response*. As discussed in Chapter 17, such designs, which characterize most studies of adjunctive atypicals in treating mania, select for

poor responders to a mood stabilizer. In a recent randomized double-blind comparison, risperidone and olanzapine had equivalent antimanic efficacy; olanzapine was associated with a greater reduction in depressive symptoms but more weight gain (Perlis et al., 2006b).

Quetiapine

Several case reports (Dunayevich and Strakowski, 2000) and retrospective case series⁴⁰ suggest a useful role for the atypical antipsychotic quetiapine when used as adjunctive treatment for mania and/or mixed states.

Two large international multicenter randomized, double-blind, placebo-controlled trials evaluated the efficacy of quetiapine monotherapy (400–800 mg/day) in hospitalized manic patients. In one (Bowden et al., 2005), 302 patients were randomized to quetiapine ($n=107$), lithium ($n=98$), or placebo ($n=95$). At 3 weeks the decrease in YRMS scores was significantly greater ($p < .001$) for both drugs compared with placebo; the extent of the improvement was virtually identical for the two drugs. The other study (McIntyre et al., 2005) was of the same size and design, except that the active comparator was haloperidol; results were similar as well, except that at 3 weeks, the effect of haloperidol was slightly more robust than that of quetiapine. In both studies, quetiapine had a significantly greater effect than placebo on depression ratings (see Chapter 19). On the basis of these two studies, quetiapine (Seroquel) received FDA approval for treatment of “acute mania associated with bipolar disorder.” Somnolence, dry mouth, and postural hypotension were the principal side effects differentiating quetiapine from placebo.

Two large randomized, placebo-controlled trials (Sachs et al., 2004; Yatham et al., 2004) examined the efficacy of adjunctive quetiapine in 402 hospitalized manic patients who were still substantially symptomatic (YMRS scores ≥ 20) after a minimum of 7 days of lithium or divalproex. In both studies, the combined treatment was significantly better than the mood stabilizer alone. As noted above regarding adjunctive olanzapine and risperidone, it is important to note that patients entered these studies after at best a partial response to a week or more on the mood stabilizers alone; thus the generalizability of the study findings is limited.

Ziprasidone

The neuropharmacology of this atypical is of interest because its effects include monoamine reuptake inhibition, which might suggest efficacy in depression. Also, ziprasidone stands with aripiprazole (see below) as one of only two atypicals producing little or no weight gain.

Keck and colleagues (2003a) conducted a multisite randomized, double-blind, placebo-controlled study involving 210 inpatients in a manic or mixed state. They assigned 140 of the patients to ziprasidone monotherapy at a dosage

of 80–160 mg/day and 70 to placebo. The patients were also allowed to receive lorazepam or temazepam. Ziprasidone was found to be significantly superior to placebo at 2, 4, 7, 14, and 21 days as measured by the YMRS and from day 4 on according to the CGI scale. The main side effects were somnolence (37 percent with ziprasidone versus 13 percent with placebo) and dizziness (22 percent with ziprasidone versus 10 percent with placebo). These results were subsequently replicated in a 21-day randomized, double-blind, placebo-controlled trial (Potkin et al., 2005) involving 202 manic patients (137 on ziprasidone, 65 on placebo); again, separation from placebo was achieved at day 2. The results of the two studies taken together show approximately linear dose–response relationships. Ziprasidone was not effective for mania at the 40 mg/day dose, whereas 160 mg/day appeared to be substantially more effective than the lower doses. Combined analysis of the two trials indicates that, as with other atypicals, the antimanic efficacy of ziprasidone was similar among those with and without mixed states or psychotic features.

The combination of ziprasidone and lithium versus lithium alone was evaluated in 198 manic patients in a 21-day randomized, double-blind, placebo-controlled trial (99 patients on ziprasidone plus open lithium, 99 on placebo plus open lithium). The group with adjunctive ziprasidone had greater mean decreases in YMRS scores, but the difference achieved significance only at day 4, suggesting that the combination of lithium and ziprasidone may accelerate response (Weisler et al., 2004). Compared with lithium monotherapy, the addition of ziprasidone was associated with more extrapyramidal symptoms, somnolence, dizziness, agitation, and discontinuation due to adverse events (8 versus 4 percent).

An IM form of ziprasidone at 10 mg was found to be very rapidly acting in a group of patients described as psychotic—in fact, more so than haloperidol (at 2.5–10 mg IM) or placebo (Brook et al., 2000). The efficacy of IM ziprasidone in psychotic manic, mixed, or schizoaffective patients was evaluated in a subgroup analysis of two randomized, double-blind studies (Daniel et al., 2004). Doses of 10–20 mg/day (up to 80 mg/day) were compared with a very low “control” dose (2–8 mg/day). There was a significantly higher response rate in the high-dose group (80 percent) than in the low-dose control group (18 percent). The FDA has approved oral ziprasidone for treatment of mania.

Aripiprazole

This atypical antipsychotic (now available as orally disintegrating tablets) has a pharmacodynamic profile that distinguishes it from other antipsychotics by virtue of its being a partial agonist rather than an antagonist at dopamine D2 receptors. Keck and colleagues (2003a) conducted a 3-week

double-blind, placebo-controlled study of aripiprazole for the treatment of mania in 262 hospitalized patients. They found a 40 percent response rate (defined as a decrease of 50 percent or more in YMRS scores) compared with 19 percent for placebo. These findings were subsequently replicated in a second multisite 3-week study involving 272 manic patients (135 on aripiprazole, 137 on placebo). On the basis of the results of these two large studies, the FDA has approved aripiprazole for the treatment of acute mania/mixed states.

How does this agent compare with haloperidol? Vieta and colleagues (2005) addressed this question in a large double-blind comparison in which 347 manic/mixed-state patients were randomized 1:1. The first 3 weeks of treatment was completed by 76.6 percent of the aripiprazole group but only 55.2 percent of the haloperidol group; by 12 weeks these percentages were 50.9 and 29.1, respectively. At week 12, significantly more patients in the aripiprazole group met response criteria of 50 percent or greater improvement (49.7 versus 28.4 percent). The high dropout rate in the haloperidol group was due at least in part to low tolerability, which can be attributed largely to the protocol's not allowing anticholinergic medication to deal with EPS. The authors also noted another factor limiting the generalizability of the comparison: the limited dose range allowed for haloperidol.

Amisulpiride

In a trial in schizophrenic patients, this selective, dose-dependant D2–D3 antagonist appeared to be more effective against affective symptoms than haloperidol or risperidone (Peuskens et al., 2002). This finding led to a preliminary open prospective 6-week study in 20 patients meeting DSM-IV criteria for mania (Vieta et al., 2005). Among the 14 patients who completed the study, a significant improvement was seen in mania ratings, as was a significant albeit less robust effect on depression ratings. The principal side effect was sedation; 10 percent of the subjects experienced EPS.

Zotepine

This first-generation atypical antipsychotic, which, like ziprasidone, inhibits reuptake of monoamines, has been studied in two small open-label trials. Harada and Otsuki (1986) reported beneficial effects in the majority of their 16 moderately manic patients, most of whom were already on lithium. More recently, Amann and Grunze (2005) evaluated zotepine somewhat more formally as monotherapy in a group of more severely manic patients. Nine of the 12 patients met response criteria (a 50 percent reduction YMRS scores), and 5 of them achieved this improvement within 4 days. There have as yet been no randomized, placebo-controlled trials.

Benzodiazepines

In the 1980s, the potential value of two high-potency benzodiazepines—clonazepam and lorazepam—for the treatment of mania was noted. Previously, it had been hoped that these agents might become alternatives to the antipsychotics that would not share their tendency to cause tardive dyskinesia. Results of early open studies suggested that efficacy and speed of onset were similar for high-potency benzodiazepines and antipsychotics, and that the benzodiazepines could be used as short-term antimanic agents for patients who had not taken lithium long enough for it to have an antimanic effect (Modell et al., 1985).

Edwards and colleagues (1991) compared clonazepam with placebo in 40 manic patients, with additional doses of chlorpromazine being given to patients in either group as needed. The clonazepam-treated group showed greater improvement on the YMRS and had a trend toward requiring fewer doses of chlorpromazine. In a crossover study comparing clonazepam with lithium in acutely manic patients, Chouinard and colleagues (1983) found the former to be more effective in reducing manic symptoms. However, the length of the study was only 10 days, with patients receiving either drug for only 5 days before switching to the other. Thus the study findings are probably better seen as reflecting the sedating effect of clonazepam and the known lag time in lithium's antimanic effect than a superior antimanic effect for clonazepam. Also of note, patients in both groups were able to receive haloperidol as needed, further casting doubt on any claim to antimanic efficacy for the benzodiazepine.

Lenox and colleagues (1992) compared lorazepam and haloperidol as adjuncts to lithium in a double-blind study involving 20 hospitalized patients. They found no significant difference between the two drugs in length of time to response. More patients in the haloperidol group dropped out because of side effects, and more patients in the lorazepam group dropped out because of lack of efficacy. Gouliarov and colleagues (1996) obtained similar results comparing clonazepam with the antipsychotic zuclopenthixol. A comparably designed study of clonazepam versus haloperidol found that the haloperidol-treated patients responded more quickly, probably reflecting that drug's more rapid onset of action (Chouinard et al., 1993). Bradwejn and colleagues (1990) found lorazepam to be superior to clonazepam in a double-blind study involving 24 acutely manic patients, a finding that in retrospect also probably reflects differences in pharmacodynamics between the two agents. On the other hand, a recent meta-analysis of the controlled studies concluded that while clonazepam is effective for the treatment of mania, the evidence for lorazepam is not as conclusive (Curtin and Schultz, 2004).

Early on in research on the use of benzodiazepines to treat acute mania, it became apparent that the antimanic effect of these agents is short-lived. Aronson and colleagues (1989) reported on a study of clonazepam monotherapy that was terminated after all five patients treated with the drug for mania relapsed within weeks. It gradually became clear that the apparent antimanic effects of benzodiazepines are more likely due to their acute sedating effect than to a more specific effect on manic symptoms, and that their appropriate role in the treatment of mania is as adjunctive agents for rapid sedation of agitated patients and stabilization of sleep. Finally, the possibility must be considered that some manic patients may experience further disinhibition with these agents.

Electroconvulsive Therapy

Although it is clear from clinical experience that ECT is an effective and rapidly acting treatment for mania (Fink, 2006), there have been only a handful of controlled prospective studies to support this conclusion. This is a reflection, perhaps, of four factors. First, given the efficacy and wide range of available pharmaceutical agents, few patients receive ECT for mania. Second, the effect is often so dramatic as to make controlled study appear unnecessary. Third, it is difficult to justify and maintain blinded conditions with sham ECT for such a controlled trial in acutely manic patients. Finally, unlike drug treatments, ECT requires written informed consent (Fink, 2006), which can be difficult to obtain, particularly from more severely ill patients for whom ECT may well have an advantage over medication.

Given this lack of data, it is difficult to say how ECT is best used for treating mania. The optimal electrode placement and number of treatments also remain unclear. For example, some have suggested that mania might be expected to respond more favorably to right-sided placement and depression more to left-sided placement. In one study of seven manic patients, however, right unilateral ECT was not effective (Milstein et al., 1987).

Although systematic and controlled studies are lacking, an excellent review of the published experience with lithium by Mukherjee and colleagues (1994) suggested that about 80 percent of manic patients treated with ECT showed marked improvement or full recovery. On the other hand, an analysis of manic and schizoaffective manic patients receiving ECT (Winokur et al., 1990) confirmed the earlier observation (Winokur and Kadmas, 1989) that these patients had more subsequent hospital admissions for mania than those not receiving ECT, although the ensuing total number of episodes of mania and depression did not differ between ECT- and non-ECT-treated patients. The authors concluded that this finding probably reflects some

difference in the patients selected to receive ECT rather than medication alone, although they could not rule out the possibility that ECT might have had an adverse effect on the severity of subsequent manic episodes.

Zarate and colleagues (1997) studied a series of seven bipolar patients who were given ECT while continuing on anticonvulsants (valproate or carbamazepine), including two who were receiving ECT for mania. They found that the combined use of ECT and anticonvulsants was safe and appeared to be effective. Seizure duration was slightly shorter with unilateral (but not bilateral) ECT despite the use of a more powerful electrical stimulus with unilateral ECT in patients on valproate or carbamazepine.⁴¹ Ciapparelli and colleagues (2001) evaluated the effectiveness of ECT for patients with mixed states and reported dramatic reductions in depression scores. The effect of maintaining ECT in mania is discussed in Chapter 20.

Rapid Transcranial Magnetic Stimulation

There have been two studies of the use of rTMS for the treatment of mania. Grisaru and colleagues (1998) evaluated the efficacy of right-sided versus left-sided rTMS in 16 hospitalized patients with mania taking various medications and found that the former produced more improvement in manic symptoms than the latter (which in fact appeared to worsen manic symptoms, leading to premature termination of the study). Since left-sided rTMS treatments have been shown to be more effective for the treatment of depression in most (though not all) studies, these results suggest a lateralized control of mood in the brain, a finding supported by experiments evaluating the results of right-sided versus left-sided rTMS on mood in normal volunteer subjects (Pascual-Leone and Catala, 1996).

Michael and Erfurth (2004) administered right-sided prefrontal rTMS treatments to nine patients hospitalized with mania. Eight of the patients were on various medications, while one received rTMS as monotherapy. All nine patients had “sustained reduction of manic symptoms.”

As is true for the treatment of depression with rTMS, clinical data on the use of rTMS to treat mania are scant and preliminary but encouraging. They suggest that rTMS may turn out to be a valuable addition to the therapeutic options available for the treatment of mania.

Other Treatments

Calcium Channel Blockers

The use of calcitonin, verapamil, and diltiazem for treatment of mania was proposed in the early 1980s, but few controlled data were brought forth to support this recommendation.⁴² Subsequent controlled studies have shown mixed results. Two parallel studies compared verapamil

with lithium. In one (Garza-Trevino et al., 1992), no difference was seen between the two agents over a 4-week period. In the other (Walton et al., 1996), lithium was found to be superior to verapamil. Janicak and colleagues (1998) found no benefit from verapamil compared with placebo in a 3-week double-blind study.

Post and colleagues (2000) studied the L-type calcium channel blocker nimodipine in patients with ultrarapid (ultradian) bipolar illness (patients who cycle several times in a 24-hour period). They noted marked improvement in some patients (Pazzaglia et al., 1998), including one whose mood again destabilized when verapamil was substituted for nimodipine.

Magnesium sulfate, used in a variety of clinical contexts, including treatment of cardiac arrhythmias, exerts at least some of its pharmacological effects through competitive antagonism with calcium at cellular calcium channels. Heiden and colleagues (1999) added intravenous magnesium sulphate to the drug regimens of 10 patients with severe, treatment-resistant manic agitation and noted a marked improvement in 7.

Levy and Janicak (2000) reviewed these and other studies of calcium channel antagonists and concluded that there is at best quite limited support for their efficacy. Because of their lack of demonstrated superiority over other agents, the calcium channel blocking agents have been relatively neglected in the clinical research literature. Thus their role in the treatment of acute mania remains to be determined.

Tamoxifen

This nonsteroidal antiestrogen is widely used in the treatment and relapse prevention of estrogen-dependent cancers, particularly of the breast. Because it is also a potent inhibitor of phosphokinase C, which is thought to be involved in the mechanism of action of mood stabilizers (see Chapter 14), it has been used experimentally for treating mania and found to be effective in a small series of patients (Manji and Chen, 2002).

Omega-3 Fatty Acids

Although there has been interest in these compounds for the treatment of bipolar disorder, reports and trials have been limited to bipolar depression and possible uses in prophylaxis (see Chapters 19 and 20). There has been at least one report of possible induction of hypomania in a patient using over-the-counter fish oil preparations (Kinrys, 2000). What if any benefit these substances may have for manic patients is as yet unknown.

Cholinergic Agents

Reports on the use of cholinergic agents, such as pilocarpine, for the treatment of mood states appeared as early

as the late nineteenth century. Severe side effects limited the use of these older agents, but new agents developed for the treatment of Alzheimer's disease have a much more favorable side-effect profile. Burt and colleagues (1999) reported on a small open case study of the use of the cholinesterase inhibitor donepezil in patients with treatment-resistant bipolar disorder. Of the 11 patients in the study, 10 were in a manic, hypomanic, or mixed state. Of these, 6 were very much improved by the end of 2 weeks. However, in a subsequent double-blind, placebo-controlled trial of adjunctive donepezil in 11 manic patients, Eden Evins and colleagues (2006) were unable to demonstrate efficacy. Cases of mania evidently precipitated by donepezil have been reported as well (Benazzi, 1998).

CONCLUSIONS

The discovery of the antimanic effects of lithium launched the psychopharmacology revolution in psychiatry, and today lithium remains one of the most documented choices for the treatment of euphoric nonpsychotic mania or hypomania. Beyond lithium, however, our armamentarium has been considerably enriched by anticonvulsants and atypical antipsychotics. In comparison with the treatment of bipolar depression or maintenance treatment, the clinician enjoys the choice of a wide range of drugs that have been shown to be effective in treating acute mania and/or mixed states. Indeed, in the United States alone there are nine FDA-approved agents for mania. Recall, however, that in the placebo-controlled literature, "response" means an improvement of 50 percent or better, and that even with this modest definition of improvement, the response rates from monotherapy studies average around 50 percent. Thus most manic patients will ultimately require a combination of medications, although when possible, it is generally advisable to evaluate monotherapies first. Given that a drug or drug combination initiated for mania or hypomania will likely be carried forward into the continuation phase of treatment (not to be confused with true maintenance or prophylactic treatment; see Chapter 17), both efficacy and tolerability must be considered from the outset. For the acute management of more severely ill patients, the older typical antipsychotics still have a role, while for the patient with moderate to moderately severe symptoms, the atypical antipsychotics represent an important addition to the armamentarium.

The manic patient presents multiple clinical challenges beyond the issue of choice of medication, such as dealing with law enforcement and deciding when to hospitalize involuntarily, how best to involve the family, and how to enhance adherence to the treatment regimen. For those patients whose manic episodes are heralded by a hypomanic

period (the "hypomanic alert"), the clinician may have an opportunity to prevent escalation through the aggressive use of drugs to restore normal sleep. An ongoing relationship with the family is the best way for the clinician to be assured of being alerted in time.

NOTES

1. Delirious mania—a syndrome of the acute onset of the insomnia, excitement, grandiosity, emotional lability, and psychotic symptoms characteristic of mania, accompanied by the disorientation and altered consciousness characteristic of delirium—is fortunately now rare. See Chapter 2 and Fink (1999) for a review.
2. IM droperidol had also been widely used for emergency sedation until concerns about cardiac arrhythmia and reports of sudden death led to its virtual elimination from the armamentarium in the late 1990s. More detailed analyses have cast some doubt on the wisdom of abandoning this highly effective agent so quickly (Chase and Biros, 2002).
3. To our knowledge there have been no studies comparing ECT with atypical antipsychotics in the treatment of mania.
4. For example, a Finnish study of bipolar patients who committed suicide found that about 1 in 10 were in or had recently recovered from a period of psychotic mania at the time of their death (Isometsa et al., 1994).
5. However, in a randomized study, Rifkin and colleagues (1994) compared three doses of haloperidol for mania (10, 30, and 80 mg/day) and found no difference among the three doses. They concluded that more than 10 mg/day offers no additional advantage in treating mania.
6. Adapted from the first edition of this text: Comparisons of lithium and neuroleptics have been limited largely to chlorpromazine. The largest such study, the Veterans Affairs (VA)–National Institute of Mental Health (NIMH) study (Prien et al., 1972), warrants extensive discussion because of its size—255 newly admitted manic and schizoaffective patients in 18 VA hospitals—and its unusual findings. Patients were differentiated not only by diagnosis but also by activity level: "highly active" or "mildly active." Among the highly active patients who completed the 3-week treatment trials, both the lithium-treated and the chlorpromazine-treated groups improved significantly on a wide range of symptoms. However, 38 percent of the lithium-treated patients dropped out, compared with only 8 percent of those treated with chlorpromazine, in part reflecting more side effects attributable to lithium in this group since the dose was pushed in an effort to control the hyperactivity. Both drugs produced significant improvement in the mildly active patients who completed the study, but in this group severe side effects were more frequent among the chlorpromazine-treated patients. The investigators concluded that chlorpromazine was superior to lithium in the initial treatment of the highly active patients. The neuroleptic not only reduced motor activity, excitement, grandiosity, hostility, and psychotic disorganization, but also sharply decreased the patients' need for ward supervision in the first week. By the end of 3 weeks, however, the two drugs were equivalent. Among the mildly active patients, there were fewer dropouts related to lithium than to chlorpromazine, primarily because lithium did not make them feel as "sluggish and

fatigued.” Neither discharge rates nor overall improvement rates were reported in this study. In other studies, however, discharge rates and clinical evaluations have favored lithium over neuroleptics, thus underscoring the ultimate advantage of lithium. The dropout rate in the VA-NIMH study may reflect limitations in clinical management more than inherent limitations of the drugs in question.

Diagnosis is also a critical issue. Prien and colleagues did not specify how the differential diagnosis was made between the manic phase of manic-depressive illness and schizoaffective psychosis. Other investigators might have diagnosed their highly active patients as schizoaffective or “atypical.” Although some studies have suggested that such patients do not respond as well to lithium as the more typical manic-depressive patients do (reviewed by Goodwin and Ebert, 1973), other investigators have failed to find any difference in lithium response between the groups (reviewed by Goodnick and Meltzer, 1984). This discrepancy is probably more apparent than real. Goodnick and Meltzer (1984) have shown that, compared with manic patients, schizoaffective manic patients require more than twice as long to achieve a full anti-manic response to lithium alone (9 weeks versus the 4 weeks for manic patients). Many of the reports of relatively poor lithium response rates among schizoaffective manic patients involve trials of 4 weeks or less. Again, from a practical point of view, this means that schizoaffective manic patients are likely to require other medications in addition to lithium for the acute treatment of mania. Finally, it is important to recall that even though the antipsychotics had been the established treatment for acute mania, and lithium’s introduction was clouded (particularly in the United States) by reports of deaths associated with its initial use as a salt substitute, lithium nevertheless became the preferred treatment for most acutely manic patients.

7. As an example of such limit setting, consider the following: “I am doing my best to appreciate your reasoning and wishes. I understand that you disagree with me, but I have decided that for now this is what must happen. We must give you x mg of olanzapine now and three times a day over the next 3 days to get to a therapeutic range.”
8. Schou et al., 1954; Maggs, 1963; Goodwin et al., 1969; Stokes et al., 1971.
9. A delay of 7–10 days in the onset of lithium action includes the 5–6 days it usually takes to establish a steady-state level.
10. Post et al., 1986a; Small et al., 1991; Bowden et al., 1994, 2006; Weisler et al., 2004, 2005.
11. Ichim et al., 2000; Lessig et al., 2001; Jochum et al., 2002; Margolese et al., 2003.
12. Ballenger and Post, 1980; Okuma et al., 1981; Desai et al., 1987; Lerer et al., 1987.
13. As noted in the first edition, in a number of these early studies the carbamazepine-treated patients were also on lithium.
14. The average carbamazepine level was 7.3 $\mu\text{g/ml}$, while the average lithium level was .46 mEq/l. In this study, both medications were used at doses that resulted in relatively low serum levels, and they had approximately the same efficacy.
15. The mean YMRS scores at the end of the 8-week study period (17/60) were the same in both groups but were nevertheless fairly high. The authors noted that although the two agents were equally effective, neither was sufficiently effective to be recommended as monotherapy for treatment of severe manic states. They suggested that combination treatment would be needed for most acutely manic patients. At the same time, they noted that most of the patients in their study had a prior history of failing a lithium trial.
16. The registration trials for extended-release carbamazepine were undertaken after encouraging results were obtained in a 6-month open-label evaluation by Ketter and colleagues (2004).
17. In this study, 63 percent of the subjects also remained on lithium therapy throughout the study period.
18. Marcotte, 1998; Normann et al., 1999; Calabrese et al., 2001; Letmaier et al., 2001; Pecuch and Erfurth, 2001; Bozikas et al., 2002.
19. An open study of 14 patients with mania (9 of whom took topiramate as monotherapy) found the drug to be helpful in 62 percent of the subjects (Bozikas et al., 2002). Calabrese and colleagues (2001) treated 10 manic patients with topiramate as monotherapy in an open trial over a period of up to 4 weeks. The subjects’ mean YMRS score dropped from 32 to 22; however, only 3 of 10 patients had a decline in score of 50 percent or more, while 5 had a decline of less than 20 percent. Marcotte (1998) reviewed the charts of 44 patients treated for bipolar-I manic or mixed or bipolar-II disorder with an average of 200 mg/day of topiramate in addition to “existing therapy” for an average of 16 weeks. Moderate to marked improvement was experienced by 23 (52 percent) of the patients, while 5 patients (11 percent) were rated as worse; 1 patient became delirious. No weight gain (or loss) was reported in the group.
20. Chengappa and colleagues (1999) used topiramate in another open-label study of 12 manic, 1 hypomanic, 5 mixed, and 6 rapid-cycling patients also taking other medications. The mean YMRS score declined from 30 to 18 in 3 weeks and to 12 by 5 weeks. In this study, patients lost an average of 6 pounds at 3 weeks and 9 pounds at 5 weeks. Grunze and colleagues (2001) gave topiramate to 11 acutely manic patients who were taking other medications, including lithium, valproate, carbamazepine, haloperidol, and lorazepam. After 10 days of receiving topiramate, 7 of the patients had positive responses that deteriorated when the drug was discontinued. When the topiramate was reinstated, 8 of the 9 patients who completed the study experienced a 50 percent or greater decrease in their YMRS score.
21. In an open study, lamotrigine was given either as monotherapy or in addition to other agents to patients experiencing acute mood episodes of bipolar disorder (Calabrese et al., 1999). Of the 31 patients with manic, hypomanic, or mixed states, 33 percent were “very much improved” on the CGI scale at the end of 48 weeks. Of the total group of 75 patients, 8 experienced a worsening of or the onset of manic symptoms that required hospitalization. A study of lamotrigine as a prophylactic agent in rapid-cycling bipolar disorder (Calabrese et al., 2000) had a preliminary open phase that included 66 patients with mania or hypomania. After being treated with lamotrigine for 6 weeks, about half of these patients had experienced sufficient remission of their symptoms to enter the next phase of the study.

23. Goldberg and Burdick, 2002; Braunig and Kruger, 2003; Grunze et al., 2003; Bersani, 2004.
24. In Grunze and colleagues' (2003) open-label study, the efficacy of levetiracetam added to haloperidol was examined in 10 acutely manic patients in an on-off-on study design. There was an improvement in mean YMRS scores during the first on phase of the study, a worsening during the off phase, and then another improvement during the second on phase.
25. The single comparison study of zuclopenthixol for treatment of acute mania was limited by its design. The study compared the combination of zuclopenthixol and clonazepam with that of lithium and clonazepam in 28 hospitalized patients with acute mania. The two combinations were found to be of similar efficacy (Gouliaev et al., 1996).
26. Miller and colleagues performed a retrospective chart review of 204 patients with acute mania admitted to a university hospital over a 30-month period, comparing typical and atypical antipsychotic medications as add-ons to mood-stabilizing medications. In this naturalistic study, patients taking atypical antipsychotic medications showed greater clinical improvement and fewer side effects than those treated with typical antipsychotic medications, but the clinicians may have tended to use the typical agents in the sicker patients (Miller et al., 2001).
27. Sachs and colleagues (2002) reported on a comparative trial of risperidone (mean dose 4 mg/day) or haloperidol (mean dose 6 mg/day) versus placebo as adjunctive treatment for patients taking either lithium or valproate for acute mania. Similar degrees of improvement on the YMRS were seen with both. In a nonrandomized observational study, Gonzalez-Pinto and colleagues (2001) evaluated the relative efficacy of adjunctive olanzapine versus an adjunctive typical antipsychotic in the treatment of 45 hospitalized patients with mixed states already on a mood stabilizer; those treated with olanzapine showed significantly more improvement in depressive symptoms compared with those taking the typical antipsychotics. In the one randomized comparison of olanzapine and haloperidol as monotherapy in treating mania, Tohen and colleagues (2003b) evaluated 453 patients and found that approximately 50 percent in each group met remission criteria (low scores on both mania and depression scales) after 6 weeks of treatment. During an additional 6 weeks of follow-up, relapses into depression occurred more rapidly with haloperidol than with olanzapine, and in a secondary analysis, those without psychotic features ("pure" mania) did better on olanzapine than haloperidol. As might be expected, olanzapine was associated with more weight gain, while haloperidol produced more EPS.
28. The absence of a placebo group in this aripiprazole-haloperidol comparison limits interpretation of the results.
29. Most patients had also had poor responses to carbamazepine or valproate. All 25 subjects had experienced at least one episode of mania in the 24 months prior to the trial. The mean number of hospitalizations was 15.
30. A chart review study of bipolar-I patients treated with adjunctive clozapine, risperidone, and olanzapine found no difference in efficacy among the groups (Guille et al., 2000). Olanzapine caused the greatest weight gain, although olanzapine plus lithium was associated with less weight gain than olanzapine plus valproate.
31. However, there was an even higher placebo response rate in this series—43 percent, compared with the 25 percent rate in the earlier study.
32. A secondary analysis of the first placebo-controlled trial (Tohen et al., 1999) by Baker and colleagues (2002) indicated that the efficacy of olanzapine in acute mania was independent of whether the patient had previously failed to respond to lithium or valproate.
33. Brief Psychiatric Rating Scale, Clinical Global Impression for Bipolar Disorder scale identifying manic, hypomanic, depressive, or mixed symptoms.
34. Simpson-Angus Scale.
35. Generalizability is quite limited for studies in which the new agent is added to ongoing treatment to which the patient is not yet responding since this is, in effect, selecting for non- or partial response to the original agent, in this case lithium or valproate.
36. The Baker et al. (2002) data could also be interpreted as suggesting that olanzapine was superior to placebo in preventing early relapses into mania after acute treatment of the episode.
37. This difference may relate to the fact that in India, families can give consent for participation in treatment research when the validity of a patient's consent is compromised by the illness.
38. In this study, there was also a haloperidol-treated group. It is interesting that three placebo- and three haloperidol-treated subjects on lithium or valproate became manic, but none of the risperidone-treated patients did.
39. In Segal and colleagues' (1998) study, mean serum lithium levels were .53, .62, and .72 mmol/l at the end of weeks 1, 2, and 3, respectively.
40. Ghaemi and Katzow, 1999; Zarate et al., 2000; Chisholm et al., 2001; Sajatovic et al., 2001.
41. Coexisting lamotrigine does not appear to require any increase in the electrical stimulus.
42. Giannini et al., 1984; Dose et al., 1986; Dubovsky et al., 1986; Barton and Gitlin, 1987.

Monsieur le Docteur, since you are quite aware of what in me is capable of being attacked (and healed by drugs). . . . I hope you have the know-how to give me the quantity of subtle liquids, of specious agents, of mental morphine which will uplift my abasement, balance what is crumbling, reunite what is separated, recompose what is destroyed.

—Antonin Artaud (1924, pp. 27–28)

The treatment options for recurrent depression, especially bipolar depression, have finally begun to expand over the last few years. In the first edition of this volume, a treatment algorithm for bipolar depression listed only four interventions, or classes of interventions, by name: lithium, the tricyclic and monoamine oxidase inhibitor (MAOI) antidepressants, and electroconvulsive therapy (ECT) (although fluoxetine and bupropion were discussed in the text). Since then, entirely new classes of medications have been introduced and shown to benefit patients with bipolar depression.¹

Medical treatments for bipolar depression are also being explored. Entirely new classes of medications have been introduced and shown to benefit patients with bipolar depression. An expanded clinical literature now informs the use of thyroid hormones for depression, and research continues into the relevance of adrenal agents. The use of sleep deprivation and phototherapy to augment pharmaceutical treatments has proven beneficial. New techniques for electrical stimulation of the central nervous system are being studied, while nonprescription pharmaceuticals, such as St. John's wort, and dietary supplements, including those containing omega-3 fatty acids, have been the subject of intense interest in the lay press. Finally, our continued, strong belief in the importance of psychotherapeutic treatments is reflected in their being the subject of a separate chapter.

Despite the newly available medical interventions, however, the successful treatment of bipolar depression remains a challenge for the clinician. Many options for the treatment of mania (discussed in the previous chapter) have been established by randomized, placebo-controlled trials, as reflected in the large number of antimanic agents approved by the U.S. Food and Drug Administration (FDA). Research on the treatment of bipolar depression has been minimal in com-

parison with that on mania, or especially that on unipolar depression. Reflecting this paucity of data, as of this writing only two agents are FDA approved for treatment of bipolar depression—the atypical antipsychotic quetiapine and the combination of olanzapine and fluoxetine. Even long-term maintenance treatment (see Chapter 20) has been the subject of more controlled studies than have been conducted for the acute treatment of bipolar depression. Moreover, although the few available controlled studies are weighted toward bipolar-I patients, some do include bipolar-II patients, but usually without separately analyzing the results for these two very different groups. Thus the treatment of bipolar-II depression remains woefully understudied, despite the disorder's being at least as common as bipolar-I disorder.

Patients with bipolar depression often respond more slowly² and less completely to pharmacotherapeutic interventions than patients who have manic or mixed symptoms, and some clinical studies suggest that they are substantially less likely to experience full remission of their symptoms (Hlastala et al., 1997; Calabrese, 2005). A 2001 survey of patients being treated for bipolar-II disorder, for example, found that despite treatment, nearly half had suffered residual depressive symptoms of at least 2 years' duration (Benazzi, 2001), findings very similar to the recent analysis of the Systematic Treatment Enhancement Program for Bipolar Disorder (STEP-BD) data (Perlis et al., 2006). Likewise, in the follow-up phase of the National Institute of Mental Health (NIMH) Collaborative Program on the Psychobiology of Depression-Clinical Studies (Judd et al., 2003), 67 percent of those receiving routine treatment available in the community continued to have substantial depressive morbidity.

This chapter begins with a discussion of the clinical management of depressed patients, addressing the evaluation

and treatment planning process and providing an overview of proven and widely accepted treatment approaches. We review the literature supporting these approaches, and then survey less proven but nevertheless promising interventions that may become more commonplace in the future. All of the drugs mentioned in the first section of the chapter are discussed in detail in the second.

Before proceeding, a note on the scope of the discussion is in order. As mentioned in Chapter 1, our discussion of depression encompasses both bipolar and highly recurrent unipolar major depression; however, given the paucity of studies of acute treatment of recurrent depression per se, our emphasis is primarily on bipolar depression. Moreover, as discussed in Chapter 17, we conceptualize treatment of manic-depressive illness in three stages—acute, continuation, and long-term maintenance. This chapter, like the preceding one, focuses on acute treatment; Chapter 20 focuses on maintenance treatment. The continuation stage is not so easily apportioned to a single chapter. Relapses into a major depressive syndrome from a state of euthymia, postmanic depressions, and breakthrough minor depressive symptoms are categories whose boundaries in real-life treatment situations can be unclear. Therefore, while the management of severe major depressive episodes, which can represent a medical emergency, is an important focus of this chapter, approaches to breakthrough or residual symptoms, particularly the former, are also addressed here, as well as in Chapter 20.

CLINICAL MANAGEMENT

This section addresses the key aspects of the clinical management of depression. Discussed in turn are the evaluation of the depressed patient, hospitalization, general considerations involved in medical treatment, and selection of a treatment approach. Our recommendations for the selection of appropriate treatments for particular patients are presented later in the chapter. Detailed discussion of special considerations in treating bipolar children and adolescents is presented in Chapter 23, and issues involving side effects of psychiatric medications and their use in pregnancy are addressed in Chapter 20.

Evaluation of the Depressed Patient

Diagnosing bipolar depression can be difficult, and the importance of taking a comprehensive history and performing a careful mental status examination as the foundation for treatment of the depressed patient cannot be overemphasized. Often the evaluating psychiatrist is not the first mental health professional, the first physician, or even the first psychiatrist to see the patient. Patients may previously have been told, erroneously, that they suffer from another

psychiatric disorder, such as unipolar depression or, less commonly, schizoaffective disorder, schizophrenia, or a personality or substance abuse disorder. The clinician should neither accept such prior diagnoses at face value nor dismiss them out of hand, but rather use them as a starting point for fuller consideration of the clinical picture, as well as a means of engaging the patient and family in a discussion of history and symptoms.

The patient should be told that the inclusion of family members or a close friend in at least part of the diagnostic interview is routine and expected. Doing so is especially important in diagnosing a depressive syndrome potentially associated with bipolar disorder. As discussed in Chapters 3 and 21, patients often lack insight into the problems associated with hypomanic or even manic episodes, and therefore may not report the salient details, even with careful questioning; the more objective perspective of an outside observer is generally necessary. In conducting the diagnostic interview, the clinician should be sure to address the following matters:

- **Course-of-illness** questions should inquire into mood cycling—over the course of a day (diurnal mood variations), month (premenstrual exacerbations), and year (seasonal affective disorder [SAD]). Mood symptoms in the postpartum (puerperal) period or exacerbation of affective symptoms following antidepressant treatment should also be addressed specifically. The use of a life chart (as described in Chapter 11) is highly recommended for recording these important course variables.
- It is imperative to take a comprehensive survey of the patient's **use of alcohol and other intoxicating substances** (see Chapter 7); the clinician should ask specifically about a family history of alcoholism or drug abuse. Substance abuse is often viewed by patients as not being a “psychiatric” problem. Surreptitious substance abuse is frequently an illness-sustaining factor responsible for refractory depressive symptoms, antidepressant-related switches, and/or cycling, medication nonadherence, and an apparent lack of response to adequate treatment. Therefore, questioning family members and previous providers about substance use and abuse may be the only way to obtain this history accurately. Practitioners should have a low threshold for obtaining urine toxicology screens and hepatic transaminase determinations if there is any suspicion in this regard.
- Patients, when asked about their **treatment history**, may present an extensive list of medications that they report have been ineffective for them in the past. Frequently such lack of benefit can be attributed to inadequate medication trials. Thus it is essential to request details on adherence, the dosing and duration of these past medication

trials, and results of blood-level determinations for appropriate agents; records from past providers should be obtained whenever possible. Reports of side effects should be treated with empathy but some skepticism and elucidated in as much detail as possible. Patients may experience a variety of minor somatic symptoms more accurately attributable to depression than to a medication, or more closely related to a total side-effect burden associated with multiple medications than to a single agent. The clinician should also ask about a history of a decreased need for sleep, abnormal increases in energy, euphoria and/or irritability, suicidal thinking or behavior, or other signs of psychomotor activation in response to treatments for depression, as these symptoms may indicate an underlying bipolar diathesis.

- In taking the **family psychiatric history**, the clinician should focus not only on the diagnosis of family members but also on their response to particular treatments. Although the field of pharmacogenetics is still in its infancy, it is possible that, given the clear genetic mechanisms at work in the etiology of mood disorders, a patient will have a favorable response to an agent that successfully treated a similarly ill family member. Clinical experience suggests that this is not uncommonly the case.

Hospitalization

The first treatment decision the clinician must make is whether a depressed patient can safely be treated on an outpatient basis. More than two-thirds of completed suicides by persons with bipolar disorder occur during a major depressive episode (Isometsa et al., 1994) (see Chapter 8). The patient expressing fear of acting on suicidal urges clearly needs to be considered for hospitalization, but the decision is often less than clear-cut, depending, for example, on whether there is a previous history of serious suicide attempts, whether the patient expresses hopelessness, whether the patient has a history of impulsiveness and/or violence, and whether the patient has access to lethal means and/or lives alone. Comorbid substance abuse substantially increases the suicide risk; thus the threshold for hospitalizing the depressed patient who is actively abusing drugs or alcohol should be lower than that for a patient who is not.

The patient with severe psychomotor retardation should usually be hospitalized. Even if the close support of family members is available to these patients, their nutritional status and ability to comply with treatment recommendations are poor, and their illness can decompensate quickly into an acutely life-threatening condition. The risk of suicide may actually rise as these patients begin to emerge from their depression. Under some circumstances, a patient may need to be placed under one-to-one observation, or suicide watch (see Chapter 8). Energy level and volition often increase well

before mood state improves; thus patients who literally have been too depressed to harm themselves may quite suddenly become much more likely to kill themselves.

Hospitalization offers many opportunities for monitoring of both symptoms and medication adherence that are not available in the course of outpatient treatment. Diurnal variations in mood, brief hypomanic periods, mixed affective symptoms, and symptoms of withdrawal from surreptitiously abused drugs are just some of the complicating factors that may become apparent only during hospitalization. Side effects can be identified and managed more quickly, and hospitalized patients can be educated and supported in tolerating the temporary discomforts often experienced with new medications. The clinician should also consider hospitalizing a depressed patient for ECT early in the process of planning treatment, not as a last resort. We discuss factors favoring ECT as a first-line treatment in a later section.

Day-hospital programs and hospital-based intensive outpatient programs can sometimes achieve the goals of inpatient treatment. Such programs are much less disruptive to the patient's personal and family life than hospitalization, while also incurring substantially lower financial costs.

Medical Treatment: General Considerations

Patients presenting to the psychiatrist with symptoms of bipolar depression vary tremendously in the severity of their symptoms, the complexity of their course of illness, and their previous treatment history. Nevertheless, some general considerations will serve the clinician well in almost all instances:

- **Adequacy of medication trials.** The benefits of pharmaceutical interventions for depression may take several weeks to become apparent, and patients may continue to improve for months after starting on a new medication. Once the presumed therapeutic dose range has been reached, further dosage increases should generally occur at intervals of not less than 2 weeks. Improvement in response to medications does not always follow a smooth pattern, so it is important for patients to be ready to experience a "sawtooth"-like pattern (see Figure 22-1 in Chapter 22).³ Symptoms should not be declared refractory to a particular agent unless the patient has taken it at the maximum recommended dosage or, if serum determinations are available, at the top of the therapeutic range, for at least 4 weeks.
- **Mood cycles and fluctuations.** Some mood fluctuations in patients being treated for bipolar disorder reflect cyclic or phasic changes associated with the illness that will normalize with time and do not necessarily require pharmaceutical intervention. Many patients will, for example,

have brief depressive periods following periods of mania or hypomania. Being too quick to intervene during these periods can result in prescribing unnecessary and sometimes ultimately destabilizing antidepressants or other agents. Watchful waiting, along with psychotherapeutic and psychoeducational support, is often the better approach. Nonpharmaceutical adjunctive treatments, such as phototherapy, sleep deprivation, and exercise, can be helpful as well.

- **Breakthrough depressions in patients on maintenance mood stabilizers.** This is the most common situation in which the clinician encounters bipolar depression. The first consideration should be optimization of the mood stabilizer regimen. As reviewed in the first edition of this volume (and now incorporated into several of the treatment guidelines for bipolar depression), a temporary increase in the patient's lithium level (to above .8 milliequivalents per liter [mEq/l]) can often abort a breakthrough episode, and there is reason to think that such a strategy may be effective with other mood stabilizers as well. While we emphasize watchful waiting above, in some situations attention to prodromal or subsyndromal symptoms may allow an intervention that can prevent an episode from progressing at a time when it may be more rapidly responsive to intervention. In our experience, cognitive symptoms, such as diminished concentration and indecisiveness, are the most frequent prodromes; this observation is consistent with that of Keitner and colleagues (1996). Subtle mood and psychomotor changes are also common (see the reviews of Jackson et al., 2003, and Marangell, 2004).
- **Assessment of progress.** Recovery from bipolar depression can be slow and characterized by starts and stops. Therefore, frequent assessment (weekly during the initial stages of treatment and at least every 2 weeks as long as there are significant residual symptoms) is essential. Family members should be encouraged to attend follow-up appointments to report their impressions. Patients can also be encouraged to keep a journal or mood chart⁴ and bring the results to appointments. In addition, the clinician should consider using an objective rating scale to record assessments of improvement. The Montgomery-Asberg Depression Rating Scale (MADRS) (Montgomery and Asberg, 1979) is more sensitive to symptom change in bipolar depression than the more frequently used Hamilton Rating Scale for Depression (HAM-D) because it focuses more on core depressive symptoms than on anxiety, insomnia, and somatic symptoms (Montgomery and Asberg, 2001). A self-administered version of the MADRS is also available. (See also Chapter 11.)
- **Rational combined pharmacotherapy and irrational polypharmacy.** Although rational combined pharma-

cotherapy (the use of several pharmaceutical agents to treat a single condition) is often necessary in treating bipolar depression, the risk of irrational or haphazard combinations (polypharmacy) looms large. Patients, family members, and, increasingly, reviewers for insurance companies insist that “something” be done to provide quicker symptom relief or discharge from the hospital, and multiple medications are added in the mistaken belief that more aggressive treatment will achieve this end. Several adjunctive medications for insomnia, anxiety, or agitation may be initiated during a period of exacerbated symptoms, and can result in such problems as oversedation and fatigue that can mimic depressive symptoms. These problems, in turn, can result in the use of even more medications. The preferable strategy is to recognize that improvement from medications used to treat depression requires time.

- **Switches and cycle acceleration associated with antidepressants.** Perhaps the most important issue regarding the risk/benefit assessment associated with combining agents is the addition of an antidepressant to a mood stabilizer; because of its importance, this issue is discussed extensively in the present chapter. In addition to the possibility of acute manic switches associated with antidepressants, we have chosen to include coverage here of the potential for long-term induction of cycles (destabilization) by these agents because it is a key consideration in planning the acute treatment of depression, especially with bipolar patients.
- **Comorbidities.** Attention to complicating comorbid conditions that may be illness-sustaining is vital (see Chapters 7 and 24). Substance abuse, anxiety and eating disorders, and thyroid dysfunction are perhaps the most important and commonly overlooked of these conditions, but alertness to any coexisting systemic, neurological, or endocrinologic illness in a patient and close collaboration with all treating practitioners are essential.
- **Highly recurrent unipolar depression.** As discussed in Chapter 1, a substantial subset of unipolar patients share certain important features with bipolar patients: a high frequency of recurrence (cycle lengths averaging 2 years or less), a family history of mania, and an early age at onset (teens and twenties). Indeed, recurrent unipolar depression was part of Kraepelin's original construct of manic-depressive illness. While there is a paucity of treatment studies focused on this group, it is probably wise to keep in mind the principles outlined here for the management of bipolar depression, particularly the cautions about sustained antidepressant monotherapy and the importance of considering the use of mood stabilizers, especially those with robust effects against depression.

Selection of a Treatment Approach

As outlined in Chapter 17, there are many published guidelines, algorithms, and consensus statements on the treatment of bipolar depression. Though the details vary, most recommend using mood stabilizers—lithium and/or the activating anticonvulsant lamotrigine—as the foundation for treatment, and adding other agents as needed to enhance an incomplete antidepressant effect or provide symptomatic treatment for insomnia, anxiety, or agitation. For many treatment decision points, however, research data are insufficient to provide confidence in recommending one approach over another. The specific pharmacological approach for an individual patient must be based on an assessment of family history, past and present symptoms, course of illness, past treatment responses, appearance and tolerance of side effects, and adherence issues.⁵ As noted above, the focus of the great majority of the literature has been on bipolar-I depression; treatment of bipolar-II depression has, unfortunately, been very inadequately studied. What information is available is addressed later in our review of the literature. Our recommendations for the treatment of bipolar-I and -II depression are presented in Figures 19–1a and 19–1b, respectively.

Lithium

Given data demonstrating the apparent ability of long-term treatment with lithium to protect patients with bipolar disorder against suicidal behavior (see Chapter 25), one can argue that lithium should be included in the regimen for many if not most bipolar patients. Lithium remains a strong choice for monotherapy for bipolar-I depression in patients presenting with no previous treatment history. Indeed, the practice guidelines of the American Psychiatric Association (APA) (2002) for the treatment of patients with bipolar disorder recommend lithium as an initial treatment for bipolar depression of mild to moderate severity. The most recent guidelines—the Texas Algorithm (Suppes et al., 2005)—recommends as a first step for bipolar depressed patients already taking lithium that the lithium level be increased to above 0.8 mEq/l.

A typical clinical scenario is the patient presenting with depressive symptoms who, on closer questioning of both patient and family member(s), is found to have experienced previous episodes of clear hypomania (or even mania) that did not come to clinical attention or were not properly diagnosed and treated. Patients with such a history will often resist the idea of having bipolar disorder rather than just “depression” and may recoil at the mention of lithium, a medication they may associate with severe mental illness. Thus, before some patients will agree to take lithium, they must be educated about its well-demonstrated, albeit often

modest, antidepressant effects and its prophylactic efficacy in treating recurrent mood disorders. It can also be helpful to point out that the side-effect profile described in reference publications, such as the *Physicians' Desk Reference*, is based on studies that are now more than three decades old in which substantially higher doses of lithium were used.

Another common clinical situation is the patient already taking an antidepressant prescribed by another physician who comes to the psychiatrist with refractory or residual depressive symptoms, and from whom a history of previously undetected hypomanic symptoms is elicited for the first time. While there is solid evidence supporting the use of lithium to augment an antidepressant (as discussed below), many patients with bipolar depression will get well and stay well on lithium alone. Should the clinician recommend discontinuing the antidepressant when such a patient recovers after starting lithium? Or (as discussed below) should the antidepressant be gradually replaced by lamotrigine, a stabilizer with antidepressant effects that appear to be more robust than those of lithium? To answer these questions, the clinician must engage the patient and family members as partners in treatment decisions. How important is taking only one medication for this patient? What is this patient's risk of self-destructive behavior upon becoming depressed? Is there a history suggesting that an antidepressant may be destabilizing for this patient (a history of mixed symptoms, rapid cycling, or substance abuse)? Is there a supportive family member who will help monitor symptoms and adherence? Can the patient afford to pay for the medication (in this case lamotrigine)?

As noted in the first edition of this volume, lithium's antidepressant effects may not become noticeable for up to 3 to 5 weeks, a lag time that can be somewhat longer than that experienced with antidepressants; some patients, however, respond within the first week or two. The original studies on lithium monotherapy for bipolar depression recommended doses that would achieve serum levels of up to 1.2 mEq/l, considerably higher than the levels now recommended for maintenance treatment. While it appears that higher levels are more effective in treating acute depressive symptoms, they are associated with more side effects and problems with adherence (Gelenberg et al., 1989; see also Chapter 21). Often, however, achieving these levels for a relatively short period of time can produce an antidepressant response, after which the dose can be lowered.

Some have suggested that rapid cycling (defined as at least four episodes of mania or depression within 12 months) predicts poorer acute antidepressant response to lithium, especially as compared with response to the anticonvulsant agents (see, e.g., Bowden, 2001). Although this work has examined primarily efficacy in preventing relapse, it has been extended to the treatment of acute depression, and

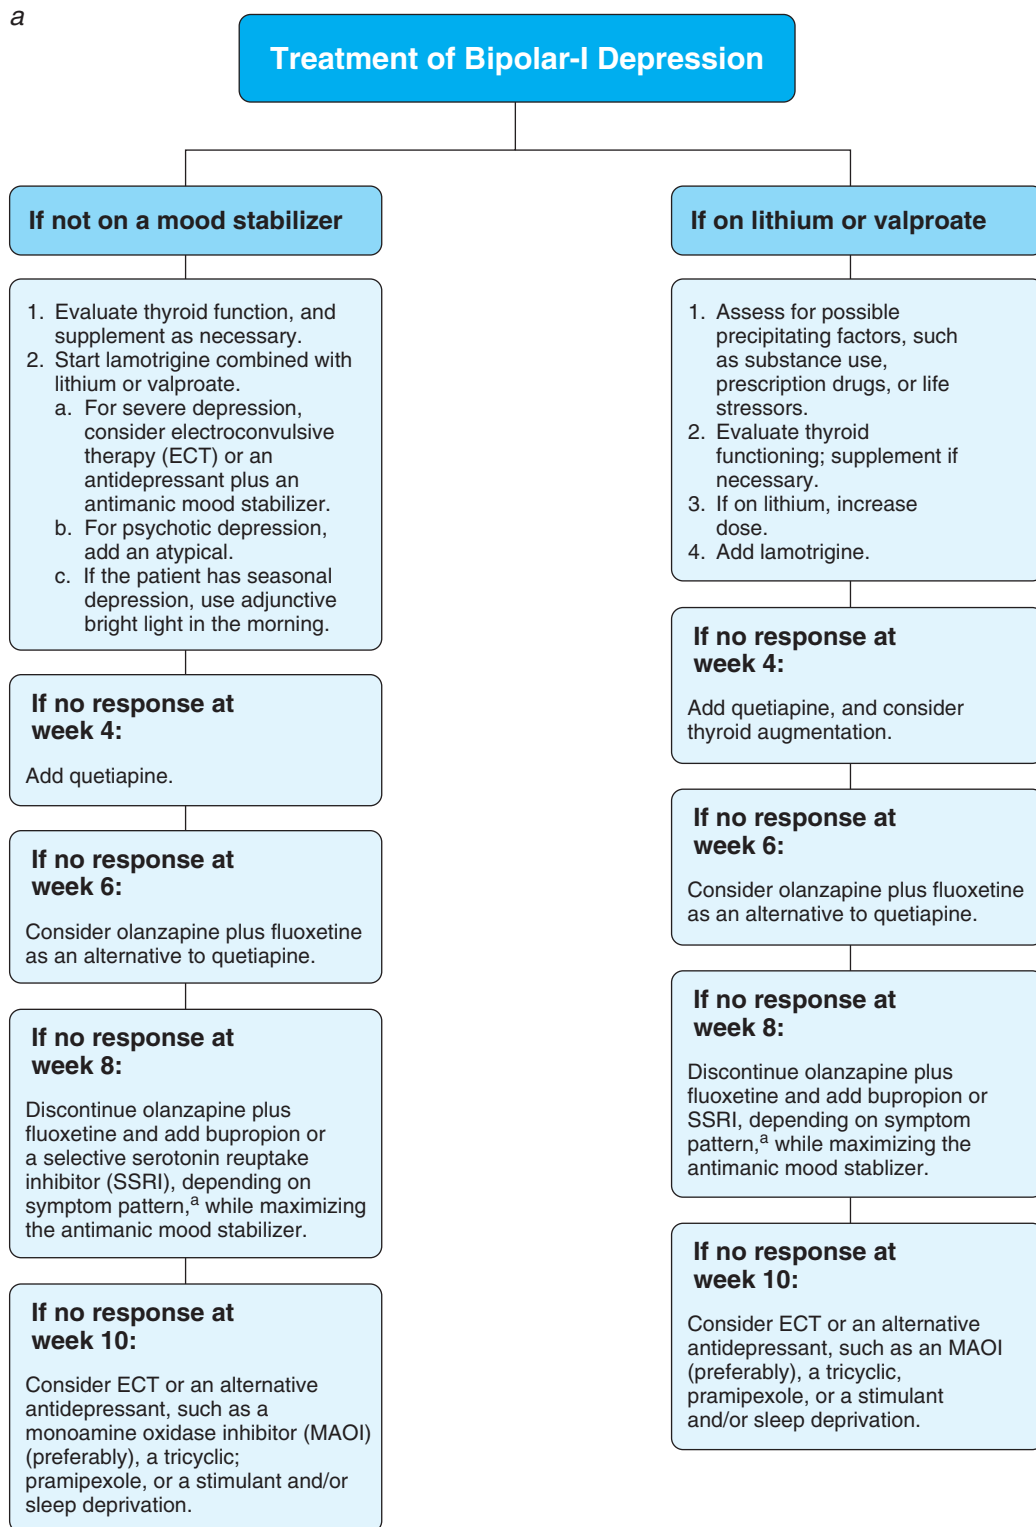

Figure 19–1. *a*: Recommendations for treatment of bipolar-I depression. Bupropion is preferred for psychomotor retardation/slowing; SSRIs are preferred for irritability or comorbid anxiety, panic, or obsessive-compulsive disorder. *b*: Recommendations for treatment of bipolar-II depression. Note: There have been very few controlled studies focusing on bipolar-II depression; therefore, any recommendations for treating this condition must be considered more tentative than those for treating bipolar-I.

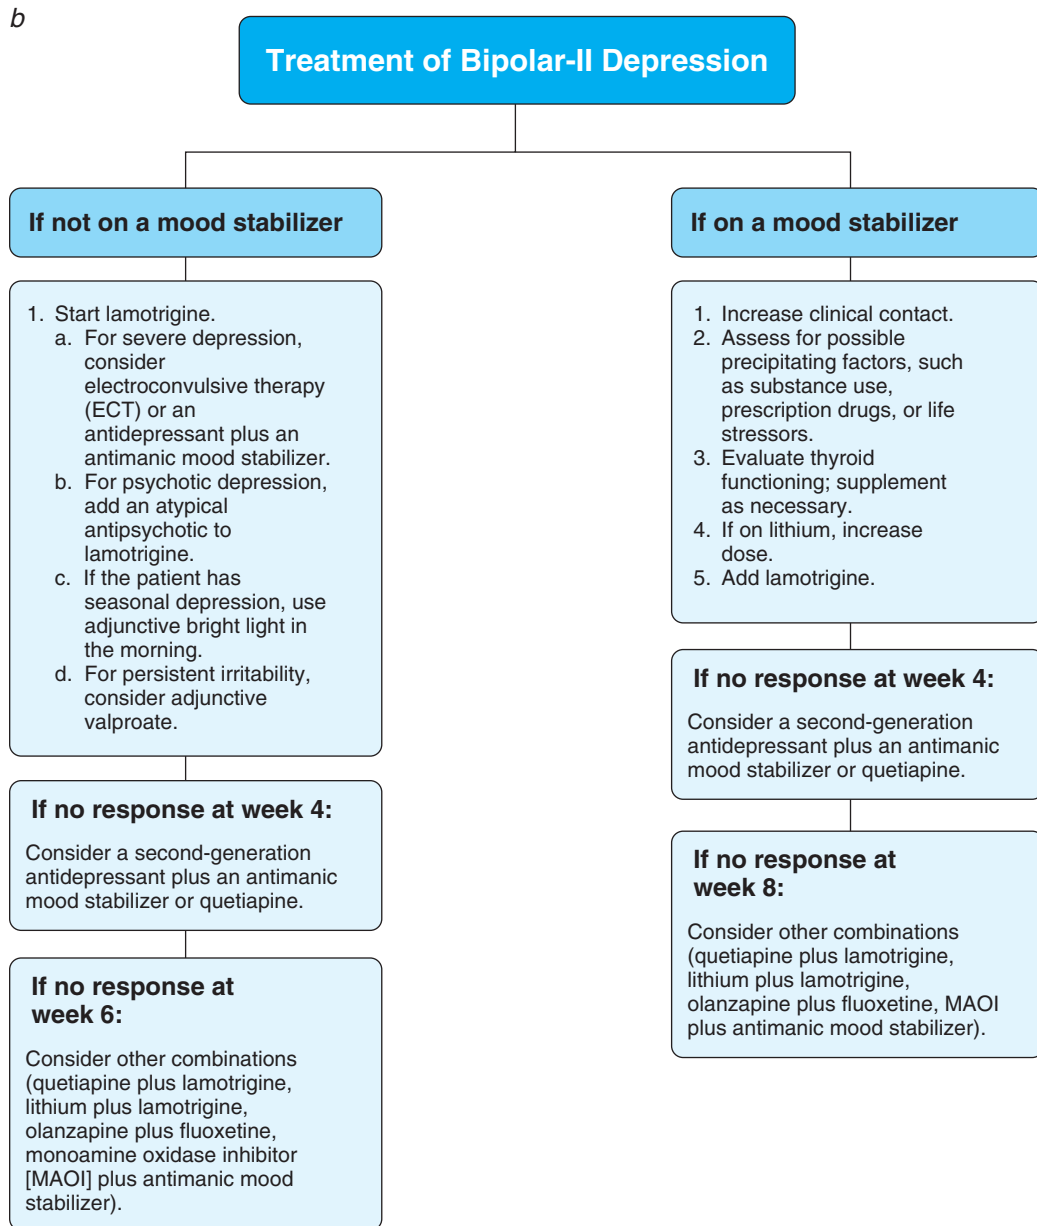

Figure 19-1. (continued)

some guidelines recommend using valproate as first-line monotherapy for depressed patients with a history of rapid cycling (see, e.g., Sachs et al., 2000). However, a meta-analysis of studies of efficacy in rapid-cycling and non-rapid-cycling bipolar patients concluded that anticonvulsants have not been shown to be more effective than lithium in preventing relapse (Baldessarini et al., 2002). As suggested by the maintenance study of Calabrese and colleagues (1999b, 2005), neither lithium nor valproate is very effective against the depressive phase in rapid-cycling patients.

Because of lithium's relatively low therapeutic index, it is important to hold a detailed discussion with patients

regarding certain precautions before they start taking the drug. Patients should be advised, for example, to take care not to become dehydrated in hot weather. Patients should also let the treating clinician know if they are taking prescription drugs from other physicians (especially thiazide diuretics) or over-the-counter preparations, especially those containing nonsteroidal anti-inflammatory drugs (NSAIDs), so their lithium blood levels can be checked. Issues also arise regarding the use of lithium during pregnancy. Potentially suicidal patients should have their access to possibly dangerous quantities of lithium limited. All of these medical issues are discussed in more detail in Chapter 20.

Anticonvulsants

For patients who remain depressed on lithium, recommendations regarding the choice of an adjunctive agent were based in the past on whether the patient had a history of symptoms associated with a more complex and brittle bipolar disorder, usually thought to be indicated by a history of rapid cycling or mixed episodes. The literature supporting the efficacy of certain anticonvulsants in the treatment of mixed states and rapid cycling supports the adjunctive use of these agents in patients with such a history who experience lithium-resistant bipolar depression, as do studies indicating synergistic or at least additive effects of lithium and valproate at both the clinical (Young et al., 2000) and cellular levels (see Manji et al., 2001; see also Chapter 14). Some patients with bipolar depression will respond to valproate monotherapy; compared with lithium, however, there is less data supporting valproate as a first-line agent for depression. However, when a bipolar depressed patient is suffering from comorbid anxiety, valproate or carbamazepine may be a reasonable first-line choice. (See also our review of the literature below.)

Lamotrigine is different from the other anticonvulsants (such as valproate or carbamazepine) in that the evidence indicates it to be effective in treating the core symptoms of bipolar depression, and unlike traditional antidepressants, it is much less likely to be associated with a switch into mania (although switches into hypomania have been reported). Indeed, lamotrigine has joined lithium as a first-line agent for bipolar depression. In the Texas Algorithm (Suppes et al., 2005), for patients not already taking lithium, lamotrigine is the first-line recommendation for bipolar depression (together with an adjunctive antimanic agent for bipolar-I patients). Because of the slow titration schedule required to minimize the risk of a serious rash, there is some concern that the acute antidepressant effect of the drug may not be rapid enough for some clinical situations. While this may well be true for severe depression, for many patients at least partial antidepressant effects can begin at doses as low as 50 mg; indeed, as noted in the review of the literature below, 50 mg of lamotrigine was found to be superior to placebo, a dose that can be reached in the third week of administration. Patients who are going to respond completely usually do so at doses between 100 and 200 mg/day, but some (who may be rapid metabolizers) fail to respond until higher doses, up to 400 mg/day.⁶ For bipolar-II depression, lamotrigine can be used as monotherapy, while for bipolar-I depression, it is generally best combined with another stabilizer that works more effectively in the prevention of mania. The British guidelines (G. Goodwin et al., 2004) specify that lamotrigine monotherapy for bipolar-I depression may be appropriate “where depressive symptoms are less severe.”

The antidepressant efficacy of gabapentin monotherapy is not well supported by the research literature (see below), but gabapentin can be useful as an adjunctive agent in the presence of comorbid anxiety and/or insomnia. For this latter use, its short half-life is an advantage because the drug is not likely to be associated with daytime sedation. Topiramate is another anticonvulsant without controlled data to support its use as monotherapy for bipolar depression, but it may be useful as an adjunctive agent because of its ability to produce weight loss.⁷ Likewise, there is a paucity of controlled data for oxcarbazepine, whose main advantage is its low incidence of drug interactions and more benign side-effect profile (compared with carbamazepine).

Antidepressants

Analysis of U.S. prescribing patterns in the 1990s indicates that approximately half of all visits to a psychiatrist by bipolar patients involved the administration of an antidepressant, often in the absence of a mood stabilizer (Blanco et al., 2002; Baldessarini et al., 2006). While such practice is, in our view, clearly inappropriate, adding an antidepressant to a mood stabilizer can be justified in some circumstances. By and large, the North American treatment guidelines suggest that antidepressant monotherapy is not appropriate for bipolar depression (especially bipolar-I depression) and that even in combination with a mood stabilizer, antidepressants should be reserved for more severe cases of depression.⁸ It should be noted that some European experts believe the North American guidelines are too negative with regard to antidepressants. At any rate, earlier reluctance (especially in the United States) to recommend antidepressants for patients with bipolar disorder because of concerns about precipitating manic symptoms has been attenuating somewhat in the face of evidence (albeit limited) that, compared with the tricyclics, the newer antidepressants (in the presence of a mood stabilizer) are less likely to be associated with acute switching into manic/hypomanic episodes (Gijsman et al., 2004). With regard to long-term cycle induction, however, the newer agents may be no safer than the older ones (Ghaemi et al., 2004).

Given the reality that most patients with bipolar disorder experience substantially more morbidity from depressive than from manic/hypomanic symptoms, antidepressants continue to have some role in the treatment of bipolar depression, perhaps especially for the bipolar-II patient. In our view, however, antidepressants should generally be reserved for patients who are severely depressed or those for whom a combination of two mood stabilizers (including lamotrigine) or a combination of a mood stabilizer and quetiapine has failed. Our conclusion, which is similar to the recommendation of the Texas Algorithm (see below)

was reinforced by the finding of the Stanley Foundation Bipolar Network that only 15 percent of 549 bipolar patients (65 percent bipolar-I) taking mood stabilizers whose breakthrough depression was treated with an adjunctive antidepressant remained in remission for a minimum of 2 months (Altshuler et al., 2003).

Because maintenance antidepressants have been implicated in mood destabilization, gradually discontinuing these agents is often the first step in eventually achieving mood stability. Indeed, in the first edition of this text we recommended that antidepressants be gradually withdrawn shortly after the antidepressant response in patients with bipolar-I disorder and maintained only in those who repeatedly relapse after antidepressant discontinuation, which in our experience are about 15 to 20 percent of bipolar depressed patients (Ghaemi and Goodwin, 2001b).

This recommendation has been called into question by the results of three open, nonrandomized studies (two retrospective, one prospective) that examined 1-year outcomes in patients with bipolar depression (approximately two-thirds bipolar-I) who had been treated with one of the newer antidepressants added to a mood stabilizer. Each of these studies found that, compared with those kept on their antidepressant for the full year of observation, those whose antidepressant was discontinued were significantly more likely to relapse into depression, whereas the risk of manic relapse was not related to the duration of antidepressant treatment (Altshuler et al., 2001a, 2003; Joffe et al., 2005).⁹ However, the patients in these studies were not randomized, nor were the studies controlled for a host of potentially confounding variables (Goldberg and Ghaemi, 2005). For example, the question remains open as to why the treating psychiatrists chose to keep some patients on the antidepressant (presumably the more stable patients) while withdrawing it from others (presumably those whose course may have been destabilized by the antidepressant, as demonstrated in several studies). In other words, it is not possible to know how many patients in these studies did worse because they were taken off antidepressants and how many were taken off because they were doing worse.¹⁰

It is also important to note that an earlier randomized study (i.e., without the confounds just discussed) found that antidepressant (tricyclic) discontinuation in bipolar-I patients maintained on lithium plus placebo did not result in more depressive episodes over 2 years compared with those maintained on lithium plus imipramine (Prien et al., 1984). A later randomized clinical trial by the same group compared lithium, imipramine, and a combination of the two (Prien et al., 1988). The authors analyzed a subgroup of 25 patients with dysphoric mania and found that imipramine (alone or in combination with lithium) was associated with higher recurrence at up to 2 years of follow-up compared

with lithium alone. Of relevance to the newer second-generation antidepressants, a recent randomized study within the NIMH STEP-BD program (detailed in our review of the literature below) found that over 1-year follow-up of bipolar patients who had responded to a mood stabilizer–antidepressant combination, the adjunctive antidepressant was not associated with a better outcome compared with the mood stabilizer alone.

Ghaemi and Goodwin (2005) applied the technique of decision analysis to all of the available literature addressing the role of antidepressants in bipolar-I disorder (the analysis was weighted toward the newer agents, as well as toward randomized controlled trials, and involved conservative assumptions). They concluded that the available literature supports mood stabilizer monotherapy or a mood stabilizer plus short-term use of an antidepressant, but does not support long-term use of an antidepressant, even with a mood stabilizer.

Among second-generation agents, the APA and Expert Consensus guidelines recommend bupropion or paroxetine, whose use for treating bipolar depression has been supported by the results of randomized, placebo-controlled studies. Ultimately, however, the clinician must tailor this decision to the particular patient, based on such factors as symptom pattern, individual or family history of response to a particular agent, and side-effect profile. For example, when psychomotor retardation/decreased energy and lack of motivation are the most prominent features of the depression, bupropion, with its activating profile, is preferred; when comorbid anxiety, panic, or obsessive-compulsive symptoms predominate, a selective serotonin reuptake inhibitor (SSRI) is likely to be the best choice. A moderate amount of crossover data is available to support such choices. On the basis of studies covered in our review of the literature, as well as our clinical experience, the following conclusions and recommendations are particularly relevant:

- Tricyclics are problematic for the treatment of bipolar depression with regard to both stabilization and efficacy. For a contrary view see Moller and Grunze (2000), as well as a detailed critique of that paper¹¹ (Ghaemi et al., 2003a).
- The MAOIs remain underutilized for treating bipolar depression (Himmelhoch et al., 1991; Balon et al., 1999). Although they are well documented to be effective for that purpose and uniquely effective for some patients who fail to benefit from any other agent, many psychiatrists never prescribe them because of misapprehensions about side effects and required diet. Many published diets are overly restrictive, however, being based on case report data on drug reactions that are of questionable validity

given that such reports focus on negative outcomes (see Walker et al., 1996). Moreover, selegiline, a MAOI now available in patch form, is reported to have a low incidence of all tyramine-related reactions. MAOIs may be particularly helpful for patients with more severe depressive symptoms with atypical features as defined in the *Diagnostic and Statistical Manual (DSM)-IV*—anergia, psychomotor retardation, and reverse vegetative signs (hypersomnia and hyperphagia)—although patients without these features can benefit as well. Guidelines for the use of MAOIs (e.g., after mood stabilizers have failed) are the same as for other antidepressants.

- Second-generation antidepressants such as bupropion and the SSRIs have largely replaced the older drugs. In addition to being somewhat less likely than tricyclics to precipitate a switch (with the exception of venlafaxine), although perhaps not less likely to be associated with cycle induction, they have a more favorable side-effect profile than the older drugs.
- Antidepressant monotherapy is contraindicated in bipolar-I depression; for bipolar-II depression, we advise caution in using antidepressant monotherapy until more data are available.
- When bipolar-I depression is treated with an adjunctive antidepressant (including the second-generation agents), an effort should be made to taper and discontinue the drug shortly after remission (or maximal response) has been achieved. For bipolar-II disorder, the risk/benefit ratio of maintenance antidepressants has not been established.
- Restoring and/or maintaining the integrity of sleep is an important consideration in choosing an antidepressant for the bipolar patient. Other things being equal, bupropion has an advantage over SSRIs in that it preserves normal sleep architecture when given early in the day (which may be why it is apparently less likely than an SSRI to be associated with a switch into mania/hypomania).

Box 19–1 outlines our conclusions about the role of antidepressants in treating bipolar disorder.

Given the differential response of individuals with major depression to different agents, tapering and switching is a reasonable strategy when a patient does not respond to one antidepressant. Most guidelines recommend switching to an antidepressant in a class different from the failed agent, for example (as noted above), to bupropion in a patient showing no response to an SSRI (see Fava, 2000, for a discussion of switching strategies with a focus on avoiding discontinuation syndromes). Differential responses to different drugs in the same class have certainly been demonstrated, however; for example, some (unipolar) depressed

BOX 19–1. The Role of Antidepressants in Treating Bipolar Disorder

- The efficacy of maintenance antidepressants in treating bipolar disorder is not established.
- Cycling and/or switches while on antidepressants have been demonstrated in three randomized, placebo-controlled studies.
- Antidepressant monotherapy is not recommended for bipolar-I disorder; data are insufficient to support a recommendation for bipolar-II.
- Antidepressants (with a mood stabilizer) should generally be reserved for severe bipolar depression, or cases in which adjunctive mood stabilizers have failed.
- When antidepressants are used, they should be tapered and discontinued after recovery from depression; they should be maintained only in those who repeatedly relapse soon after discontinuation.

Source: Adapted from Ghaemi et al., 2003.

patients not responding to sertraline have been shown to benefit from fluoxetine (Thase et al., 1997).

Antipsychotics

Some patients with bipolar depression will benefit from antipsychotic medications. These agents are certainly indicated for patients with depression complicated by delusions and hallucinations. The agitation and extreme dysphoria and distress associated with severe depression can be significantly ameliorated with antipsychotics as well. And given in the evening, these agents can be especially helpful in stabilizing sleep.

The newer, atypical antipsychotics have positive effects on mood while also being somewhat less prone to cause acute or delayed extrapyramidal symptoms; thus they are clearly preferred over the older agents. Indeed, given the ability of some of these drugs to improve mood, even when the clinical picture does not include psychotic features, they may be preferable to benzodiazepines in patients with severe insomnia or extreme anxiety with physical restlessness and agitation. It should be noted that the doses of these agents useful in treating depression are often lower than those needed to treat schizophrenia or manic states. The atypicals are 5-hydroxytryptamine(2) (5-HT₂) receptor antagonists at low doses, and it has been suggested that as a result, they may have an antidepressant effect through serotonergic mechanisms at these doses.

Olanzapine has been studied extensively in bipolar disorder. In addition to its clear antimanic action, there is evidence of a modest antidepressant effect, even in monotherapy (Tohen et al., 2003a), although the size of this effect is

small and derives almost entirely from the drug's beneficial effect on insomnia, anxiety, and irritability. When olanzapine is combined with fluoxetine (Tohen et al., 2003b) or other antidepressants (Thase, 2002), the effect is more robust. Recently, another atypical, quetiapine, was found to have a robust antidepressant effect, including some effect on core depressive symptoms, in two large randomized, placebo-controlled studies of bipolar patients; indeed, quetiapine is the first drug to have attained an FDA indication for bipolar depression (see our review of the literature below).

There have been reports of olanzapine and other atypical antipsychotic medications causing hypomanic and manic symptoms in patients with bipolar disorder. Two critical reviews by the same group (Aubry et al., 2000; Rachid et al., 2004) evaluated published case reports covering a total of 60 patients and concluded that for more than half of these patients, a causative role for an atypical antipsychotic was "highly suggestive." On the other hand, an analysis of 129 patients participating in controlled trials of olanzapine found a significantly higher switch rate in the placebo group than in those taking the drug (Baker et al., 2003). It should be noted, however, that patients participating in controlled trials are less likely than nonparticipants to have some of the risk factors (such as substance abuse) associated with switching. Also, because the participants had to have just experienced a spontaneous manic episode to qualify for the trial, their situation was different from that of the bipolar patient being treated for depression.¹²

Although the risk of causing extrapyramidal symptoms is likely lower with the atypical than with the typical antipsychotics (see Chapter 20), some, though not all, of the former have metabolic side effects, including increased serum lipids, triglycerides, and glucose (Osser et al., 1999). Weight gain associated with the use of some of these medications is well documented,¹³ and cases of new-onset diabetes mellitus have been reported (Wirshing et al., 1998). Monitoring of weight is therefore essential when certain of these medications are prescribed, as is the usual attention to the serum lipids that are important to cardiac health (see Chapter 20 for details on the individual drugs).

Complex Regimens

Many bipolar patients with refractory depressive symptoms will need to take lithium as well as an anticonvulsant, such as lamotrigine, and clinical experience has shown that a few will need to take lithium and more than one anticonvulsant, an atypical antipsychotic, and an antidepressant as well. The clinician must be sure to approach such complex regimens cautiously. Optimizing of dosages (using serum drug-level determinations when possible) or simply watchful waiting for full benefit to be achieved from the addition of an agent may be all that is necessary. The

clinical utility of the latter strategy cannot be overemphasized; increased mood instability from adding an antidepressant can take many months to become apparent, and even then it is easily missed by clinicians not employing a life chart methodology (see Chapter 11).

Thyroid Augmentation

Attention to the thyroid status of the depressed bipolar patient is essential. Determination of thyroid-stimulating hormone (TSH) and free thyroxine (fT_4) by dialysis should be part of the assessment of patients with depression at the first sign of resistant symptoms. Correction of thyroid deficiencies is obviously important, but patients with "normal" thyroid determinations may benefit from adjunctive treatment with thyroid hormone as well (see our review of the literature below). In the next chapter, we review studies indicating that lower mean thyroid indices (albeit in the "normal range") are associated with incomplete recovery from bipolar depression. Psychiatrists should thus be familiar with thyroid physiology, know the signs and symptoms of hyper- and hypothyroidism, and, most important, understand the concept of subclinical hypothyroidism.

Recommendations as to which depressed patients to treat with adjunctive thyroid hormone and at what point can be difficult to make. Female patients, those with rapid-cycling disorders, and those with levels of TSH above the 50th percentile of normal and with fT_4 below the 50th percentile have shown particular benefit from thyroid augmentation. Given that about 50 percent of patients with treatment-resistant depression benefit from augmenting antidepressant medication with triiodothyronine (T_3), a low-risk intervention, it would be reasonable to recommend adding T_3 to an antidepressant sooner rather than later, perhaps even after concluding that the patient has not benefited from the second or even the first antidepressant added to lithium and anticonvulsant(s). For long-term management of bipolar patients, it is appropriate to shift gradually to T_4 (see Chapter 20).

Sleep Deprivation and Phototherapy

Sleep deprivation has clearly been demonstrated to benefit depressed patients and can bring about rapid and dramatic relief in those with bipolar depression. While the antidepressant benefits of sleep deprivation can be short-lived, they can be prolonged by lithium and antidepressant medications, as detailed later in our review of the literature. Even if the actual antidepressant effects of sleep deprivation are short-lived, there is an important psychological effect whose implications can be more lasting: the hopeless feeling that one will never recover is clearly challenged by the dramatic, albeit temporary, improvement. Patients can

thus be helped to realize that they still have the capacity to feel well; the remaining challenge is to sustain this feeling.

In the first edition of this text, we suggested that partial sleep deprivation (during the second half of the night) was probably as effective as total sleep deprivation, noting that the former was easier for patients. However, results of recent research appear to indicate that total sleep deprivation is indeed the most effective technique (Giedke et al., 2003). Although somewhat difficult to achieve in the outpatient setting, it can easily be accomplished in the hospital with the support and direction of nursing staff. Patients should be kept awake for 36 hours (all night and the following day) and then allowed a night of recovery sleep. Several published efficacy studies recommend a series of three sleep-deprived nights alternating with recovery-sleep nights, although even one night of sleep deprivation is sufficient for some sensitive patients to benefit. For certain patients, however, partial sleep deprivation may be effective, and for outpatients it is not unreasonable to try this approach first and then move on to total sleep deprivation if necessary.

Sleep deprivation can be a highly effective technique for accelerating the response to a new medication for a depressive episode, and can also provide relief for minor breakthrough depressive symptoms without necessitating a change in the patient's medication regimen. Some, though not all, studies have found a greater response in bipolar than in unipolar patients, but the clinical features that predict response are generally not controlled for in these comparisons. Switches into mania/hypomania have been reported following sleep deprivation, so clinicians are well advised to employ the treatment only in patients on mood stabilizers. In addition to the clinical correlates of the treatment's effectiveness, studies relevant to its mechanism of action are reviewed in Chapter 16.

Phototherapy is another low-risk treatment for depression that is accomplished even more easily than sleep deprivation.¹⁴ The most obvious situation requiring this treatment is when the depressive phase is occurring during the winter months, a pattern not uncommon among bipolar patients. However, phototherapy can also be helpful at other times of the year, probably because of its nonspecific activating effects (it can be especially effective against daytime somnolence that can be associated with mood stabilizers) and its ability to help synchronize the circadian cycle, thereby contributing to the stabilization of sleep.

Despite over a decade of research, the precise timing of light exposure necessary to derive its maximum benefit for winter depression has not been definitively established, although most experts recommend first thing in the morning. Certainly early-morning exposure is required for normalizing a phase-delay sleep disorder in which the patient gets to sleep late and then finds it difficult to get up in the morning.

No advantage of broad-spectrum light over bright white light has been demonstrated.¹⁵ Current recommendations are for at least 30 minutes of exposure to 5,000–10,000 lux at a distance of 18 to 24 inches. All patients with a seasonal pattern to their mood symptoms, as well as those with phase-shifted sleep patterns, should probably invest in their own phototherapy light box, as should all psychiatric inpatient units. It should be noted that occasional switches into hypomania and mania have been reported to be associated with phototherapy.

Electroconvulsive Therapy

In our opinion, it is unfortunate that ECT is often relegated to last-resort status in treatment guidelines and protocols. We believe the clinician should not hesitate to recommend ECT to severely ill patients as a first-line treatment. For the delusional or suicidal patient—indeed, for any depressed patient who is so ill that only the most reliably and rapidly effective treatments should be considered—ECT is the clearly superior alternative. ECT should also be offered to patients with treatment-resistant depression who have a history of adverse reactions to antidepressants (increased cycling, induced mania or agitation) whenever their symptoms threaten to become chronic or begin to have a significant negative impact on family or on occupational or academic functioning.

Depression in elderly patients is especially responsive to ECT. Since older patients often need to be started on lower doses of medications and their dosages titrated up more slowly than is the case for younger patients, ECT is frequently the most rapidly effective treatment for severe depression in this population.

It is important to remember that the antidepressant effect of a standard course of ECT is generally temporary, and that patients who are not started on medication at the conclusion of their course of treatment are likely to relapse. For a discussion of maintenance ECT, see Chapter 20.

Alternative Treatments

A variety of alternative treatments have been claimed to benefit some patients with bipolar depression. These include novel antidepressant combinations, stimulant medications, dopamine agonists, the “wakefulness” agent modafinil, nutritional supplements (including omega-3-fatty acids), and others. (See our review of the literature for details.) It is appropriate here to comment on one especially important form of “alternative” treatment—regular exercise (see Chapter 17). Not only has regular vigorous aerobic exercise been shown to have an antidepressant effect in numerous studies, but when at least some exercise is done at approximately the same time every day and not too close to the time for

sleep, it can help stabilize circadian rhythms and enhance the integrity of the sleep cycle (see Chapter 16). The positive psychological impact of successfully pursuing a treatment whose benefits derive entirely from the patient's own efforts is difficult to overstate.

REVIEW OF THE LITERATURE

This section presents a detailed review of the evidence regarding the treatments surveyed above. We review in turn the literature on lithium, anticonvulsants, antidepressants, antipsychotics, ECT, novel central nervous system stimulation techniques, dopamine agonists, psychostimulants, hormonal agents, sleep deprivation, phototherapy, and nutritional supplements. Results of randomized, double-blind monotherapy trials for each of the major pharmacological agents are summarized in Table 19–1, while results of randomized, non-placebo-controlled monotherapy trials and placebo-controlled add-on trials are summarized in Table 19–2.

Lithium

Several early reports on lithium's efficacy in treating mania suggested that it lacked significant antidepressant effects (Cade, 1978). Subsequent studies, however, demonstrated its effectiveness in preventing depressive relapses in patients with recurrent major depression (see, e.g., Baastrup and Schou, 1967; Baastrup et al., 1970). By the early 1980s, several studies, focused on patients hospitalized for depression, had found that lithium was superior to placebo (see Table 19–3, as well as the review by Zornberg and Pope, 1993). Several of these studies suggested that lithium was more likely to be effective in patients with bipolar than unipolar depression (especially less recurrent forms) and that the time to therapeutic response was longer than was typically reported for tricyclic antidepressants—on the order of 3 to as long as 8 weeks. In several double-blind studies comparing lithium with tricyclics, lithium was found to be as effective as amitriptyline, desipramine, and imipramine

TABLE 19–1. Randomized, Double-Blind, Placebo-Controlled Monotherapy Trials Demonstrating Acute Antidepressant Efficacy of Various Drugs

Drug	No. of Studies	Sample Size ^a	Findings
Lithium	10	179	Moderate effect size
Carbamazepine	3	30	Small effect size
Lamotrigine	3	432	Moderate to large effect size
Olanzapine	1	833	Small effect size; primarily improves insomnia, anxiety, and anorexia
Valproate	3	89	Moderate effect size; trend ($p=.1$) in one study; significant separation from placebo by random regression analysis in the other
Imipramine	5	638	Effect size similar to that of lithium
Desipramine	1	12	Effect size similar to that of lithium
Flouxetine	3	255	Methodological problems, but probably equivalent to tricyclic antidepressants in efficacy and rate of switch into mania
Meclobemide	2	537	Low mania switch rate ^b
Total	31	3,005	

^aCombined drug and placebo groups.

^bBipolar-II patients

TABLE 19–2. Drugs Demonstrating Acute Antidepressant Efficacy in Randomized, Non-Placebo-Controlled Comparison Trials or in Placebo-Controlled Add-On Trials

Drug	No. of Studies	Sample Size	Findings
Lithium	2	144	Equivalent to imipramine and to paroxetine
Valproate	1	27	Valproate and lithium equivalent to paroxetine + lithium or valproate
Topiramate	1	36	Equivalent to bupropion when added to lithium
Risperidone	1	22	May speed onset of response when added to paroxetine
Bupropion	3	99	Equivalent to desipramine, with lower switch rate
Imipramine	3	191	Equivalent to lithium, with higher switch rate
Desipramine	1	15	Equivalent to bupropion when added to lithium, with higher switch rate
Tranlycypromine	1	56	More effective than imipramine when added to lithium; acute switch rates equivalent to those with imipramine
Pramipexole	2	43	More effective than placebo when added to lithium; low switch rate

TABLE 19–3. Lithium Treatment in Patients Hospitalized for Depression: Results of Placebo-Controlled Studies

Study	Sample Size	Patient Characteristics	Results
Goodwin et al., 1969	18	13 with bipolar depression, 5 with “noncyclic depression”	10 of 13 bipolar patients showed some response, versus only 2 of 5 “noncyclic” depressed patients
Stokes et al., 1971	18	Manic-depressive	Lithium trial lasted only 10 days, showed a nonsignificant trend toward response
Goodwin et al., 1972	52	Primary affective disorder—40 bipolar (-I or -II), 12 unipolar	32 of 40 bipolar patients responded, versus 4 of 12 unipolar patients ($p < .05$)
Noyes et al., 1974	22	Manic-depressive, depressed with “endogenous features”—6 bipolar, 16 unipolar	6 of 6 bipolar patients responded, versus 7 of 16 unipolar patients ($p < .05$)
Johnson, 1974	10	Endogenous depression with recurrent histories	5 showed “marked improvement”
Baron et al., 1975	23	Primary affective disorder (Feighner criteria)—9 bipolar (-I and -II), 14 unipolar	7 of 9 bipolar patients responded, versus 3 of 14 unipolar patients ($p < .05$)

Note: Response rates (complete and partial) for all studies combined are bipolar, 64/81 = 79%; unipolar, 20/55 = 36%.

in treating mixed groups of bipolar and unipolar depressed patients (see Table 19–4). One of these studies (Watanabe et al., 1975) found lithium to be equally effective in bipolar and unipolar depressed patients.

These earlier studies have been criticized on a number of methodological grounds, including the on–off nature of some of the designs (perhaps confounding the placebo period with lithium withdrawal symptoms) and the modest number of subjects, increasing the risk of type II (false negative) errors (Bhagwagar and G. Goodwin, 2002). In the understudied area of treatments for bipolar depression, however, methodological limitations are by no means confined to lithium. Thus two reviews of treatment options for bipolar depression (Yatham et al., 2003; Ghaemi and Hsu, 2005) concluded that lithium comes closest to meeting those authors' criteria for a first-line treatment for bipolar depression (that is, the treatment should be efficacious in treating bipolar depressive symptoms, should be effective in preventing further depressive and/or manic episodes, and should not be associated with manic switching or increased cycling).

There has been only one randomized, double-blind clinical trial comparing lithium monotherapy for acute bipolar depression with the use of second-generation antidepressants (Nemeroff et al., 2001). In a secondary analysis, these investigators found that at blood levels of .8 mEq/l or above, lithium alone was as effective as lithium plus either paroxetine or imipramine. Since many of the patients in

the study had previously failed to respond to lithium, it is reasonable to assume that these results likely understate the effectiveness of lithium in a more representative group of patients with bipolar depression.

Numerous studies have shown that the addition of lithium to antidepressant therapy results in remission of symptoms that have not improved or have been ameliorated only partially with antidepressants alone. This has been shown to be true for patients with both bipolar and unipolar depression and for lithium added to tricyclics, MAOIs, SSRIs, and other newer antidepressants. These studies are reviewed here because of their possible relevance to the antidepressant effects of lithium.¹⁶ Table 19–5 summarizes three meta-analyses of lithium augmentation of antidepressants, primarily tricyclics.

One of the first of these studies (De Montigny et al., 1981) found that eight of eight unipolar depressed patients who had failed to respond to 3 weeks of various tricyclic antidepressants experienced notable relief from their symptoms with lithium. This effect was observed in all these patients within 48 hours of starting lithium, although this rapid improvement was not always seen in subsequent studies. Numerous open and blind studies have shown lithium to be an effective augmentation agent for the tricyclics in about 50 percent of patients to whom it is given (Joffe et al., 1993). Lithium added to MAOIs was shown to be an effective strategy in several case reports and small open trials in the 1970s.¹⁷

TABLE 19–4. Lithium Treatment of Patients Hospitalized for Depression: Results of Double-Blind Comparisons with Tricyclic Antidepressants

Study	Sample	Design	Results
Fieve et al., 1968	21 bipolar	Imipramine comparison	Significantly more improvement on imipramine; lithium had “mild” antidepressant effects
Mendels et al., 1972	12 bipolar and 12 unipolar	Desipramine comparison	Lithium as effective as desipramine
Watanabe et al., 1975	45 mixed	Imipramine comparison	Lithium as effective as imipramine
Worrall et al., 1979	29 bipolar and unipolar	Imipramine comparison with elimination of initial placebo responders	All 14 patients on lithium improved, but not until second week; patients on imipramine who improved did so during first week; response was significantly more uniform on lithium
Khan, 1981	30 recurrent unipolar	Amitriptyline comparison	Lithium as effective as amitriptyline
Arieli and Lepkifker, 1981	33 bipolar	Clomipramine comparison	Lithium as effective as clomipramine
Linder et al., 1989	22	Clomipramine comparison	Lithium as effective as clomipramine
Total sample size	276	Conclusion: 6 of 7 studies found lithium equivalent to the antidepressant.	

Note: Most of these relatively small studies were underpowered to detect modest differences between active treatments.

TABLE 19–5. Lithium Augmentation of Antidepressants: Results of Three Meta-Analyses

Analysis	Studies Analyzed	Patients	Conclusions	Odds Ratio (CI)
Austin et al., 1991	5 double-blind, placebo-controlled studies in which patients with treatment-resistant depression took lithium and had a serum lithium level ≥ 4 mEq/L	99	Response rate of approximately 40%	6.85 (2.27–20.00)
Bauer and Döpfmer, 1999	9 double-blind, placebo-controlled studies in which patients took 250–1,200 mg of lithium daily; lithium levels reported for 5 studies (serum levels of .5–1.1 mEq/L)	234	Response rate of 50%	3.89 (2.14–7.08)
Bauer and Döpfmer, 1999 (strict criteria)	3 double-blind, placebo-controlled studies in which patients took at least 800 mg/day of lithium or had serum lithium level ≥ 5 mEq/L for at least 2 weeks	110	Response rate of 27% during lithium treatment tripled compared with placebo	3.31 (1.46–7.53)

CI = confidence interval.

Some, though not all, studies of lithium augmentation of SSRIs have also shown positive results.¹⁸ Successful lithium augmentation of venlafaxine-refractory depression has been reported in open trials.¹⁹ Lithium augmentation of mirtazapine has been identified as an effective strategy in case reports (Moustgaard, 2000). However, a double-blind comparison indicated that this strategy may be less effective than a lithium–imipramine combination (Bruijn et al., 1998).

One of the meta-analyses listed in Table 19–3, encompassing studies of lithium augmentation of various (mainly tricyclic) antidepressants (including five studies that were placebo-controlled), concluded that the odds of remaining ill were cut in half by the addition of lithium (Austin et al., 1991). A more rigorous analysis examined only the three double-blind, placebo-controlled studies (totaling 110 patients) in which lithium was administered at a dosage of at least 800 mg/day for a minimum of 2 weeks (or a serum lithium level of at least .5 mEq/l was achieved) (Bauer and Döpfmer, 2000). The authors reported a response rate 27 percent higher in patients who received lithium than in those receiving placebo. When the authors incorporated into the analysis an additional 234 patients who had taken lower doses of lithium or had participated in studies in which the results were gathered after less than 2 weeks on lithium, the overall response rate was approximately 50 percent. These results suggest that lower lithium doses (600–800 mg/day) may be sufficient to achieve successful antidepressant augmentation, at least in some depressed patients. The study also indicates that patients whose symptoms have not responded to lithium augmentation within 12 days are unlikely to respond to a longer trial of the drug. Finally, an-

other placebo-controlled study found that patients were more likely to respond to lithium augmentation of either fluoxetine or lofepramine (a tricyclic similar to imipramine) if they had serum lithium levels of at least .4 mEq/l (Katona et al., 1995).

Surveys of practicing psychiatrists have indicated that lithium augmentation in treating refractory depression is, despite its proven efficacy, probably underutilized. A 1996 survey found that 39 percent of responding U.S. psychiatrists and only 12 percent of U.K. psychiatrists would add lithium as their next step in treating a patient with refractory major depression who had shown no improvement after taking 150 mg of amitriptyline for 6 weeks (Shergill and Katona, 1997).

Finally, an extensive body of literature has established that lithium dramatically reduces the risk of suicide (see Chapter 25). For up-to-date analyses of the antidepressant effects of lithium as monotherapy and as augmentation for traditional antidepressants, see the reviews by Davis and colleagues (1999) and Bauer and colleagues (2006).

Anticonvulsants

Reports of the antidepressant effects of anticonvulsant medications have appeared in the clinical literature for several decades, resulting in the incorporation of these agents into several algorithms for the treatment of bipolar disorder, including bipolar depression. Unfortunately, however, there have been few controlled studies of the use of anticonvulsants as antidepressants to inform their use in depressed bipolar patients. An exception is a growing literature on the antidepressant uses of lamotrigine, an agent that appears to be effective in treating bipolar depression.

Valproate

Results of case reports and open studies suggest that valproate has antidepressant properties in some patients.²⁰ An open study of 33 unipolar depressed outpatients (some of whom had not responded to previous antidepressant treatment) found a 54 percent response rate (Davis et al., 1996). However, in a review of four open studies of 195 acutely depressed patients with bipolar (-I or -II not designated) or schizoaffective diagnoses, only 30 percent had an antidepressant response to valproate (McElroy and Keck, 1993). With regard to the three controlled studies of the efficacy of valproate as an antidepressant, the results are modest. In one study, Sachs and colleagues (2004) found a 45 percent response rate for valproate compared with 27 percent for placebo, but with only 45 subjects, this difference failed to reach statistical significance ($p < .3$).²¹ On the other hand, a relatively small 8-week study of 25 outpatients by Davis and colleagues (2005) was able to show a 43 percent decrease in HAM-D scores with valproate compared with 27 percent with placebo, which was statistically significant in a random regression analysis. As might be expected with a gamma-aminobutyric acid (GABA)ergic anticonvulsant, the effect on anxiety was greater than that on depression. Finally, in a recent randomized double-blind study of 19 bipolar depressed patients (mostly type I) (Dunn et al., 2006), valproate was found to be superior to placebo. Analysis of individual MADRS items, the primary outcome, demonstrated some benefit in treating core mood symptoms. The effect size in this study was larger than that in the previous studies.

With regard to bipolar-II depression, there has been one small open study of valproate in 11 medication-naïve patients, 82 percent of whom responded (as measured by a 50 percent decrease in HAM-D scores) (Winsberg et al., 2001). As in Sachs and colleagues' (2004) study, the effect of valproate nearly reached statistical significance among the bipolar-II subgroup. In a recent review of the literature, Bowden, the investigator associated most prominently with the evaluation of valproate in treating bipolar disorder, and his colleagues (2006) concluded that "the acute effectiveness of valproate in depression is modest." It has been suggested that response to valproate may be predicted by failure to respond to lithium and vice versa. That is, lithium-responsive and valproate-responsive depressed patients may represent distinct clinical subgroups (Bowden et al., 1994; Ghaemi and Goodwin, 2001b).

There are even fewer controlled data on the commonly used strategy of combining valproate and lithium. A double-blind study of 27 patients with bipolar-I or -II disorder who had experienced major depression while taking

either lithium or valproate compared the antidepressant response to the SSRI paroxetine with that to a second mood stabilizer (valproate was added if the patient had become depressed on lithium, and vice versa). Significant and comparable improvement in depression scores was seen among the SSRI and adjunctive mood stabilizer groups after 6 weeks of treatment (Young et al., 2000). These results can be interpreted as supporting the suggestion that, with respect to lithium and valproate, patients who do not respond to one will benefit from the other; the results may also suggest a synergistic effect of the two agents. It should be noted that in this study, more patients in the mood stabilizer group than in the SSRI group developed drug intolerance, perhaps reflecting the side-effect burden when full doses of these agents are used simultaneously.²² We await a controlled study of drug combinations in which less-than-full doses of each drug are used. Such a study would provide a more accurate test of both clinical practice and the laboratory-based conclusion that lithium and valproate (and perhaps other anticonvulsants) can act synergistically.

Carbamazepine and Oxcarbazepine

There have been six relatively small randomized, placebo-controlled trials of carbamazepine in the treatment of depression, with an average response rate of 44 percent (Post et al., 1996). Three of these trials involved a total of 30 bipolar patients, and in one of these studies carbamazepine was combined with lithium; again the antidepressant effect can be described as modest (Ghaemi and Hsu, 2005). The findings of these controlled studies are consistent with those of the open study of Dilsaver and colleagues (1996).

Oxcarbazepine is a 10-keto analog of carbamazepine that has a clinical profile similar to that of an anticonvulsant but a somewhat more benign side-effect profile and fewer drug interactions than the parent compound. Although there have as yet been no randomized controlled trials of this agent in treating bipolar depression, results of two open studies indicate that it may have some antidepressant effect (Berv et al., 2002; Ghaemi et al., 2002).

Lamotrigine

Lamotrigine differs from the GABAergic anticonvulsants (carbamazepine and valproate) by virtue of its modulating effects on glutaminergic transmission, which appear to contribute to its activating profile. Antidepressant efficacy was reported in the early 1990s in case reports and small open case series.²³

There have been three positive randomized, placebo-controlled trials of lamotrigine monotherapy—two with a

crossover design and one a large industry-supported study with a parallel-group design. In the two placebo-controlled crossover studies, lamotrigine was found to be significantly more effective than placebo or gabapentin in treating refractory depressed patients. The first study involved 31 bipolar patients at NIMH (Frye et al., 2000); the second (Obrocea et al., 2002) involved 35 bipolar and 10 unipolar patients who underwent randomized successive 6-week trials with lamotrigine, gabapentin, and placebo separated by 1 week. In the latter trial, the responders to lamotrigine were more likely to have a bipolar diagnosis and to be male (Obrocea et al., 2002).

The large parallel-group study revealed clear antidepressant efficacy (Calabrese et al., 1999b). In this study, 195 depressed outpatients received either 50 or 200 mg/day of lamotrigine or placebo for 7 weeks. Because of the gradual dosing necessary with lamotrigine to minimize the risk of serious rash, both lamotrigine groups took the same dose of medication for the first 3 weeks of the study (i.e., up to 50 mg); both showed improvement over the placebo group within this time—response rates of 48 and 54 percent, respectively, compared with the placebo rate of 29 percent. On the other hand, there have been two unpublished adequately powered double-blind, randomized, placebo-controlled trials involving patients with bipolar depression in which lamotrigine failed to separate from placebo (Goldsmith et al., 2003; Gao and Calabrese, 2005). The lamotrigine response rates across all 5 studies were remarkably consistent; what differentiated the two failed trials was higher placebo response rates. Indeed, in an analysis of the pooled data from all three of these parallel-group trials, involving 291 patients treated with lamotrigine and 282 with placebo, the drug was found to be significantly better than placebo for those MADRS items that reflect core symptoms of depression—apparent and reported sadness, lassitude, and inability to feel; pessimistic thoughts nearly achieved statistical significance (Gao and Calabrese, 2005; Hirschfeld et al., 2005).

Taken together, results of the above five studies are quite suggestive of an acute antidepressant effect of lamotrigine. The drug was very well tolerated in all five studies, with transient headache being the only side effect that differentiated it from placebo.

A 9-week placebo-controlled, double-blind study involving 40 patients with acute bipolar or unipolar major depression compared the antidepressant efficacy of a combination of lamotrigine and paroxetine with that of paroxetine alone (Normann et al., 2002). Although HAM-D scores did not differ between the two groups at the end of the study, the patients who took the combination reported improvement in several depressive symptoms significantly

sooner than patients on paroxetine alone; the numbers were not sufficient for a separate analysis of the bipolar subgroup. In a recent randomized double-blind comparison of adjunctive lamotrigine versus citalopram in bipolar depression, the mean reduction in MADRS scores was virtually identical in the 2 groups (Schaffer et al., 2006). Finally, a randomized²⁴ comparison of adjunctive lamotrigine versus risperidone or inositol in 66 treatment-resistant bipolar depressed patients (documented failure to respond to a mood stabilizer and at least one antidepressant) enrolled in the NIMH STEP-BD program (Nierenberg et al., 2006), lamotrigine was associated with the numerically highest rate of recovery (sustained for at least 8 weeks); post hoc analyses of “relevant continuous outcomes” indicated that adjunctive lamotrigine is superior to risperidone or inositol for treatment-resistant bipolar depression.

Can lamotrigine precipitate or exacerbate manic symptoms, as is seen with antidepressants? There have been a few case reports of switches in bipolar patients on lamotrigine, which may be related to relatively rapid titration and higher doses (Raskin et al., 2006) and/or combination with a high dose of an antidepressant (Margolese et al., 2003). Unfortunately, many published studies on the drug’s efficacy have not addressed this issue specifically, often incorporating the development of mania or hypomania into analyses of “adverse effects.” In the pooled analysis of the three large randomized, placebo-controlled studies cited above, switch rates for lamotrigine and placebo did not differ. Further, in an analysis of pooled data on 827 patients taking lamotrigine and 685 taking placebo in eight controlled studies lasting from 3 weeks to 18 months, the risk of developing manic, hypomanic, or mixed symptoms with lamotrigine was comparable to that associated with placebo, as well as to that among subjects taking lithium (Bowden et al., 2003; G. Goodwin et al., 2004).²⁵ It should be noted, however, that these studies were not sufficiently powered to rule out an increase in manic switches (Ghaemi et al., 2003b).²⁶ Finally, there is an interesting recent report of the simultaneous use of lamotrigine and ECT (Penland and Ostroff, 2006) noting that the combination was well tolerated and that, importantly, lamotrigine had a minimal effect on standard ECT parameters, unlike most other anticonvulsants.

Riluzole

This drug is related to lamotrigine by virtue of its effects on glutamatergic transmission; it is FDA-approved for the treatment of amyotrophic lateral sclerosis. In an 8-week open-label study of riluzole in 14 treatment-resistant bipolar depressed patients, Zarate and colleagues (2005) found significant antidepressant effects across a wide range of items on the MADRS. There were no switches into hypomania or

mania. It is of interest that three of the four patients who had previously failed to respond to lamotrigine responded to riluzole. While these open data are preliminary, they are consistent with the results of a recent trial of riluzole in patients with treatment-resistant unipolar depression (Zarate et al., 2004).

Topiramate

Interest in the possibility that the novel anticonvulsant topiramate may provide some benefit in bipolar depression has been heightened by its ability to reduce weight. Several case reports and open studies in fact do suggest that the drug may have some effect in treating bipolar depression, especially in the 100–200 milligrams per deciliter (mg/dl) range (Marcotte, 1998; Ghaemi et al., 2001). In an open trial, topiramate was given to 45 bipolar-I and 18 bipolar-II patients who were suffering from a major depressive episode and had not benefited from or were intolerant of two mood stabilizers. Although nearly a third of these patients dropped out of the study because of side effects or lack of efficacy, 42 percent had an essentially complete antidepressant response within 4 weeks (HAM-D scores below 7), and another 27 percent had a partial antidepressant response (HAM-D scores between 8 and 12) (Hussain and Chaudhry, 1999).

McIntyre and colleagues (2002) found that topiramate compared favorably with bupropion as an adjunctive treatment in depressed bipolar-I and -II patients who had not improved despite 2 weeks of treatment with either lithium (13 patients) or valproate (23 patients). In this randomized, single-blind study (blind rater), the addition of either topiramate or bupropion resulted in a reduction in HAM-D scores of at least 50 percent in about half of the patients, and about a quarter of both groups had scores below 7.²⁷ As is typically the case with new agents, an assessment of the safety and efficacy of topiramate must rely on sometimes conflicting case reports and small open studies in complex, often treatment-refractory patients who are frequently taking other medications as well. Although results thus far are encouraging, further research and clinical experience will be required before the role of this agent in the treatment of bipolar depression becomes clear.

Other Anticonvulsants

Data on the efficacy of other anticonvulsants in treating bipolar depression are quite preliminary. To our knowledge there has been only one double-blind, randomized clinical trial involving gabapentin as monotherapy, and it had negative results.²⁸ Gabapentin has, however, been reported to be useful as an adjunctive agent (primarily for its

anxiolytic and sedative properties) in several open studies of bipolar depression.²⁹

Clinical data are limited on the use of tiagabine for treating bipolar disorder. A series of three refractory bipolar patients with mixed but predominantly depressive symptoms benefited from tiagabine added to other agents, including valproate, carbamazepine, and antidepressants (Kaufman, 1998). Clearly, however, it is difficult to draw conclusions from such a small sample size.

Another anticonvulsant with mechanisms of action that overlap both the GABAergic and ant glutamatergic agents is zonisamide; the ability of this agent to reduce weight is of obvious interest to clinicians managing bipolar patients.³⁰ Since the initial open study noting some benefit of this agent in treating mania (Kanba et al., 1994), there have been several reports on its use in treating depression. Baldassano and colleagues (2004) reviewed the charts of 12 patients with bipolar depression (-I and -II), finding 6 that met their response criteria based on a change in scores on the Clinical Global Impressions (CGI) scale. Anand and colleagues (2005) found open-label adjunctive zonisamide effective in 5 of 10 bipolar depressed patients who had not tolerated or were resistant to their existing treatment.³¹ A similar open adjunctive trial in 22 bipolar depressed patients not responding to at least one “standard” mood stabilizer also found a significant decrease in mean bipolar depression severity scores on the CGI scale ($p < .001$); however, only 32 percent of the subjects completed the 8-week trial and were classified as responders (McElroy et al., 2005). Recently, Ghaemi and colleagues (2006) conducted an open prospective study of adjunctive zonisamide (mean dose 222 mg) in 20 depressed bipolar patients (bipolar-I, -II, and -not otherwise specified [NOS]); while the observed antidepressant effect was relatively robust (a mean 8 point decrease in MADRS ratings, $p < .001$), half of the patients terminated because of side effects, principally nausea/vomiting, cognitive dysfunction, and sedation. Obviously, controlled data (especially monotherapy data) on zonisamide are needed.

Antidepressants

Tricyclics and Monoamine Oxidase Inhibitors

The existing literature on the efficacy of tricyclic antidepressants is dominated by studies in patients with unipolar depression. The consensus of this literature is quite clear: tricyclics have been more effective than placebo in more than two-thirds of controlled trials, with an overall efficacy rate in the treatment of major depression ranging from 50 to 85 percent and averaging 65 to 70 percent. The data

on bipolar depression are much thinner, however. Indeed, in a recent Cochrane analysis it was noted that bipolar patients (that is, bipolar patients recognized and treated as such) represent only 1 percent of all depressed patients in randomized, placebo-controlled clinical trials (Gijsman et al., 2004).

In the first edition of this text, after analyzing 77 studies involving 3,226 patients, we concluded that the clinical literature provided almost no information about the relative efficacy of this group of drugs in treating bipolar versus unipolar depression. Small studies suggesting that bipolar depression was tricyclic-resistant had occasionally appeared (e.g., Kupfer and Spiker, 1981). Uniformly, however, these studies had not set out to compare medication efficacy in bipolar and unipolar depressed patients. Rather, “bipolarity” or a history of mania was reported as one of several predictors of antidepressant nonresponse in drug efficacy studies or course-of-illness investigations. Yet the results of a large retrospective study intended to answer the question of the efficacy of tricyclics in treating bipolar versus unipolar depression (Moller et al., 2001) indicate that this may not be the case. In this naturalistic chart review, the treatment of 2,032 consecutive patients admitted for a major depressive episode between 1980 and 1992 was assessed to determine whether there was a difference in antidepressant efficacy between bipolar and unipolar patients as measured by several outcome scales. Almost all these patients were prescribed tricyclic (or “tetracyclic”) antidepressants; no difference in drug efficacy was found between the bipolar and unipolar patients. However, this observational study did not attempt to control for confounding variables.

Two recent but conflicting meta-analyses bear on this question. The first is the Cochrane meta-analysis of five acute (4–10 weeks duration) randomized, parallel-group, double-blind, controlled trials (Gijsman et al., 2004) in which a traditional unimodal antidepressant ($n = 213$) was compared with placebo ($n = 449$); 75 percent of these bipolar depressed patients were on a concomitant atypical antipsychotic (the majority) or a mood stabilizer. Relevant to our discussion here, only two of the trials involved a tricyclic. Compared with those on placebo, the antidepressant-treated patients were 1.96 times more likely to respond and 1.4 times more likely to achieve remission. The overall effect size was judged to be comparable to what has been published for unipolar depression and for lamotrigine in bipolar depression. The tricyclics were somewhat less effective than the newer antidepressants (risk ratio [RR] = .84), but this difference did not achieve statistical significance.

As with meta-analyses in general (discussed in Chapter 17), considerable care is in order when interpreting these conclusions. The results are substantially driven by one very

large study (456 patients) in which olanzapine alone (the “placebo” condition) was compared with olanzapine plus a nontricyclic antidepressant—fluoxetine (Tohen et al., 2003a). Whether an antidepressant effect of fluoxetine plus olanzapine should be the principal basis for a generalization about the effectiveness of antidepressants in bipolar patients on a mood stabilizer is questionable at best. One study included in the Cochrane analysis (Nemeroff et al., 2001) directly addressed the question at hand—whether combinations of an antidepressant and a mood stabilizer are more effective than standard mood stabilizers alone. In that study, 117 patients, all on lithium, were randomized to placebo, imipramine, or paroxetine; among those with lithium levels adequate for an antidepressant effect (.8 mEq/l or above), no added advantage was associated with either antidepressant. Unfortunately, in the meta-analysis this study was overwhelmed by the much larger study of fluoxetine plus olanzapine. Another recent meta-analysis (Ghaemi et al., 2003b) examined nine studies of long-term prophylactic use of antidepressants, including but not limited to tricyclics (with follow-up periods of 6 months or longer), and concluded that there is no overall benefit with use of an adjunctive antidepressant.³² The discrepancy between these two meta-analyses likely relates to the fact that one focused on acute studies and the other on long-term studies.

MAOIs have been claimed to be particularly effective in treating bipolar depression. Starting in the early 1970s, a group of investigators at the Western Psychiatric Institute in Pittsburgh published a series of studies on the use of tranylcypromine in patients with bipolar depression, alone and in combination with lithium. Following several reports of MAOI efficacy in open studies of depressed patients who had not benefited from lithium or lithium plus a tricyclic, Himmelhoch and colleagues (1991) carried out a double-blind study on 56 patients with “anergic” bipolar-I or -II depression, comparing the efficacy of tranylcypromine and imipramine monotherapy. “Anergic” depression was defined as a syndrome similar to DSM’s “atypical features,” including psychomotor retardation and “reverse vegetative signs” (i.e., hypersomnia and hyperphagia). The response rate (defined as “moderate” or “marked” improvement on the CGI scale) in the tranylcypromine group during the “acute treatment” phase of this study (4 weeks) was 81 percent, double that of the imipramine group. A year later, the same investigators reported on a double-blind crossover study of depressed bipolar patients taking either imipramine or tranylcypromine: 9 of 12 patients who crossed over from imipramine to tranylcypromine responded, compared with only 1 of 4 patients crossing over from tranylcypromine to imipramine (Thase et al., 1992).

Moclobemide is a reversible inhibitor of monoamine oxidase A (MAO-A) approved for the treatment of depression in many countries throughout the world, but not in the United States. In a randomized, double-blind, multicenter study of bipolar depressed patients, most of whom were on a mood stabilizer,³³ Silverstone (2001) found no significant difference between moclobemide (n = 81) and imipramine (n = 75) with respect to changes in HAM-D and MADRS scores, although there were nonsignificant trends favoring the tricyclic. Switches into mania were observed in 3.7 percent of those on moclobemide versus 11 percent of those on imipramine. The fact that MAOIs were only slightly (and nonsignificantly) better than tricyclics in the analysis of Gijssman and colleagues (2004) may be due to the inclusion of this moclobemide study (the largest one in the analysis): moclobemide is generally thought to be less effective than other MAOIs, and in the Silverstone study tended to be less effective than imipramine (as perhaps also reflected in the lower mania switch rate).

Bodkin and Amsterdam (2002) conducted a double-blind, placebo-controlled study of 177 unipolar depressed outpatients in which transdermal selegiline was found to be effective and well tolerated. This MAOI is more specific to the isoenzyme monoamine oxidase B (MAO-B) at low doses and is less active in inhibiting MAO-A, the isoenzyme that predominates in intestinal epithelium and whose inhibition necessitates a low-tyramine diet. This specificity is unfortunately lost at the higher oral doses required to treat depression; in this study, however, a comparatively low dose (20 mg/day) delivered by a transdermal patch was effective. Although patients in this study kept to a low-tyramine diet, the study raises the possibility that MAOI therapy without (or with less stringent) dietary restrictions may be possible by means of a transdermal drug delivery system.³⁴ The selegiline patch was recently approved by the FDA.

Second-Generation Antidepressants

Selective Serotonin Reuptake Inhibitors. As is true of the tricyclics, SSRIs have clearly been shown to be effective in the acute treatment of unipolar depression. However, this general conclusion may be more applicable to the mainstream unipolar depressed patient without frequent recurrences. Thus it is interesting that in the recent report from the “real-world” NIMH Sequenced Treatment Alternatives to Relieve Depression (STAR*D) trial of the antidepressant citalopram, only 28 percent of patients with fairly recurrent forms of unipolar depression (average of six prior episodes) achieved remission (Trivedi et al., 2006).

Compared with unipolar depression in general, data on

the efficacy of SSRIs in the acute treatment of bipolar depression are more limited (see Table 19–6). Kupfer and colleagues (2001) conducted an 8-week open study of citalopram added to lithium, valproate, carbamazepine, or a combination of these agents in 33 patients with bipolar-I or -II depression. They found that 64 percent experienced a reduction in depressive symptoms (Kupfer et al., 2001).³⁵

The largest controlled study of the acute antidepressant effect of an SSRI in bipolar disorder, noted above in our discussion of tricyclics, involved comparing fluoxetine plus olanzapine with olanzapine alone; there was no fluoxetine-alone group. While there is no question that this combination is effective—indeed, it was given an FDA indication for the treatment of bipolar depression—one cannot use these results to assess the efficacy of SSRIs themselves in treating bipolar depression.

A 6-week double-blind study of 89 patients with bipolar depression (-I or -II not specified) found response rates for fluoxetine, imipramine, and placebo of 86 percent, 57 percent, and 38 percent, respectively (Cohn et al., 1989). The results are difficult to interpret, however, because about half of the study participants were also taking lithium, and a disproportionate number of those patients were in the fluoxetine group.³⁶ In the largest and best-designed study comparing the efficacy of paroxetine and imipramine in bipolar depressed patients (mentioned previously), Nemeroff and colleagues (2001) compared each antidepressant with placebo over 10 weeks under double-blind conditions in 117 patients who were also taking lithium (some were taking valproate or carbamazepine as well). No significant differences in efficacy among the three groups were found. In a post hoc analysis, the groups were stratified according to their lithium levels. It was found that imipramine and paroxetine were superior to placebo (and equivalent to each other), but only in patients with lower lithium levels (less than .8 mEq/l). Thus lithium was as effective as the two antidepressants when given at doses that achieved levels of .8 mEq/l or greater.

There has been considerable interest in using second-generation antidepressants to treat bipolar-II depression (see Box 19–2). Several studies of SSRI monotherapy for this indication are available. In a post hoc analysis of pooled data from randomized clinical trials involving patients with unipolar depression (in which some bipolar-II patients were included), Amsterdam and colleagues (1998) noted that the efficacy of fluoxetine in 89 bipolar-II patients was comparable to its efficacy in matched and unmatched unipolar depressed patients.

Bupropion. This drug, which enhances both noradrenergic and dopaminergic transmission through different mechanisms, may have unique advantages in the treatment

TABLE 19–6. Studies of Selective Serotonin Reuptake Inhibitors in Treating Bipolar Depression

Study	Sample	Design	Results
Cohn et al., 1989	89 bipolar (-I or -II not specified)	6-week double-blind comparison of fluoxetine, imipramine, and placebo; results confounded because more of the fluoxetine patients were also taking lithium	86% of fluoxetine-treated patients improved, compared with 57% of imipramine- and 38% of placebo-treated patients.
Simpson and DePaulo, 1991	16 bipolar-II	Open case series of fluoxetine monotherapy in patients refractory to other treatment (including tricyclics, MAOIs, and/or lithium); patients treated 13.6 ± 5.2 months	15/16 patients showed some benefit; 10/13 taking fluoxetine for at least 10 months had a good to very good response.
Young et al., 2000	11 bipolar-I, 16 bipolar-II	6-week double-blind, randomized study comparing the addition of paroxetine or a mood stabilizer to the regimen of patients already taking a mood stabilizer	Both treatments were effective in improving depressive symptoms; however, the mood stabilizer add-on group had a significantly lower completion rate (related to more side effects).
Kupfer et al., 2001	30 bipolar-I, 15 bipolar-II	8-week open-label add-on study	33 patients completed the study, 21 of whom were considered responders (64%).
Nemeroff et al., 2001	117 bipolar (-I or -II not specified)	10-week double-blind, placebo-controlled study comparing paroxetine, imipramine, and placebo; patients also took lithium or anticonvulsants	Both paroxetine and imipramine were superior to placebo only in patients with subtherapeutic lithium levels.
Ghaemi et al., 2004	78 patients (41 bipolar, 37 unipolar); 63% of bipolar patients were bipolar-I	228 trials as adjunct; naturalistic with systematic diagnostic criteria and assessment of response	Nonresponse was 60% more likely in the bipolar group; loss of response was 3.4 times more likely in the bipolar group.

Note: In evaluating this literature, it is important to be aware of the observation by Sachs and colleagues (2003) that there is no systematic method for correcting for improved depression scores that occur as part of a switch into mania. For example, about a quarter of the impressive response rates reported in some studies of tranylcypromine and imipramine monotherapy represent subjects who became manic during the study.

Source: Adapted from Ghaemi and Hsu, 2005.

of bipolar depression. Many experts believe it is at least as efficacious as SSRIs and tricyclics for the treatment of bipolar depression while having a significantly more benign side-effect profile, causing neither the heavy anticholinergic side effects of the tricyclics nor the problems of sexual dysfunction and long-term weight gain common with the SSRIs. Moreover, as an activating agent, it may have some advantage in the majority of bipolar patients whose depression involves primarily psychomotor retardation. In addition, results of two randomized trials suggest bupropion may be less likely to provoke a switch into mania than either a tricyclic or venlafaxine (see below).

In an open prospective study of adjunctive bupropion, 8 of 13 patients with complex, refractory bipolar disorder

taking a variety of other agents, including some who were taking other antidepressants, had a greater than 50 percent reduction in their MADRS scores (Erfurth et al., 2002). A prospective 8-week double-blind study compared bupropion and desipramine in 15 depressed bipolar patients also taking lithium, valproate, or carbamazepine (Sachs et al., 1994).³⁷ About two-thirds of all the patients had at least a 50 percent reduction in their HAM-D scores, with comparable efficacy being observed for the two antidepressants. The most comprehensive comparison of adjunctive bupropion with other second-generation antidepressants is the randomized, double-blind Stanley Foundation Bipolar Network study (Post et al., 2006), in which 174 bipolar patients experiencing a breakthrough depression were randomized

BOX 19-2. Treatment of Bipolar-II Depression

While numerous studies have examined the clinical characteristics and epidemiology of bipolar-II disorder, relatively few have focused on treatments specifically for bipolar-II depression. Because patients with bipolar-II disorder have more frequent episodes of depression than bipolar-I patients and may be at higher risk for suicide, research into the treatment of bipolar-II depression deserves urgent attention.

Bipolar-II patients have been included in efficacy studies of lithium, anticonvulsants, antidepressants, and other agents. All too often, however, bipolar-II patients are not separated out in the discussion of results. Nevertheless, a survey of the literature leads to the conclusion that available treatments for bipolar-I depression are also effective for the treatment of bipolar-II depression (see MacQueen and Young, 2001, for a discussion of efficacy studies).

A number of studies of the use of the sedating anticonvulsants (such as valproate or carbamazepine) in treating bipolar-II disorder suggest that these agents are quite useful in treating the impulsiveness, irritability, and dysphoric moods often seen in these patients, symptoms that, while not classic, may lead to more self-harming behavior and psychosocial disability. Results of several preliminary studies suggest that valproate may be modestly effective in treating bipolar-II patients. In a small open study of divalproex monotherapy in 19 bipolar-II depressed outpatients, nearly two-thirds of the subjects showed a greater than 50 percent reduction in HAM-D scores after 12 weeks (Winsberg et al., 2001). There have been two double-blind, placebo-controlled studies. The first investigated the effects of valproate

as monotherapy in 30 patients with bipolar-II disorder who also met criteria in the *Diagnostic and Statistical Manual (DSM)-IV* for borderline personality disorder. The valproate group experienced a significant reduction in dysphoric symptoms, such as irritability and anger. There was also a nonsignificant trend toward reduction of depressive symptoms, though this finding may be explained by the fact that patients with active major depression had been excluded from the study (Frankenburg and Zanarini, 2002). The second controlled study, conducted by Sachs and colleagues (2001), failed to show a significant advantage over placebo for the overall group, but did identify a trend favoring valproate over placebo in the bipolar-II subgroup.

Lamotrigine may be effective in patients with bipolar-II depression, but there have been no placebo-controlled studies or head-to-head comparisons with lithium or other anticonvulsants.

Any number of studies of antidepressants for the treatment of bipolar depression have included bipolar-II patients. For example, bipolar-II patients have been included in studies of the use of selective serotonin reuptake inhibitors (SSRIs) for treating bipolar disorder (see Table 19-6). As with lithium and the anticonvulsants, however, the data are insufficient to conclude that any particular agent is especially superior for treating bipolar-II depression. The key issue here is whether the risk of switch and/or destabilization is lower among bipolar-II than among bipolar-I patients. While recent data suggest that this might be the case, there is still no consensus and we still recommend that if antidepressants are used in treating bipolar-II depression, they be combined with a mood stabilizer.

to adjunctive bupropion, sertraline, or venlafaxine (see Fig. 19-2). The three drugs showed modest efficacy overall, with about one-third of the patients achieving remission; however, on the outcome of most importance to the clinician—remission without a switch into mania/hypomania (see below)—on average an uncomplicated remission was achieved by only 25 percent of the patients. With regard to the drugs individually, bupropion performed best (38 percent), compared with sertraline (27 percent) and venlafaxine (just 18 percent). In other words, with respect to the most desirable outcome, bupropion was twice as good as venlafaxine (RR for bupropion versus venlafaxine = 2.13 [95 percent confidence interval (CI) 1.15–3.94]).

Serotonin/Norepinephrine Reuptake Inhibitors (SNRIs). Venlafaxine has garnered significant interest because of its “dual reuptake” effects—acting as both a serotonin and noradrenergic reuptake inhibitor. Some data suggest that venlafaxine has a more rapid onset of therapeutic action

and results in higher remission rates than SSRIs in patients with unipolar depression (Thase et al., 2001). However, these differences have not been demonstrated as yet in the few studies on bipolar patients. Amsterdam and Garcia-Espana (2000) reported on a nonrandomized study of venlafaxine monotherapy for 15 bipolar-II and 17 unipolar patients being treated for major depression. About two-thirds of the patients in both groups had a reduction in HAM-D and MADRS scores of 50 percent or greater. A 6-week single-blind (blind rater) study of 60 patients with bipolar-I or -II major depression taking lithium or anticonvulsants found equal response rates (about half the patients) in those taking venlafaxine and paroxetine, with no significant difference in the bipolar-I and -II patients (Vieta et al., 2002). With regard to the proportion who responded without a switch, however, paroxetine outperformed venlafaxine. This result is consistent with the Stanley Foundation Bipolar Network results noted above (Post et al., 2006), and both reports suggest that venlafaxine

Figure 19–2. Outcomes for patients taking bupropion, sertraline, and venlafaxine. Note: Response and remission rates based on Inventory of Depressive Symptomatology (IDS) criteria only; mania switch and remission/no switch rates based on Young Mania Rating Scale or Clinical Global Impressions-Bipolar criteria. (Source: Post et al., 2006. Reproduced with permission.)

may be more like tricyclics, with a less favorable ratio of responses to switches compared with other second-generation antidepressants, especially bupropion.

Results of several open studies of the use of nefazodone in treating bipolar depression have not been encouraging. El-Mallakh (1999) found only transient improvement over a period of 8 weeks in 5 outpatients who took nefazodone with other medications. In another open trial, Goldberg and colleagues (2002) noted that about two-thirds of 13 patients who took nefazodone in addition to lithium, anti-convulsants, and antipsychotics had a 50 percent reduction in HAM-D scores during the course of the study, but that half of these patients experienced some relapse of depressive symptoms by the eighth week.

The new SNRI duloxetine was approved by the FDA for the treatment of major depression in 2004 on the basis of several large placebo-controlled trials involving more than 1,400 patients (Detke et al., 2002; Goldstein et al., 2002; Nemeroff et al., 2002). To our knowledge, studies of this agent focused on bipolar depression have not yet been published.

Selective Noradrenergic Reuptake Inhibitors. Reboxetine is a norepinephrine reuptake inhibitor with a structure distinct from that of the tricyclics. Although it is comparable in norepinephrine reuptake inhibition potency to the tricyclics, its selectivity for noradrenergic reuptake inhibition can be compared with that of the SSRIs in inhibiting serotonin reuptake. Reboxetine has thus been referred to as the first selective norepinephrine reuptake inhibitor, and

as such represents the first of what may become a new class of antidepressants (Wong et al., 2000). Reboxetine has been shown to be superior to placebo in treating unipolar depression and comparable to tricyclics and fluoxetine (Berzowski et al., 1997; Versiani et al., 1999; Schatzberg, 2000). To date, there have been no published studies of its use in treating bipolar depression, although three cases of probable reboxetine-induced mania in bipolar patients have been reported (Vieta et al., 2001).

Long-Term Efficacy of Antidepressants in Bipolar Disorder

As noted earlier, we chose to introduce the issue of the long-term effects of antidepressants (both benefits and risks) in this chapter because they are important considerations in the choice of a treatment for acute depression. With regard to highly recurrent unipolar depression, insufficient data are available to estimate a risk-benefit ratio, so our focus here is on bipolar depression.

In a university clinic, Ghaemi and colleagues (2004) found that, over periods of observation that averaged approximately 1 year, there was a 51.3 percent nonresponse rate among 41 bipolar depressed patients, compared with only a 31.6 percent nonresponse rate among 37 unipolar patients. In addition, loss of response during treatment occurred 3.4 times more often among the bipolar than the unipolar patients. These results are in the same range as those of the Stanley Foundation Bipolar Network study: Post and colleagues (2003) found that while about 50 percent of

their bipolar-I patients given a second-generation antidepressant in addition to a mood stabilizer were “much” or “very much” improved (as measured by the CGI scale), only 19 percent were able to complete the intended 1 year of continued antidepressant use. In a similar vein, Sachs and colleagues (2003) reported preliminary outcomes for the first 1,000 subjects enrolled in the NIMH STEP-BD program. During the first year of follow-up, 181 subjects experienced the new onset of at least one episode of major depression, and 50 of these patients experienced multiple depressive episodes³⁸; no statistically significant advantage was associated with the adjunctive use of second-generation antidepressants.³⁹ Finally, a recent randomized study within the NIMH STEP-BD program (mentioned briefly in the section on clinical management) evaluated 69 bipolar patients who had recovered from a depressive episode on a combination of a second-generation antidepressant and a mood stabilizer (Ghaemi et al., 2006). After being stable for 2 months, the patients were openly randomized to continue with the combined treatment or the mood stabilizer alone (that is, antidepressants were tapered and discontinued); after adjusting for other clinical variables,⁴⁰ antidepressant continuation did not result in lower overall mood morbidity at 1-year follow-up compared with mood stabilizer alone.⁴¹ Note that these results are quite different from those of the three nonrandomized studies reviewed in the section on clinical management that have, unfortunately, been interpreted by some as indicating that bipolar patients who have responded acutely to antidepressants should be continued on them. Clearly only a minority of bipolar patients do well when kept on antidepressants plus mood stabilizers, but the results of observational studies do not provide clinicians with a basis for judging which of their patients might be expected to do so.

The reader will note that scattered throughout our review of the literature are studies of the effectiveness of various agents in “treatment-resistant depression.” The importance of such studies is underscored by evidence that resistance to standard antidepressants is one of the characteristics that may make the condition of a given patient more likely to be part of the bipolar spectrum (see Chapter 1). For example, Sharma and colleagues (2005) studied 61 patients with major depression who had failed to respond to two adequate antidepressant trials, two-thirds of whom had initially been diagnosed as unipolar. Upon careful diagnostic reevaluation in the course of 1-year follow-up, only 21 percent were still diagnosed as unipolar, with 79 percent now meeting criteria for bipolar disorder, primarily bipolar-II. Rybakowski and colleagues (2005) reported on a cohort of 447 unipolar depressed patients, 106 of whom met criteria for bipolar spectrum disorder; those with bipolar spectrum features were twice as likely as the “pure” unipolar patients to have

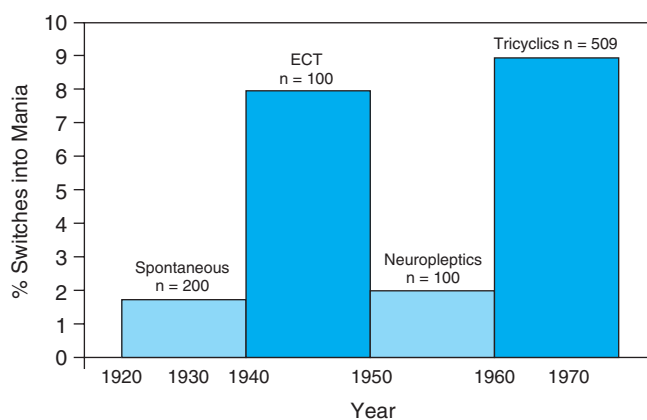

a history of treatment-resistant depression (30 versus 15 percent). Approaching this relationship from a different direction, Hantouche and colleagues (2005) evaluated the lifetime treatment history of 256 patients diagnosed as having unipolar major depression and found that those whose antidepressant had been augmented by a mood stabilizer (implying antidepressant resistance) had higher scores on a hypomania checklist and were more likely to have cyclothymic temperaments. However, not all studies have found a relationship between bipolar features and antidepressant resistance in unipolar patients (personal communication, D.J. Smith, October 14, 2005, University of Edinburgh).

Switches and Cycle Acceleration Following the Initiation of Antidepressants

Switches. In the first paper describing the antidepressant effects of imipramine, Kuhn (1958, p. 463) observed that “if [a patient’s] depressions are easily and frequently replaced by manic-like phases or actual manic states, the reaction [to imipramine] is less favorable. . . . [T]he tendency arises for the depression to switch over into a manic phase.” This observation is not limited to imipramine. Angst (1985) conducted an intriguing retrospective study of patients admitted to the Burghoelzli Psychiatric Hospital with a mood disorder between 1920 and 1982 (see Fig. 19–3). His findings indicate that the incidence of depressed patients experiencing manic symptoms increased with the development of medical treatments for depression (ECT and medications).⁴²

In the ensuing decades, this “switch” phenomenon has been reported for every class of antidepressant, for many other classes of psychotropics, for medications used to treat nonpsychiatric conditions, for nonpharmacological

Figure 19–3. Switch rate of hospitalized depressed patients (unipolar or bipolar). Note: Only one episode per patient was considered. (Source: Angst, 1985.)

interventions (ECT, phototherapy, sleep deprivation), and even for herbal preparations.⁴³ In our above discussion of the efficacy of antidepressants in bipolar patients, we briefly noted reports of switching.⁴⁴ Table 19–7 builds on our considerable coverage of this issue in the first edition by summarizing recent studies of mania/hypomania following the initiation of antidepressants. Similarly, reports have appeared since the 1960s that in some bipolar patients, an antidepressant medication can be associated with increased mood cycling (see below). It has been posited that these agents can hasten the onset of new mood episodes in patients, accelerating the rhythm of their cycles and destabilizing mood.

If anything, the question of possible antidepressant-related worsening of bipolar illness has taken on more urgency since the first edition was published as a result of the enormous increase in prescriptions for antidepressants that has followed from the continuing introduction of new, easier-to-use agents into the market. Thus since 1990 there has been more than an eight-fold increase in prescriptions within the SSRI class alone (Grunebaum et al., 2004). Because the bulk of this increased prescribing is by nonpsychiatric physicians, there is an increased risk of undiagnosed bipolar patients being on antidepressants without a mood stabilizer.

A variety of methods have been used in an attempt to quantify how frequently switches occur, to assess whether drug-related and spontaneous switches differ,⁴⁵ to identify which agents are more likely to cause switching, and to alert clinicians to risk factors that may make particular patients more vulnerable. A number of factors have conspired to make this work quite difficult: (1) the inherent cycling pattern of the disorder makes it challenging to separate spontaneous from drug-induced changes in symptoms and course of illness; (2) the diagnostic categories for bipolar disorder are empirically derived and may not validly differentiate patients according to the undoubtedly complex and heterogeneous neurobiological underpinnings that may determine how they respond and react to pharmacological interventions; and (3) changes in treatment patterns over the years, especially the increasing use of multiple agents and complex treatment regimens, make gathering groups of patients with a similar treatment history increasingly difficult for the long-term studies needed to answer questions about the effects of specific pharmaceuticals on course of illness.

First, what do we know about the frequency of the switching phenomenon in patients on antidepressants? Estimates of the rate of switching into manic, mixed, and hypomanic states in bipolar patients treated with antidepressants range broadly among different studies (10 to nearly 70 percent, with the higher rates generally associated with

the tricyclics), a variability no doubt associated with the confounding factors just noted, especially patient selection and methods used to ascertain and score occurrences of mania/hypomania (Ghaemi et al., 2003c; Goldberg and Truman, 2003; Goldberg and Ghaemi, 2005).⁴⁶ As an example, one of the largest studies to date (Altshuler et al., 1995) used a retrospective life chart method to analyze the temporal association between tricyclic and MAOI antidepressants and the course of illness of 51 patients hospitalized with an episode of bipolar disorder. Manic or hypomanic episodes were categorized as likely to have been antidepressant related on the basis of such criteria as an episode occurring within 8 weeks of initiation of the drug or a change in illness pattern (the episode would have been “unexpected” given the prior course of the patient’s illness). The authors concluded that one-third of the patients experienced an antidepressant-induced mania and that one-fourth experienced cycle acceleration at some time during the course of their illness. Of the switches that occurred, 75 percent were in bipolar-I patients and 25 percent in bipolar-II; half of the patients experienced rapid cycling (having had four or more mood episodes in the year prior to the study), and all were lithium refractory. Some patients were taking lithium at the time of the switch or cycle acceleration, and others were not. Given this heterogeneous group of ill patients, generalizing of these rates of adverse effects to other patient groups and the total group of patients with bipolar disorder is not possible.

Results of prospective studies that have specifically set out to identify manic episodes following the initiation of antidepressants indicate that approximately one-quarter of patients with bipolar disorder experience mania or hypomania within weeks to months of first taking these drugs (most studies set the criterion at 2 months; see Table 19–7). Some have suggested that patients with bipolar-I disorder are more likely than those with bipolar-II to experience a switch, but to our knowledge, these two populations have never been compared prospectively in the same study.

Switch rates calculated from clinical trials of antidepressants in bipolar depression (see Tables 19–8a and 19–8b) tend to be lower than those reported from naturalistic studies. For one thing, controlled trials tend to screen out patients who are at a higher risk of switching, such as those with substance abuse histories (Goldberg and Whiteside, 2002; Manwani et al., 2006). In addition, as Sachs (2005) has pointed out, given the ethical constraints associated with randomized, double-blind trials, antidepressants would hardly be continued if there were any signs of incipient mania. Patients showing evidence of abnormal mood elevation are typically removed from the study

TABLE 19–7. Observational Studies Since the First Edition (1990) Focused on the Emergence of Mania/Hypomania Following Initiation of Antidepressants

Study	Sample	Study Design	Results
Altshuler et al., 1995	38 bipolar-I, 13 bipolar-II	Lifetime life chart review of consecutive patients admitted to a clinical research ward	35% had a manic episode “likely” due to heterocyclic antidepressants, 21% due to MAOIs
Benazzi, 1997	103 unipolar, 8 bipolar-I, 92 bipolar-II	3–6 month prospective, naturalistic treatment of private-practice patients	Manic/hypomanic switch occurred in 25% of bipolar-I, 17.3% of bipolar-II, and 5.8% of unipolar patients; unipolar patients who switched resembled bipolar-I patients in age at onset and “atypical” features
Boerlin et al., 1998	29 bipolar-I (79 “episodes”)	2-month prospective, naturalistic study in which patients taking antidepressant alone were compared with patients taking antidepressant and lithium or anticonvulsant	28% of patients had mania/hypomania, but in only 10% was it “severely disruptive”; there was no significant difference between patients taking antidepressant and those taking antidepressant plus lithium or anticonvulsant; switch rates were lower for SSRIs vs. tricyclics or MAOIs
Bottlender et al., 1998	158 bipolar depression	Retrospective study of medical records	25% of patients had switched to a maniform (mania and hypomania) state during the treatment period in the hospital; among that group, the phenomenon occurred in 23 patients (15%) as a hypomania and in 16 patients (10%) as a mania
Ghaemi et al., 2000	85 bipolar or unipolar	Retrospective study of medical records	55% of bipolar patients taking antidepressants developed hypomania or mania; 23% developed new or worsening rapid-cycling course
Henry et al., 2001	31 bipolar-I, 13 bipolar-II (95 “treatment phases”)	6-week prospective, naturalistic study comparing patients who switched with those who did not; 90% of patients were on an SSRI, 10% on a tricyclic	27% of patients switched; there was no difference between rates in bipolar-I and -II patients or between antidepressants and ECT; lithium was more protective than anticonvulsants
Goldberg and Whiteside, 2002	53 bipolar (-I or -II not specified)		39.6% switched into mania or hypomania; no apparent impact of concomitant mood stabilizers
Joffe et al., 2002	51 bipolar-I, 18 bipolar-II (113 “trials”)	1-year prospective, naturalistic study comparing SSRIs (including venlafaxine) with bupropion; all patients taking lithium or anticonvulsant	12.4% of patients developed mania; bipolar-I > bipolar-II; there was no difference between rates in the two drug classes

(continued)

TABLE 19–7. Observational Studies Since the First Edition (1990) Focused on the Emergence of Mania/Hypomania Following Initiation of Antidepressants (*continued*)

Study	Sample	Study Design	Results
Post et al., 2003	127 bipolar patients on lithium and/or valproate given an adjunctive secondary antidepressant for depression; 42% reported a history of rapid cycling	Assessed using National Institute of Mental Health life chart methodology for 1 year; 10-week prospective study with 1-year continuation phase; randomized to bupropion, sertraline, or venlafaxine; nonresponders rerandomized	Half responded (= <50% improvement) to acute antidepressant treatment, but half of responders switched into hypomania/mania (with some dysfunction) in either the acute or the continuation phase
Serritti et al., 2003	297 bipolar-I, 119 bipolar-II	Retrospective case–control study with interviews, medical records, and life charts	43% of switchers were bipolar-I vs. 19% of switchers who were bipolar-II ($p < .0001$); switchers were 5.8 times more likely to have history of rapid cycles; 3 times fewer switches occurred with antidepressant + mood stabilizer vs. antidepressant alone (51% vs. 17%); depression–mania–interval (DMI) pattern more frequent among switchers ($p < .0002$)
Ghaemi et al., 2004	41 bipolar depression, 37 unipolar depression	Analysis of clinical records for outcomes of antidepressant trials	Switches into mania were not observed in any unipolar patient, but occurred in 84.2% of bipolar patients not taking any antimanic agent, vs. 31.6% taking at least one antimanic agent; compared with tricyclics, newer antidepressants were not associated with lower rates of cycle acceleration

and their response reported as an adverse event, “manic reaction,” but not as an episode of mania or hypomania.

In most studies comparing apparent antidepressant-related switch rates in bipolar patients with and without mood stabilizers, those on mood stabilizers have been found less likely to switch.⁴⁷ Thus in those studies in which all patients were taking lithium or anticonvulsants, the rate of switching was roughly half that reported in studies of patients treated with antidepressants in the absence of a mood stabilizer. The protective effect of mood stabilizers (especially atypical antipsychotics) is illustrated by the recent Cochrane meta-analysis of five randomized trials of short-term treatment for bipolar depression, comparing antidepressants and placebo (Gijsman et al., 2004). In this study, 84 percent of the patients were on a “mood stabilizer,” primarily (77 percent) olanzapine. The switch rates were low in both the antidepressant plus “mood stabilizer” and “mood stabilizer” alone groups.⁴⁸

A number of studies have addressed potential risk factors for drug-related switching. One such factor is gender. In a randomized, double-blind, 3-year prospective comparison of lithium versus lithium plus imipramine, Quitkin and colleagues (1981) noted 2.5 times more switches in the combined-treatment group, but this differential was significant only among females, a finding similar to that of Yaldez and Sachs for antidepressant-related cycling (see below). In an observational study, by contrast, Goldberg and Whiteside (2002) found no difference in the gender ratio of bipolar patients who switched on antidepressants versus those who did not.

Another factor examined is episode sequence. Koukopoulos and colleagues (1980) noted that the episode sequence mania–depression–interval (MDI) was less likely to be associated with switching than the depression–mania–interval (DMI) sequence, a conclusion presumably related to his observation that the MDI pattern was associated with longer,

TABLE 19–8A. Reported Rates of Emergent Mania in Association with Antidepressants in Randomized Studies of Bipolar Depression

Study	Medication	Sample Size	Study Duration	Mean Dose	Switch Rate	Comments
Cohn et al., 1989 (95)	Fluoxetine	30	3–6 weeks	62 mg/day	0.0%	Concurrent lithium in 23% taking fluoxetine, 17% taking imipramine, 20% taking placebo; 16% of imipramine or placebo nonresponders who then took fluoxetine became hypomanic within 1 month during unblinded extension
	Imipramine	30	3–6 weeks	62 mg/day	7.0%	
	Placebo	29	3–6 weeks	N/A	3.0%	
Himmelhoch et al., 1991 (71)	Tranlycypromine	16	6 weeks	37 mg/day	21.0%	No concomitant mood stabilizers used
	Imipramine	16	6 weeks	246 mg/day	25.0%	
Thase et al., 1992 (91)	Tranlycypromine	12	4–12 weeks	39 mg/day	17.0%	Double-blind crossover of study of nonresponders from a prior tranlycypromine study
	Imipramine	4	4–12 weeks	246 mg/day	25.0%	
Sachs et al., 1994 (75)	Bupropion	9	8-week acute	358 mg/day	11.0%	Cotherapy with lithium, valproate, or carbamazepine
	Desipramine	10	1-year continuation	140 mg/day	50%	
Young et al., 2000 (78)	Paroxetine	11	6 weeks	36 mg/day	0.0%	All subjects initially took lithium or valproate; study drug was then added
	Lithium or valproate	16	6 weeks	Lithium 1,300 mg/day Valproate 1,200 mg/day	6.3%	
Nemeroff et al., 2001 (77)	Paroxetine	35	10 weeks	33 mg/day	0.0%	All patients on lithium; switch rate significantly lower on paroxetine vs. imipramine, but two of the three imipramine patients who developed mania and the 1 placebo patient who developed mania were in subtherapeutic serum lithium level group
	Imipramine	39	10 weeks	167 mg/day	7.7%	
	Placebo	43	10 weeks	N/A	2.3%	
Silverstone, 2001(81)	Moclobemide	78	8 weeks	450–750 mg/day	3.7%	“Switch” defined as Young Mania Rating Scale score >10
	Imipramine	78	8 weeks	150–250 mg/day	11.0%	
Vieta et al., 2002 (92)	Paroxetine	30	6 weeks	32 mg/day	3.0%	Open-label randomized; paroxetine and venlafaxine both effective and safe in treatment of depressive breakthrough episodes in bipolar disorder; there was a suggestion of a slightly higher risk for switch to mania or hypomania with venlafaxine
	Venlafaxine	30	6 weeks	79 mg/day	13.0%	

N/A = not available.

TABLE 19–8B. Reported Rates of Emergent Mania in Association with Antidepressants in Nonrandomized Studies of Bipolar Depression

Study	Medication	Sample Size	Study Duration	Mean Dose	Switch Rate (%)	Comments
Fogelson et al., 1992 (65)	Bupropion	11	6 weeks	286 mg/day	54.5	Coexisting lithium and carbamazepine or valproate in 5 of 6 patients who switched
Baldassano et al., 1995 (64)	Paroxetine	20	8 weeks	23 mg/day	5.9	1 patient on lithium + carbamazepine developed hypomania
Kupfer et al., 2001 (93,94)	Citalopram	45	8-week acute, then 16-week continuation	34.5 mg/day	6.7	All subjects on lithium, valproate, or carbamazepine
Erfurth et al., 2002 (90)	Bupropion	13	4 weeks	286 mg/day	0.0	Bupropion added to diverse combination therapies in a treatment-refractory group

more stable depressions. More recently, Serretti and colleagues (2003) conducted a retrospective case–control study of 169 bipolar patients who switched while taking an antidepressant versus 247 who did not (matched for age and gender); they also found switches more likely with the DMI pattern. On the other hand, MacQueen and colleagues (2002) presented detailed life-chart data for 42 bipolar depressed patients indicating that those whose depression was preceded by a manic/hypomanic episode (presumably the MDI pattern) were more likely to have an antidepressant-related switch than those whose depression was preceded by a period of euthymia. Given the design and size of these studies, it appears fair to conclude that the weight of the literature suggests switching is more likely to be associated with the DMI pattern. A third factor studied is comorbid substance abuse. Goldberg and Whiteside (2002) found that switch risk was associated with a history of substance abuse and/or multiple previous antidepressant exposures.

What about the relative risk in bipolar-I versus bipolar-II? By far the majority of the data on switching has come from studies of bipolar-I patients, although some of the studies reviewed above included both bipolar-I and -II patients. Two studies (Joffe et al., 2002; Serretti et al., 2003) noted more switching in bipolar-I than in bipolar-II, while two found no difference (Henry and Demotes-Mainard, 2003; Bauer et al., 2005). The resolution of this question has been advanced considerably by two sets of data from the

Stanley Network—one concerning acute treatment (Altshuler et al., 2006) and the other focused on long-term follow-up (Leverich et al., 2004). Both reveal that, compared with bipolar-I patients, those with bipolar-II have a lower switch rate, and when they do switch, it is into hypomania.

Finally, as might be expected, Sato and colleagues (2004) found that bipolar patients with depressive mixed states (see Chapters 1 and 2) are more likely to switch when antidepressants are added to mood stabilizers than are bipolar patients with “pure” depression. Related findings come from an analysis of the NIMH STEP-BD database (Goldberg et al., 2004), which found that among bipolar patients with depressive mixed states, antidepressants worsened manic symptoms without improving depressive ones. In a recent comparison of switchers and nonswitchers among bipolar patients on antidepressants in the Stanley Network, Frye and colleagues (2006) found three specific manic-like symptoms during depression that were associated with a switch—more motor activity, more talkative, and showing new interests; increased sexual activity just missed significance. The results of these last three studies are important for the clinician to keep in mind because such “depressive mixed states” are often confused with agitated depression; the specificity of the individual symptom predictors in Frye and colleagues’ study should prove especially useful to the clinician.

Do antidepressant-related switches differ from spontaneous ones? In a prospective study of consecutive admissions, Tamada and colleagues (2004) compared 12 patients

on mood stabilizers who switched within 12 weeks of starting an antidepressant and 12 patients with spontaneous mania. Those who switched while taking an antidepressant had been ill longer with more previous episodes, had a higher prevalence of subclinical hypothyroidism, and had a history of more previous antidepressant-related switches. In the largest observational study comparing spontaneous and antidepressant-related switches, Akiskal and colleagues (2003) evaluated 493 consecutive patients with DSM-IV major depression (196 were bipolar-II or bipolar-NOS; bipolar-I patients were excluded). Spontaneous hypomania was experienced by 29 percent of the entire cohort; an additional 10.5 percent were hypomanic only while on antidepressants. The latter group had experienced significantly more psychotic features, greater suicide risk, a more chronic course with more previous hospitalizations, and more previous treatment with mood stabilizers, and were less responsive to lithium. Finally, in an interesting retrospective case-control study of 56 bipolar depressed patients on an antidepressant, Mundo and colleagues (2001) found that those with the short allele of the promoter region of the serotonin transporter gene experienced twice as many switches as those without that allele.⁴⁹

In summary, the most consistently reported predictors of antidepressant-related switching among patients with bipolar-I disorder are a history of multiple acute episodes (particularly those with a course characterized by the DMI sequence), exposure to multiple antidepressant trials, a history of previous antidepressant-related switches, a history of substance abuse, and isolated manic-like symptoms (“depressive mixed states”). Risk among patients with bipolar-II disorder is also associated with substance abuse and perhaps with psychotic features, but appears to differ from bipolar-I risk by its association with a more chronic course. In light of the two recent Stanley Network studies, it now appears likely that the relative risk is greater in bipolar-I than in bipolar-II, but more data are needed to settle this point, particularly with respect to long-term destabilization. For comprehensive reviews of clinical and demographic predictors of antidepressant-related switching, see Goldberg and Truman (2003) and Visser and Van der Mast (2005).

Related to switching is the phenomenon of conversion from a unipolar to a bipolar diagnosis, which bears on the question of which patients with unipolar depression might be vulnerable to an antidepressant-related switch. Examining the relationship between the likelihood of such a conversion and premorbid personality characteristics, Akiskal and colleagues (1995) followed 559 patients with major depressive disorders for up to 11 years.⁵⁰ They reported a “temperamental triad” of mood lability, energy/activity,

and “daydreaming” as being predictive of the conversion from unipolar to bipolar-II, but not to bipolar-I. This triad was associated with early age at first depression, chronicity, and a high rate of substance abuse. The association between early age at onset of unipolar depression and subsequent switch to a bipolar diagnosis has been noted in several studies.⁵¹ In the Akiskal et al. (1995) study just described, switching from unipolar to bipolar-I was associated with psychotic features when the patient was depressed, a finding that agrees with those of Kovacs (1996), Coryell and colleagues (1995), and Goldberg and Whiteside (2002).

Are there differences among the antidepressants in their propensity to precipitate switching? Among the older drugs there was some indication that, compared with MAOIs, tricyclics were associated with switches that occurred more rapidly and led to more severe dysphoric manias (Himmelhoch et al., 1991). The most important question today is whether the newer, second-generation drugs are associated with a lower prevalence of switching. Peet (1994) assessed manic symptoms in unipolar depressed patients taking part in clinical trials (some bipolar-II patients participated since DSM-III-R did not include that condition under bipolar illness) who were taking SSRI versus tricyclic antidepressants. To do so, he performed a post hoc analysis of data from randomized clinical trials of fluoxetine, fluvoxamine, paroxetine, and sertraline and comparison groups treated with tricyclics or placebo. He found switch rates below 1 percent in all the unipolar groups. The switch rate in the bipolar group taking an SSRI was not significantly different from that in the placebo group—about 4 percent—and was significantly lower than an 11 percent switch rate reported in the studies involving tricyclics. The relative position of the newer versus older drugs in this study is probably more valid than the absolute percentages because the database of clinical trials Peet examined reflected the result of vigorous efforts to screen out patients with mania/hypomania or even with risk factors for switching, such as a history of substance abuse. Also, as noted above, the ethical requirements of randomized controlled trials mean that patients with any sign or symptom suggesting the possibility of mania are very likely to be dropped from the study, resulting in the undercounting of manic switches. Therefore, it is not surprising that Peet’s post hoc analysis yielded results differing from those of some observational studies, including the work of Altschuler and colleagues (1995) and Ghaemi and colleagues (2004). For example, the latter study found that 49 percent of bipolar depressed patients switched within 2 months of starting a second-generation antidepressant (primarily SSRIs); most of these patients were also on a mood stabilizer.

In a study comparing desipramine and bupropion, Sachs

and colleagues (1994) found a switch rate in the tricyclic group five times higher than that in the bupropion group over a 1-year follow-up period (50 percent [5/10] versus 11 percent [1/9]). The authors therefore speculated that bupropion might be especially safe with respect to switching. Consistent with this speculation is the observation of Erfurth and colleagues (2002), who reported no switches with bupropion in a 4-week study of 13 bipolar patients on a mood stabilizer. However, the results of one nonrandomized study employing a much higher dose of the old immediate-release (IR) formulation (450 versus 200 mg) are at odds with the purported low incidence of mania following the initiation of bupropion. Fogelson and colleagues (1992) found that 6 of 11 bipolar patients taking lithium or an anticonvulsant developed hypomanic or manic symptoms when 450 mg of IR bupropion was added. However, 10 of these 11 patients had previously cycled into mania when prescribed an antidepressant, suggesting that this may have been a particularly vulnerable group, not representative of the larger population of patients with bipolar disorder. Also relevant here is the report of Goren and Levin (2000) on the case of a bipolar patient who did not develop manic symptoms until his dose of bupropion was raised to 600 mg/day. The authors reviewed several other case reports of manic symptoms associated with bupropion and concluded that the risk of inducing manic symptoms increases significantly in patients taking more than 450 mg/day.⁵²

What about venlafaxine? In our earlier review of efficacy studies, we cited the work of Vieta and colleagues (2002), who compared venlafaxine and paroxetine in bipolar depressed patients on a mood stabilizer. The rate of development of manic symptoms was four times higher in the venlafaxine group (13 versus 3 percent), a rate similar to that reported for tricyclics in other studies.⁵³ This result is consistent with that of a 10-week study from the Stanley Network (Post et al., 2003) (previously mentioned in our review of efficacy) in which 174 bipolar patients (73 percent bipolar-I) experiencing a breakthrough depression on lithium, valproate, or a combination of the two were randomized under double-blind conditions to bupropion, sertraline, or venlafaxine. While response and remission rates were similar with all three antidepressants, there were significantly more switches into mania/hypomania⁵⁴ with venlafaxine (29.2 percent) than with sertraline (8.6 percent) or bupropion (9.8 percent). If venlafaxine resembles the tricyclics in its tendency to precipitate manic symptoms, this may be due to its dual reuptake inhibition, both serotonergic and noradrenergic. However, in a short-term (6-week) study of venlafaxine monotherapy in 17 bipolar-II patients, Amsterdam (1998) observed no switches into mania.

Cycle Acceleration. In addition to the issue of acute switches following the initiation of antidepressants, antidepressants may be associated with increased cycling over the longer course of bipolar disorder. While maintenance treatment is the subject of the next chapter, we discuss here the effect of antidepressants on the long-term course of the illness since this is a key consideration in planning the acute treatment of bipolar depression. Indeed, compared with the issue of acute switching, of which most clinicians are well aware, we consider it even more important to emphasize the potentially damaging effects of cycle acceleration because it is a phenomenon so easily missed by clinicians who do not use life charting. Moreover, formal studies addressing cycle acceleration involve methodological challenges. As far back as 1965, the German literature reported that tricyclic antidepressants may cause destabilization, increasing the frequency of recurrences after the acute treatment of a depressive episode (Arnold and Krysprün-Exner, 1965; Till and Vuckovic, 1970). Furthermore, the very first report of an antidepressant (the MAOI iproniazid) cited rapid cycling following initiation of the drug (Crane, 1956). In the first edition of this text we reviewed a number of case reports, retrospective reviews, and uncontrolled prospective studies, as well as the placebo-controlled studies of Wehr and Goodwin (1979b) and Quitkin and colleagues (1981) (see below), all of which involved tricyclics (with some MAOIs included in the naturalistic studies). Taken together, the results of these studies were consistent with the conclusion reached by earlier observers, as were the more contemporary findings of Altshuler and colleagues (1995) (cited above in our discussion of acute switches). The latter authors studied 51 hospitalized bipolar-I patients retrospectively using life charting; 25 percent of the subjects experienced cycle acceleration while on tricyclics or MAOIs. Similar studies finding no such association have also been conducted (for a review see Altshuler et al., 1995). Nonetheless, the best data available—from both a small and a larger randomized clinical trial (see below)—indicate that cycle acceleration following the initiation of tricyclics does occur.

One factor that may contribute to the mixed results in the literature is that antidepressant-related cycling may be relatively gender specific, with females being more vulnerable. This confound was suggested by Yildiz and Sachs (2003), who found that among 129 bipolar patients, the association between subsequent cycling and prior antidepressant use held only for females. This finding is reminiscent of an earlier report by Quitkin and colleagues (1981), discussed above in the section on antidepressant-related switching.

Much of the literature examining the issue of increased cycling in bipolar disorder in apparent association with tricyclics or MAOIs has approached the question by attempting

to identify episodes of rapid cycling that are temporally related to initiation of the antidepressant. A large observational study of patients with bipolar disorder conducted by Coryell and colleagues (1992) found no association between periods of antidepressant use and rapid cycling. In this study, 919 patients were followed for at least 1 and up to 5 years, with semiannual evaluations; patients' treatment was monitored but not controlled by the study. Nearly 1 in 5 patients experienced a period of rapid cycling; after controlling statistically for episodes of major depression, the authors found that treatment with tricyclics or MAOIs "did not seem to anticipate rapid cycling" (p. 129). Rather, the authors suggested that an episode of major depression heralding a period of rapid cycling is a feature of the natural history of the illness, and that any association between antidepressant treatment and rapid cycling is thus an epiphenomenon. However, this conclusion appears to be overstated since the patients were not randomized to receive or not receive antidepressants, and it is impossible to know why clinicians chose to use or not use the drugs for some patients or at certain times.

In the first edition we made a similar point about the influential study of Lewis and Winokur (1982), who opened the debate when they reported no increase in switching or cycling among a group of bipolar patients receiving acute and continuation treatment with tricyclics chosen by the physician. The interpretation of their finding is quite problematic, however, in view of the high switch rate among the untreated controls (41 percent) and the variety of uncontrolled factors that could lead to such a high rate among patients whose

physicians chose not to administer antidepressants. The negative conclusion from this study was reinforced by Angst (1985), who, when reanalyzing his data on admission patterns from 1920 to 1982 (see Fig. 19–3), inexplicably combined the ECT-era data (with their expected high switch rates) with the data from the presomatic treatment era and concluded that switch rates did not increase after the introduction of tricyclics. In sum, controlled studies examining the course of bipolar disorder over the longer term have consistently identified patients in whom there appears to be a clear relationship between tricyclic antidepressants and acceleration of the illness cycle (see Table 19–9).

Wehr and Goodwin (1979a) presented data on a small group of patients closely followed prospectively over a period of years at NIMH in a placebo-controlled clinical trial. These patients entered and exited a series of double-blind studies in which they took lithium plus placebo or lithium plus tricyclics for periods of up to a year, thus serving as their own controls. When the length of the cycle (onset of mania to onset of mania) was compared for periods on and off antidepressants, a striking shortening of cycle became evident during periods of antidepressant therapy. Moreover, cycling slowed again when the antidepressant was stopped. Lithium provided no protection against cycling in these patients.

In a subsequent and larger controlled clinical trial, Wehr and colleagues (1988) found a similar temporal relationship between antidepressant treatment and shortening of the mood cycle in about half of a group of 51 patients with rapid-cycling bipolar disorder on lithium (see Table 19–9). The inability of a mood stabilizer to prevent tricyclic-related

TABLE 19–9. Randomized, Placebo-Controlled Studies of Antidepressant-Related Long-Term Mood Destabilization of Bipolar Illness

Study	Sample Size	Mean Duration of Follow-up (Months)	Treatments	Results
Wehr and Goodwin, 1979a	5	27	Lithium + desipramine vs. lithium + placebo	4 times more rapid cycling in lithium + desipramine treatment vs. lithium + placebo treatment alone
Quitkin et al., 1981	75	19	Lithium + imipramine vs. lithium + placebo	2.4 times more manic episodes in lithium + imipramine group vs. lithium + placebo group
Wehr et al., 1988	51	59	Lithium + tricyclics vs. lithium + placebo	33% higher rapid-cycling rate with lithium + tricyclics vs. lithium + placebo

Note: Long-term mood destabilization in these studies is limited to cycle acceleration, defined as two or more DSM-IV affective episodes during antidepressant treatment versus similar exposure times immediately before antidepressant treatment. The Quitkin and colleagues (1981) finding was a post hoc finding. Other randomized controlled trials with tricyclics failed to find evidence of worsened course in post hoc analyses. The Wehr and Goodwin (1979) and Wehr and colleagues (1988) studies were the only studies designed to assess prospectively the issue of antidepressant-induced mood destabilization, and they both found evidence for this association.

cycling was also noted in the randomized, double-blind, parallel-group comparison of lithium plus placebo versus lithium plus imipramine discussed earlier; over the 3 years of this prospective study, there were 2.4 times more manic episodes in the lithium plus tricyclic group than in those taking lithium plus placebo (Quitkin et al., 1981) (see Fig. 19-4). These placebo-controlled prospective trials represent the best data available for establishing that tricyclic-related cycle acceleration does indeed occur. The answer to the question of how frequently it occurs must come from larger naturalistic studies. As noted earlier, Altshuler and colleagues (1995) reported cycle acceleration occurring in about a quarter of recently hospitalized bipolar patients when their course of illness was studied retrospectively. Other observational studies have likewise reported frequent tricyclic-related cycle acceleration (for example, Koukopoulos et al., 1980).

What about the effects of the second-generation antidepressants on cycle length? Joffe and colleagues (2002) addressed this question in a prospective, open, naturalistic study of SSRIs and bupropion. They examined 113 individual antidepressant trials involving 69 bipolar-I and -II patients, identifying cycle shortening using the life-charting method developed by Post and colleagues (1986); patients were followed for at least 1 year. In 6 of the individual trials (7.8 percent), patients showed acceleration in their cycling. Of these 6 patient trials, 5 involved bipolar-I disorder, and all 5 were SSRI trials; all the patients were taking lithium or anticonvulsant medication or a combination thereof in addition to the antidepressant.

In two other naturalistic studies (Ghaemi et al., 2000, 2004) rates of antidepressant-related cycle acceleration were

23 and 25.6 percent, respectively, figures higher than those reported by Joffe and colleagues (2002) but very similar to data from the Stanley Network. In a year-long evaluation of the treatment of bipolar depression with adjunctive antidepressants, 39 percent of patients experienced at least one switch during the continuation phase, suggesting cycle acceleration (Post et al., 2003; Altshuler et al., 2006). In a subsequent analysis of the Stanley Network trial of the use of newer antidepressants for breakthrough depression in patients maintained on lithium, valproate, or a combination of the two (Post et al., 2006), 49–53 percent of patients met criteria for response, but switching and/or cycle acceleration (overall rate of 21 percent) was twice as likely among responders. As discussed earlier, bupropion had the most favorable ratio of response to switch/cycle acceleration, while venlafaxine had the least favorable. In a preliminary analysis of the STEP-BD data, Sachs and colleagues (2003) found that while depressive morbidity did not differ between bipolar patients given a second-generation antidepressant with a mood stabilizer and those given a mood stabilizer alone, the antidepressant-treated patients experienced 60 percent more manic episodes. Sachs and colleagues (2004) coined the term “roughening” to describe destabilization involving mood lability of an amplitude that does not reach criteria for an episode of depression or mania, but there have not yet been quantitative studies of this phenomenon. Here it is worth recalling the STEP-BD study described earlier (Filkowski et al., 2006; Ghaemi et al., 2006), in which bipolar patients randomized to antidepressant continuation did no better (in terms of overall mood morbidity over 1 year) than those on a mood stabilizer alone, and in fact experienced more rapid relapse and more manic episodes, albeit fewer full depressive episodes.⁵⁵

In another independent examination of data from STEP-BD, Goldberg and Truman (2003) found that a switch into mania/hypomania was observed in 19.5 percent of 1,250 antidepressant trials within 3 months of initiation of the antidepressant. These antidepressant “switchers” were more likely to switch again if reexposed to another antidepressant of the same class. By contrast, a recent naturalistic prospective study of 80 bipolar-I and -II patients, 47 of whom were taking antidepressants (92 percent were second-generation drugs), found no more switches or cycling in those on antidepressants (Bauer et al., 2005). The incidence of switching and rapid cycling did not differentiate bipolar-I from -II. It is important to note that 89 percent of those taking antidepressants were also taking at least one mood stabilizer. Of interest, patients on antidepressants in this naturalistic setting reported more depression than those not on antidepressants. Of course, as we observed previously, it is impossible in a naturalistic study of this kind to know what factors may have influenced the decisions of

Figure 19-4. Inability of mood stabilizer to prevent antidepressant-related cycling during a 3-year randomized double-blind prospective study. Note: Average relapse time was 7–19 months, reflecting cycle induction rather than acute switching. (Source: Quitkin et al., 1981.)

individual clinicians to use or not use antidepressants in a particular patient (confounding by indication).

Although not absolutely conclusive, results of the available studies indicate that at least some patients with bipolar disorder experience an acceleration of their illness during periods of treatment with antidepressants and that for many if not most patients, this effect is reversible when the antidepressants are stopped (Wehr and Goodwin, 1979b; Wehr et al., 1988). As is apparently the case with the induction of mania and hypomania by antidepressants, cycle acceleration may be more common in bipolar-I than in bipolar-II patients, although this has not been established by comparative controlled trials. Rates associated with SSRIs may not be lower than those associated with tricyclics or MAOIs, and results of one study suggest that the risk may actually be higher (Goldberg and Truman, 2003). In contrast to switches, the risk of cycle acceleration may not be reduced by simultaneous treatment with lithium or anti-convulsant medications, although further research on this critical question is clearly needed.

It is often assumed that cycle induction must involve manic or hypomanic symptoms. But in patients taking a combination of an antidepressant and an effective antimanic mood stabilizer, the mood stabilizer may well prevent the manic symptoms, so that the underlying cycle is evidenced only by an increased frequency of depressive episodes. Finally, a frequently observed phenomenon that may reflect cycle induction is the development of tolerance to an antidepressant; that is, rather than being viewed as a loss of the effect of the antidepressant, tolerance can just as easily be thought of as the medication's ongoing effect—driving the cycle and bringing the next natural episode closer. Thus in a previously mentioned observational study of 40 bipolar and 38 unipolar patients (Ghaemi et al., 2003c), loss of effectiveness after response was noted in 57 percent of the bipolar patients but only 18 percent of the unipolar patients. Consistent with this observation are the findings of Sharma and colleagues (2005), who studied clinical characteristics of 61 depressed patients initially referred as unipolar with a history of loss of response to at least two antidepressants. On follow-up and reevaluation, 80 percent of these patients were found to have DSM-IV bipolar disorder or met criteria for bipolar spectrum disorder by the criteria of Ghaemi and colleagues (2002).

Antipsychotics

Prior to the introduction of the newer atypical antipsychotic agents, the literature on the use of antipsychotic medications in the depressed phase of bipolar disorder was quite sparse. In one open study, flupenthixol decanoate was given to 30 lithium-intolerant periodic and cyclic de-

pressive patients, some of whom had a history of mania, and was found to have a “prophylactic effect . . . similar to the effect of lithium salts” (Kielholz et al., 1979, p. 307). Consistent with this finding, several retrospective studies have reported depressive relapse in patients with bipolar disorder after discontinuation of typical antipsychotics (see, e.g., Hendrick et al., 1994). On the other hand, as noted in the previous chapter, the treatment of mania with typical antipsychotics alone was not infrequently followed by a postmania depressive episode.

The use of atypical antipsychotics in the treatment of depression has drawn increasing interest. In case reports and open studies, these agents appear to have beneficial effects when added to SSRI and MAOI antidepressants (for a review see Thase, 2002). A randomized, double-blind clinical trial found an olanzapine–fluoxetine combination to be superior to either agent alone in nonpsychotic treatment-resistant depressed patients (Dube et al., 2002).

With regard to bipolar depression, in the largest randomized clinical trial ever conducted in this population ($n = 833$), olanzapine monotherapy was found to be superior to placebo. The effect size was quite modest, however, and the bulk of the improved rating items related to sleep and appetite rather than to core mood symptoms. On the other hand, combination of olanzapine and fluoxetine (included in the Cochrane analysis discussed above) was found to be substantially superior to placebo and to olanzapine alone (Tohen et al., 2002), with an effect size equivalent to that for lamotrigine and, like lamotrigine, producing improvement in core depressive symptoms (Williamson et al., 2006). During the 8-week duration of the study, the switch rate was low and comparable in all three groups, and it stayed low (5.9 percent) throughout a subsequent 24-week open-label extension study (Corya et al., 2006). A fixed-dose olanzapine–fluoxetine combination (OFC-Symbyax) has been approved by the FDA as a treatment for bipolar depression. Recently, OFC was compared head to head with lamotrigine in a 7-week randomized double-blind trial in 410 bipolar-I depressed patients. While there was no significant difference in response rates,⁵⁶ time to response showed an advantage for OFC, as did the extent of reduction in MADRS ratings and CGI severity scores. However, there were significantly more side effects with OFC (somnolence and sedation, increased appetite, weight gain, dry mouth, and tremor), as well as higher levels of triglycerides and cholesterol. Indeed, the seriousness of the weight gain and metabolic problems associated with some atypicals (especially olanzapine and OFC) has to be taken into account when assessing the risk/benefit ratio of these drugs; this point is made in the most recent set of guidelines for the treatment of bipolar depression, the Texas Algorithm (Suppes et al., 2005).

Evidence for the efficacy of another atypical—quetiapine—in the treatment of depressive symptoms in a variety of psychotic and mood disorders (including bipolar disorder, rapid-cycling bipolar disorder, and adolescent mania) has been reported in several open-label studies.⁵⁷ More recently, two large randomized, placebo-controlled trials revealed robust antidepressant effects for quetiapine in bipolar patients. These 8-week multisite studies involved a total of 506 bipolar depressed patients (339 on quetiapine and 167 on placebo; two-thirds bipolar-I, one-third bipolar-II) (Calebresse et al., 2005). The first study found a 58 percent response rate (greater than 50 percent decrease in MADRS scores) compared with 36 percent for placebo; the rate for remission (decline in MADRS scores of less than 12) was 53 percent for quetiapine versus 28 percent for placebo. The core depressive items on the MADRS scale⁵⁸ showed significant separation from placebo ($p < .001$). Onset of action was rapid, with separation from placebo at the end of week 1; both doses of quetiapine—300 and 600 mg—were roughly equivalent in efficacy, but side effects (dry mouth, sedation/somnolence, dizziness, constipation) were more common at the higher dose. The effect size with the 300 mg dose was equivalent to that achieved with the olanzapine–fluoxetine combination (OFC), and at 600 mg it exceeded the latter results. However, the magnitude of the quetiapine effect was substantially reduced when the items related to insomnia and anxiety were removed from the analysis. Similar results were obtained in the replication study (Hirschfeld et al., 2006), and the FDA has now approved quetiapine for the treatment of bipolar depression.

It is important to note that studies of DSM-IV-defined bipolar depression (such as the above quetiapine studies) can include patients with up to three manic-like symptoms (because of the strict DSM-IV definition for a mixed episode, that is, meeting full criteria for both mania and depression). Whether these “depressive mixed-state” patients may respond preferentially to antipsychotics has not yet been reported, but the possibility should be assessed. Most formal studies of antipsychotics in mixed states per se use the DSM-IV criteria and therefore involve dysphoric mania rather than depressive mixed episodes, but such data may still have relevance to the evaluation of these agents as possible antidepressants. For example, Gonzalez-Pinto and colleagues (2001) compared two groups of patients with dysphoric mania, all of whom were treated with either valproate or lithium but also took either typical antipsychotics (haloperidol and/or levomepromazine) or an atypical (olanzapine). Patients treated with the adjunctive atypical had statistically significant reductions in HAM-D scores (as well as Young Mania Rating Scale scores) compared with those who took the typical antipsychotic.

Other atypical antipsychotics, including clozapine, risperidone, ziprasidone, aripiprazole, and amisulpride (which is available in Europe but as of this writing not in the United States), have, to varying degrees, been shown to be effective in ameliorating depressive symptoms in patients with schizophrenia, and for some of these drugs, when used adjunctively, there is evidence of efficacy in treatment-resistant depression. Some are now undergoing testing in bipolar depression. Whether monotherapy with some atypical antipsychotic agents will turn out to be sufficiently robust to achieve remission in the majority of patients with bipolar depression remains an open question.

Electroconvulsive Therapy

There is an extensive literature on the use of ECT in the treatment of major depression (see Fink, 2001, for a review, and Abrams, 1997, for a comprehensive discussion). Approximately 50 years after the introduction of ECT, Janicak and colleagues (1985) conducted a careful meta-analysis of 25 studies selected for their rigorous methodology, which together included more than 1,200 patients. These studies variously compared ECT with simulated ECT, placebo, tricyclics, and MAOIs and found indisputable evidence of the superiority of ECT over all these other treatments for severe depression. Most of these studies included patients with both unipolar and bipolar illness. This conclusion was reinforced by the most recent and most extensive meta-analysis comparing ECT with pharmacotherapy, conducted by the UK ECT Review Group (2003). Examining 18 trials (1,144 patients), they found that ECT was significantly better than antidepressant medication. As noted earlier, ECT has been shown to be a safe and especially effective treatment for elderly patients, including the very elderly (Salzman et al., 2002); it has also proven to be safe in pregnant patients (Miller, 1994) and even those with intracranial mass lesions (Zwil et al., 1990). Indeed, one can find reports of ECT having been administered to patients safely and successfully regardless of almost any imaginable medical or psychiatric complication.

There is a modest amount of data on the use of ECT specifically to treat bipolar depressed patients. Zornberg and Pope (1993) reviewed nine studies of the use of ECT in 723 such patients. Of the seven trials comparing ECT with antidepressant agents, five found it be more effective. ECT appears to be equally effective for unipolar and bipolar depressed patients. Daly and colleagues (2001) compared the response rates and rapidity of response to ECT in 228 patients with unipolar and bipolar-I and -II depression who were participating in three different protocols. There was no difference in efficacy rates⁵⁹ among the diagnostic groups, although the bipolar patients who responded to ECT needed fewer treatments than the unipolar responders.

Grunhaus and colleagues (2002) also found no unipolar–bipolar differences.

It appears that clinically significant ECT-induced mania is rare. Given that ECT is a highly effective treatment for mania, this is perhaps not surprising. Nevertheless, there have been a number of case reports of mania and hypomania following ECT (see, e.g., Serby, 2001), and one case series found that about a third of 57 patients with depression (unipolar or bipolar not specified) treated with ECT had hypomanic symptoms following their course of treatment (Koukopoulos et al., 1980). In another retrospective chart review study, however, the switch rate into mania or hypomania in hospitalized bipolar patients who had received ECT did not differ from that in bipolar patients who had not received the therapy (Angst et al., 1992). The evidence for cycle induction or acceleration caused by ECT per se is even less convincing, especially since most patients who receive ECT are treated with antidepressants either during or following the therapy (see Koukopoulos et al., 1980).

Novel Central Nervous System Stimulation Techniques

Transcranial Magnetic Stimulation

Transcranial magnetic stimulation (TMS) takes advantage of a principle of electromagnetism first demonstrated in 1831 by the British physicist Michael Faraday: one can induce an electrical current in a conductor by bringing a changing magnetic field in close proximity to it. In TMS, an apparatus that develops a rapidly changing magnetic field is applied to the scalp (hence the more common name for the technique—rapid transcranial magnetic stimulation, or rTMS) to induce a small current in underlying neural tissue (see Daskalakis et al., 2002, for a review). Unlike ECT, rTMS does not produce a seizure⁶⁰ or even alteration of consciousness, and thus can be carried out without anesthesia on individuals with only the most minimal discomfort from scalp tingling and the noise generated by the apparatus. The technique has been used for neurophysiological studies and is increasingly being used as a treatment for depression and other psychiatric conditions.

Because sham rTMS is easily performed, it has been possible to carry out placebo-controlled studies of the treatment. In a comprehensive review and meta-analysis of 23 randomized controlled studies of rTMS in treating depression, Burt and colleagues (2002) noted that the effect was highly significant statistically, and the average effect size was substantial, raging from .67 to .79. This is essentially the same conclusion reached in an earlier meta-analysis of 12 studies by Holtzheimer and colleagues (2001).⁶¹

As with other new interventions for treating depression, the literature on rTMS is evolving. The current lack of

consistency regarding the size of the effect across studies may be due to differences in technique (right- versus left-side stimulation, for example) and overselection of treatment-resistant patients for some studies, as well as other factors. The ultimate role of rTMS in the treatment of mood disorders is far from clear, but the results of controlled studies thus far are encouraging. There have been two small studies involving patients with bipolar depression. In the first, Dolberg and colleagues (2002) randomized 20 patients to TMS or sham TMS (5 sessions per week); by the end of the second week, the TMS group showed a greater reduction in HAM-D ($p < .05$) and BPRS ($p < .01$) scores compared with the sham group. In a subsequent study of bipolar depression (Nahas et al., 2003), left prefrontal TMS showed only a nonsignificant trend to outperform the sham condition, but there were too few subjects ($N = 23$) to rule out a type II error.

Other types of magnetic stimulation may turn out to be helpful in the treatment of bipolar depression. Rohan and colleagues (2004) investigated the antidepressant effects of exposure to magnetic stimulation less intense than that of the rTMS technique, spurred by the serendipitous observation of mood improvement in subjects with bipolar depression who had volunteered for a neuroimaging study of bipolar disorder. Echo-planar magnetic resonance spectroscopic imaging (EP-MRSI) is a neuroimaging technique that also employs oscillating magnetic fields, but the magnetic force generated is weaker and more generalized than that in rTMS. Significant differences in mood improvement were observed in subjects who received actual EP-MRSI compared with those receiving sham EP-MRSI (Rohan et al., 2004).

Vagus Nerve Stimulation

Zabara (1988) first demonstrated that experimental seizures in dogs could be ameliorated by electrical stimulation of the vagus nerve (cranial nerve X), and in 1988, the first vagus nerve stimulator was implanted in a human patient to treat epilepsy. The sensory connections of the vagus project to many brain regions, including the locus coeruleus and other regions implicated in the regulation of mood. After antidepressant effects were reported in patients who had received a vagus stimulator, interest developed in vagus nerve stimulation (VNS) as a treatment for depression, and the first VNS device was implanted in a patient to treat depression in 1998. In VNS, a programmable electrical pulse generator (much like a cardiac pacemaker) is implanted subcutaneously in the chest wall, and a lead is connected to the left vagus nerve near the carotid artery in the neck. (For reviews of VNS, see George et al., 2000, and Krahl et al., 2004.)

Rush and colleagues (2000) conducted an open multicenter study of 21 unipolar, 4 bipolar-I, and 5 bipolar-II

patients with treatment-resistant major depressive episodes. They found that 40 percent achieved at least a 50 percent reduction in symptoms (as measured by the HAM-D and MADRS) after 10 weeks of VNS. Analysis of the efficacy of VNS in this group, expanded by the addition of another 29 patients (for a total of 59, including 6 bipolar-I and 10 bipolar-II subjects), found similar results—a 31 percent response rate with a 15 percent remission rate (Rush et al., 2005)—but those with the most treatment resistance (having failed 7 or more antidepressant trials) did not benefit (Sackeim et al., 2001). In a 1-year follow-up of those completing 3 months of acute treatment, the benefits of VNS were sustained, and there was some indication of additional benefit, with a significantly increased proportion of these patients achieving remission from their symptoms—29 percent versus 17 percent in the original 10-week study (Marangell et al., 2002). In a subsequent 2-year follow-up of the same cohort, Nahas and colleagues (2005) confirmed that the response rate at 1 year surpassed that at 3 months (31 percent versus 44 percent), with the additional improvement persisting at 2 years (42 percent response rate). The same collaborative group (George et al., 2005) compared the 1-year results of Marangell and colleagues (2002) with those achieved in a separate study of patients with treatment-resistant depression receiving similar treatment as usual (TAU); the patients in this 1-year observational study of TAU had baseline clinical characteristics and demographics that were statistically comparable to those of the patients in the VNS study. VNS plus TAU was superior to TAU alone as assessed by monthly improvement in the self-rated Inventory of Depressive Symptomatology (IDS-SR) across 12 months ($p < .001$) or by response rates (last observation carried forward [LOCF] analysis of changes in HAM-D scores): 27 percent for TAU plus VNS versus 13 percent for TAU alone ($p < .01$); post hoc analysis revealed no unipolar–bipolar difference in response to VNS.

In the largest controlled study of acute VNS to date, Rush and colleagues (2005) randomized 235 patients with treatment-resistant depression⁶² to VNS or sham VNS for 10 weeks. While the primary outcome variable—response as measured by a 50 percent decline in HAM-D score (LOCF analysis)—did not show a significant difference between VNS (15.2 percent response rate) and sham treatment (10 percent response), a secondary outcome—IDS-SR—did (17 percent versus 7.3 percent response rate, $p = .032$, by LOCF analysis). Thus it appears that VNS, especially when evaluated over 1 year or more, is somewhat more effective than TAU for a very difficult-to-treat group of patients, many of whom have bipolar or recurrent unipolar depression. A VNS device has been approved by the U.S. FDA for just such patients and is now marketed by Cyberonics.

Dopamine Agonist Agents

The role of dopaminergic agents in the treatment of mood disorders is evolving, and preliminary data are encouraging. Several currently available antidepressants (bupropion, sertraline, and venlafaxine) inhibit presynaptic dopamine reuptake to varying degrees. One selective dopamine reuptake inhibitor, nomifensine, was marketed as an effective antidepressant for about 10 years in Europe and more briefly in the United States before being withdrawn because of associated hemolytic anemia.

Bromocriptine, a dopamine agonist used in the treatment of Parkinson's disease, has been reported to be an effective antidepressant in several small studies comparing it with tricyclic antidepressants in patients with major depressive disorder (see Perugi et al., 2001, for a review). The drug has never gained wide acceptance as an antidepressant, however, perhaps because it lacks clear superiority over available agents and is associated with a substantial side-effect burden. Pergolide, a dopamine agonist 20 to 30 times more potent than bromocriptine, has been used to augment antidepressant treatment of major depression in both unipolar and bipolar patients. In one open study, 11 of 20 refractory depressed patients experienced improvement when pergolide was added to either a tricyclic or MAOI. Transient hypomanic symptoms in some patients responded to lowering the dose of the drug (Bouckoms and Mangini, 1993).

The antidepressant effects of pramipexole, another potent dopamine agonist that has been used to treat Parkinson's disease, have also been investigated in both unipolar and bipolar patients. A number of case reports and open studies indicate those effects to be significant, especially when the drug is combined with other agents. In one of these open trials, a related compound, ropinirole, showed similar results. In a retrospective evaluation of 32 unipolar and bipolar patients treated with pramipexole for depression for an average of 6 months, there was only one case of transient hypomania (Sporn et al., 2000). And in the first double-blind, randomized clinical trial of pramipexole in treating bipolar depression, Goldberg and colleagues (2004) found it to be significantly superior to placebo and reported a mania/hypomania switch rate of 7 percent. A second randomized, placebo-controlled study involving 21 patients with bipolar-II disorder found a 60 percent response rate (greater than 50 percent decrease in MADRS score) for pramipexole compared with 9 percent for placebo; 1 patient developed hypomania, compared with 2 in the placebo group (Zarate et al., 2004). Ironically, there are more data from randomized, double-blind, placebo-controlled trials for the efficacy and safety of pramipexole in bipolar depression than for all but one standard antidepressant

(paroxetine), yet the other standard antidepressants are used much more extensively than pramipexole.

Psychostimulants

The use of amphetamine drugs and related compounds, such as methylphenidate, in the treatment of symptoms of depression has a long history. These agents have been used alone, as well as in conjunction with antidepressant and other psychotropic agents, for several decades in the treatment of mood disorders, and a large but often rather confusing body of literature is frequently cited in support of these uses. The verdict on stimulants as the sole agents for treating major depression is, however, quite clear. In a review of the literature on the use of stimulants as monotherapy for the treatment of primary depressive disorders, Satel and Nelson (1989, p. 248) concluded that these agents “demonstrated no significant advantage over placebo in the treatment of primary depression.” Nevertheless, a large body of literature supports the use of stimulants to treat depressive symptoms for patients with debilitating medical conditions in which fatigue and lethargy are prominent features, such as acquired immunodeficiency syndrome (AIDS) (Wagner and Rabkin, 2000), as well as for those who experience the opiate-related fatigue and somnolence that occur in the palliative care of patients with cancer (see Rozans et al., 2002, for a review). Whether the improvement seen in these patients can be called an antidepressant effect or simply the amelioration of primarily somatic depressive symptoms seen in seriously ill patients is a matter of debate, however. The lack of significant and sustained efficacy in patients who have more uncomplicated depression would appear to argue for the latter conclusion.

Several case reports and open series support the use of stimulants as an augmentation strategy in patients with major depression who have only a poor or incomplete response to antidepressant medications. Stoll and colleagues (1996), for example, reported on five patients who cited robust symptom reduction when methylphenidate was added to SSRI antidepressants. The literature on the use of stimulant medications in treating bipolar depression is very limited, however, perhaps in part because of clinicians’ reluctance to report their experiences treating patients with a controlled substance. A retrospective chart review of eight adolescent bipolar patients (both bipolar-I and -II) treated consecutively with adjunctive stimulants for comorbid attention-deficit hyperactivity disorder (ADHD) indicated moderate symptomatic improvement and substantial functional improvement, with no evidence of switching or abuse (Carlson et al., 2004). Still, a number of case reports suggest that stimulants can induce manic and hypomanic states (see Lake et al., 1983, for a review), and this work is often cited as a reason to avoid the use of these

drugs in bipolar patients. In one open case series, when methylphenidate was added to an existing mood stabilizer in 15 bipolar patients experiencing a breakthrough depression, a 56 percent mean reduction in MADRS scores was observed over the next 3 weeks. However, 20 percent of the patients dropped out because of hypomania or anxiety/agitation (El-Mallakh, 2000). This issue is an important one in planning the treatment of children or adolescents with bipolar disorder because of the comorbidity of bipolar disorder and ADHD in these age groups and because of suggestive evidence that stimulants may hasten the onset of bipolar disorder in children (see Chapter 23).

Modafinil is a novel psychostimulant that has less dopaminergic activity and appears to have less abuse potential than older stimulant medications. In a retrospective case series of seven patients who took modafinil as an adjunct to antidepressant medication, three patients with bipolar depression achieved full or partial remission (Menza et al., 2000). A subsequent prospective trial (DeBattista et al., 2004) indicated that among 33 patients whose major depression had been only partially responsive to 4 weeks of antidepressant use, there was a rapid and significant improvement in both fatigue and overall depressive symptoms for the group as a whole ($p < .0001$). This was followed by a large ($N=314$), multicenter, 8-week randomized, placebo-controlled study of adjunctive modafinil (200 mg) among partial responders to SSRIs with persistent fatigue/sleepiness (Fava et al., 2005); compared with placebo, modafinil was associated with significantly more improvement on the CGI scale. To our knowledge, there has been only one controlled study of adjunctive modafinil in bipolar depression (Frye et al., 2005). Among the 41 patients randomized to modafinil (100–200 mg/day), there were significantly more responders than among the 44 placebo patients ($p = .038$), with no difference in manic switches. The absence of switches was also noted in a retrospective chart review of 39 bipolar patients who received modafinil at some point during their treatment (Nasr et al., 2006). However, we should note that two cases of manic-like symptoms have been reported among patients taking this drug (Ranjan and Chandra, 2005).

Hormonal Agents

Hypothalamic–Pituitary–Thyroid Axis

There is a substantial literature on the use of thyroid hormones in the treatment of mood disorders, as well as on the interrelationships between mood disorders and abnormalities of the hypothalamic–pituitary–thyroid axis. A higher-than-expected prevalence of clinical and subclinical hypothyroidism, elevations of circulating antithyroid antibodies, and levels of fT_4 significantly lower than those

of controls have all been reported in patients with bipolar disorder.⁶³

The early reports of Gjessing (1938) (from the prelithium era) that hypermetabolic doses of thyroid hormone could stabilize periodic catatonia (now thought to be related to bipolar disorder) represented the first suggestion that thyroid enhancement could affect behavioral or mood stability. Since then, virtually all of the data on the subject have related to adjunctive use of thyroid hormone, generally T_3 in acute depression and T_4 in maintenance treatment.

Results of open and placebo-controlled studies conducted over several decades support the adjunctive use of T_3 for patients unresponsive to antidepressants alone. The positive results of the first controlled study of this combination treatment (Goodwin et al., 1982) were confirmed by most subsequent studies, as indicated by a meta-analysis (Aronson et al., 1996) that examined eight studies involving a total of nearly 300 patients with depression refractory to tricyclic antidepressants whose treatment was augmented with T_3 . The authors concluded that this strategy effectively doubled the response rate compared with that of control groups, but also cautioned that the various studies were uneven in quality and, although encouraging, could not be considered definitive. In another analysis of this literature, Joffe (1992) concluded that the addition of T_3 was an effective augmentation strategy in 55–60 percent of tricyclic-refractory depressed patients. Reports of successful augmentation of SSRIs (Joffe, 1992; Abraham et al., 2006) and MAOIs (Joffe, 1988) have appeared as well.

Another treatment strategy involving thyroid hormone is the use of T_3 to accelerate the response of depressive symptoms to antidepressant medications. A meta-analysis of this literature by Altshuler and colleagues (2001b) included six placebo-controlled studies in which “relatively untreated” depressed patients (unipolar or bipolar not specified)—that is, patients who had not been selected for refractory depressive symptoms—were started on T_3 along with amitriptyline or imipramine. It was found that patients who started on 20–25 micrograms (μg) of T_3 along with a tricyclic experienced a statistically significant acceleration of their treatment response compared with those who did not receive the thyroid hormone. It was also found that the effect size of this intervention increased as the proportion of female patients in the studies increased.

It has been proposed that the augmentation effect of T_3 on antidepressant treatment is the result of an interaction between thyroid hormone and serotonergic neurotransmitter systems. This hypothesis is based on various findings—for example, that administration of T_3 to animals results in increased cortical serotonin concentration and reduced sensitivity of auto-inhibitory 5-hydroxytryptamine (1A) (5-HT_{1A}) receptors in the raphe area (see Bauer et al., 2002).

It has also been postulated that the benefits of thyroid hormones in treating depression derive from their effect on subtle thyroid dysfunction that might be clinically insignificant in persons who are not depressed. Cole and colleagues (2002) examined the relationship between pretreatment thyroid hormone levels and time to treatment response in 65 depressed bipolar-I patients and found a significant association between lower-normal fT_4 index (FTI) and higher-normal TSH levels. Patients with FTI values above the mean and TSH values below the mean experienced remission of their symptoms an average of 4 months sooner than other patients in this group. The authors concluded that nearly two-thirds of bipolar patients may have a thyroid profile that, although technically in the normal range, is nevertheless inadequate for an optimal treatment response. They cited these results in support of the hypothesis that the low-normal thyroid functioning seen in some patients represents an inadequate homeostatic response to the stress of a depressive episode. Similar results come from a recent chart review of 135 bipolar-I patients on maintenance medication (primarily lithium), which revealed that the 36 percent with chemical evidence of hypothyroidism, compared with those without such evidence, spent significantly longer in acute treatment and had significantly higher HAM-D scores during maintenance treatment (Fagiolini et al., 2006).

The use of supraphysiological thyroid hormones in the treatment of bipolar disorder has also been the subject of considerable interest, primarily for patients with rapid-cycling mood episodes, but also for depressed patients (Bauer and Whybrow, 1986, 1990; Whybrow, 1994). After noticing what appeared to be a more rapid response of depressive symptoms to high-dose T_4 in treatment-resistant, non-rapid-cycling bipolar patients, Bauer and colleagues (1998) conducted an open trial of a high-dose T_4 augmentation strategy. In this study, 17 patients with major depression (12 with bipolar depression) who were taking various combinations of antidepressants, lithium, and anticonvulsants were started on T_4 , with the dose gradually being raised to 500 mg/day, double the usual maximum recommended dose for the treatment of hypothyroidism. Of the 17 patients, 10 experienced remission (defined as a greater than 50 percent reduction in HAM-D scores, with a final score of less than 9) within 12 weeks of starting on high-dose T_4 . In open-trial investigations of high-dose T_4 treatment by this same group, approximately 50 percent of patients with treatment-resistant depression of a mean duration of more than 15 months experienced remission (defined as above) (Rudas et al., 1999). Patients with nonrapid but nevertheless “intractable” bipolar cycling experienced a significant reduction in the number of mood episodes when T_4 was added to other treatments.

Although the importance of normal thyroid functioning for the regulation of mood appears clear, the mechanisms by which thyroid function, dysfunction, and manipulation affect mood are unclear, and apparent contradictions abound. It is well known, for example, that depression can be a symptom of both hyperthyroidism and hypothyroidism. The administration of thyroid hormones, sometimes in supraphysiologic doses, to some depressed patients is effective in treating depression. Yet increased levels of T_4 are consistently reported in association with major depression, and a reduction of circulating T_4 (free and/or total) is seen after successful treatment with ECT, antidepressants, and bright light, as well as after cognitive psychotherapy (see Bauer et al., 1998).

Whether the addition of thyroid hormones to other treatments for depression corrects a subtle thyroid dysfunction in some patients, sensitizes a target cortical system important to mood regulation through manipulation of monoamine mechanisms, or works by some other as yet unknown mechanism remains to be elucidated. (These issues are also discussed in Chapter 20.)

Hypothalamic–Pituitary–Adrenal Axis

Abnormalities in the functioning of the hypothalamic–pituitary–adrenal (HPA) axis have been reported in association with mood disorders for several decades (see Chapter 14). Elevated plasma cortisol levels in depressed patients were first reported in the 1950s. Subsequent investigations have demonstrated in depressed patients elevated cortisol levels in the urine and cerebrospinal fluid, enlarged pituitary and adrenal glands, and a loss of the normal circadian rhythm of cortisol secretion by the adrenal gland (as demonstrated by a positive dexamethasone-suppression test). This HPA overactivity is thought to be caused by oversecretion of corticotropin-releasing hormone (CRH) by the hypothalamus, possibly in response to a dysfunction of glucocorticoid receptors in patients with mood disorders.⁶⁴ Chronically high levels of circulating glucocorticoids have been implicated in the mood symptoms and cognitive impairment seen in depressed patients.

Cortisol-lowering agents have been used to treat unipolar and bipolar depressed patients, with mixed results. Ketoconazole has been the most frequently investigated cortisol-lowering drug, but aminoglutethimide and metyrapone have been used as well. Case reports and small open series in unipolar and bipolar depressed patients have shown encouraging results, with some patients experiencing dramatic and long-lasting symptom remission (see Brown et al., 2001, for a review). One small placebo-controlled study found significant reductions in HAM-D scores in nine patients with major depression (unipolar or bipolar not specified) treated with ketoconazole monotherapy for 4

weeks compared with patients given placebo, but only in those patients who were hypercortisolemic prior to participating in the study (Wolkowitz et al., 1999a). Another placebo-controlled study found no advantage of ketoconazole over placebo (Malison et al., 1999).

Substantial risks of hepatotoxicity and hypoadrenalism have limited the investigation and routine clinical use of cortisol-lowering agents. Nevertheless, because of the striking and consistent findings of glucocorticoid abnormalities in patients with mood disorders, interest in the HPA axis as a therapeutic target remains high. Substantial work on corticotropin-releasing factor (CRF) antagonists is ongoing (see Holsboer, 2001), and the glucocorticoid receptor antagonist mifepristone (RU-486) has been investigated as well (see Wolkowitz and Reus, 1999, for a review of the use of various antiglucocorticoid agents).

Dehydroepiandrosterone (DHEA) is a steroid compound secreted by the adrenal gland that, along with its sulfate-ester metabolite (DHEA-S), is one of the most abundant circulating adrenal hormones. DHEA and DHEA-S are precursors to testosterone and estrogen and have been proposed to have a broad range of effects on mood. DHEA levels progressively decrease after age 30, and treatment with supplemental DHEA has been reported to increase the sense of well-being in aging men and women. DHEA acts as an antiglucocorticoid and has been shown in animal studies to counteract deleterious neuronal effects of cortisol. Young and colleagues (2002) found an elevated cortisol/DHEA ratio in 39 drug-free unipolar depressed patients compared with 41 healthy comparison subjects. In a small double-blind study, DHEA either alone or with an antidepressant effected a greater than 50 percent decrease in HAM-D scores in about half of depressed patients and none of those receiving placebo. This study included two bipolar-II depressed patients, but the authors did not report which group they were assigned to or whether they were responders (Wolkowitz et al., 1999b).

DHEA is widely available in vitamin stores and supermarkets in the United States as a dietary supplement and is promoted as an antiaging compound that enhances mood, immune functioning, and even libido. Younger persons, especially young men, also take DHEA because of its reported effect of increasing muscle mass. There have been several case reports of mania in individuals with bipolar disorder (Dean, 2000), as well as in those with no previous psychiatric history (Kline and Jagers, 1999), who started taking DHEA. Decisions on its use in men over 50 should take into account a possible increase in the risk of prostate cancer related to any elevation of androgen levels.

While the potent effects of various glucocorticoids in producing or exacerbating affective syndromes have been clearly demonstrated, elucidation of the mechanisms of

these effects remains speculative. The rational therapeutic use of pharmaceutical manipulation of the HPA axis to ameliorate mood disorder symptoms has thus far proven an elusive goal.

Hypothalamic–Pituitary–Gonadal Axis

As with the other endocrine systems discussed above and in Chapter 14, clinical research and epidemiological data clearly indicate that the physiology of the hypothalamic–pituitary–gonadal (HPG) endocrine axis is important in mood disorders. The increased prevalence of depressive illness in women and the striking vulnerability of women with bipolar disorder to manic episodes during the postpartum (puerperal) period are but two examples of the probable influence of this system on mood. The mechanisms of these influences are, however, even more obscure than in the case of other endocrine systems. HPG abnormalities in patients with mood disorders have yet to be convincingly demonstrated, in either women (for an overview see Young and Korszun, 2002) or men (see Schweiger et al., 1999).

There is some evidence that depressive symptoms in women who also have low serum estrogen levels can be ameliorated by the administration of estrogen. Several open studies have demonstrated the benefits of estrogen therapy in women with postpartum depression. Ahokas and colleagues (2001) found that the administration of β 17-estradiol reduced MADRS scores from a mean of over 40 to 11 in 23 postpartum women who had abnormally low serum estrogen levels. The authors found similar results in 10 women with postpartum psychosis also having abnormally low estrogen levels (Ahokas et al., 2000). Although these studies did not include women diagnosed with bipolar disorder, their findings may have some relevance to the treatment of bipolar depression, given the high risk of developing mania during this period for women with bipolar disorder.

The addition of estrogen did not improve the response of premenopausal depressed women to imipramine in several early studies (see, e.g., Shapira et al., 1985). Results of more recent studies in perimenopausal and postmenopausal women, however, support the efficacy of physiologic doses of estrogen in treating a variety of depressive disorders. The largest study to date was a double-blind, placebo-controlled study conducted by Soares and colleagues (2001) in which 50 women received transdermal β 17-estradiol for 12 weeks as monotherapy for major depression, minor depression, or dysthymia. More than 68 percent of the patients experienced remission as measured by scores of less than 10 on the MADRS, compared with 20 percent of the patients who received placebo.

Although there have to our knowledge been no studies on the treatment of bipolar depressed women with estrogen

preparations, results of the above studies suggest a possible role for the hormone in bipolar women with low serum estrogen levels. The risk of malignancies and other serious complications of estrogen replacement therapy, however, makes estimating the risk/benefit ratio of such a strategy difficult, particularly since the Women's Health Initiative Study (National Institutes of Health, 1991) did not include data on depression.

Testosterone replacement has been reported to help alleviate depressive symptoms in men with low testosterone levels. In an open study conducted by Seidman and Rabkin (1998), five men with low testosterone levels and SSRI-resistant major depression experienced complete remission of depression (mean score of 4 on the HAM-D) after 8 weeks of taking testosterone in addition to the SSRI (Seidman and Rabkin, 1998). As with estrogen, long-term side effects of testosterone treatment are not known, including whether there is an increased risk of prostate cancer, and the relevance of this finding to the treatment of bipolar disorder is far from clear.

Sleep Deprivation

Since first being described in the 1970s, the antidepressant effect of sleep deprivation has been replicated in numerous studies involving various diagnostic groups: unipolar as well as bipolar depression, depression with psychotic features, premenstrual dysphoria, depression associated with dementia, and even negative symptoms of schizophrenia (for a review see Wirz-Justice and van den Hoofdakker, 1999, and Wu and Bunney, 1990). Indeed, nearly two-thirds of depressed patients will experience an improvement in mood after sleep deprivation. Unfortunately, about 80 percent of such (unmedicated) patients experience a relapse into depressed mood after their next night's sleep (Wu and Bunney, 1990). Indeed, even a brief nap has been found to result in relapse of depressed mood in 50 percent of patients (Wiegand et al., 1987), with morning naps being more detrimental than those in the afternoon (Weigand et al., 1993). Repeated sleep deprivation has been evaluated as a strategy for maintaining the initial antidepressant effect, and studies alternating 3 nights of total sleep deprivation (three cycles of 36 hours of wakefulness) with 3 nights of sleep (Benedetti et al., 1996; Barbini et al., 1998; Colombo et al., 2000) have found some sustained benefit.

There is some evidence that patients with bipolar depression respond better than unipolar depressed patients to sleep deprivation. In a carefully designed study, Barbini and colleagues (1998) compared the response to sleep deprivation in patients with bipolar-I depression, bipolar-II depression, a first episode of major depression, and "unipolarity" (defined as having had three or more previous major depressive episodes and no family history of bipolar disorder

in first-degree relatives). No patients had taken lithium or antipsychotics in the 6 months before sleep deprivation, and none had taken antidepressants in the week prior to the study. After three cycles of total sleep deprivation (no sleep on nights 1, 3, and 5 of the study and ad lib sleep on nights 2, 4, and 6), both groups of bipolar patients had significantly larger decreases in HAM-D scores compared with the unipolar patients. The bipolar patients also reported significantly more improvement in their perceived mood than did the unipolar patients, as measured by a visual analog scale. Although the numbers of patients in this study were small, the results are striking and confirm the findings of several (though not all) earlier studies hampered by methodological problems.

Pharmacotherapy has been demonstrated to prevent rapid relapse into depression following sleep deprivation in a significant proportion of patients. Benedetti and colleagues (1999) found that hospitalized depressed patients with bipolar-I disorder who had responded to three cycles of total sleep deprivation were more likely to continue to be in remission 10 days after the last sleepless night if they had been taking lithium for at least 6 months (14 of 20 patients) prior to the sleep deprivation cycles, compared with patients not treated with lithium (2 of 20 patients).⁶⁵ In subsequent studies of bipolar depressed patients also on lithium, this same group (Benedetti et al., 2001a,b, 2005) found that the beneficial effect of sleep deprivation could be extended by 3 days of subsequent phase advance (in which the patient both goes to sleep and wakes up about 4 hours earlier than normal), a result in agreement with those of others (see e.g., Berger et al., 1997; Riemann et al., 2002) and a strategy suggested in the first edition of this text. In other studies of pharmacological enhancement, Smeraldi and colleagues (1999, 2003) found that mood benefits were sustained 4 days after sleep deprivation when depressed bipolar-I patients were given pindolol, an antagonist of the presynaptic serotonin receptor (which therefore increases serotonin release in the central nervous system). In addition, pindolol significantly improved the overall efficacy of sleep deprivation, suggesting that the effect may involve serotonergic mechanisms.

The rate of switch into mania and hypomania after sleep deprivation appears to be at least comparable to that associated with the SSRIs and other newer antidepressants. In an open series of 206 bipolar depressed patients treated with three cycles of total sleep deprivation either alone or in combination with other medications, Colombo and colleagues (1999) observed that about 5 percent of the patients developed manic and 6 percent hypomanic symptoms. However, some patients may be more vulnerable than these data suggest. In the NIMH study reviewed in the first edition (Wehr et al., 1982), nine rapidly cycling patients in a depressed

phase were asked to simulate a 48-hour sleep-wake cycle by remaining awake for 40 hours; eight switched out of depression, and seven were rated as manic or hypomanic. For further discussion of sleep deprivation and phase advance, see Chapter 16.

Phototherapy

A seasonal pattern of symptoms is common among mood disorder patients (see Chapter 16). A retrospective analysis of the records of more than 1,500 patients with affective disorders entering outpatient treatment in Italy found that about 10 percent had a seasonal pattern of symptoms. Of these patients, about half had a unipolar and half a bipolar affective disorder, with bipolar-I diagnoses outnumbering bipolar-II about three to two in the group (Faedda et al., 1993). In the first edition of this text, we reviewed 11 studies of SAD, reporting that the proportion of patients who met criteria for bipolar disorder (-I or -II) ranged from 8 to 90 percent, a degree of variation that may reflect both regional differences in seasonal extremes and variation in diagnostic criteria. Our weighted average of the 11 studies in the first edition (45 percent) is higher than that of the Faedda data, as well as that of other more recent studies. This difference may reflect some broadening of the diagnostic criteria for SAD since the syndrome was first described by Goodwin's group at NIMH (Rosenthal et al., 1984).

Since the first description of the improvement of symptoms of SAD in response to bright light (Rosenthal et al., 1984), there have been numerous studies of phototherapy in depressed patients. An early meta-analysis of trials involving a total of 332 patients found improvement rates of 67 percent in mildly depressed patients and 40 percent in patients with "moderate to severe depression" (Terman et al., 1989); maximum improvement was correlated with exposure to at least 2,500 lux for 2 hours a day. Morning light exposure appears to be more effective than evening (Lewy et al., 1998). More recently, shorter exposure to higher-intensity light has been demonstrated to have equal benefit.⁶⁶

While these open studies have demonstrated the benefits of monotherapy with bright light in depressed patients, the results of attempts at placebo-controlled studies have been much more mixed, perhaps because these studies have been hampered by methodological problems. The studies have varied in the timing and intensity of light exposure, and designing true placebo-controlled studies has been challenging. A study comparing light exposure of 6,000 lux for 1.5 hours a day in the morning or evening with "sham negative ion generators" in 96 patients with SAD found a statistically significant difference between morning light and the sham condition in the number of

patients achieving complete or nearly complete remission (61 versus 32 percent).⁶⁷ When the mean change in depression ratings was measured in this study, however, there was no difference in efficacy between bright light and placebo (Eastman et al., 1998). A similar study comparing bright light with an active negative ion generator found no difference in the two treatments (Terman et al., 1998).

Although earlier work emphasized the benefits of phototherapy in patients with disorders displaying a seasonal component, the treatment appears to help those without a seasonal symptom pattern as well (Kripke, 1998; Tuunainen et al., 2004; Golden et al., 2005). As with other treatments effective in depression, there have been case reports associating light therapy with switches into mania/hypomania, and a meta-analysis of 20 controlled studies of light therapy in nonseasonal depression (from the Cochrane database) found a 4.9-fold increase in risk for hypomania associated with the treatment (Tuunainen et al., 2004). As with sleep deprivation, the combination of phototherapy and pharmacotherapy appears to be the most useful strategy. Results of several European studies indicate a possible synergistic effect of the two treatments (see, e.g., Colombo et al., 2000; Benedetti et al., 2003; and the review of Kripke, 1998). For a more comprehensive discussion of SAD and the antidepressant effect of bright light, see Chapter 16.

Nutritional Supplements

Various herbal preparations and other nutritional supplements reported to help individuals with mood disorders have received extensive publicity in the lay press. Often touted as “natural” and therefore supposedly superior to synthetic pharmaceuticals, nutritional preparations have fervent adherents and equally fervent critics (a rather striking exception is the tendency to overlook lithium as a natural substance). Frequently, neither group is well informed about the scientific literature, or lack thereof, that supports their use. Patients will frequently ask about nutritional supplements, and the clinician should have some familiarity with them and be comfortable in making suggestions regarding their use (for an overview, see Wong et al., 1998a; Desai and Grossberg, 2003).

St. John's Wort

The medicinal use of St. John's wort (*Hypericum perforatum*) dates to ancient times and is recommended in the medical texts of Pliny and Hippocrates, as well as in Burton's seventeenth-century classic *The Anatomy of Melancholy*. Contemporary use of hypericum extract has been as an antidepressant, with hypericin being the putative active ingredient. Hypericum extract shows affinity for the several neurotransmitter receptors, and serotonin reuptake

inhibition and monoamine oxidase inhibition have been proposed as its mechanisms of action (reviewed by Wong et al., 1998a). Hypericum's side-effect profile is generally quite benign, but clinically significant interactions with warfarin, human immunodeficiency virus (HIV) proteases, theophyllin, digoxin, and pharmaceuticals metabolized by the cytochrome P450 system have been reported (Henderson et al., 2002). Hypericum has also been noted to be associated with the onset of hypomania.

Early studies of hypericum extracts as antidepressants were hampered by variability in the extracts used, subtherapeutic doses of comparison drugs, and heterogeneity of patients. Subsequent controlled studies have led to conflicting conclusions about efficacy and resulted in intense controversy in both the scientific and lay press. Although several placebo-controlled studies from Europe have demonstrated superior efficacy for hypericum compared with placebo (see Kasper and Dienel, 2002, for a meta-analysis), two large studies from the United States have not (Shelton et al., 2001; Hypericum Depression Trial Study Group, 2002). Shelton and colleagues' study assigned 340 outpatients with major depression to three groups treated with either hypericum, sertraline, or placebo. No difference in efficacy was found among any of the groups as measured by the HAM-D. Sertraline but not hypericum was more effective than placebo in bringing about improvement as measured by the CGI scale. Hypericum extracts have not been studied as a treatment for bipolar patients, although there have been case reports of manic symptoms thought to have been caused by their use (Nierenberg et al., 1999).

Hypericum extract continues to be widely recommended in Europe for the treatment of depression. Enthusiasm for its use has waned in the United States, however, perhaps as a result of increasing concern about significant drug interactions in the face of its equivocal efficacy for treating depression.

Omega-3 Fatty Acids

Docosahexaenoic acid (DHA), ethyl-eicosapentaenoate (EPA), and linoleic acid are naturally occurring fatty acids abundant in brain tissue and the retina that cannot be synthesized by the body (hence the term *essential* fatty acids). Dietary intake is thus the only source of these substances, which are found in significant amounts in cold-water fish and such plant oils as canola, soybean, and flaxseed oils.

Omega-3 fatty acids are thought to play important roles in cell membrane fluidity and neuronal signal transduction. Epidemiological studies have indicated that a diet rich in omega-3 fatty acids is protective against coronary and cerebrovascular disease (Djousse et al., 2001), and it has been suggested that omega-3 fatty acids have anti-inflammatory effects and may even inhibit tumor growth (Tevar et al.,

2002). It has also been suggested that differences in diet, specifically fish consumption, may underlie epidemiological differences in rates of depression among various populations (such as certain Asian and Western populations) and explain the increasing incidence of depression in contemporary societies (Hibbeln et al., 1998; Mischoulon and Fava, 2000; Hibbeln, 2002; Freeman et al., 2006). These data have led to intense interest in supplemental omega-3 fatty acids as treatment for mood disorders (reviewed by Parker et al., 2006 and Freeman et al., 2006).

Stoll and colleagues (1999) reported that fish oil capsules containing omega-3 fatty acids were superior to placebo (olive oil capsules) in preventing relapse over a 4-month period in 30 patients with bipolar disorder otherwise receiving (and resistant to) “usual” treatment.⁶⁸ In this study, very high doses of fish oil capsules were used (over 9 grams/day of the combination of EPA and DHA), but later studies have generally used much lower doses. In a subsequent study of bipolar patients with depressive symptoms and functional impairment, Osher and colleagues (2005) reported that the open-label addition of 1.5–2.0 grams of EPA was associated with 50 percent or greater improvement in 8 of 10 patients who were followed for at least 1 month. More recently, Frangou and Lewis (2006) conducted a study involving 75 moderately depressed bipolar patients not responding to 8 weeks of conventional treatment. The patients were randomized under double-blind conditions to adjunctive placebo (n = 26) or EPA at either 1 gram (n = 24) or 2 grams (n = 25) over 12 weeks. There was significantly more improvement in the EPA-treated groups than in the placebo group, while the two doses of EPA were equivalent.

There have been somewhat more studies focusing on major depression. In a placebo-controlled study of 20 unipolar patients who were experiencing major depressive symptoms despite 4 months of treatment with antidepressants (mainly SSRIs), the addition of 2 grams/day of EPA, DHA, or both resulted in a more than 50 percent reduction in HAM-D scores, compared with a 10 percent reduction among patients taking placebo (Nemets et al., 2002). Likewise, in a double-blind, placebo-controlled trial of adjunctive combined EPA/DHA, Su and colleagues (2003) found a significantly greater reduction in HAM-D scores in the omega-3 group.

There have been fewer studies of omega-3 fatty acids as monotherapy. In a double-blind, placebo-controlled study of DHA, 36 patients with major depressive disorder showed no significant difference compared with placebo (Marangell et al., 2003). On the other hand, in a study of EPA monotherapy in patients with unipolar depression, Peet and Horrobin (2002) found 1 gram/day more effective than placebo; however, there was no effect at higher doses (4 and 9 grams). Their positive findings at lower doses of EPA are

similar to those of Zanarini and Frankenburg (2003) in an 8-week study of 30 borderline personality disorder patients. The negative results of Peet and Horrobin at higher doses are similar to those of the Stanley Foundation Bipolar Network study (Keck et al., 2006), in which EPA monotherapy at 6 grams/day over 4 months was no more effective than placebo in 59 patients with bipolar depression and 62 with rapid cycling.

In summary, results of four controlled studies of *adjunctive* omega-3 fatty acids have been positive—two involving bipolar patients and two unipolar patients—but experience with these compounds as *monotherapy* has been, at best, mixed. Since these supplements have essentially no side effects, many clinicians are routinely recommending them for their patients in addition to standard treatment, although more systematic study is still needed.

Inositol

About 1 gram/day of inositol, a precursor of the phosphatidyl inositol second messenger system, is present in a normal diet. There have been reports of reduced inositol in the cerebrospinal fluid (CSF) of patients with unipolar and bipolar depression (Coupland et al., 2005), as well as in the frontal cortex of bipolar patients (Shimon et al., 1997), and one of the proposed mechanisms of action of mood stabilizers involves stabilization of inositol signaling. Orally administered inositol has been shown to increase CSF levels in humans substantially, and at doses of 6–20 g/day has been associated with improvement in unipolar and bipolar depression (Levine et al., 1995; Chengappa et al., 2000). Recently, Edens and colleagues (2006) reported that among 17 bipolar patients already on lithium or valproate, compared with those on placebo, there was a trend for more subjects on inositol to show improvement in depressive symptoms; this was the case especially in those with high baseline levels of anger and hostility.

S-Adenosylmethionine

S-adenosylmethionine (SAME) is formed in the body when methionine, one of the essential amino acids, is activated by adenosine triphosphate (ATP) in a reaction catalyzed by methionine adenosyltransferase. SAME serves as a methyl donor in numerous important transmethylation reactions, including deoxyribonucleic acid (DNA) methylation reactions involved in gene regulation, as well as the catalysis of proteins, phospholipids, and neurogenic amines, including norepinephrine, dopamine, and serotonin (see Lieber and Packer, 2002, for an introduction to this compound). SAME has been a prescription antidepressant in some parts of Europe for several decades, where it has often been administered parenterally,

and it was released for sale in the United States as an (oral) over-the-counter nutritional supplement in 1998. In addition to its purported benefits in treating affective disorders, SAME has been reported to benefit individuals with osteoarthritis and cirrhosis, perhaps through its antioxidant effects.

Bressa (1994) published a meta-analysis of clinical studies using SAME either orally or parenterally in doses ranging from 45 mg /day intravenously to 1,600 mg/day orally to treat depressed patients. These studies were hampered by small numbers of patients, variations in route and dosing of SAME, and short duration (several as short as 7 days and most 14–21 days). Nevertheless, Bressa concluded that SAME's antidepressant efficacy was significantly superior to that of placebo and comparable to that of tricyclic antidepressants.⁶⁹ An earlier open study of 9 patients who were given intravenous SAME at a dose of 100–200 mg/day for major depressive symptoms included 6 patients with bipolar disorder (Lipinski et al., 1984). Two of these patients developed manic symptoms within days of starting SAME. A more recent open study of the adjunctive use of this compound (Alpert et al., 2004) noted a 50 percent response rate and a 43 percent remission rate among 45 patients with major depression showing no more than a partial response to an SSRI or venlafaxine.

SAME appears to have a benign side-effect profile, with only mild gastrointestinal discomfort commonly reported. It has been recommended that individuals taking SAME supplement its use with a multivitamin that contains folic acid and vitamins B12 and B6 to avoid increases in homocysteine levels.⁷⁰ This methyl donor appears to be a promising compound that has been curiously neglected in studies of antidepressants, probably because of questions about whether meaningful amounts reach the brain after oral administration. More study is clearly needed before SAME can confidently be recommended to patients with depressive disorders, and it should probably be avoided by individuals with bipolar disorder, certainly in the absence of a mood stabilizer.

Botanicals and Vitamin and/or Mineral Supplements

Botanical preparations often recommended by herbalists for symptomatic treatment of insomnia and anxiety include chamomile, kava, lemon balm, skullcap, and valerian. These preparations contain a variety of flavonoids, pyrones, and fatty acids, and several have been shown to provide symptomatic relief of more minor psychiatric symptoms with a very low incidence of side effects (see Wong et al., 1998b, for a more extended discussion).

There has long been interest in treating psychiatric disorders with vitamins and minerals, an endeavor known variously as *nutritional* or *orthomolecular psychiatry*. During the

revival of interest in alternative medicine that occurred in the late 1990s, a preparation of vitamins, minerals, amino acids, and various botanicals (including ginkgo biloba and germanium sesquioxide), manufactured under the brand name "E.M. Power +," was developed by family members of bipolar patients specifically for the treatment of bipolar disorder. An open study found that 11 patients with bipolar disorder taking other standard medications experienced a 50 percent reduction of symptoms over a period of 6 months when this preparation was added to their other medications (Kaplan et al., 2001). Another nutritional supplement purported to have mood-stabilizing properties is Equilib, but as yet no systematic trials of this supplement have been published. Reports from uncontrolled trials that chromium was associated with substantial improvement in treatment-resistant mood disorders (see, for example, McLeod and Golden, 2000) led to a placebo-controlled trial in 15 patients with major depressive disorder, atypical type (as noted earlier, atypical depression is often antidepressant resistant and overlaps considerably with bipolar depression) (Davidson et al., 2003). This group found that 70 percent of the chromium-treated patients met response criteria compared with none in the placebo group ($p < .02$).

CONCLUSIONS

Even though depression accounts for the preponderance of the morbidity in bipolar disorder, research on bipolar depression has until very recently been minimal compared with that on the acute treatment of mania or the treatment of unipolar depression. As an illustration of this imbalance, one has only to note that every drug developed for the treatment of bipolar disorder—with one recent exception (lamotrigine)—has been introduced as an antimanic agent. Furthermore, we believe the tacit assumption that the antidepressant drugs developed for unipolar depression will show the same risk/benefit ratio for bipolar depression can now be challenged, primarily by data on switch rates and increased cycling among patients taking antidepressants; while such data are not yet conclusive, they are highly suggestive.

The relatively recent findings on the antidepressant effects of the anticonvulsant lamotrigine, the atypical antipsychotic quetiapine, and the combination of olanzapine plus fluoxetine have significantly enlarged the armamentarium for dealing with bipolar depression and clearly represent good news. The bad news, however, is that even with these agents, most patients do not achieve remission. Thus for the majority of patients with bipolar depression, a combination of medications will still be required, a situation that only highlights the unfortunate reality that virtually all of the available controlled data are on monotherapy.⁷¹

NOTES

1. These new medications include the anticonvulsant lamotrigine and the atypical antipsychotic quetiapine. In addition, the combination of olanzapine and fluoxetine, marketed as a single pill, has been shown to be efficacious in treating bipolar depression.
2. A rapid response to an antidepressant may presage a subsequent manic switch.
3. The “mini relapses” associated with drug-related recovery from a depressive episode can be very discouraging to the patient until they are explained as evidence that the drug is beginning to work.
4. An excellent patient-generated mood chart with instructions on its use can be downloaded from the Web site of the Harvard Bipolar Research Program at <<http://www.manic-depressive.org/moodchart.html>>, as can the mood chart of the National Institute of Mental Health (NIMH). See the further discussion in Chapter 22.
5. In addition to the literature review that forms the second part of this chapter, these recommendations are drawn from Sachs et al., 2000; Grunze, et al., 2002; and Thase et al., 2003.
6. In the positive parallel-group controlled trial, the 400 mg arm was not statistically different from the 200 mg arm, but these represent averages.
7. The fact that topiramate has been reported to produce depressive symptoms in some patients (*Physicians' Desk Reference*, 2006) should be kept in mind.
8. It has also been suggested that this combination may be called for when a more rapid antidepressant response is needed, but there are no controlled data to support this suggestion.
9. Altshuler and colleagues (2001a) found that over two-thirds of bipolar patients treated with an antidepressant had a relapse of depression within a year of discontinuing the drug, versus less than a third of those who continued it. The incidence of manic relapse was the same in both groups. However, treatments were not randomly assigned, and it appears likely that the patients taken off their antidepressant were doing poorly, including cycling. Further, of the original sample exposed to antidepressants, only 15 percent remained well on antidepressants for up to 1 year, despite continuation. The others either did not respond, became manic, or had other adverse reactions. Thus it is not clear that there are grounds for generalizing these results to more than a minority of bipolar patients.
10. In response to a letter to the editor about potential confounds in the Altshuler et al. study, the authors noted that no subjects with a history of rapid cycling were included among those remaining on an antidepressant during the 1-year observational study; that is, no rapid-cycling patients remained well on long-term antidepressants.
11. For example, Moller and Grunze (2000) cited naturalistic data supporting antidepressant effectiveness in bipolar depression, but not similarly naturalistic data supporting the opposite conclusion.
12. Baker and colleagues' (2003) data could be interpreted as suggesting that olanzapine was superior to placebo in preventing early relapses into mania after acute treatment of the episode.
13. Clozapine appears to pose the highest risk of causing weight gain, followed by olanzapine and quetiapine. There is a lower risk with risperidone and sertindole. Ziprasidone and aripiprazole do not appear to cause weight gain (McAskill et al., 1998; Taylor and McAskill, 2000).
14. Common side effects include headache, eyestrain, jitteriness, and insomnia. It has been suggested that prolonged exposure to full-spectrum light in the absence of a mechanism to screen out ultraviolet wavelengths (which most light boxes have) poses a risk for the development of cataracts and skin cancer. There have also been case reports of the induction of manic symptoms by phototherapy (Terman and Terman, 1999).
15. Although there is now at least one marketed product that employs blue light, almost all efficacy and safety studies have used bright white light.
16. While it may be intuitively appealing to expect that depressed bipolar patients will respond better than unipolar patients to lithium augmentation, this notion has never been studied. A related question—whether a favorable response to lithium augmentation in bipolar patients is simply a response to lithium rather than to the combination of agents—also remains unanswered (see Austin et al., 1991; Ernst and Goldberg, 2002).
17. One study examined the lithium–MAOI combination in patients who had not responded to lithium added to other antidepressants. In this open trial, 12 patients who had not responded to 2 weeks of lithium augmentation of a non-MAOI antidepressant (either desipramine, bupropion, or the experimental drug adinazolam) took the MAOI tranylcypromine with lithium instead (Price et al., 1985). All 12 patients experienced significant improvement in their depression, including two patients with bipolar-II depression who were discharged from the hospital either “much” or “very much” improved.
18. A double-blind, placebo-controlled study involving bipolar and unipolar depressed patients found that 6 of 10 patients refractory to treatment with citalopram alone had a greater than 50 percent reduction in HAM-D scores when lithium was added, whereas only 2 of 14 patients taking citalopram and placebo experienced a similar reduction in symptoms (Baumann et al., 1996). On the other hand, Fava and colleagues (1994) randomized depressed patients refractory to 20 mg of fluoxetine to three groups: an increased dose of fluoxetine (40–60 mg) and augmentation with either lithium or desmethylimipramine (DMI); the 40–60 mg fluoxetine group did significantly better than either augmented group, leading the authors to the conclusion that high-dose fluoxetine is the most effective treatment for partial responders to previous treatment.
19. In a study conducted by Hoencamp and colleagues (2000), 23 patients who had a less than 50 percent reduction in their initial HAM-D scores despite 7 weeks of treatment with 225 mg/day of venlafaxine were given a dose of lithium sufficient to maintain serum levels of .6–1.0 mEq/L. After 7 weeks of this combination treatment, 35 percent of the subjects had a HAM-D score reduction of at least 50 percent. Likewise, Walter and colleagues (1998) found that two adolescents with major depression experienced a rapid improvement in their symptoms when lithium was added to venlafaxine.
20. Some studies purporting to investigate the effect of pharmaceuticals on bipolar “depression” actually focused on the reduction of depressive symptoms in patients in a mixed

- affective state, a common finding for a number of anticonvulsants. Unless otherwise noted, the studies of efficacy in bipolar depression detailed here involved patients without mixed symptoms.
21. Given that there were only 45 subjects, this failure to find a difference between valproate and placebo may well reflect a type II error (false negative); such data might be analyzed more meaningfully by using odds ratios with confidence intervals, as suggested by Ghaemi and Hsu (in press). In this study, response to valproate occurred 50 percent more often than response to placebo.
 22. Given the evidence suggesting that lithium and valproate (and perhaps other anticonvulsants) may act synergistically on postsynaptic signal transduction, studies of these agents used simultaneously at less than full doses are needed.
 23. Kusumakar and Yatham, 1997; Sporn and Sachs, 1997; Calabrese et al., 1999a; Suppes et al., 1999.
 24. Patients were randomly assigned to receive one of the three treatments—lamotrigine, risperidone, or inositol. Since many patients had previously taken at least one of these three medications, they could be randomized to two of the three or only one of two, a strategy referred to as “equipoise randomization.”
 25. See our later discussion of the possibility of underestimating the risk of manic switches when examining data from controlled studies.
 26. In an analysis of all controlled studies to date (Ghaemi, personal communication, 2006), the combined frequency of mania, hypomania, or mixed states was 3.7 for lamotrigine-treated patients versus 2.5 for placebo (risk ratio 1.45; 95 percent confidence interval [CI] .62–3.41). To properly evaluate whether this 45 percent difference is real would require a sample size of over 1,000, nearly three times the sample available from the controlled studies. For further discussion of this point, see Chapter 17.
 27. On the other hand, Klufas and Thompson (2001) reported on three patients with bipolar disorder taking a variety of other medications who became profoundly depressed shortly after being prescribed topiramate for mild symptoms of irritability, agitation, or depression, a state that remitted within days of discontinuation of the drug. It should also be noted that induction of mania has been reported with topiramate (Schlatter et al., 2001).
 28. As noted above, Frye and colleagues (2000) compared gabapentin monotherapy with lamotrigine monotherapy and placebo in 31 patients suffering from refractory bipolar depression (11 bipolar-I and 14 bipolar-II) or unipolar depression (6 patients) using a crossover design. Gabapentin was no more effective than placebo in treating either manic or depressive symptoms.
 29. See, for example, Young et al., 1997; Ghaemi et al., 1998; Altshuler et al., 1999; Ghaemi and Goodwin, 2001a.
 30. Patients with sensitivity to sulfa compounds should probably not take zonisamide.
 31. Of the 8 subjects who completed the 8-week study, 5 had a greater than 50 percent reduction in HAM-D scores and were “much improved” on the Clinical Global Impressions of Improvement (CGI-I) scale.
 32. The conclusion of Ghaemi and colleagues is consistent with results of an earlier retrospective chart review that found no difference in the length of the depressive episode among bipolar patients on mood stabilizers and those on mood stabilizers plus antidepressants (Frankle et al., 2002).
 33. Fifty-nine percent of those treated with moclobemide were on lithium or an anticonvulsant, compared with 64 percent of those treated with imipramine.
 34. Several selective reversible MAO-A inhibitors have been reported to be effective in studies on depression. None are available in the United States. Brofaromine is discussed by Waldmeier (1993) and moclobemide by Waldmeier (1993) and Kennedy (1997).
 35. The open design of the Kupfer et al. study was intended to minimize barriers to enrollment in treatment studies: the use of placebo and the need to accept randomization. Surprisingly, however, not only did the study fall far short of its recruitment target, but only 21 of the 45 (47 percent) enrolled subjects met the acute response criteria, and only 31.1 percent achieved sustained remission.
 36. Another problem with the study by Cohn and colleagues (1989) was that the imipramine group was titrated up to a target dose of 300 mg, which induced many dropouts due to intolerance, distorting the efficacy comparison with the more tolerable fluoxetine.
 37. Three patients who had no response to one agent after 8 weeks made a blind switch to the other agent, for a total of 19 acute treatment trials (10 bupropion and 9 desipramine). No attempt was made to classify the patients as bipolar-I or -II.
 38. A standardized clinical monitoring form is used in STEP-BD to collect prospective assessments of symptom severity and assigns a clinical status based on DSM-IV criteria at every follow-up visit.
 39. A subsequent report on 349 bipolar depressed patients with concomitant manic or hypomanic symptoms (mixed-state patients) from the STEP-BD program (Goldberg et al., 2004) noted that, while time to recovery was not altered by the addition of an antidepressant to a mood stabilizer, those with a higher level of manic symptoms at baseline experienced more severe manic symptoms later when on the antidepressant–mood stabilizer combination.
 40. Patient expectations were one of the variables included in the regression analysis because the study was not blinded.
 41. Also, it appeared that antidepressant continuation led to more rapid relapse into a full mood episode, although less frequently a depressive one.
 42. Angst actually concluded in this later paper that his data did not support “treatment-induced switching.” He suggested that the apparent increase in switching since the introduction of medical treatments for depression was due to an increase in the diagnosis of bipolar disorder in the later decades of the study.
 43. A comprehensive listing of references on agents reported to induce manic states, dating from the 1960s through the mid-1990s, can be found in Moller and Grunze (2000).
 44. See the studies of Fogelson et al. (1992), Sachs et al. (1994), Amsterdam and Garcia-Espana (2000), Goren and Levin (2000), Nemeroff et al. (2001), Vieta et al. (2001), Erfurth et al. (2002), and Peet (2004).
 45. For example, Stoll and colleagues (1994) retrospectively matched the charts of 49 patients who met their criteria for an antidepressant-related switch to 49 patients with spontaneous mania and reported that the antidepressant-related episodes were shorter and less severe.

46. For example, studies of outpatients that do not include family members as sources of information will certainly underestimate the occurrences of mania/hypomania.
47. See, for example, Prien (1984), Bottlender et al. (1998), Serretti et al. (2003), and Mundo et al. (2006); not all studies agree, however (see, for example, Goldberg and Whiteside, 2002).
48. In this meta-analysis, however, important issues of heterogeneity were not explored. In two studies comparing use of an antidepressant without a mood stabilizer and no treatment (placebo only), no mania was observed in any patients—an oddity, if true, since it would suggest that even spontaneous mania did not occur while those patients were studied or that perhaps manic symptoms were not adequately assessed. Another study preferentially prescribed lithium more in the antidepressant group (Cohn et al., 1989), providing possibly unequal protection against mania. While the olanzapine/fluoxetine data suggest no evidence of switch while using antipsychotics, it is noteworthy that in our reanalysis of the lithium plus paroxetine (or imipramine) study, there was a three-fold higher manic switch rate with imipramine versus placebo (relative risk 3.14), with asymmetrically positively skewed confidence intervals (.34, 29.0). As discussed earlier, these studies were not powered to assess antidepressant-induced mania, and thus lack of a finding is liable to be due to type II (false negative) error. It is more effective to use descriptive statistics as above, which suggest some likelihood of a higher manic switch risk at least with tricyclics compared with placebo. Taken together with the results of other studies reviewed showing higher switch rates with tricyclics than with other antidepressants, this heterogeneity suggests that one cannot rule out antidepressant switch. Thus, apparent agreement among studies masks major conflict between the results of the only adequately designed study using the most proven mood stabilizer, lithium, and the results of the remaining studies (which used either no mood stabilizer or less proven agents).
49. Unfortunately, Mundo and colleagues' (2001) nonrandomized study did not analyze important potential differences between the two groups, such as treatment duration and use of mood stabilizers.
50. The patients were from the NIMH Collaborative Program on the Psychobiology of Depression—Clinical Studies and had initially sought treatment at one of five university centers, 80 percent of which was inpatient treatment. During prospective follow-up, they received routine care in the community.
51. Rao and Nammalvar, 1977; Coryell et al., 1995; Hantouche et al., 1998; Geller et al., 2001.
52. Of course, at these levels the dose of bupropion must be divided, and with half of it given in the late afternoon, the likelihood of sleep disruption may increase. This in turn may increase the risk of switch.
53. This difference did not achieve statistical significance by *t* test. Since this study was not powered to rule out mania, the finding is more appropriately evaluated as relative risk ratio with confidence intervals (RR 4.00; 95 percent CI .47–33.7).
54. Defined as an increase of 2 on the 7-point CGI scale for mania. Using the CGI, the mean switch rate for all three drugs was 21 percent, whereas by the more stringent requirement of a Young Mania Rating Scale score of 13 or above, the mean was only 9 percent.
55. Overall mood morbidity, which was the primary outcome of this study, relates to the roughening concept. *Mood morbidity* is defined as meeting any number of DSM-IV mood episode criteria for mania or depression, thus capturing subsyndromal and chronic outcomes, which have been shown to constitute the major morbidity of bipolar illness. Further, overall mood morbidity represents a more sensitive outcome measure than relapse into a full mood episode.
56. Response was defined as a 50 percent or greater reduction in MADRS scores.
57. Zarate et al., 2000; Sajatovic et al., 2001, 2002; DelBello et al., 2002; Vieta et al., 2002; Ghaemi et al., 2003c; Post et al., 2003; Suppes et al., 2004.
58. Sadness, lassitude, inability to feel, pessimistic thoughts, suicidal thoughts.
59. This study did not attempt to determine an overall efficacy rate for ECT in treating unipolar or bipolar depression, and the treatment techniques in the three protocols differed in electrode placement and stimulus strength. A 1986 retrospective review of the naturalistic treatment with ECT of about 400 patients with unipolar and bipolar depression at a university medical center found that about 70 percent of patients in both groups showed marked improvement with the treatment (Black et al., 1986).
60. Seizures can be induced at high levels of stimulation, and rTMS has, in fact, been proposed as an alternative seizure-induction strategy to the direct application of electrical current used in ECT (Lisanby et al., 2001a).
61. For example, in a double-blind controlled study involving 70 depressed patients, Klein and colleagues (1999) demonstrated that right prefrontal rTMS led to a greater than 50 percent reduction in HAM-D scores after 2 weeks (compared with only 25 percent with sham treatment), whereas Lisanby and colleagues (2001b) and others found only a small effect. In a study of 20 bipolar patients, Dolberg and colleagues (2002) reported a significant but only modestly robust effect. However, in interpreting these data it is important to be aware that studies of TMS involve patients who have failed conventional treatments.
62. The patients in both the VNS and sham treatment groups continued to receive their usual treatment.
63. For an overview of the psychoneuroendocrinology of mood disorders and thyroid physiology, see Frye et al. (1999) and Bauer et al. (2002, 2003).
64. For an overview of HPA physiology with special reference to mood disorders, see McQuade and Young (2000).
65. These results are similar to those of the study by Szuba and colleagues (1994).
66. An excellent review of the details of the technique is found in Daskalakis et al. (2002).
67. Measured by a 50 percent decrease in scores on the Structured Interview Guide for the Hamilton-Seasonal Affective Disorder (SIGH-SAD) (the 21-item HAM-D plus 8 additional items concerning common SAD symptoms, such as hypersomnia and increased appetite), as well as a score at the end of the study of 8 or lower.
68. This 4-month relapse prevention study is not clearly either an acute trial or a maintenance trial, so it is reviewed both here and in the next chapter. The benefit of the omega-3 fatty acids appeared to be related primarily to an antidepressant effect; however, the definition of improvement was vague, rendering problematic a definitive interpretation of these results.

69. An Italian group carried out two double-blind comparison studies of SAME and imipramine (Delle Chiaie et al., 2002). Unipolar depressed patients who met the DSM-IV diagnostic criteria for major depression without psychosis received 150 mg/day of imipramine and either SAME 400 mg/day given intramuscularly (in a 4-week study) or 1,600 mg/day taken orally (in a 6-week study). In these studies, patients in both SAME groups had decreases in mean HAM-D and MADRS scores that were not significantly different from those of patients given imipramine. The percentage of responders in the SAME groups (defined as a greater than 50 percent decrease in HAM-D score) was not significantly different from that in the imipramine group.
70. High homocysteine levels have been thought to contribute to atherosclerosis.
71. The focus of the pharmaceutical industry on monotherapy trials no doubt reflects its perception that regulatory agencies strongly prefer such trials. This strong preference, however, has historically applied selectively to psychiatric drugs.

Art is long, life short, opportunity fleeting, experiment dangerous, judgment difficult, nor is it sufficient that the physician should attend to his work, but it is necessary also that the patient and those around him should do theirs.

—Hippocrates (cited in Whitwell, 1936, p. 61)

Preventing new episodes of manic-depressive illness has been an ambition of clinical investigators since the inherently recurrent nature of the illness was first recognized. In the middle of the twentieth century, the pursuit led many clinicians to treat their patients with intensive psychotherapy, but with little success. Maintenance electroconvulsive therapy (ECT) appeared to be effective for some patients, but it was pharmacology that enabled the realization of this long-standing ambition. The development of lithium as an effective prophylactic treatment for manic-depressive illness was one of the most important advances in modern psychiatry, and it fundamentally altered both the prognosis for patients and the concepts of the disorder. While the earlier trials of lithium prophylaxis were for manic-depressive illness (they encompassed both bipolar and recurrent unipolar disorders), the contemporary literature focuses on the bipolar form.

In the first edition of this text, the terms “maintenance” and “prophylactic” were both used to indicate prevention of a *new episode*, and the maintenance phase of treatment (for non-rapid-cycling bipolar patients) was defined as beginning only after 6 to 12 months had passed since an acute episode. Anything short of 6 months was considered continuation treatment of the acute episode.¹ However, the meaning of these classic concepts has become somewhat obscured in recent years because of the proliferation of “relapse prevention” trials in which (1) the length of the trial is less than 1 year, or (2) even when the length of the trial is adequate, the critical period during which most of the drug–placebo differences can be demonstrated is in the range of 2 or 3 months—in effect, the period of *relapse* after withdrawal of the active drug to which the patient had responded acutely. We took note of these methodological issues in Chapter 17 and do so again in

our subsequent review of the literature when we consider how to interpret relapse prevention data for individual drugs. We do not consider studies whose entire period of observation is less than 6 months to be “maintenance” or “prophylactic” studies, so they are not reviewed in this chapter.

A related issue is how to define “mood stabilizer,” a question to which we devoted a great deal of attention in the first edition of this text. The U.S. Food and Drug Administration (FDA) has not defined the term, nor is there yet consensus on the issue among researchers. The strictest definition requires that an agent demonstrate efficacy in the acute treatment of both mania and depression, as well as the ability to prevent future episodes of both (Goodwin and Jamison, 1990; Calabrese and Rappaport, 1999; Bauer and Mitchner, 2004). As proposed later in our review of the literature, lithium comes closest to meeting that definition. A somewhat less stringent definition, suggested by Ghaemi (2001), requires a drug to be efficacious in two of three phases of treatment of the illness (acute mania, acute depression, and prophylaxis of mania and/or depression), one of which must be prophylaxis; lithium, lamotrigine (and possibly valproate) fits this definition. The least stringent definition, suggested by Bowden (1998) and Sachs (1996), requires an agent to demonstrate efficacy against only one phase of the illness as long as it does not worsen any other phase, including increasing the frequency of episodes. The atypical antipsychotics as a class fit that definition. Our view is that a demonstration of *prophylactic* efficacy (that is, the prevention of new episodes) should be fundamental to the definition of a mood stabilizer, and that including drugs in this category simply on the basis of acute efficacy against depression and/or mania renders the term so broad as to be essentially meaningless.

As reviewed by Bech (2006) in an essay written in tribute to Mogens Schou, the use of lithium in “endogenous affective disorder” was first recommended by Frederick Lange in 1893 and subsequently by his brother Carl Lange in 1897 (reviewed more extensively by Schioldann [2001] in an excellent commemorative tribute to Carl Lange). After the rediscovery of lithium by Cade half a century later (for the acute treatment of mania), lithium prophylaxis in manic-depressive illness was first described by Noack and Trautner (1951), who observed that the drug appeared to prevent additional manic episodes in patients in whom it had alleviated acute mania. Shortly thereafter, Schou and colleagues (1954) provided the first case report demonstrating the benefits of lithium for treating both manic and depressive episodes. The 10 to 12 episodes a year that their patient had experienced before treatment were markedly attenuated in duration and severity after 2 years of taking lithium continuously. In the above-mentioned essay, Bech (2006) reminds us of some important history:

The term “mood normalizer” for lithium (Cade, 1949) was originally introduced by Mogens Schou in 1963, with reference to Baastrup’s findings regarding long-term therapy of lithium and its high recurrence prevention of both manic and depressive episodes in bipolar patients. In the 1950s, clinicians used the term “mood stabilizer” to refer to a combination of amphetamine and a barbiturate to treat patients with neurotic instability, but not patients with bipolar disorders. By “mood-normalizer” Schou meant a compound acting specifically on a disease process rather than on a symptom level (Schou, 1963). During long-term therapy with lithium in bipolar disorder, Schou and Baastrup saw a normalisation of the abnormal mood swings, while normal emotions seemed not to be affected in any way, as they were when the combination of amphetamine and barbiturate was used. Now, forty [*sic*] years later, the definition of a “mood stabilizer” has changed to exactly what Schou had called “mood-normalizer”, i.e. a drug with prophylactic properties in regard to mania and depression, and in this sense lithium still is the only drug that meets the criterion.

In the first section of this chapter, we provide practical clinical guidelines for the long-term maintenance treatment of manic-depressive illness, focusing on the bipolar form. These guidelines cover the complex issues of the selection of medications, the management of side effects, and the problem of breakthrough episodes. The second section examines the relevant research literature, emphasizing studies of treatment efficacy, predictors of response, and the important issue of the effects of long-term treatment on other organ systems.

CLINICAL MANAGEMENT

In this section we discuss key aspects of clinical management for maintenance treatment of manic-depressive illness. Following an overview of the issues involved, we address, in turn, embarking on maintenance treatment, selecting medications, treating the elderly patient, treating pregnant and breastfeeding women, and dealing with breakthrough episodes. Note that issues of maintenance treatment for children and adolescents are addressed separately in Chapter 23.

Overview

Manic-depressive illness, especially the bipolar-I form, is the prototypical diagnostic indication for maintenance treatment. When to commence maintenance therapy and whether it is ever reasonable to stop are currently matters of only modest controversy.² As detailed in Chapter 4, mood disorders are often highly recurrent illnesses, frequently characterized by residual symptoms and substantial risk of chronicity (this appears to be especially true of illness characterized by more prominent depressive symptomatology). One 5-year prospective follow-up study found that nearly 90 percent of 172 individuals with bipolar-I disorder experienced a relapse of illness within 5 years after their recovery from an acute mood episode (Keller et al., 1993). Many of these patients had been actively in treatment throughout the period since recovery (see also Keller et al., 1992). In a recent prospective study of 1,469 bipolar patients participating in the National Institute of Mental Health’s (NIMH) Systematic Treatment Enhancement Program for Bipolar Disorder (STEP-BD) (Perlis et al., 2006), 58 percent achieved recovery, but nearly half of these patients (49 percent) had a recurrence of illness during the follow-up period of up to 2 years. Recurrence was associated with the persistence of residual symptoms after treatment of the acute episode.³

The substantial morbidity (including medical morbidity) and significant mortality associated with recurrences of bipolar disorder, the financial burden resulting from the decreased productivity of affected persons and associated health care costs, and the toll in human misery (including substance abuse, violence, and suicide) all argue for making every possible effort to prevent new episodes. Patients who have had a manic episode and a major depressive episode—thus all patients with bipolar-I disorder—are at high risk of relapse throughout their lives; barring contraindications, long-term maintenance therapy is indicated for all such patients. We agree with the recommendations of the various North American treatment guidelines that long-term prophylactic treatment should generally begin after the first manic episode; in most of the European guidelines, prophylaxis is recommended after the second episode of mania, but it can be “considered” after the

first manic episode if that episode is severe enough (Vestergaard, 2004). At the same time, it is important to note that treatment decisions must be made in context of individual patients and their diagnoses. In clinical situations, moreover, a significant amount of time, often several months, is usually required to determine whether an individual can tolerate a particular long-term maintenance medication at a dose that is likely to be helpful. And it takes at least a year, and more often 2 to 3 years, to develop a clear picture of how effective the treatment is in preventing recurrence. When evaluating treatment times of less than 1 year, it is difficult to distinguish prevention of relapse back into the acute episode from true prophylaxis (prevention of a new episode). Thus decisions about prophylactic medications must be made and reconsidered over periods of many years.

Long-term maintenance is also indicated for bipolar-II patients, primarily because of the toll of depressive morbidity (Judd et al., 2005) and the availability of new mood stabilizers that can reduce the likelihood of new depressive episodes in a significant percentage of bipolar patients. Bipolar-II disorder differs from bipolar-I in several ways that suggest a modification of the usual maintenance recommendations for the latter. The defining characteristic that differentiates bipolar-II from bipolar-I is, of course, the absence of full-blown manic episodes. For example, the risk of manic switch is lower, which may make antidepressants safer than they are in bipolar-I patients. The importance of maintenance treatment for bipolar-II is underlined by the finding that individuals with the disorder have more frequent mood episodes and are ill a greater percentage of time than those with bipolar-I disorder (Tondo et al., 1998; Judd et al., 2005). There are suggestions that patients with bipolar-II disorder are at greater risk of suicide as well; this may increase the importance of lithium prophylaxis in these patients (see Chapter 25), the clear benefits of which for bipolar-II patients have repeatedly been demonstrated in studies extending back several decades (Suppes and Dennehy, 2002). Fewer data are available on anticonvulsant medications in treating bipolar-II disorder. The increased cycling seen in patients with the disorder suggests that valproate may have a role, although its antidepressant efficacy (like that of lithium) has been shown to be modest at best in patients with rapid cycling (Calabrese and Delucchi, 1990; Calabrese et al., 2005). Valproate may be useful in treating the impulsiveness, irritability, and dysphoric moods often seen in bipolar-II patients, features that may be associated with more self-harming behavior and psychosocial disability.

Lamotrigine's demonstrated maintenance effect against depression in bipolar disorder suggests an important role for this agent in the treatment of patients with bipolar-II. In contrast to bipolar-I patients, for whom it is recommended

that lamotrigine be coadministered with an agent such as lithium or valproate that can protect more completely against mania/hypomania (i.e., "from above" [Ketter and Calabrese, 2002]), lamotrigine monotherapy is generally appropriate for the bipolar-II patient, for whom the risk of a manic switch is lower. Also, as noted later in our review of the literature, lamotrigine is the only mood stabilizer with any evidence of a prophylactic effect as monotherapy for rapid cycling, and this effect was seen (in a secondary analysis of one study) only among the bipolar-II subgroup. Studies demonstrating the clear benefits of lithium and some of the anticonvulsants in preventing relapses in bipolar-II patients also reveal the shortcomings of these agents: they delay but rarely eliminate further mood episodes in studies of sufficient length. Patients in these studies not infrequently suffer from relapses, usually with depressive symptoms, despite taking lithium and the anticonvulsants carbamazepine and valproate. Thus the new data on lamotrigine are especially encouraging. By "stabilizing from below" (i.e., reducing or preventing depression), this agent may obviate the need for adjunctive antidepressants, which pose some risk of switching and cycle induction even in bipolar-II patients; before the availability of lamotrigine, maintenance antidepressants were widely used in treating bipolar-II disorder (even as monotherapy), given the substantial morbidity associated with its frequent depressive phases (see the discussion of switching and cycle acceleration in Chapter 19).

At the same time, lamotrigine, even in combination with another stabilizer, is not always effective in treating or preventing bipolar-II depression. Therefore, antidepressants will continue to play a role in treatment for some patients. Whether patients with bipolar-II are at lower risk of antidepressant-induced mood destabilization than bipolar-I patients is still something of an open question, and, as noted earlier, there are clearly some bipolar-II patients for whom antidepressant treatment is not without risk (Suppes and Dennehy, 2002). Of the 28 bipolar-II depressed patients who completed a 26-week study of fluoxetine monotherapy, only 1 developed hypomanic symptoms, but the dropout rate was nearly 90 percent. Although the numbers are small, this 1 patient represented 3.6 percent of those who completed the study; moreover, among the large number of dropouts, it is not known how many were due to mania (Amsterdam et al., 1998). A number of studies of the use of antidepressants for the acute treatment of bipolar depression have included bipolar-II patients (see Chapter 19), but the data are insufficient to conclude that any particular antidepressant is superior in preventing depression in patients with bipolar-II disorder.

With regard to maintenance treatment of recurrent unipolar depression, contemporary U.S. guidelines recommend antidepressants. However, it is important to realize

that this recommendation is based on studies in which “recurrent” represents patients with as few as two episodes (the minimum *Diagnostic and Statistical Manual* [DSM]-IV definition). It has been estimated that as many as half of patients with DSM-IV recurrent unipolar depression will experience a relapse despite maintaining a full dose of the antidepressant to which they have responded acutely (Byrne and Rothschild, 1998). This phenomenon is variously referred to as “poop out,” “tachyphylaxis,” or “tolerance.” All of these terms imply that the relapse represents a loss of the drug’s therapeutic effect, a phenomenon for which many explanations have been advanced (Fava, 2003; Solomon et al., 2005). Yet rarely is the possibility considered that in some patients, the phenomenon may reflect the *ongoing efficacy* of the antidepressant, bringing the next depression on sooner by accelerating the natural cycle of the more recurrent forms of unipolar depression (Goodwin, 1989).⁴ In this regard, it is interesting that in the recent report from the “real-world” NIMH Sequenced Treatment Alternatives to Relieve Depression (STAR*D) trial of the antidepressant citalopram, only 28 percent of patients with fairly recurrent forms of unipolar depression (average of six prior episodes) achieved remission (Trivedi et al., 2006).

With regard to the use of mood stabilizers for prevention of recurrent unipolar depression, as reviewed in the first edition of this text and more recently in two meta-analyses (Souza et al., 1990; Davis et al., 1999), substantial evidence indicates that lithium is highly efficacious in the prevention of recurrent unipolar depression. Most of this evidence has involved patients with frequent recurrences, often as frequent as those experienced by the typical bipolar patient. Thus in their careful analysis, Davis and colleagues (1999) noted that most of the earlier maintenance studies of unipolar patients had involved subjects with two to three episodes during the 2 years before the study, a frequency well within the range of that of the typical bipolar patient. For highly recurrent unipolar patients, recommended lithium monotherapy levels are in the same range as those for bipolar-II (.4 to .6 mEq/l). While some of the patients in these earlier studies might today be considered as falling within the “bipolar spectrum,” the size of the effect (which is as large as that in all of the lithium studies of bipolar disorder taken together) and the remarkable consistency across studies argue against misdiagnosis as an adequate explanation for these findings. To our knowledge, there have been no studies of other putative mood stabilizers in the prevention of recurrent unipolar depression.

Embarking on Maintenance Treatment

Patients recovering from an episode of mania will usually be taking lithium and/or an anticonvulsant and/or an atypical antipsychotics. Patients recovering from an episode of

depression may be taking an antidepressant in addition to lithium and/or an anticonvulsant. Since many patients can be protected against recurrences of their illness with lithium or an anticonvulsant alone, adjunctive medications often can be gradually tapered off and discontinued. However, substantial numbers of patients with bipolar disorder will need to take a combination of medications to remain well.

For the recently manic patient, standard practice, reflected in published guidelines and consensus statements from North America, is to continue the medication or medications found to be effective during the acute phase of illness.⁵ While this practice is appropriate for managing the period immediately after resolution of the acute episode (the continuation phase of treatment), it is certainly not the best approach to true prophylaxis. Unfortunately, the North American guidelines do not distinguish adequately between true prophylaxis and continuation treatment. Simply because a drug has antimanic properties (and if continued, will protect against relapse back into mania in the months after the acute episode), one cannot assume that it will be effective in the prevention of new episodes in the future, particularly depressive episodes. While this assumption may be true (to some extent) for lithium, it is not well supported by the data with respect to all the other antimanic agents. Indeed, a recent post hoc analysis of the combined data from two 18-month randomized comparisons of lithium, lamotrigine, and placebo that focused on the period between 6 and 18 months (i.e., beyond the continuation phase) demonstrated that for the patients maintained on placebo, 84 to 86 percent of recurrences were to an episode whose polarity was *opposite* of that of the index episode (Calabrese et al., 2006; Goodwin and Calabrese [in preparation]). Box 20–1 outlines some issues involved in understanding what “maintenance” treatment means as the term is used today and provides a perspective on contemporary maintenance treatment guidelines, the evidence base for which is heavily weighted by trials involving relapse prevention after acute response, primarily antimanic response (see also Chapter 17).

Perhaps the most valuable and necessary resources for successful maintenance treatment of bipolar disorder are ones that, especially in the United States, are available in ever-decreasing supply: adequate time for assessment (in terms of both duration and frequency of appointments), and continuity of care over a period of months and years that allows the physician to become familiar with the rhythms and permutations of the patient’s illness and the individually unique signs of relapse. Evaluation of patients on a weekly basis during the initial stages of recovery from an acute episode and at least every 2 weeks thereafter as long as significant residual symptoms remain is necessary for an accurate assessment of continued recovery. Patients can be

BOX 20-1. Understanding Maintenance Treatment Guidelines

- Classically, three phases of treatment have been distinguished:
 - *Acute*: control of acute symptoms
 - *Continuation*: ongoing control of the acute episode (the length of this phase is proportional to the natural history of episodes)
 - *Maintenance or prophylactic*: prevention or attenuation of new episodes
- Because the natural history of bipolar disorder is for it to recur, on average, every 16–18 months, true prophylaxis cannot be evaluated in 6 or 12 mo.
- Contemporary relapse prevention designs that have generated U.S. Food and Drug Administration (FDA) “maintenance” indications show drug–placebo differences primarily in the continuation phase.
- Some guidelines recommend different maintenance treatments depending on whether the most recent episode was a mania or depression. However, this recommendation appears to be based on two studies* of drug–placebo differences in the first few months after an acute episode; later relapses (which were more likely to be new episodes) were of the opposite polarity 85 percent of the time.

*The two studies were of maintenance lamotrigine versus placebo—one with patients who had recently been depressed and the other with those who had recently been manic or hypomanic.

encouraged to keep a journal and a mood chart⁶ and to bring the results to appointments. Family members should always be encouraged to attend follow-up appointments with some regularity to report their impressions.

Selecting Medications

Clinical decision making is the art of making prudent choices based on insufficient information. Controlled data have not yet caught up with the realities and exigencies of clinical practice in the treatment of bipolar disorder (including, among other things, individual differences, comorbidities, and combined medications), especially in the area of long-term prophylactic treatment. Clearly, lithium is the most proven agent for the prevention of affective episodes, followed by lamotrigine, both of which have generated FDA “maintenance” indications; valproate may be effective in long-term prevention, but this conclusion is based on secondary analysis of one controlled trial, insufficient to support an FDA indication. In the North American guidelines (with the notable exception of those for the Veterans Health Administration), lithium and valproate are nonetheless given equal rank as first-line maintenance treatments. However, other guidelines around the world still rank lithium ahead of valproate, a position in line with

the most recent (and rigorous) Cochrane review of controlled studies of valproate, which concluded that “at present, the observed shift of prescribing practice [from lithium] to valproic acid is not based on reliable evidence of efficacy” (Macritchie et al., 2001). Olanzapine and aripiprazole have also been approved by the FDA for “maintenance” treatment of bipolar disorder (although, as discussed later, the evidence for atypicals is focused less on long-term prophylaxis and more on prevention of relapse into mania shortly after recovery from a manic episode, which is more properly referred to as continuation treatment). Finally, substantial data, primarily European, support use of the non-FDA-approved anticonvulsant carbamazepine. Other agents and combinations clearly have a role as well, as discussed in detail later in this chapter. A medication regimen for an individual patient will be based on diagnosis, the relative preponderance and severity of manic versus depressive symptoms, responses of the patient and family members to particular agents, comorbid conditions, cost, and drug allergies and sensitivities.

The 2006 prescription data for bipolar disorder in the United States show that lithium is the most prescribed agent, followed closely by lamotrigine, then divalproex, then quetiapine. In 2001, divalproex was the most prescribed, followed closely by lithium. For 2006, carbamazepine and oxcarbazepine combined had less than half the market share achieved individually by lithium, lamotrigine, or divalproex. The most dramatic change in U.S. prescription patterns from 2001 to 2006 is the sharp increases in market share for lamotrigine and quetiapine, accompanied by comparable decreases in divalproex and lithium. The European market for medications for bipolar disorder is somewhat different. Lithium remains the market leader with a share almost identical to that in the United States; valproate and valpromide combined are second, followed by olanzapine, then lamotrigine, then carbamazepine. Between 2001 and 2006, lithium’s market share in Europe declined by 24 percent, while carbamazepine’s share dropped by 48 percent and valproate’s share doubled. It should be noted that these data reflect all uses of the drugs in bipolar patients, including both acute and maintenance treatment.

It is important to bear in mind that some fluctuations of mood in patients being treated for bipolar disorder reflect cyclic or phasic changes of the illness that will normalize with time and do not necessarily call for additional pharmaceutical intervention. Patients may have brief depressive periods following a period of mania or transient episodes of mild hypomania following recovery from depression. Experienced clinicians know that being too quick to intervene during these periods can result in the prescription of unnecessary additional medications that may ultimately

be destabilizing in the case of antidepressants or oversedating in the case of anticonvulsants and antipsychotics. During the maintenance phase of treatment, mood *stability* should be a treatment goal comparable with that of euthymia. At times, interventions designed to further one of these goals may require restraint in interventions addressing the other.

The decision as to when and how quickly to attempt tapering off and discontinuing a medication that may have been used for an acute episode must always be an individualized one as well. The patient's previous course of illness, demonstrated response to and requirement for particular medications, and willingness to accept the risks of ongoing medication treatment versus the risk and consequences of relapse will offer important guidance. Likewise, although the best available research data indicate that lithium should be the mainstay in the treatment of bipolar disorder in most circumstances, an individual patient's inability to tolerate lithium therapy, as well as breakthrough or residual symptoms, may dictate the selection of alternative or adjunctive agents. That said, it is beyond regrettable that many young psychiatrists in the United States have never really learned the science and art of lithium treatment, and that they excuse their ignorance by convincing themselves that lithium has been surpassed by more effective medications or that it is too difficult to use—a self-fulfilling prophesy. It is our belief that clinicians who are unable or unwilling to include the skillful use of lithium in their armamentarium should not be considered competent to treat bipolar disorder.

There are, of course, many patients who legitimately need and benefit from alternatives or adjuncts to lithium, and fortunately, controlled data and clinical experience are increasingly available to guide the clinician in identifying those agents. Emerging data suggest that lamotrigine may be especially helpful for the prevention of depressive episodes, and valproate and carbamazepine for the prevention of manic episodes. As noted earlier, the role of the atypical antipsychotics, such as olanzapine and aripiprazole, in the long-term prevention of new manic episodes is less clear. Although these two drugs have "maintenance" indications from the FDA, results of existing studies are probably best interpreted as demonstrating their prevention of relapse back into the acute manic episode (continuation treatment), leaving open the question of whether they can prevent future new episodes, especially of depression (that is, whether they are true prophylactic agents).

The full range of available clinical data will be necessary in making decisions for individual patients, many of whom inevitably resemble the subjects that are excluded from or drop out of controlled studies because of severe and/or complex illness or inability to tolerate particular agents. For

example, the data on the ability of lamotrigine to prevent depressive relapses, taken together with the more ambiguous data on this agent's mania-preventing effects, might argue for its being added to rather than substituted for lithium in a patient with bipolar-I disorder who experiences breakthrough depressive symptoms on lithium alone. On the other hand, the addition of an antidepressant rather than lamotrigine makes sense for a patient with bipolar-II disorder who has similar symptoms but a history of developing a severe rash when taking an antibiotic. For the bipolar-I patient whose history suggests a high risk of manic recurrences and who is developing renal complications while taking lithium, valproate, carbamazepine, or an atypical antipsychotic might be used as a substitute for lithium (accompanied by the latter's *gradual* withdrawal) rather than as an adjunctive agent.

In each of the above situations, there are reasons not to pursue the particular course of action described, and it is quite possible to justify other approaches. In the absence of definitive data, the clinician has little choice but to craft each patient's treatment plan gradually based on a careful assessment of target symptoms over time and on the patient's response to treatment—always with an eye to the development of medication intolerances and side effects. It is well to keep in mind that the great majority of the time, the next new episode following a mania is a depression and vice versa (see our later review of the literature).

Below we review in turn the use of lithium, valproate, carbamazepine/oxcarbazepine, lamotrigine, other anticonvulsants, and the atypical antipsychotics for maintenance treatment of manic-depressive illness, with an emphasis on the bipolar subgroup. The pretreatment evaluation and ongoing monitoring recommended for maintenance mood stabilizers are outlined in Table 20-1; similar recommendations for maintenance atypical antipsychotics are outlined in Table 20-2.

Lithium

Some debate continues regarding optimal serum lithium levels for maintenance monotherapy of recurrent affective disorders, particularly the bipolar subgroup. How to balance the greater efficacy and increased side-effect burden with increasing serum levels is a clinical decision that must be individualized for each patient (Luby and Singareddy, 2003). Gelenberg and colleagues (1989) compared the ability of "standard" (.8 to 1.0 mEq/l) and lower (.4 to .6 mEq/l) levels to prevent recurrences among bipolar-I patients. Although the higher levels were associated with superior protection against relapse, they were also associated with greater dropout rates due to side effects. A major problem with this study, however, is that the findings actually reflect the effect of lowering the lithium level from the

TABLE 20–1. Pretreatment Evaluation and Ongoing Monitoring for Maintenance Mood Stabilizers

Agent	Therapeutic Range (blood level)	Monitoring	Other Considerations
Lithium	0.6–0.8 mEq/l for bipolar-I; lower for bipolar-II, highly recurrent unipolar, and adjunctive use (0.4–0.6 mEq/l)	<ul style="list-style-type: none"> • Serum lithium level: 6-mo intervals in euthymic patients. Consider more frequent determinations in the elderly or medically ill or in special circumstances, such as need to check postoperative status or compliance. • Serum creatinine: 6- to 12-mo intervals (more frequent in elderly or medically ill patients). • Urine volume (24-hr output) if history of substantial polyuria is obtained. • TSH free triiodothyronine (T₃), T₄ by dialysis, thyroid peroxidase antibodies at 12-mo intervals. Consider ultrasound thyroid scan after 1–2 yr of treatment. 	<ul style="list-style-type: none"> • Monitor weight; intervene at >5 lb (focus on carbohydrate control and exercise). • Tremor generally responds to low-dosage beta-blockers. • Once-a-day dosing is best for most patients. • Slow/extended-release preparations are associated with fewer side effects. • Office-based lithium assay technology markedly increases convenience for both patient and clinician.
Carbamazepine	4–12 µg/ml	<ul style="list-style-type: none"> • Pregnancy test (HCG) • Hepatic profile. • Complete blood count (CBC), including platelets every 2 wk for 2 mo, then quarterly. • Electrolytes, especially sodium. 	<ul style="list-style-type: none"> • Induces metabolism of many agents, including itself. • Higher doses of oral birth control agents recommended. • Monitor weight; intervene at >5 lb.
Valproate	45–125 µg/ml (median = 84)	<ul style="list-style-type: none"> • Pregnancy test (serum HCG). • Hepatic profile, amylase, and electrolytes periodically. 	<ul style="list-style-type: none"> • Regular monitoring of reproductive history (menstrual cycle, galactorrhea, and hirsutism) recommended especially for younger women. • Monitor weight; intervene at >5 lb.
Lamotrigine	Not determined	<ul style="list-style-type: none"> • Assessment for rash, especially during first 12 wk. • Pretreatment antigen screen can reduce background rate of benign rash (see text). 	<ul style="list-style-type: none"> • Severe dermatological reactions are rare with gradual titration (≈ 1/5,000). • Plasma level is doubled by valproate and decreased by carbamazepine but not oxcarbazepine.

(continued)

TABLE 20–1. Pretreatment Evaluation and Ongoing Monitoring for Maintenance Mood Stabilizers (*continued*)

Agent	Therapeutic Range (blood level)	Monitoring	Other Considerations
Oxycarbazepine	Not determined	<ul style="list-style-type: none"> • Pregnancy test (serum, HCG). 	<ul style="list-style-type: none"> • Less induction than carbamazepine. • Higher dosage of oral contraceptive required.

Notes: General pretreatment evaluation for mood stabilizers encompasses medical history focusing on renal, endocrine, cardiac, hepatic, hematopoietic, and nervous systems; catalog of present and past drug use, including prescriptions, over-the-counter drugs, illicit drugs, caffeine, nicotine, and alcohol; baseline blood pressure, complete blood count (CBC), electrolytes, hepatic profile, creatinine, thyroxine (T_4), thyroid-stimulating hormone (TSH), and urinalysis; and pregnancy test (serum human chorionic gonadotrophine [HCG]) where appropriate. Only lithium and lamotrigine have been approved by the U.S. Food and Drug Administration for maintenance use.

Source: Adapted with permission from Bowden et al., 2000b.

standard to the low level, which may have been associated with a lithium withdrawal effect (Perlis et al., 2002). Another limitation of the study is that it did not include a group with levels in the key range of .6 to .8 mEq/l. A finer-grained analysis was provided by Maj and colleagues (1986), who randomized 80 consecutive bipolar patients to one of four different plasma levels: .3–.45, .46–.6, .61–.75, and .76–.9 mEq/l. All but the group with the lowest level showed a significant reduction in affective episodes and overall morbidity.

Recommended serum levels have trended downward over the decades since lithium was first introduced, with most experts now recommending a compromise between the levels studied by Gelenberg and colleagues (1989) and Maj and colleagues (1986). Akiskal (2000) recommended a rather broad range of .3 to .8 mEq/l in his chapter on mood disorders in the *Merck Manual*. Schou (2001), the father of modern maintenance lithium therapy, narrowed this range a bit to .5 to .8 mEq/l, while Maj and colleagues (1986) concluded that beyond .8 mEq/l, negative outweigh positive effects. It may be that most studies have failed to show a relationship between lithium levels within the generally accepted range of .5 to 1.0 mEq/l and clinical response (see, e.g., Vestergaard et al., 1998) because the potentially greater efficacy at higher levels is offset by more problems with adherence (G. Goodwin and Geddes, 2003). The guidelines of the American Psychiatric Association (2002) note that .6 to .8 mEq/l is the range commonly chosen by bipolar-I patients and their psychiatrists for lithium monotherapy, while .4 to .6 mEq/l is recommended for adjunctive lithium therapy for bipolar-I or monotherapy for bipolar-II or highly recurrent unipolar depression (Goodwin and Goldstein, 2003).⁷ An interesting recent paper (Severus et al., 2005) reviewed the lithium-level data from both earlier and more recent studies (in the latter, lithium was included as an active “control” in trials of new putative mood stabilizers). The conclusion of this paper was that relatively lower levels are optimal for prevention of

depression (as we noted in the first edition of this text), whereas relatively higher levels may be best for prevention of mania, yielding an optimal range of .5 to .8 mEq/l for overall stabilization.

Serum lithium levels should be obtained whenever there has been a change in dosage and at least every 6 months in stable patients. Recently, obtaining lithium levels has become significantly easier for both patient and physician with the development of a reliable office-based instant blood test that can be accomplished as part of the patient’s regular visits to the psychiatrist (Glazer et al., 2004). The instant feedback provided by this technology has obvious advantages for clinical management, particularly in addressing issues related to adherence.⁸ Elderly and medically frail patients should, of course, be tested more often (treatment of the elderly is discussed in greater detail later in this chapter). Most of lithium’s side effects correlate with serum levels and can often be ameliorated by changing the dosage schedule or using sustained-release preparations (which result in lower peak levels). Gastrointestinal symptoms are not uncommon but are generally transient.⁹ Polydipsia and polyuria, as well as edema that occurs early on, often resolve with time and can be managed with low doses of loop diuretics or potassium-sparing diuretics, such as amiloride; patients who develop polyuria only after months or years should be evaluated for nephrogenic diabetes insipidus (see the later discussion). Diuretics, especially thiazide diuretics, may alter lithium excretion, and serum lithium levels must be closely monitored in these patients to avoid toxicity.¹⁰

Side effects associated with lithium treatment, with particular reference to long-term effects, are shown in Table 20–3; they include weight gain, some cognitive dulling and fine hand tremor (both dose-related), dermatological problems, nephropathy in a very small number of patients, nephrogenic diabetes insipidus, and thyroid-suppressing effects. The latter effects may be temporary in some patients, but in others may proceed to clinical or subclinical

Notes: General pretreatment evaluation for atypical antipsychotics: medical history focusing on endocrine, cardiac, hepatic, hematopoietic, and nervous systems; catalog of present and past drug use, including prescriptions, over-the-counter drugs, illicit drugs, caffeine, nicotine, and alcohol; baseline blood pressure, complete blood count (CBC), electrolytes, hepatic profile, creatinine, thyroxine (T_4), thyroid-stimulating hormone (TSH), urinalysis; pregnancy test (serum human chorionic gonadotrophine [HCG]) where appropriate. In addition (for clozapine, olanzapine, risperidone, and quetiapine), weight (and body mass index [BMI]), waist measurement, personal/family history of weight problems and/or diabetes, fasting plasma glucose, and fasting lipid profile. Olanzapine and aripiprazole are FDA-approved for relapse prevention. Data derived primarily from controlled monotherapy trials with little or no comorbidity. Prevalence of extrapyramidal syndrome (EPS) with use of atypical antipsychotics in bipolar patients appears to be considerably higher among those treated in the community (Ghaemi et al., 2006).

hypothyroidism (which of course should be treated early with replacement thyroid hormones). Indeed, thyroid supplements may enhance stability and help reduce some side effects in bipolar patients in whom formal hypothyroidism is not present (Bauer and Whybrow, 2001; Goodwin and Goldstein, 2003). We recommend starting at .025 mg of thyroxine (T_4), increased by .025 mg every 3 to 4 weeks until the free T_4 level is in the upper quartile of the normal range or until side effects ensue (such as, overactivation, tachycardia, tremor, or changes in body temperature regulation), at which point the dosage can be decreased. Unfortunately, some of the published guidelines for maintenance treatment do not even mention thyroid supplementation.

Weight gain is not uncommon with lithium use, and the mechanisms of this weight gain remain unexplained.¹¹ Approximately one-quarter to one-half of patients taking lithium experience a 5 to 10 percent weight gain (Perselow et al., 1980; Fagiolini et al., 2002). Excessive weight gain, in

addition to its inherent deleterious effects, is a common reason for nonadherence to lithium use (see Chapter 21). Temporary fluid retention can be expected to result in a gain of 2 to 3 pounds; however, the clinician should act aggressively to prevent a gain of more than 5 pounds. Increased serum leptin levels have been detected in lithium-treated bipolar patients (Atmaca et al., 2002) but not in healthy volunteers taking lithium (Baptista et al., 2000). Diet (especially the control of simple carbohydrates), exercise, and perhaps correction of reduced thyroid function may be helpful in managing lithium-induced weight gain.¹² There are also reports of reduction of lithium-induced weight gain with the adjunctive use of topiramate (Chengappa et al., 2002; Nemeroff, 2003), but the additive effects of the two drugs on cognitive function often limit the usefulness of this combination.

Cognitive dulling, with complaints of poor concentration, impaired memory, and mental slowing, is known to be

TABLE 20–3. Principal Adverse Effects of Drugs Used as Monotherapy at Recommended Doses for Maintenance Treatment

Drug	Neurocognitive Impairment	Sedation	Weight Gain	Other (see also Table 20–2)
Lithium	++	0 / +	++	Gastrointestinal (initially), thyroid, renal (nephrogenic diabetes insipidus), tremor, dermatological
Carbamazepine	+ / ++	+	+	Hematological, rash, diplopia, ataxia, drug interactions
Oxycarbazepine	+	+	+ / 0	Rash, drug interaction with oral contraceptives, diplopia
Valproate	+ / ++	+ / ++	++	Tremor, hair loss, hepatic and reproductive changes including polycystic ovary syndrome, pancreatitis (rare)
Lamotrigine	0	0	0	Rash, transient headache
Clozapine	? ^a	++	+++	Aplastic anemia (monitor for), orthostatic hypotension, anticholinergic effects, hyperlipidemia and metabolic syndrome
Olanzapine	? ^a	++	+++	Hyperlipidemia, metabolic syndrome
Risperidone	? ^a	++	+	Hyperprolactinemia, extrapyramidal syndrome, hyperlipidemia (low risk), metabolic syndrome
Quetiapine	? ^a	++	++	Hyperlipidemia
Ziprasidone	0	0	0	Some QTc prolongation, but its clinical significance is questionable; initial (low-dose) activation/agitation
Aripiprazole	^a	0/+	0	Activation/anxiety initially in some patients

^aTo varying degrees, atypical antipsychotics cause sedation, which some may regard as a neurocognitive side effect. EPS = extrapyramidal syndrome; PCOS = polycystic ovary syndrome.

caused by lithium; this problem generally responds to reducing the dosage, shifting the entire dose to bedtime,¹³ and/or enhancing thyroid function. Fine tremor is another dose-related side effect. Tremor sometimes subsides spontaneously after several weeks of treatment, and it can be worsened by coadministered medications such as selective serotonin reuptake inhibitors (SSRIs) and bupropion; it generally responds to treatment with beta-blockers. Dermatological problems associated with lithium use include acne and, occasionally, hair loss, problems that are usually minor. Acne responds to local treatment and antibiotics; isotretinoin should be used with caution because of the possible risk of exacerbating suicidality. Lithium can exacerbate preexisting psoriasis so severely as to preclude its use, although some patients with psoriasis will respond to the agents usually effective for the condition (Tsankov et al., 2000).¹⁴ Lithium has also been associated with a variety of benign electrocardiogram (ECG) changes, but significant cardiac conduction changes or arrhythmias are very uncommon (Steckler, 1994).

As the long-term effects of lithium on the kidney have become clearer, earlier concerns about its nephrotoxicity have eased significantly.¹⁵ While the risk of reduced glomerular function with lithium appears to be very low,

a small number of patients appear to develop glomerular and tubulointerstitial nephropathy¹⁶ that can progress to renal insufficiency and be irreversible if not detected early enough. It appears that in this small group of vulnerable patients, lithium interacts with other medical conditions (e.g., hypertension) or familial or environmental problems to cause progressive renal failure. In a review of such cases, the reversibility of renal insufficiency after discontinuation of lithium appeared to be associated with serum creatinine levels lower than 2.5 mg/dl, further highlighting the need for monitoring of renal function in patients taking lithium. Creatinine clearance determinations are no longer recommended for routine monitoring; obtaining serum creatinine determinations every 3 to 12 months, depending on such factors as age and general medical conditions, is reasonable. Patients who have serum creatinine levels consistently greater than 1.6 mg/dl (or whose level is 25 percent or more above the pretreatment baseline) should be referred for medical evaluation, which should start with a creatinine clearance determination. The more common lithium-associated renal problem is nephrogenic diabetes insipidus (reflected in “creeping creatinine”), seen in about 20 percent of those taking lithium for 15 to 20 years or longer (Lepkifker et al., 2004),¹⁷ which is caused by lithium-induced

reductions in the capacity of the distal tubules to reabsorb electrolytes. This condition is accompanied by a mild but significant decrease in urine-concentrating ability,¹⁸ which has been demonstrated in most (though not all) longitudinal studies of lithium's effects on the kidney. It appears that this effect is due to a lithium-induced interference with the sensitivity of the distal tubule to antidiuretic hormone. Earlier cross-sectional studies suggested a correlation between duration of lithium treatment and decreased maximum urine osmolality. More recent longitudinal studies have not found a progressive decrease over time, however, suggesting that there is a decrease in urine-concentrating ability during the first few years of lithium treatment and little or no further progression in ensuing decades. Results of lithium discontinuation studies indicate that increases in 24-hour urine output remain the same or decrease only slightly (at least in the short term) after the drug is discontinued. Patients should be asked about polyuria and a 24-hour urine volume measurement obtained if polyuria is suspected.¹⁹ Reducing polyuria can be especially important when nocturia is significant enough to interfere with sleep since sleep disruption can destabilize the illness.

All the studies of lithium's renal effects have involved standard immediate-release lithium. There are some data to suggest that slow- or extended-release preparations have significantly less impact on urinary osmolality (Miller et al., 1985) and might therefore be expected to have a more benign renal profile. There have as yet been no long-term studies of slow- or extended-release preparations to permit direct evaluation of this hypothesis, however.

Results of two relatively recent studies appear to suggest that serious long-term effects of lithium use on renal functioning may not be rare (Markowitz et al., 2000; Bendz et al., 2001). However, these studies involved a small sample of lithium users within a much larger sample of patients with renal deficiencies, and in one study (Markowitz et al., 2000), the proportion of lithium users within the sample was the same as that within the general population, a finding not consistent with a lithium effect. Kallner and colleagues (2000) studied nearly 500 patients treated with lithium for up to 30 years and found no deaths related to chronic renal insufficiency. Likewise, to our knowledge no clinical studies have found an increase in end-stage renal disease that could be attributed to lithium use in the absence of other risk factors.

Lithium decreases thyroid hormone release and may interfere with other steps in the synthesis of thyroid hormones, and has been reported to inhibit the conversion of T_4 to triiodothyronine (T_3) in the periphery and neurons (reviewed by Kleiner et al., 1999). Patients may respond to these thyroid-suppressing effects with a rise in thyroid-stimulating

hormone (TSH) that is usually temporary. Some patients on lithium therapy, however, progress to clinical or subclinical hypothyroidism. Bocchetta and colleagues (2001) reported on the thyroid function of patients followed in an Italian lithium clinic for more than 10 years and concluded that patients are at increased risk of developing clinical or subclinical hypothyroidism during the first few years of lithium therapy, with rates declining to near those of the general population thereafter.²⁰ Their 10-year follow-up study of 150 patients who had already been taking lithium for various lengths of time when they entered the study found that the incidence of new-onset hypothyroidism, goiter, and thyroid autoimmunity did not differ from that reported for the general community (Bocchetta et al., 2001). This study found that women and individuals with thyroid autoimmunity were at highest risk of developing hypothyroidism while taking lithium. The authors recommended testing for baseline thyroid function at the start of lithium therapy; determination of TSH, free T_3 , free T_4 , and thyroid peroxidase antibodies (TPO Abs), as well as ultrasonic scanning of the thyroid, after 1 or 2 years of lithium treatment; annual TSH determinations thereafter; and TPO Abs and thyroid ultrasound scans at 2- to 3-year intervals. Regarding autoimmune thyroiditis itself, a large study by the Stanley Foundation Bipolar Network (Kupka et al., 2002) found that the prevalence of TPO Abs was significantly higher among 226 bipolar patients than among 3,190 psychiatric patients of any diagnosis or 252 community controls; while the frequency of TPO Abs was not associated with lithium exposure, hypothyroidism was. Kleiner and colleagues (1999) suggested that both TPO Abs and antithyroidglobulin be determined for patients at the beginning of lithium therapy to identify those at greater risk for developing hypothyroidism. They recommended TSH determinations as the most sensitive and therefore only needed test to monitor patients for lithium-induced thyroid dysfunction. They recommended that TSH be measured every 3 months during the first year of lithium therapy and semiannually to annually thereafter (Kleiner et al., 1999).²¹

Treatment of Lithium Toxicity

Prevention is the most important principle in managing lithium toxicity or intoxication. By detecting early signs and adjusting dosages, the problem can be averted. The most sensitive indicator of incipient lithium toxicity is the central nervous system (CNS) perhaps particularly the cerebellum. Patients must be alerted in advance to CNS symptoms, and each encounter with the patient should include some assessment of CNS functioning. The agitation and restlessness of early lithium intoxication are similar to symptoms of mixed affective states, and distinguishing between the two phenomena can be difficult.

If the intoxication is so severe that lithium withdrawal is not sufficient, the patient should be admitted to a hospital and cared for by a specialist in the treatment of poisoning. The first of several methods used to treat lithium poisoning is the vigorous application of general supportive measures appropriate in any CNS poisoning. Obviously, kidney function should be preserved by maintaining blood pressure and replacing fluids and salt, but if it falters, hemodialysis is necessary. Although most patients recover after deliberately or accidentally overdosing on lithium, some are left with a persistent neurological or renal defect, and a few die. Because of these severe complications, the possibility of lithium intoxication should never be taken lightly. Patients with preexisting vulnerabilities, particularly in kidney or CNS function, plainly require more careful monitoring. Further information about lithium intoxication and treatment guidelines for managing it are available on our Web site.

Valproate

Compared with lithium, there are fewer data on effective levels of valproate for maintenance treatment; at this point it appears reasonable to use the levels published in the large, multisite 1-year maintenance trial conducted by Bowden and colleagues (2000a) (see Table 20–1). Side effects become increasingly problematic at levels greater than 125 µg/ml. Dose-related side effects of valproate (see Table 20–3) include neurocognitive dysfunction and weight gain, as well as nausea, vomiting, and other gastrointestinal complaints, such as abdominal pain and heartburn. If possible, the drug should be started gradually to avoid these gastrointestinal symptoms, and a temporary reduction in dose can often alleviate them. Sedation is a common side effect, so it is best to take most if not all of the daily dose at bedtime. Indeed, given the importance of maintaining sleep stability in bipolar patients, this particular side effect can be turned into an advantage. Tremor is not uncommon; indeed, in the 1-year comparison of lithium, valproate, and placebo carried out by Bowden and colleagues (2000b), both drugs produced tremor at the same rate, sedation and hair loss were significantly greater with valproate, and weight gain showed a trend to be more frequent with valproate than with lithium. There are reports that adjunctive topiramate can reduce valproate-induced weight gain (McElroy et al., 2000; Chengappa et al., 2002), but as with lithium, additive cognitive side effects limit the usefulness of this combination for many patients. Transient minor elevations in hepatic transaminases are common when treatment with valproate is initiated and usually subside over time. Valproate can cause severe hepatotoxicity, but the risk to adults appears to be very low; most fatalities have occurred within 4 months after initiation of therapy. Careful

monitoring of liver function is recommended when valproate is first administered as the hepatotoxicity is reversible in some cases if the drug is withdrawn. Similarly, rare cases of hemorrhagic pancreatitis have been reported that appear to be related to initiation of the drug or dosage increase in susceptible individuals. Delay of diagnosis has been implicated as a factor contributing to these rare cases, and patients should be warned about the symptoms and potential severity of pancreatitis. Another observed idiosyncratic response with valproate is thrombocytopenia, although documented cases of abnormal bleeding are lacking.

Some though not all reports of women treated for epilepsy have linked valproate with a high rate of gynecological problems, including menstrual irregularities, polycystic ovary syndrome (PCOS), and androgenization.²² A recent large, multicenter study of epileptic patients compared valproate ($n = 225$) and lamotrigine ($n = 222$)²³ and found significantly more PCOS symptoms among the valproate-treated patients (54 versus 38 percent; $p < .01$). Although it has been suggested that women taking valproate for psychiatric conditions have less risk of these reproductive abnormalities, two small studies of bipolar patients taking valproate obtained results similar to those of the Isojarvi study of epileptic patients (O'Donovan et al., 2002; McIntyre et al., 2003). More important, a recent NIMH STEP-BD study of 230 bipolar women aged 18 to 45²⁴ found 7.5 times more PCOS (10.5 versus 1.4 percent, $p < .002$) in the 12 months following initiation of valproate compared with women who had initiated a variety of other mood stabilizers (Joffe et al., 2006). Obviously, regular monitoring of reproductive function in female patients taking valproate is needed, with questions being raised during visits regarding menstrual disorders, fertility, weight gain, hirsutism, and galactorrhea. Table 20–1 summarizes the monitoring that should be performed when valproate and the other anticonvulsants (discussed in the following sections) are used for maintenance treatment of bipolar disorder.

Carbamazepine/Oxcarbazepine

A therapeutic range for carbamazepine in the maintenance treatment of bipolar disorder has not been determined by studies correlating serum levels with clinical efficacy (see Table 20–1). In clinical trials, however, levels comparable to those used to treat epilepsy have typically been attained (Post et al., 1986, 1987). Carbamazepine has the ability to induce the hepatic microsomal enzymes responsible for its own metabolism, and considerable dosage adjustments may be necessary during the first weeks of therapy. In several studies of epileptic patients or volunteers on dosage regimens exceeding 1 month, the clearance of carbamazepine

increased two-fold over initial treatment. Carbamazepine also decreases the clearance of other drugs, including valproate and benzodiazepines, and increases the metabolism of lamotrigine, ethinylestradiol, and progesterone. Contraceptive failure can occur with oral contraceptives containing less than 50 µg of ethinylestradiol (see Crawford, 2002).

The most common dose-related adverse effects of carbamazepine are diplopia and ataxia. Other dose-related complaints include mild gastrointestinal upset, unsteadiness, cognitive slowing, and, at much higher doses, drowsiness.²⁵ Hyponatremia and water intoxication have occasionally occurred and may be dose-related (see Table 20–3). Idiosyncratic blood dyscrasias, including fatal cases of aplastic anemia and agranulocytosis, are the most serious concern with carbamazepine.²⁶ Periodic blood counts are recommended to monitor for these effects of the drug, along with educating the patient on the signs and symptoms of these reactions. A retrospective study of 977 psychiatric inpatients taking carbamazepine found a 2.1 percent incidence of moderate to severe leucopenia, occurring mainly within the first few weeks, with none of the cases progressing to life-threatening illness (Tohen et al., 1995). A mild and persistent leukopenia is seen in some patients and is not necessarily an indication to stop treatment. There have been a few reports of hepatic failure in patients taking carbamazepine. A complete blood count with platelet count and liver function tests should be performed on patients starting carbamazepine every 2 weeks during the first month of treatment, at least every 3 weeks for the next few months, and then every 2 to 3 thereafter. Patients should be instructed regarding the signs and symptoms of hematological and hepatic reactions.

Other blood dyscrasias, including thrombocytopenia and hemolytic anemia, can also occur. Because of this risk, hematological monitoring is required before carbamazepine is initiated and fortnightly for the first few months

of treatment. If the white blood cell count falls to less than 3,000 cells/mm³ or the neutrophil count to less than 1,000/mm³, the carbamazepine should be reduced or stopped while further monitoring takes place (Sobotka et al., 1990). It may take 2 weeks or longer for white blood counts to return to normal after the drug is discontinued. Clinically, apparent hepatitis is uncommon, but transient elevation of the liver enzymes is not. Benign rashes are quite common (up to 15 percent) in carbamazepine-treated patients. Dermatological hypersensitivity, including Stevens-Johnson syndrome and the sometimes fatal toxic epidermal necrolysis, is a serious though rare idiosyncratic reaction to carbamazepine (Table 20–4).

Although controlled data on the efficacy of oxcarbazepine in treating bipolar disorder are still scant, it has at least one advantage over carbamazepine—aplastic anemia and agranulocytosis have not been associated with its use (Chen et al., 1999). Effective doses of oxcarbazepine are a third to a half higher, but unlike carbamazepine, oxcarbazepine does not induce its own hepatic metabolism, obviating the need for dosage adjustment after the initial treatment period. Moreover, oxcarbazepine is a much weaker inducer of the cytochrome P450 system and is not as highly bound to serum proteins, so it has fewer interactions with other protein-bound drugs, such as phenytoin and warfarin; also, it does not affect the metabolism of lamotrigine or valproate. As with carbamazepine, however, plasma levels of estrogen and progesterone tend to be reduced by oxcarbazepine, so only high-dose contraceptives should be used, to counteract this effect (see Ahmed and Anderson, 2001). To our knowledge there have been no studies examining the relationship between plasma levels of oxcarbazepine and clinical efficacy in treating bipolar disorder. The most common side effects of oxcarbazepine are dizziness, sedation, and blurred vision. Rashes also occur, and although they are seen less commonly than with carbamazepine, 25 to 30 percent of

TABLE 20–4. Estimated Risk of Stevens-Johnson Syndrome and Toxic Epidermal Necrolysis among Anticonvulsants

<i>Anticonvulsant</i>	<i>Risk per 10,000 New Users</i>
Phenytoin	8.3
Phenobarbital	8.1
Lamotrigine	2.5

patients with hypersensitivity to carbamazepine are also hypersensitive to oxcarbazepine.

Lamotrigine

Clinical trials of lamotrigine for acute and maintenance treatment of bipolar disorder have employed doses ranging from 50 to 400 mg/day, and a target daily dose of 200 mg/day for maintenance treatment appears to be reasonable (Calabrese et al., 1999a; Bowden, 2003b). Adjunctive use of an anticonvulsant drug that induces hepatic microsomal enzymes (e.g., carbamazepine, phenobarbital, phenytoin, primidone) increases the clearance of lamotrigine; conversely, valproate interferes with the metabolism of lamotrigine, approximately doubling its half-life. Although serum levels of lamotrigine are routinely available, a therapeutic range for the treatment of bipolar disorder has not been determined.

As noted in Table 20–3, lamotrigine has a very favorable side-effect profile, with transient headache and dizziness being the most common complaints. In contrast to lithium and valproate, when lamotrigine is used as monotherapy at recommended doses, it does not appear to be associated with neurocognitive side effects (Lieberman and Goodwin, 2004) and unlike lithium and valproate and most of the atypical antipsychotics, it does not cause sedation or weight gain (Sachs et al., 2006). Indeed, it has been associated with weight loss in obese bipolar patients (body mass index greater than 30 kg/m² [Bowden et al., 2006]).

Of particular concern with lamotrigine, however, are reports of severe dermatological reactions associated with rapid initial upward titration of the dose, including Stevens-Johnson syndrome and toxic epidermal necrolysis.

Serious rash may be more common in younger patients, and lamotrigine therefore is not approved for use in patients under age 16.²⁷ Based on results of clinical trials in bipolar patients, the incidence of serious rash has been estimated to be 1 in 1,200 (the current FDA labeling), but this estimate was derived by counting all patients who had a rash of any sort in whom the drug was discontinued and the patient was hospitalized. In reality, the drug was typically discontinued for any rash, and the hospitalizations were not necessarily related to rash. Indeed, among 2,624 patients in the clinical trials, only 1 was hospitalized for a rash, and that patient's dose had reached 100 mg by the end of the second week (data on file, GlaxoSmithKline). The most reliable rash data come from the German rash registry, which estimates the risk of serious rash to be about 1 in 5,000 lamotrigine exposures among patients being treated for epilepsy. Since almost all of these data are based on the use of the drug by neurologists, even this estimate is probably too high when applied to the more gradual titration employed in the treat-

ment of bipolar disorder. Because benign rashes are not uncommon with this drug (about 2 to 5 percent greater frequency than with placebo), it is important to be able to distinguish them²⁸ from those rare cases in which a rash may signal the development of Stevens-Johnson syndrome or toxic epidermal necrolysis.

Figure 20–1 provides a decision-making flowchart for dealing with rash in patients taking lamotrigine. Dangerous rashes typically are confluent (covering virtually all of the skin) and/or involve the facial or genital area given the proximity of each to mucous membranes; also, dangerous rashes are almost always accompanied by systemic symptoms such as fever, elevated white blood cell count, and flu-like symptoms. It is of interest to note that in the German registry, a number of other drugs, including some anticonvulsants, rank ahead of lamotrigine in the frequency with which they are associated with serious rashes (see Table 20–4). Kanner and Frey (2000) reported that valproate can be added to lamotrigine safely if the dose of the latter is lowered by 50 percent after the start of valproate therapy. These findings suggest that rash resulting from the combination of the two drugs is not due to a pharmacodynamic interaction, but to a pharmacokinetic one in which a sudden increase in lamotrigine levels occurs in the presence of valproate. Finally, there have been a few case reports of agranulocytosis among patients taking lamotrigine (de Camargo and Bode, 1999; Solvason, 2000), but a causal relationship has not been established.

Other Anticonvulsants

No therapeutic ranges have been established for gabapentin, tiagabine, or topiramate. These agents generally have favorable side-effect profiles, with the exception of the dulling cognitive effects of topiramate. Thus no routine therapeutic monitoring is presently recommended for patients taking these agents.

Atypical Antipsychotics

Typical antipsychotic medications have been used mainly as adjunctive agents in the acute phases of bipolar disorder, especially for manic states (see Chapter 18), and they still form the mainstay of acute treatment for mania in many European centers. Given the risk of tardive dyskinesia with the typical antipsychotics,²⁹ they have usually been viewed as having only a temporary role in the treatment of bipolar disorder, with discontinuation recommended as soon as symptoms stabilize. Because they were for a long time the only psychotropics available as long-acting depot agents,³⁰ they have been used, when effective, in a small number of patients who have failed to adhere to oral medication regimens (Littlejohn et al., 1994).

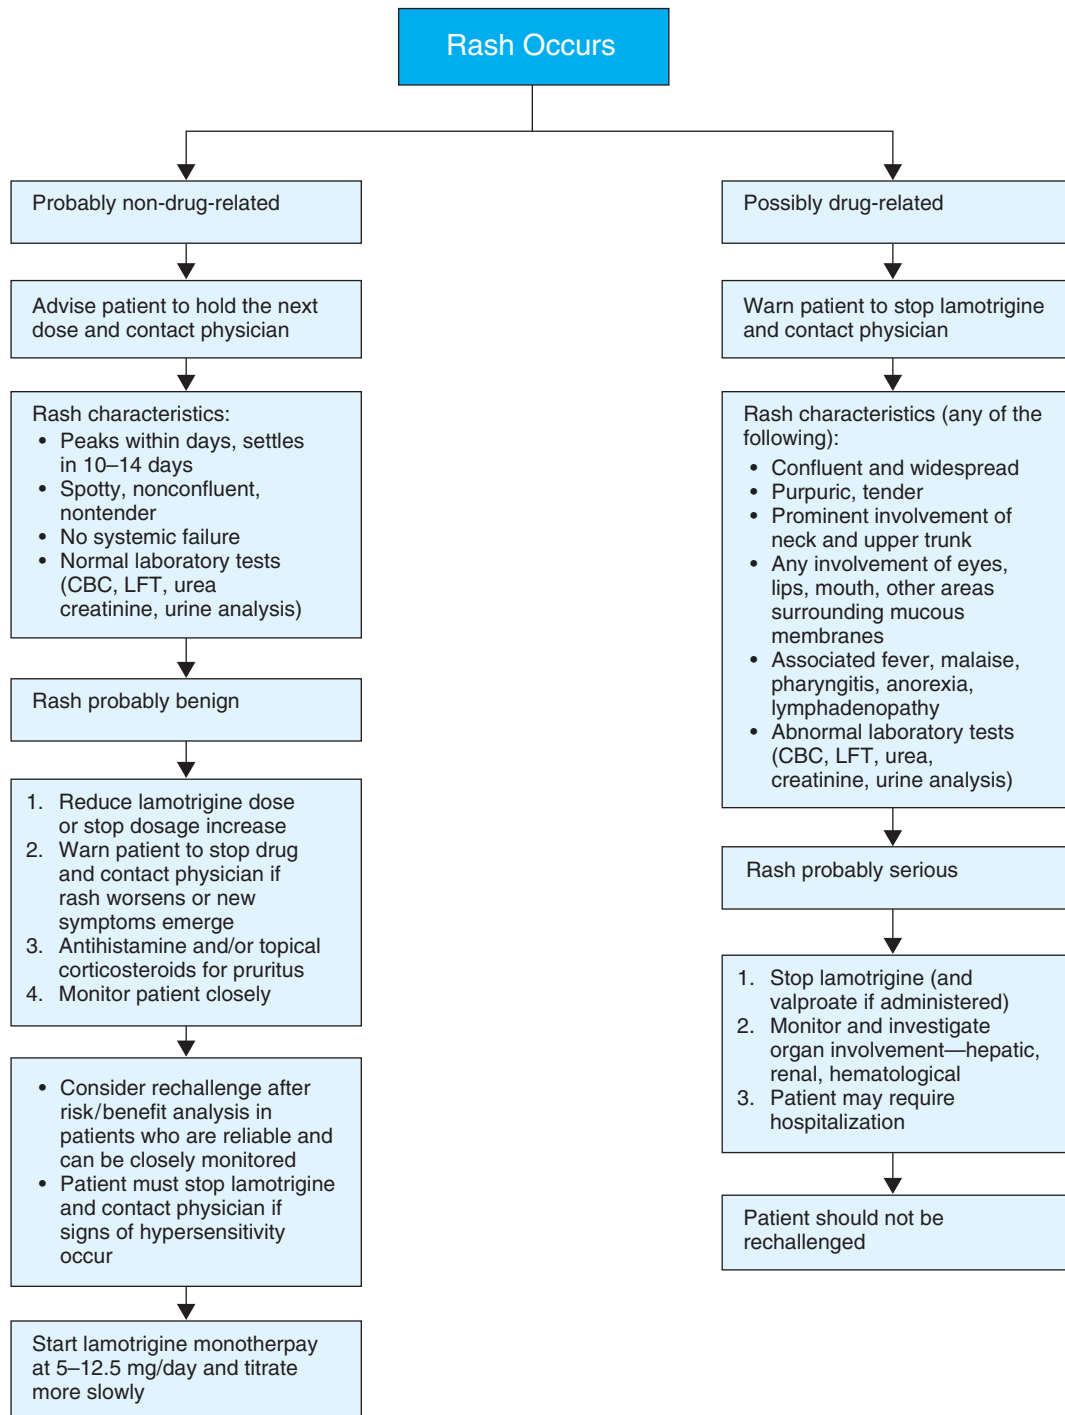

Figure 20–1. Lamotrigine Rash Decision-Making Flowchart. CBC=complete blood count; LFT=liver function test. (Source: Calabrese et al., 2002. Reprinted with permission.)

While the atypical antipsychotics are generally considered safer than the typicals because they are less likely to cause extrapyramidal syndrome (EPS), the relatively low EPS rates found in large multicenter registration trials may be misleading because they reflect monotherapy in patients without psychiatric or medical comorbidities and

are based on data from the randomized phase, which are limited to patients who have already demonstrated that they can tolerate the drug. A recent study conducted in a “real-world” setting (reflecting combined treatment of patients often with comorbid disorders) found rates of EPS that exceeded 60 percent, principally akathisia (Ghaemi

et al., 2006).³¹ Furthermore, Leucht and colleagues (2003) noted that most of the controlled trials comparing EPS rates in patients taking typical versus atypical antipsychotics have used the high-potency agent haloperidol (which is associated with a high rate of EPS) as the comparator. In their meta-analysis of 31 studies comparing atypical antipsychotics with lower-potency typical antipsychotics such as chlorpromazine (median of mean doses = 440 mg/day),³² only clozapine (15 studies) was associated with significantly less EPS, while the lower frequency seen with olanzapine (4 studies) was of borderline significance ($p = .07$), and the rates for zotepine (6 studies) were similar to those for the low-potency typicals. We should note, however, that for quetiapine, ziprasidone, aripiprazole, amisulpride, and sertindole, the data were insufficient to draw conclusions.³³

Perhaps the feature that most distinguishes the atypical antipsychotics from their older cousins is that they are more effective as thymoleptic agents; that is, they appear to have a more specific ameliorative effect on mood, including depressive symptoms. The use of these agents to treat breakthrough hypomanic/manic/mixed and depressive symptoms is discussed in Chapters 18 and 19, respectively. Their use as monotherapy for maintenance treatment of bipolar disorder is still being evaluated in controlled trials, but positive results have been obtained with olanzapine and aripiprazole in studies of relatively short-term relapse prevention (see the later discussion), specifically relapse into mania among those who recently had a full antimanic response to the atypical. These results have led to FDA approval of these two agents as “maintenance treatment” for relapse prevention, primarily manic relapse, and suggest an ongoing role for their use in patients with illness characterized by more frequent and treatment-resistant manic symptoms, either in combination with lithium and/or an anticonvulsant or perhaps as a sole agent. As of this writing, the only atypical antipsychotic available in depot form is risperidone. As more such formulations become available, a much greater role for the atypicals can be anticipated for patients who are nonadherent, even partially or episodically, to treatment with lithium or anticonvulsants.

Our recommendations for pretreatment evaluation and ongoing monitoring for maintenance atypical antipsychotics are outlined in Table 20–2. Most are administered initially in low dosages and titrated upward based on clinical response and tolerance of side effects. Typically, clozapine is begun at 12.5 mg/day and increased in 25 mg increments as tolerated. Final effective doses for clozapine range from 300 to 800 mg/day. It is crucial for patients to take the prescribed clozapine daily as syncope is not uncommon in those who miss several doses and then restart it at the therapeutic dose previously achieved through titration. Laboratory monitoring of white blood cell count

should be carried out for patients taking clozapine to detect agranulocytosis. The usual initiating dose of olanzapine is 2.5 to 5 mg/day. For risperidone, the initial dose is usually 1 mg, with the effective dose ranging from 2 to 6 mg/day for most patients. Quetiapine is begun at doses of 25 to 50 mg, with usual effective doses ranging from 150 to 750 mg/day. Ziprasidone is usually started at 40–80 mg BID with food,³⁴ while for aripiprazole the starting dose is 5–15 mg. When possible, atypical antipsychotics should be tapered slowly to reduce the likelihood of withdrawal symptoms.

Because bipolar disorder itself has been associated with obesity, as well as an elevated risk of diabetes and related metabolic disturbances (see Chapter 7), it becomes critical to understand the potential contribution of the atypical antipsychotics to these problems. Soon after the introduction of clozapine in the mid-1970s, excessive weight gain was reported in many patients taking certain atypical antipsychotics, especially clozapine and olanzapine. Although weight gain in the short term is often modest, several studies have shown that it can continue for many months. Table 20–3 shows the weight gain risks of the various atypical antipsychotics. Clozapine and olanzapine are associated with the highest risk; risperidone and quetiapine are intermediate; and ziprasidone, aripiprazole, and amisulpride pose the lowest risk (there is also no evidence associating these latter three drugs with adverse metabolic effects). In a 5-year study of weight changes associated with clozapine, the gain did not level off until 46 months after treatment was initiated (Henderson et al., 2000). Thus the potential for significant weight gain in patients receiving long-term treatment with some atypical antipsychotic medications is substantial. Furthermore, the weight gain associated with these drugs most commonly results in central or abdominal obesity, a pattern thought to pose more health risks, particularly cardiovascular risk, than generalized obesity. These risks also include dyslipidemia and insulin resistance, which along with abdominal obesity, constitute the “metabolic syndrome,” associated with an increased risk of type 2 diabetes mellitus, coronary artery disease, and other conditions.³⁵ Although the risk of diabetes with these drugs appears to be of the same rank order as that of weight gain, weight gain alone may not fully explain all of the metabolic effects (Newcomer et al., 2002).

The primary mechanism for the weight gain associated with some atypical antipsychotics appears to be a centrally mediated increase in appetite, although it has also been suggested that atypical antipsychotics alter the regulation of leptin, a polypeptide synthesized in adipose tissue and thought to be involved in insulin sensitivity and regulation of adiposity. A direct effect of these agents on glucose uptake by target cells has also been proposed (for excellent reviews

see Baptista et al., 2002; Newcomer 2006). The effects of the drug probably interact with genetic predispositions to pancreatic and glucose dysfunction, putting some individuals at higher risk than others for the development of diabetes (Guo et al., 2006).³⁶ Psychiatrists should take these risks into account when selecting antipsychotic agents, and when possible prescribe those agents less likely to cause weight gain in already obese patients and those with diabetes or a family history of the disease. Body weight, blood glucose, and serum lipid levels should be monitored at the beginning of treatment and regularly thereafter in patients taking atypical antipsychotics for maintenance treatment; obviously, the drugs with the greatest potential to cause weight gain require the closest monitoring. It is especially important to monitor weight closely during the first few weeks of therapy since it has been shown that a gain of 2 kg (4.4 lb) or more during the first 3 weeks of olanzapine administration is a reasonably accurate predictor of substantial subsequent weight gain (Lipkovich et al., 2006). Clinicians should discuss with patients symptoms that could reflect emerging diabetes, such as excessive thirst and urination, fatigue, frequent infections, and blurred vision. Nutritional counseling for patients taking these agents is important, emphasizing portion-size control, low-fat and low-carbohydrate foods, and regular exercise.

Several small studies of the pharmacological treatment of antipsychotic-related obesity with fenfluramine and other appetite-suppressing agents have yielded results that can be characterized as modest at best (Allison, 2001). On the other hand, a recent double-blind, randomized, placebo-controlled trial of adjunctive amantadine in patients who had gained at least 5 lb while taking olanzapine found that, compared with placebo, amantadine plus olanzapine was associated with no further weight gain (Graham et al., 2005). In another encouraging report, Vieta and colleagues (2004) found that the combination of olanzapine and topiramate over 12 months appeared to prevent the weight gain that would have been expected with olanzapine.³⁷ Finally, orlistat, a lipase inhibitor that is not active in the CNS, may also have some potential for the treatment of medication-induced weight gain. However, while orlistat has a very benign side-effect profile, its use in psychiatric patients has not been systematically investigated.³⁸

Several drugs, including lithium, valproate, carbamazepine, and SSRI antidepressants, have been known to increase the therapeutic effects of atypical antipsychotics when administered concurrently.³⁹ Other drugs, including fluoxetine, paroxetine, quinidine, and tricyclic compounds, can inhibit the metabolism of atypical antipsychotics. Bupropion and almost all antipsychotics, including the atypicals, can lower the seizure threshold, and this possibility should be considered before combined use of these agents is initiated.

Treating the Elderly

Modifications of recommendations for the maintenance treatment of bipolar disorder when treating the elderly address primarily the increased sensitivity of these patients to adverse effects and toxicity associated with the usual agents. There are no data suggesting differences in the efficacy of various agents in older patients, although this issue has not been investigated directly with controlled studies. In their prospective study of 166 bipolar and recurrent unipolar outpatients, Murray and colleagues (1983) found no age-related decrease in lithium efficacy. They did note that manic symptoms grew increasingly prevalent and severe with age, a trend they interpreted as reflecting the natural course of the illness. It has been suggested that lower serum lithium levels are effective in the elderly, although this observation has been based on retrospective literature reviews rather than controlled data (Van Gerpen et al., 1999). However, lower levels are clearly associated with fewer adverse effects, an important consideration in this population. Further, some experienced clinicians believe, and we agree, that “stability can beget stability”; accordingly, we recommend that clinicians consider discussing with some patients a gradual and modest reduction in dose after years of stability have been achieved.

A number of case reports and open studies indicate that valproate is safe in the elderly, although no controlled studies addressing its prophylactic efficacy in this population are available. A retrospective chart review involving 72 long-term nursing facility patients over age 55 taking lithium or valproate for bipolar disorder, dementia, or both found that lithium was associated with more adverse medication-related effects and concluded that valproate was a safer treatment, at least in this very fragile population. However, the bulk of the lithium-related adverse effects appeared to reflect poor management in that they were associated with “toxicity and/or dehydration,” including blood levels in excess of 1.2 mEq/l (Conney and Kaston, 1999). Furthermore, a recent study comparing patients in their 70s who were taking comparable doses of lithium and valproate (Shulman et al., 2005) found that the two drugs were quite similar in their impact on neuropsychological functioning (Fig. 20–2).

Lamotrigine may have an advantage in this population because of its impressive tolerability; particularly important in older patients is the absence of cognitive impairment and sedation. Sajatovic and colleagues (2005) analyzed the data for 98 bipolar subjects over the age of 55 who were part of two large 18-month studies comparing lamotrigine, lithium, and placebo (G. Goodwin et al., 2004) and found lamotrigine to be significantly better than placebo in preventing depressive relapses (and lithium significantly better than

Figure 20–2. Kaplan-Meier survival curves for incidence of delirium in new users of lithium, valproate, or benztropine among older adults. (Source: Shulman et al., 2005. Reprinted with permission.)

placebo in preventing manic/hypomanic relapses); there were significantly fewer side effects with lamotrigine than with lithium. When using antipsychotics in this population, agents with a low risk of postural hypotension (such as ziprasidone and aripiprazole) should be considered.

Treating Pregnant Women

Maintenance treatment for women during their childbearing years involves the art of balancing competing priorities. A healthy pregnancy and postpartum (puerperal) period and, of course, a healthy baby, as well as continued remission from symptoms of bipolar disorder, are no longer regarded as being mutually exclusive. In balancing the risks (Table 20–5) and benefits of continuing some medication during at least a portion of the pregnancy (Altshuler et al., 1996; Warner, 2000; Chaudron and Pies, 2003; Gentile, 2006), it must be remembered that bipolar episodes themselves pose a risk to the fetus or newborn⁴⁰ (Box 20–2). Table 20–6 presents a more detailed review of the FDA categories of drug safety during pregnancy.

It has been suggested that pregnancy exerts a protective effect against the recurrence of mood symptoms in women with “classic” bipolar disorder, as characterized primarily by complete recovery between episodes (Grof et al., 2000). However, this suggestion is not supported by the results of studies of unselected bipolar patients, largely in U.S. tertiary care academic centers (Viguera et al., 2002). Whether pregnancy is or is not “protective” in some patients, the postpartum (puerperal) period is clearly a time of greatly increased risk for relapse, especially into mania and psychosis, rates of which are estimated at 50 to 75 percent, respectively.⁴¹

Several large studies have documented that postpartum (puerperal) episodes in patients with manic-depressive illness cluster in families (Dean et al, 1989; Jones and Craddock, 2001; Forty et al, 2006). In the one study that focused only on bipolar women (Jones and Craddock, 2001) those

with a family history of postpartum psychosis were more than six times more likely to have a postpartum episode than those without such a family history. Given the magnitude of this difference in risk, it is prudent to consider family history when advising women of the risks of being off medication during pregnancy and/or when considering adjunctive treatments aimed at preventing postpartum episodes. (See, for example, Sharma et al, 2006).

For several decades, lithium was considered quite teratogenic and thus virtually contraindicated during pregnancy because of an increased incidence of major cardiac defects, notably Ebstein’s anomaly. More recent data, based on consecutive series rather than case registries, have substantially reduced the risk estimates for Ebstein’s anomaly to a range of 1 in 1,000 to 1 in 2,000 live births (Jacobson et al., 1992; Cohen et al., 1994). Nevertheless, a gradual reduction of the lithium dose for women who wish to become pregnant can be considered, at least for the first trimester. If the patient’s episodes have been seasonal in the past (seen most commonly with manic/hypomanic episodes in the spring or summer), the pregnancy might be timed so that there will be a relatively safe period for temporary lithium withdrawal. The tapering off should be done slowly, over at least several weeks, because abrupt discontinuation of lithium substantially increases the risk of suicide and relapse, particularly manic relapse. Restarting lithium after the first trimester does not appear to increase the risk of teratogenicity. It is advisable to restart the drug well before parturition so as to minimize the risk of postpartum mania, psychosis, and depression (Stewart et al., 1991; Austin, 1992). It is important to keep in mind that the maximum therapeutic and prophylactic effect of lithium may take many months, even years, to achieve, and there is no guarantee that restarting the drug in the second trimester will recapture the prior level of protective efficacy, which is essential during the high-risk postpartum period. There have been reports of neonatal lithium toxicity in infants exposed to lithium during labor and delivery, but this appears to be rare as long as the lithium level is lowered to .3 mEq/l or less for a day or two before parturition (Newport et al., 2005). On the other hand, discontinuing lithium altogether clearly puts the mother at substantial risk of relapse (especially into mania, which itself, as noted above, puts the baby at risk) and should be avoided if at all possible.⁴² For some patients whose history suggests a high risk of relapse when off lithium even for a few months (or who evidence breakthrough symptoms when the tapering is undertaken), the drug should be continued even through the first trimester.

A variety of malformations have been linked to treatment with valproate (Thisted and Ebbesen, 1993) and carbamazepine (Kallen, 1994) during pregnancy. These two

TABLE 20–5. Fetal and Neonatal Risks Associated with Drugs Used for Maintenance Treatment

Drug	Fetal Risks
Lithium	<ul style="list-style-type: none"> • Ebstein’s cardiac malformation (risk much lower than earlier estimates, now .05–.1% (1 in 1,000 to 1 in 2,000) • Neonatal hypothyroidism, nephrogenic diabetes insipidus, polyhydramnios (rare) • Secreted in breast milk at one-half maternal plasma concentration • FDA Pregnancy Category C (see Table 20–6) based on old data
Carbamazepine and oxcarbazepine	<ul style="list-style-type: none"> • Spina bifida (approximately 1–2% risk), dysmorphic facies • Secreted in breast milk • FDA Pregnancy Category D
Valproate	<ul style="list-style-type: none"> • Spina bifida (approximately 3–5% risk) • Structural defects in heart and limb, dysmorphic facies • Secreted in breast milk • FDA Pregnancy Category D
Typical antipsychotics	<ul style="list-style-type: none"> • Teratogenic risk low, but limited data available • Secreted in breast milk • FDA Pregnancy Category C, except clozapine (Category B) • Phenothiazines—not yet categorized
Atypical antipsychotics	<ul style="list-style-type: none"> • Teratogenic Risk unknown • Secreted in breast milk • FDA Pregnancy Category C
Benzodiazepines	<ul style="list-style-type: none"> • Possible cleft palate, cleft lip • Secreted in breast milk • FDA Pregnancy Category D
Lamotrigine	<ul style="list-style-type: none"> • Increase in nonsyndromic cleft palate or cleft lip associated with first-trimester exposure in the North American Antiepileptic Drug (AED) Registry, but not in four other registries • Secreted in breast milk • Risks of major defects may increase with concomitant use of valproate • FDA Pregnancy Category C
Other anticonvulsants	<ul style="list-style-type: none"> • Unknown teratogenic risks for gabapentin, oxcarbazepine, topiramate • Secreted in breast milk • FDA Pregnancy Category C
Antidepressants	<ul style="list-style-type: none"> • Selective serotonin reuptake inhibitors (SSRIs) and tricyclic antidepressants thus far not associated with major fetal anomalies • Infants exposed to SSRIs in utero may experience respiratory distress, irritability, and feeding problems • Infants exposed to tricyclics in utero may experience transient withdrawal effects • Secreted in breast milk • FDA Pregnancy Category C^a

^aApplies to most SSRIs, including fluoxetine; some tricyclic medications are in Category D.

BOX 20–2. Increased Risks to Fetus and Newborn during an Affective Episode

- Stress, including release of stress-related hormones
- Alcohol and drug use (including nicotine)
- Poor nutrition
- Sexually transmitted diseases
- Risk to newborn from postpartum mania, depression, and psychosis
- Maternal suicide
- Physical violence
- Impaired maternal care of infant

drugs are much more dangerous to the fetus than lithium, causing a variety of major and minor congenital defects, most notably neural tube defects such as spina bifida. Because of teratogenicity and the increased risk of reproductive abnormalities, some guidelines now recommend that alternatives to valproate be used for mood stabilization in women of childbearing age; we agree. Information regarding the teratogenicity of the newer anticonvulsants gabapentin, oxcarbazepine, and topiramate is sparse, and until proven otherwise, they should probably be considered higher-risk agents.⁴³ Initial reports on lamotrigine monotherapy during the first trimester were reassuring: among 596 first-trimester exposures to lamotrigine monotherapy or combined therapy excluding valproate, the incidence of anomalies was 2.9 percent, consistent with the risk in the general population (Cunnington and Tennis, 2005). However, recent analysis

of the ongoing North American Antiepileptic Drug (AED) Pregnancy Registry noted 5 cases of isolated nonsyndromic cleft palate or cleft lip out of 564 first trimester monotherapy exposures (.89 percent)—higher than the rates in general population registries (which range from .037 to .22 percent). However, an increased risk of cleft lip or palate has not been observed in a number of other international registries. Three recent studies (reviewed by Gentile, 2006) noted a 60 to 65 percent decrease in plasma lamotrigine levels in the third trimester compared with prepregnancy levels.

Relative to lithium and most anticonvulsants, the typical neuroleptics pose a low risk of teratogenicity, and apparently this is true of the newer atypical agents as well (Ernst and Goldberg, 2002; McKenna et al., 2005), although pregnancy appears to increase the risk of metabolic syndrome in women treated with olanzapine (reviewed by Gentile, 2006). Both first- and second-generation antidepressants are also generally considered low-risk during pregnancy, although this view is at odds with package insert labeling for various drugs.⁴⁴

Treating Breastfeeding Women

While data on the impact on the fetus of psychoactive drug use by pregnant women are sparse, they are even more so when it comes to the question of how these drugs might affect newborns who are breastfed.

Compared with most other drugs used in the maintenance treatment of manic-depressive illness, a relatively high percentage of maternal lithium—ranging from 24 to

TABLE 20–6. U.S. Food and Drug Administration (FDA) Categories of Drug Safety during Pregnancy

Category	Description
A	Adequate, controlled human studies have demonstrated no fetal risks; these drugs are the safest.
B	Animal studies show no risk to the fetus and no controlled human studies have been conducted, or animal studies show a risk to the fetus but well controlled human studies do not.
C	No adequate animal or human studies have been conducted, or adverse fetal effects have been shown in animals but inadequate human data are available.
D	Evidence of human fetal risk exists, but benefits may outweigh risks in certain situations (e.g., life-threatening conditions or serious diseases for which safer drugs cannot be used or are ineffective).

Notes: These categories can be quite misleading because they are, by and large, based on data available at the time of the drug’s initial approval. Typically, once a drug is off patent, new data are not submitted to the FDA. For example, newer data indicate that lithium (Category D) is safer than either carbamazepine (Category D) or valproate (Category C). Adequate human data for valproate were not available at the time it was approved, and newer data indicate a substantial risk of spina bifida with the drug.

72 percent—is found in breast milk (Chaudron and Jefferson, 2000). Because of this and a handful of case reports of adverse effects, the American Academy of Pediatrics (AAP) recommends that if lithium is administered to a breastfeeding woman, it should be done with caution and with careful monitoring of the infant, especially for lethargy and hypotonia (see the review by Ernst and Goldberg, 2002).⁴⁵

Chaudron and Jefferson (2000) and the AAP consider use of anticonvulsants to be compatible with breastfeeding. The concentration of valproate in breast milk is low, representing less than 10 percent of maternal levels. For carbamazepine, a higher percentage of the drug's maternal blood level gets into breast milk than is the case with valproate, and there are at least nine case reports of adverse effects of carbamazepine in breastfed babies (Ernst and Goldberg, 2002). There are fewer data on lamotrigine in breast milk (and very little of this is monotherapy data), but because the amount found in breast milk represents a relatively high proportion of maternal levels (estimated at 60 percent), caution is advised (Ernst and Goldberg, 2002; data on file, GlaxoSmithKline).

Few or no data exist on the penetration of the atypical antipsychotics, as a group, into breast milk; however, use of these agents is generally considered compatible with breastfeeding, perhaps because of older (albeit still limited) evidence that a low proportion of the mother's dose of typical antipsychotics enters breast milk.

A prospective, controlled study of mothers exposed throughout pregnancy to either tricyclic antidepressants ($n = 46$) or fluoxetine ($n = 40$) (half of whom breastfed their babies) compared with 36 mothers who were not exposed to antidepressants (Nulman et al., 2002) found no adverse effect of drug exposure on the children's global intelligence quotient (IQ), language development, or behavior when they were tested between ages 15 and 71 months. In contrast, IQ and language development were significantly and adversely affected by uncontrolled depressive symptoms in the mothers. Further discussion of the risk/benefit calculation for the use of psychotropic drugs in pregnancy and breastfeeding can be found in two recent reviews (Gentile, 2004, 2006; Malone et al., 2004).

Dealing with Breakthrough Symptoms

The appearance of hypomanic/manic or (especially) depressive symptoms during the course of maintenance treatment of bipolar disorder is so common as to appear almost inevitable. The clinician who has treated a particular patient for years will likely know how to react (or not react) to breakthrough symptoms in that patient, but more often the decision is a difficult one. A young person who is early in the course of illness presents an obvious challenge; the patient whose adherence to treatment recommendations is difficult

to judge is another. The first step in addressing breakthrough symptoms is to assess their etiology. Possible reasons for such symptoms in previously stable patients include the following:

- *Nonadherence to recommended treatment*—Nonadherence can be both intentional and unintentional. It may be due, for example, to the patient's reducing the dosage of a medication to alleviate side effects, misunderstanding instructions, or forgetting doses; in a study of patients referred for lithium prophylaxis and followed prospectively for 2 years, ongoing substance abuse emerged as the best predictor of nonadherence (Aagaard and Vestergaard, 1990). Regular laboratory monitoring is important not only because of the medical issues involved, but also because it reinforces for the patient the clinician's understanding that the proper dose of medication is important to treatment. As suggested earlier, the use of long-acting depot medications (haloperidol, fluphenazine, risperidone) is an option for patients in whom regular adherence to oral medications is consistently problematic. Family members are excellent resources for evaluating the possibility of nonadherence in the patient with unexplained worsening of symptoms. Treatment adherence is discussed in detail in Chapter 21.
- *Psychosocial stressors*—It is important to differentiate between mood symptoms that represent recurrence of illness and those that represent normal reactions to circumstances. That having been said, drawing this distinction can be a fiendishly difficult task. The appearance of mild depressive symptoms is not uncommon in the context of a personal setback and may respond to reassurance and support; thus it is important for the clinician to convey interest in and a willingness to discuss the patient's personal issues. On the other hand, a period of psychosocial stress can precipitate an episode of illness, and neither the patient nor the physician should be too complacent about symptoms that appear to be explained by circumstances. At the very least, more frequent contact with the patient will be required to monitor the symptoms and intervene promptly if more aggressive treatment is indicated. Often the mechanism by which psychosocial stress destabilizes the illness is sleep loss, so careful monitoring of sleep is as essential as the clinician's willingness to address the problem pharmacologically. Brief supportive psychotherapy, with referral to a competent psychotherapist if necessary, is an intervention easily undertaken by all psychiatrists caring for patients with mood disorders (see Chapter 22). Indeed, as noted throughout this volume, it is our belief that manic-depressive illness is best managed by a combination of pharmacological and psychotherapeutic treatment.
- *Destabilizing factors*—These may include substance abuse; antidepressants; medications with psychotropic effects

prescribed by other physicians, such as steroids or interferon; or endogenous factors, such as the onset of thyroid abnormalities. The symptomatic patient may not be the best source of information on these factors, an observation that reinforces the need to develop collaborative relationships with family members and other professionals involved in the patient's care.

- *True relapse*—Only after other possibilities have been ruled out should the clinician contemplate changes in medication to address breakthrough symptoms. Even then, questions will remain. How aggressively should the symptoms be treated? The severity of the immediate symptoms will naturally inform this decision, as will consideration of the course of the patient's illness. Have mild symptoms progressed to severe illness previously, and if so, how quickly? Can this breakthrough episode be related to previous ones in a way that suggests a specific intervention? (For example, if depressive symptoms recur in winter months, supplemental phototherapy may be helpful.) Once the decision has been made to treat breakthrough symptoms, a reasonable first step is to maximize the effectiveness of the patient's current medication regimen. Therapeutic monitoring is crucial in determining whether dosages can be increased safely. Dosages of agents with dose-related efficacy should generally be maximized before the addition of new agents is considered. As noted previously, the trigger for or earliest indication of a breakthrough manic or hypomanic episode often is decreased sleep. Thus the early, short-term use of sedative hypnotics may be able to abort an emerging episode before it escalates. Agents useful for this purpose include benzodiazepines, zolpidem, eszopiclone, ramelteon, gabapentin and some other sedative anticonvulsants, and some atypical antipsychotics.

Approaches to managing breakthrough manic/hypomanic and depressive symptoms are discussed in Chapters 18 and 19. Here we only emphasize that there are almost no controlled data to guide the clinician in choosing a particular combination regimen for an individual patient. Medication combinations are clearly effective for many patients. Goodwin and Goldstein (2003), for example, reviewed data on several medications, such as valproate, that may work synergistically with lithium (allowing reduced dosages of each drug), potentially enhancing maintenance treatment by increasing the ratio of therapeutic to side effects. Another frequently used combination is lithium plus lamotrigine, combining a stabilizer that works best "from above" (lithium) with one that works best "from below" (lamotrigine) (Ketter and Calabrese, 2002). When using combinations, however, downward dosage adjustment should generally be attempted (which is feasible for both of the

combinations just mentioned) since combinations of two or more drugs at full monotherapy doses increase the risk of side effects and nonadherence.

REVIEW OF THE LITERATURE

In this section, we provide a detailed review of the literature on the medications discussed above for maintenance treatment of manic-depressive illness: lithium, valproate, carbamazepine/oxcarbazepine, lamotrigine, other anticonvulsants (for which the data on efficacy are sparse), and the antipsychotics. We also review the literature on combination maintenance treatments and on other agents and approaches, including maintenance ECT, thyroid hormones, calcium channel blockers, nutritional supplements, and extended bed rest and darkness. Maintenance treatment for children and adolescents is discussed in Chapter 23.

Lithium

In the introduction to this chapter, we noted the pioneering work of the Lange brothers, as well as that of Cade and Noack and Trautner. But the first major systematic study of lithium's prophylactic efficacy in manic-depressive illness occurred through the collaboration of Baastrup and Schou (1967). They analyzed the results of a retrospective study initiated at the Psychiatric Hospital in Glostrup, Denmark, involving all patients with recurrent affective disorders admitted from 1960 through 1966 (a total of 88 patients). Those selected for analysis had an episode frequency ranging from two or more episodes in a year to one episode per year for at least 2 years before lithium administration. All had taken lithium for at least 1 year.

The study's results were striking. Following the initiation of lithium, episodes (defined as rehospitalization) had become clearly less frequent among 83 (94 percent) of the 88 patients. The magnitude of the effect is suggested by the fact patients were ill on average 13 weeks a year before starting lithium, compared with less than 2 weeks a year while taking lithium—an almost seven-fold reduction. The frequencies of manic and depressive episodes were affected equally; however, lithium's ability to prevent rehospitalization for depression, not always evident initially, appeared to improve with time. In this sample, lithium was equally effective in patients with bipolar and recurrent unipolar depression⁴⁶ (see the review below of lithium studies in this group) but was less so in schizoaffective patients (Baastrup and Schou, 1967). In a follow-up study, Angst and colleagues (1970) obtained similar results.

Baastrup and Schou's 1967 report, a medical landmark, stimulated many trials of the use of lithium in the prophylactic management of manic-depressive illness. By 1972, more than 60 clinical studies comparing the course of the

illness before and while taking the drug had been published. Virtually all showed decreases in the frequency, duration, and severity of episodes; those studies that distinguished between manic and depressive episodes found that lithium reduced both.

By this time, most clinicians who had studied lithium's effects on recurrent affective illness were favorably impressed. Skeptics such as Blackwell and Shepherd (1968), however, noted that patients selected for a trial because of a history of relatively frequent episodes might be expected to experience a decreased frequency of episodes during the study period as part of the natural course of the illness, reflecting a regression toward the mean rather than a drug effect. But the assumption underlying this view—that the natural course of manic-depressive illness is random—was contradicted by data indicating a strong tendency for the average frequency of manic-depressive episodes to be non-random and to increase with time (see Chapter 4). Three independent studies (Laurell and Ottosson, 1968; Isaksson et al., 1969; Angst et al., 1997) examined the natural course of manic-depressive illness in patients with 2-year histories of frequent episodes—the kind of patients selected for the trials just discussed. Patients in all three studies were found to be at high risk for subsequent episodes in the next 2 years if they remained off lithium. Blackwell and Shepherd (1968) had also noted that in the absence of double-blind procedures, observer bias or patient expectation may have accounted for the favorable results obtained. Clinicians highly familiar with the illness knew, however, that full-blown mania (and probably also severe depression) is unlikely to respond meaningfully to psychological suggestion alone.

In the remainder of this section, we review in turn the results of placebo-controlled studies of the prophylactic efficacy of lithium conducted before 1980, the renewed controversies that arose during the mid-1980s regarding the drug's effectiveness and results of contemporary studies in which lithium served as an active comparator in maintenance trials of new agents, lithium's relative prophylactic efficacy in treating mania and depression, its effect on normal mood, the issues of withdrawal and rebound, clinical features that may predict the drug's prophylactic effectiveness, its prophylactic efficacy in bipolar-II disorder, and finally the surprisingly robust literature supporting its prophylactic efficacy in recurrent unipolar depression. Finally, we should note that maintenance lithium can prolong life, not only by dramatically reducing the likelihood of suicide, but also by reducing the elevated cardiovascular mortality associated with manic-depressive illness (Ahrens et al., 1995) (see Chapter 7). The relationship between lithium and the risk of suicide in patients with recurrent affective disorders is reviewed in Chapter 25.

Results of Placebo-Controlled Studies Prior to 1980

The first substantial response to Blackwell and Shepard's (1968) criticism came when the Danish group undertook a study in which female patients were given lithium in a clinic setting and stabilized on the drug for at least 1 year, then continued on either lithium or placebo under double-blind conditions (Baastrup et al., 1970). Although the results of this study were even better than those of the open studies discussed previously, the study was also widely criticized. One criticism was that limiting the trial to patients who had been successfully stabilized on lithium for a year prior to the study introduced a bias in favor of lithium responsiveness (a problem, discussed later, that continues to plague contemporary studies using relapse prevention designs). Another criticism was the possibility that abrupt cessation of lithium made the placebo group relapse more quickly than would otherwise have been the case (a criticism that clearly deserves consideration; see below). A subsequent study in England by Coppen and colleagues (1971) also involved prior lithium responders, but the period of stabilization on lithium prior to randomization was only 6 weeks, which is perhaps why the findings of this investigation helped increase acceptance of lithium in Europe.

The major study influencing the acceptance of lithium prophylaxis in the United States was that of Prien and colleagues (1974), a collaborative effort of the Veterans Health Administration and NIMH.⁴⁷ This study, which formed the principal basis for the FDA's 1974 decision to approve the marketing of lithium, was initiated at a time when the drug was poorly accepted in the United States, largely because of unfortunate experiences with toxicity when it was being used as a salt substitute.

For most observers, the positive randomized, placebo-controlled, parallel-group studies of Baastrup and colleagues (1970), Melia (1970), Coppen and colleagues (1971), Stallone and colleagues (1973), and Prien and colleagues (1974) (summarized in Fig. 20–3) essentially laid to rest reservations based on the results of the earlier mirror-image studies.⁴⁸ However, there was still the question of whether patients selected for and maintained on lithium become “dependent” on it; if so, they would be more likely to relapse when taken off the drug. Three studies examined this question directly. Schou and colleagues (1970), Grof and colleagues (1970), and Sashidharan and McGuire (1983) all compared patients' relapse rates during lithium withdrawal with those before lithium treatment and found no difference in either frequency or severity. These results appear to differ from those of more contemporary studies in which the frequency of relapse during the first year after abrupt lithium withdrawal appears to have exceeded

Figure 20-3. Results of double-blind lithium versus placebo maintenance trials conducted in the 1970s. Blue bars = lithium treatment ($n = 251$); white bars = placebo treatment ($n = 263$). (Source: Gyulai et al., 2003. Reprinted with permission.)

baseline recurrence rates (see the later discussion of the work of Suppes and colleagues [1991]). Perhaps the best explanation for this discrepancy is that offered by Grof and colleagues (1994) and Grof and Alda (2000)—that the earlier studies were of classic Kraepelinian manic-depressive illness with free intervals and without the mood-incongruent psychotic features allowed by contemporary diagnostic systems. It is also worth noting that in a more recent analysis of the older randomized, placebo-controlled studies, Keck and colleagues (2000) noted that the likelihood of relapse on placebo was not related to whether the lithium withdrawal occurred in newly treated patients or after a long period of stabilization on the drug.

Renewed Controversies and Results of Contemporary Studies Using Lithium as a Comparator

From the mid- to late 1980s until recently, despite the apparently definitive study results reported above, the clinical effectiveness of lithium was again called into question by a series of reviews proposing that there had been a steady decrease in the drug's effectiveness in the treatment of bipolar disorder since the studies of the 1970s had been conducted (Dickson and Kendell, 1986; Markar and Mander, 1989). It was suggested that the earlier studies had led to an overly optimistic view of the benefits of lithium, and that the drug's inadequacies were becoming apparent with wider and longer-term use.

Coryell and colleagues (1997) published a naturalistic (nonrandomized) study of the course of illness of 181 patients with bipolar-I disorder who were followed semiannually for 5 years, comparing the course of 139 patients who were taking lithium with that of 42 patients who were not.

Lithium showed a clear prophylactic effect against the return of symptoms only during the first 32 weeks of treatment following an episode of mania or depression; during weeks 33 through 96, there appeared to be no relationship between lithium treatment and relapse. The authors questioned the necessity of longer-term lithium prophylaxis for patients who have had 8 months or more of euthymia, suggesting that lithium discontinuation studies be performed to elucidate the issue. They also speculated that patient selection bias in treatment decisions may have reduced the size of the lithium treatment effect, and that only a minority of patients with bipolar disorder are at risk of relapse over the longer term and thus require continuous treatment. Kleindienst and colleagues (1999) reanalyzed these data using a complex mathematical model assuming that lithium's efficacy is not transient and, most important, that some patients are at high risk of relapse and others at lower risk. They were thereby able to generate survival curves virtually identical to those of Coryell and colleagues (1997). They concluded that individuals at low risk for relapse would inevitably predominate in the later months of a nonrandomized naturalistic study, thus accounting for the very small treatment effect observed for that period.

Maj and colleagues (1996) reported on 65 patients with bipolar disorder who had remained well on lithium for 5 years and who were followed for another 5 years during which they remained adherent to treatment. During the 5 years of follow-up, 12.7 percent of these stable patients experienced at least two episodes despite good adherence. These "late nonresponders" had experienced a significantly higher number of previous affective episodes and hospitalizations and a significantly longer duration of illness. The authors argued that these factors indicate a more severe illness that will eventually overwhelm the prophylactic efficacy of lithium, a conclusion they suggested is supported by their review of previous studies.

It is not surprising that the notion that the intrinsic inadequacies of lithium as a prophylactic treatment for bipolar disorder emerged at a time when alternatives to lithium were becoming available. Overlooked in most of these reviews was the inherent selection bias that arises once a treatment has become established in the community: those who tend to respond to the treatment are likely to remain in the care of practitioners, while those who are less responsive become overrepresented in samples available to investigators, who usually work in referral centers. Indeed, a recent naturalistic comparison of lithium and valproate among 201 bipolar-I patients followed for 1 year after hospitalization (Revicki et al., 2005) found that the two treatments were equally effective for those patients who stayed in treatment.⁴⁹ Nevertheless, it is likely that certain secular trends (such as increased substance abuse and much greater use of antidepressants)

have resulted in more lithium-resistant cases (at least in some countries) compared with a decade or two ago.

Baldessarini and Tondo (2000) addressed these issues in a review of the 24 open and controlled long-term lithium trials published between 1970 and 1996 (most of which were from outside the United States). They found that subjects in more recent studies (1982–1996) actually had lower recurrence rates than those in earlier ones (1970–1981). They also found that pretreatment recurrence rates did not differ in earlier as opposed to later studies, suggesting the absence of secular factors that had been hypothesized to worsen the illness in more recent decades. Moreover, and importantly, recurrence rates were not significantly different in open versus blinded trials of lithium, a point also made by Davis and colleagues (1999). In another analysis of 28 studies comparing the recurrence risk with and without lithium treatment, the same authors addressed the concern that earlier studies had exaggerated lithium–placebo differences by including patients who had been withdrawn from lithium before randomization to placebo (Baldessarini et al., 2002). They showed that the reduction in recurrence attributable to lithium was the same in the half of the studies that involved prior lithium withdrawal as in the half that did not, which challenged the notion that lithium “dependence” skewed the data on its prophylactic effects. Furthermore, among the 11 “gold standard” blinded, randomized, placebo-controlled, parallel-group studies, the average reduction in recurrence risk associated with lithium was 3.6-fold. In a meta-analysis of the five randomized, placebo-controlled trials that met the requirements of the Cochrane database,⁵⁰ Geddes and colleagues (2004) concluded that lithium was clearly effective, reducing overall relapses to 65 percent of the frequency observed with placebo.

Critics had also charged that lithium’s *efficacy* in treating bipolar disorder (its proven ability to treat the illness successfully in research studies) was much better than its *effectiveness* (its ability to treat the broad range of patients with bipolar disorder successfully under real-life clinical conditions).⁵¹ To address this question, Baldessarini and Tondo (2000) also retrospectively analyzed the illness course of 360 patients treated with lithium over a period of 30 years at an Italian mood disorder clinic. Patients had been in treatment for at least 1 year and for a mean of about 5 years. These patients apparently adhered to lithium treatment and had no complicating substance abuse diagnoses, but were otherwise not selected by clinical factors; they included bipolar-I and -II patients, as well as patients with rapid cycling, some with predominantly mixed states, and some with psychotic features. Again, the authors found no cohort effect and no evidence of any decrease in lithium’s effectiveness for these patients over time (see Tondo et al., 2001, for a detailed analysis). A slight increase in the numbers of patients with

mixed and psychotic illness was offset by a decrease over time in the numbers of patients with rapid cycling.

It is worth noting that these data are from a large lithium clinic in Italy where the use of antidepressants is minimal. In our opinion, some of the reported decline in lithium’s effectiveness in the United States is real; that is, it cannot be attributed to either referral bias or changes in the nature of maintenance studies. Some possible reasons for this decreased effectiveness (including the sharp increase in the use of antidepressants) are discussed below.

In three relatively recent large randomized controlled trials, lithium was compared with placebo for prophylaxis in bipolar-I disorder. In these studies, which were designed to evaluate the prophylactic efficacy of valproate and lamotrigine, those two agents were compared with lithium and with placebo. The valproate trial (Bowden et al., 2000a) is the only long-term trial not to have shown statistical superiority of lithium over placebo in a maintenance protocol (valproate was also not superior to placebo). The authors suggested several possible reasons for this surprising finding: the number of lithium-treated subjects entered into the study was small (half the number treated with valproate); there were many dropouts in the lithium group (67 percent, a rate perhaps related to the high doses of lithium used); and the study duration (1 year) was shorter than that of studies showing clear differences between lithium and placebo (2 years). Perhaps the overriding issue was this: because the primary outcome variable was relapse, there were ethical concerns about including very sick patients in the trial; with mild to moderately ill patients, it is likely that the placebo did too well. In Chapter 17 we review design issues relevant to studies of maintenance treatment for bipolar disorder.

In the two studies of lamotrigine versus lithium versus placebo, lithium was shown to be superior to placebo in preventing recurrence of mood episodes over 18 months in patients with bipolar-I disorder who had recently been manic or hypomanic (Calabrese et al., 2003) or depressed (Bowden et al., 2003b). The demonstrated efficacy of lithium in these two studies is all the more remarkable given that the sample was partially enriched with lamotrigine responders, and there is some evidence that lithium and lamotrigine responses represent different clinical profiles (Passmore et al., 2003). In both studies, lithium was found to be more effective in preventing mania than depression; in a combined analysis of both studies (G. Goodwin et al., 2004), however, lithium showed a trend toward superiority over placebo against depression ($p = .12$) (lamotrigine was also more effective than placebo, as discussed later). The authors noted that this was “the first study in which lithium differentiated from placebo using modern survival analytic methods and arguably

provides some of the strongest evidence available for the efficacy of lithium in maintenance treatment of bipolar disorder” (Bowden et al., 2003b, p. 398).

In these two multicenter trials, lithium was included as an active control to assess “assay sensitivity”—that is, the ability of the trial to reveal differences between active drug and placebo. The size of the lithium effect was not as large as that seen in the earlier lithium studies reviewed above. In a careful comparison of the older and newer lithium literature, Deshauer and colleagues (2005) analyzed nine randomized, placebo-controlled trials involving 1,432 patients. They noted that the older studies tended to start with patients who were already taking lithium, whereas in the two recent studies in which lithium separated from placebo, the patients had already been stabilized, at least briefly, on lamotrigine. With regard to the size of the lithium effect, there was an 11-fold difference between the older, “lithium-enriched” and the newer, “lamotrigine-enriched” studies.⁵²

In a 5-year prospective naturalistic study of more than 400 bipolar-I patients in the lithium clinic at the University of Naples, Maj and colleagues (1998) noted that about 25 percent of these patients had no relapses while taking lithium, about 40 percent had at least one relapse, but nearly 33 percent had stopped taking lithium (often because they felt well and saw no need for further treatment). A 2-year prospective study from New Zealand yielded similar results (Silverstone et al., 1998). A retrospective analysis of 76 patients attending a lithium clinic found that nonadherent patients were less accepting of the need for lithium prophylaxis, less convinced of its efficacy, and less likely to believe they had a serious illness (Schumann et al., 1999).

Several factors led to the above reappraisal of lithium’s central role in the prophylactic treatment of manic-depressive illness (with the contemporary studies focusing on the bipolar form) and of the previously held view of lithium as the “gold standard” of treatment for the illness:

- Changes in the nature of the randomized controlled trials, including referral bias, as discussed above.
- The emergence of “effectiveness” in addition to “efficacy” studies, which included among their outcome variables differences due to patients’ adherence to treatment, clinicians’ adherence to good prescription practices, and toxicity, as well as blood-level monitoring. That is, real-world experience will not, on average, match the practice standards that obtain in controlled efficacy studies.
- Changes in the apparent nature of bipolar disorder in recent years:
 - Expansion at the lower end of severity with the new category of bipolar-II, perhaps bringing more Axis II comorbidity into the picture

- The inclusion of more psychotic features in the diagnostic criteria for mania, especially in the United States
- Lower age at onset
- Increased comorbidity with substance abuse (the rates of which vary across countries)

– Substantially increased use of antidepressants
The latter three factors are associated with “atypical” features of bipolar disorder (e.g., rapid cycling, mixed states, psychotic features) that may respond better to some of the newer drugs, such as anticonvulsants (lamotrigine, valproate, carbamazepine) and the atypical antipsychotics, than to lithium (Bowden et al., 1994; Goodwin and Goldstein, 2003).

- The development of potential alternatives to lithium maintenance (especially anticonvulsants and the newer atypical antipsychotics), which remain under patent protection and thus can support substantially more marketing and sponsored educational events for psychiatrists than is the case for lithium—the perennial “low earning orphan” drug.

Nonetheless, contemporary reviews and meta-analyses of older data, as well as new data generated during investigations of more recently introduced agents, support the conclusion that reports of the demise of lithium’s central role in the treatment of manic-depressive illness, including bipolar disorder, were, indeed, premature.

Lithium’s Relative Prophylactic Efficacy in Treating Mania and Depression

Some earlier reviewers, primarily Americans, appeared to assume that lithium is better at preventing mania than depression, a position perhaps influenced by then-prevailing biological theories postulating that mania and depression are opposite states. Conversely, many European investigators and clinicians apparently expected that both phases would respond equally since both were viewed as intrinsic aspects of the same illness. Few of the important early European studies distinguished manic from depressive episodes in reporting relapse frequencies. In their landmark study, Bastrup and Schou (1967) did not specifically analyze the differential effects of lithium on mania and depression. As noted earlier, however, inspection of their individual case histories indicates equivalent prevention of manic and depressive episodes (defined as a period in which symptoms were sufficiently pronounced to require hospitalization or supervision in the home). The authors also noted that “very many of the patients suffered during these non-psychotic intervals from phases with slight to moderate depressive or, less often, hypomanic symptoms” (Bastrup and Schou, 1967, p. 90).

Three studies using balanced mirror-image pretreatment and on-lithium periods, careful selection of patients,

and quantitative rating instruments attempted to answer directly the question of lithium's relative efficacy in preventing depression versus mania. In one of these studies (Holinger and Wolpert, 1979), a similar decrease in manic and depressive episodes was observed among patients taking lithium. The other two studies (Poole et al., 1978; Rybakowski et al., 1980) actually found better prophylaxis against depression than mania.

Of eight double-blind, placebo-controlled studies conducted in the 1970s to address this question, two found a greater effect in preventing mania or hypomania than depression (Cundall et al., 1972; Dunner et al., 1976), two had indeterminate results (Stallone et al., 1973; Fieve et al., 1976), and four found lithium to be equally effective in preventing both types of episodes.⁵³ More recent retrospective studies have also failed to demonstrate significant differences in lithium's effectiveness against manic and depressive symptoms (Berghofer et al., 1996; Tondo et al., 1998). In two more recent randomized, placebo-controlled maintenance trials involving lithium and lamotrigine (discussed earlier), lithium was found to be more effective in preventing mania than depression, but recall that this was a population partially enriched with lamotrigine responders. In the Cochrane meta-analysis cited earlier, Geddes and colleagues (2004) found the effect of lithium to be somewhat more robust for mania than for depression (relative risk .62 and .72, respectively), but this result may be due to the fact that two of the five trials included in the analysis involved the partially lamotrigine-enriched samples.

As is clear from a detailed analysis of the controlled studies conducted to date, there is little support for the notion that lithium is substantially more effective in the prevention of mania than of major episodes of depression. However, mild depressive symptoms do appear to be noted more frequently than mild hypomanic symptoms among patients taking maintenance lithium. In an early study, Jamison and colleagues (1979) found that physicians were more likely than patients to report lithium's being less effective against depression than mania. In interpreting this finding, however, one should remember that patients are probably less likely to report hypomanic than depressive symptoms.

Lithium's Effect on Normal Mood

Lithium's effect on nonpathological mood states has intrigued researchers for many decades. Schou and colleagues (1968), for example, took lithium at therapeutic doses for several weeks and reported feelings of indifference, decreased initiative, and a sense of being "separated from [the] environment by a glass wall" (Schou et al., 1968, p. 93). The issue has significant therapeutic implications: an agent that prevents abnormal mood episodes at the cost of blunting or

even deadening normal mood variability may be quite undesirable for many patients.

Several researchers have compared mood states and day-to-day mood variation in normal subjects and euthymic bipolar patients taking lithium. Folstein and colleagues (1982) reported the results of two such studies, in which they found that bipolar subjects had mean mood ratings similar to those of controls but less day-to-day mood variation as measured by visual analog mood scales (DePaulo et al., 1982; Folstein et al., 1982). Although these results were consistent with a mood-constricting effect of lithium, the authors cautioned that it may not be valid to compare the mood ratings of bipolar subjects, who have experienced major depressions and manias, with those of control subjects, who have not. Two crossover comparison studies of lithium and placebo were conducted to assess whether lithium attenuates mood fluctuations to the same extent in bipolar patients and controls. Both studies showed no difference in mood variation related to lithium use in those without a history of mood disorders, suggesting that lithium does not have a significant effect on normal mood (Calil et al., 1990; Barton et al., 1993). As more putative mood stabilizers appear, it will be important to evaluate their effects on normal mood fluctuations as well.

Lithium Withdrawal and Rebound

Lithium withdrawal delirium or nonspecific agitation was suggested by a few case reports (DePaulo et al., 1982; King and Hullin, 1983) but was never strongly supported by subsequent studies. More attention has been focused on the issue of whether rapid (as opposed to gradual) cessation of lithium in patients with bipolar disorder actively promotes rapid relapse, particularly into mania. This question is important clinically for obvious reasons, but as alluded to earlier, it also is salient to the interpretation of results of lithium studies in which rapid cessation of the drug is part of the protocol. Suppes and colleagues (1991) performed a meta-analysis of 14 studies involving 257 bipolar-I patients and found that more than half of new episodes (which were primarily mania) occurred within 3 months after stopping lithium⁵⁴; the number of relapses was 28-fold higher than that seen when the patients were taking lithium, suggesting that the withdrawal-related relapses represented more than just a return of the illness. Coming to a different conclusion, Davis and colleagues (1999) performed an exhaustive meta-analysis of 19 randomized controlled studies of prophylactic lithium in "recurrent affective illness" (including both bipolar and unipolar disorders), calculating the frequency of relapses before, during, and after lithium use in the reviewed studies. They assumed for their analysis that if a lithium-cessation rebound existed as a withdrawal phenomenon, it should be seen in the first several days after abrupt cessation,

a time course consistent with the pharmacodynamics of lithium. In fact, most relapses occurred 3 to 9 months after cessation, suggesting to the authors that there was little support for the concept of relapses related primarily to lithium withdrawal as opposed to return of the illness in the absence of an effective medication. The difference in the conclusions reached by Davis and colleagues and Suppes and colleagues is probably due to the fact that the former group included in their analysis the substantial literature on lithium in recurrent unipolar depression, in which lithium withdrawal relapse has not been demonstrated (not surprising given that the majority of withdrawal relapses in bipolar patients are into mania).

Baldessarini and colleagues (1996, 1997, 1999a) addressed this issue by analyzing a clinical population rather than research subjects, pooling data from 227 patients with bipolar disorder (136 bipolar-I, 91 bipolar-II) in whom lithium had been discontinued for various reasons in the course of their treatment at a university-affiliated mood disorders clinic. They divided patients into “abrupt” (1–14 days) and “gradual” (15–30 days) discontinuation groups and performed a survival analysis to identify recurrences of mania or depression (by DSM-IV criteria). They found that time to 50 percent risk for any illness recurrence was four times shorter in the abrupt-discontinuation than in the gradual-discontinuation group. Rapid discontinuation of lithium resulted in a 50 percent risk of mania at 2 months and a 50 percent risk of depression at 6 months, compared with 10 months for mania and 17 months for depression in the gradual-discontinuation group. Bipolar-I patients fell ill more rapidly than bipolar-II patients in both groups. Patients who discontinued abruptly were most likely to fall ill during the first year after lithium discontinuation, primarily in the first 10 weeks; relapse rates returned thereafter to those experienced by untreated bipolar subjects.⁵⁵ Although it is not clear that this phenomenon should be called lithium “rebound” or lithium “withdrawal,” rapid discontinuation of lithium in bipolar patients is clearly associated with increased relapses and an increased risk of suicide (see Chapters 8 and 19) during the first few months. These data suggest, moreover, that this phenomenon represents something distinct from simple loss of the benefits of lithium in patients with bipolar disorder, although its mechanism remains obscure.

It has also been reported that a subgroup of bipolar patients (perhaps 15 to 20 percent) who abruptly discontinue lithium become refractory to the drug when it is restarted (see Post et al., 1992; Maj et al., 1995). Other studies, however, have found that lithium is neither more nor less effective following a period of cessation in bipolar patients (see Tondo et al., 1997; Coryell et al., 1998). G. Goodwin (1994) suggested that the phenomenon of relapse after abrupt withdrawal of lithium should be taken into account in

treatment planning. Based on the data in the above-noted analysis of Suppes and colleagues (1991), he recommended that lithium not be started unless the patient is committed to taking it for at least 2 years, advice that found its way into the treatment recommendations of the International Exchange on Bipolar Disorder (Bowden et al., 2000b).

A related issue is whether a longer latency in initiating preventative treatment for bipolar disorder is associated with worse outcomes. The “kindling” hypothesis would predict that patients who start prophylactic treatment early in the course of their illness will have a lower risk of relapse and better treatment response. Although earlier studies of this question yielded contradictory answers, two relatively recent large studies appear to have settled the matter. Baldessarini and colleagues (2003) studied 450 bipolar patients (two-thirds bipolar-I, one-third bipolar-II), 86 percent of whom were maintained on lithium essentially as monotherapy. While longer treatment latency did not predict greater morbidity during treatment, *pretreatment* morbidity was associated with shorter treatment latencies; that is, the sicker patients entered treatment earlier, resulting in a larger relative reduction in morbidity with earlier treatment. The second study, this one prospective, followed 147 bipolar patients receiving maintenance therapy over an average of 7 years (Baethge et al., 2003) and, like the work of Baldessarini and colleagues (2003), used a multivariate approach. This study, too, found no relationship between treatment latency and subsequent response to treatment. Both groups of authors pointed out that studies finding the opposite (i.e., that prompt initiation of maintenance treatment ameliorates the course of illness) did not control for illness severity prior to prophylaxis. Although there are certainly many arguments for the prompt initiation of prophylaxis in bipolar disorder, favorable modification of the future course of illness would not appear to be one of them. Nevertheless, the results of these studies clearly indicate, as the authors concluded, that it is never too late to start maintenance therapy.

Predictors of Lithium's Prophylactic Efficacy

It has generally been thought that patients with typical euphoric manias and a clearly episodic course of illness with well intervals (Duffy et al., 2002; Passmore et al., 2003) have an especially good prophylactic response to lithium monotherapy, while those with dysphoric or mixed manias (Goldberg et al., 1998) are less likely to have a favorable long-term response. As noted in the first edition of this text, the relationship between episode frequency and lithium response was first evaluated in a placebo-controlled study by Dunner and Fieve (1974), who found that bipolar patients with rapid cycles (four or more episodes per year) were more likely to relapse while taking lithium than those without rapid cycles. Table 20–7 reviews the major studies

TABLE 20–7. Results of Studies Evaluating Maintenance Lithium and/or Anticonvulsants in Rapid-Cycling Illness

Study	Sample	Design	Conclusion
Dunner and Fieve, 1974	55 BP NS	Naturalistic prospective cohort study of patients taking lithium over 6–66 mo	Patients with >4 episodes/year were disproportionately represented among 27 of 56 patients with prophylaxis failure.
Dunner et al., 1977	390 BP NS	Retrospective chart review	Most patients treated with lithium had fewer and less severe mood episodes while taking lithium.
Okuma, 1993	215 BP NS	Retrospective chart review	Rapid-cycling patients had poorer outcomes than non-rapid-cycling counterparts, whether taking lithium or carbamazepine.
Maj et al., 1998	402 BP NS	Prospective study of lithium therapy in a cohort of patients with BP	Rapid cycling absent in BP patients deemed good responders to lithium, but observed in 26% of those with poor response. Rapid cycling predicted poor outcome independently of treatment.
Bowden et al., 1999	75 BP NS	Add-on study of lamotrigine in patients with refractory BP (60 patients received add-on therapy; 15 received monotherapy)	Lamotrigine was generally effective and well tolerated.
Baldessarini et al., 2000	218 BP-I, 142 BP-II	Naturalistic prospective cohort study of patients taking lithium over an average of 13.3 yr	Lithium was equally effective in patients with and without a history of rapid cycling in delaying relapse and decreasing total time ill. Rapid-cycling patients, however, experienced more relapses.
Baldessarini et al., 2000	360 BP NS	Naturalistic, prospective; patients with BP-I or -II monitored on average for more than 13 yr	Similar morbidity was observed while both rapid-cycling and non-rapid-cycling patients were taking lithium, arguing against the idea that lithium is less effective in rapid-cycling BP.
Calabrese et al., 2000	225 BP-I, 98 BP-II	Randomized study of lamotrigine added to current regimen of euthymic or ill patients; other agents then tapered off	Adding lamotrigine resulted in remission or continued wellness in about half of patients, and the remission was sustained after other agents were tapered over 4–8 wk.
Swann et al., 2000	372 BP NS	Stabilized BP patients randomized to divalproex, lithium, or placebo	Although response to lithium decreased in patients with increased numbers of past depressive or manic episodes, only one subject randomized to lithium had rapid-cycling BP.
Kupka et al., 2003	3,709 BP NS	Meta-analysis of 20 studies that made direct comparisons between rapid-cycling and non-rapid-cycling BP	59% of all lithium-treated rapid cyclers achieved at least 50% improvement. A significant association between current rapid cycling and hypothyroidism was noted.
Tondo et al., 2003	317 BP NS	Meta-analysis	Overall, rapid cycling was associated with lower effectiveness of all treatments evaluated; not specific to lithium.

(continued)

TABLE 20–7. Results of Studies Evaluating Maintenance Lithium and/or Anticonvulsants in Rapid-Cycling Illness (*continued*)

Study	Sample	Design	Conclusion
Calabrese et al., 2005	24 BP-I, 36 BP-II	Patients first stabilized on lithium + valproate for up to 6 mo, then randomized to monotherapy with one of the two drugs gradually withdrawn and placebo substituted; then followed for 20 mo	Relapse into any mood episode occurred in 56% of patients taking lithium vs. 50% of those taking valproate. Time to relapse not specified.

BP = bipolar disorder; BP NS = bipolar-I or bipolar-II not specified.

that have evaluated this question. It has been suggested that the finding that rapid-cycling patients do poorly on maintenance lithium may simply mean such patients are more severely affected and as such are more difficult to treat; they may have a likelihood of improvement on lithium equal to that of non-rapid-cycling patients, but the improvement often is not sufficient to bring them into or sustain them in remission. Tondo and colleagues (2001) found that about two-thirds of their patients with bipolar disorder, including those with illness features often thought to predict less lithium responsiveness, experienced a reduction in frequency of episodes, as well as in total time ill, of at least 50 percent when observed over at least 1 year of lithium treatment. This same group (Tondo et al., 2003) conducted a meta-analysis of comparative studies of mood stabilizers in rapid-cycling versus non-rapid-cycling patients (16 studies; 905 rapid-cycling and 951 non-rapid-cycling patients), and found that lithium was superior to anticonvulsants among the latter and equivalent to valproate among the former patients.⁵⁶ The most definitive comparison of lithium versus divalproex in rapid-cycling patients (Calabrese et al., 2005), discussed later in the section on valproate, likewise found that the two drugs were not significantly different. As noted earlier, the use of antidepressants may also play a role in the relative treatment resistance of rapid-cycling patients. For example, there have been several reports of more favorable lithium results in the absence of (or with minimal use of) antidepressants (Kukopulos et al., 1980; Wehr et al., 1988; Baldessarini et al., 2000). In fact, the only intervention shown in a double-blind, placebo-controlled design to be effective in rapid-cycling bipolar-I disorder is discontinuation of antidepressants (Wehr et al., 1988).

There is evidence that mood-incongruent psychotic features predict a more lithium-resistant illness, although it appears clear that such patients can nevertheless derive substantial benefit from lithium prophylaxis. For example, Maj and colleagues (2002) followed patients with

mood-incongruent psychotic features for 5 years and compared the course of their illness with that of a control group of patients with no such history. They found that the former patients were more likely to have stopped taking lithium at the 5-year point (78 versus 57 percent), and although about half of them had experienced at least a 50 percent reduction in time spent in the hospital, as a group they did not fare as well as those without psychotic features, 80 percent of whom had a comparable decrease in hospitalization time. In a randomized controlled trial that compared lithium and carbamazepine for prevention of mood episodes in bipolar patients with mood-incongruent features, the two agents were found to be equally effective (Greil et al., 1997).

Recently, Kleindienst and colleagues (2005) made a substantial contribution to the response-predictor literature. They found nearly 2,000 papers on lithium response predictors written from 1966 through 2003, 43 of which met their criteria for analysis.⁵⁷ Seven of the studies were randomized controlled trials, 10 involved a prospective cohort design, and 26 were retrospective case-control studies. Because of substantial heterogeneity in the effect sizes of different studies and the well-known publication bias in favor of positive studies, the authors applied a highly conservative “fail safe” procedure to increase the likelihood that a predictor reported in several studies was real: they added two large ($N=1,000$) hypothetical studies with zero correlation; if a particular predictor was still statistically significant after this maneuver, it was considered likely to be real. Among the 42 possible response predictors, this conservative analysis could identify only 5 for which there was enough agreement across studies to consider them likely predictors. The two predictors of good lithium response were the mania-depression-interval (MDI) course pattern and an age at onset in the intermediate range. Predictors of poor lithium response were a large number of previous hospitalizations, the course pattern of depression-mania-interval (DMI), and continuous cycling. Given that the effect sizes for any one predictor are, at best, moderate, the authors suggested that

TABLE 20–8. Clinical Characteristics Likely to be Associated with Differential Maintenance Response to Lithium versus Anticonvulsants

LITHIUM		VALPROATE, CARBAMAZEPINE, LAMOTRIGINE	
Good	Poor	Good	Poor
Family history of bipolar disorder	Negative family history for bipolar disorder	Negative family history for bipolar disorder	
Course variables: Intermediate age at onset	Earlier age at onset	Course variables:	
Mania–depression–interval course sequence	Depression–mania–interval course sequence		
Fewer previous hospitalizations and/or episodes	More previous hospitalizations and/or episodes	Multiple previous episodes (valproate)	
Non-rapid-cycling	Rapid-cycling ^a	Non-rapid-cycling; rapid-cycling bipolar-II (lamotrigine)	Rapid cycling (valproate)
Full remissions between episodes	Chronic course with comorbid substance abuse and anxiety	Chronic course with comorbid substance abuse and anxiety (lamotrigine)	

^aMay not apply in the absence of antidepressant use; see text for details.

the application of clinical predictors should be based on many variables (Table 20–8). Some of the clinical characteristics previously identified in individual studies that did not hold up in this meta-analysis are rapid cycling,⁵⁸ duration of illness, nature of the index episode, type of mania (euphoric-grandiose versus mixed), and bipolar-I versus bipolar-II.⁵⁹ The authors noted that in general, past history was better than the current clinical picture at predicting prophylactic lithium response.

Lithium's Prophylactic Efficacy in Bipolar-II

Table 20–9 outlines the limited literature on the efficacy of maintenance treatments for bipolar-II disorder. With regard to lithium, we know of only one adequately powered study that directly compared its prophylactic efficacy for bipolar-I and bipolar-II disorder. This open prospective study of bipolar patients on lithium maintenance for an average of 6.35 years, which included 129 patients with bipolar-II disorder, found that the latter patients had interepisode intervals nearly six-fold longer than those of the bipolar-I patients and were twice as likely to have no new mood episodes after lithium was initiated (Tondo et al., 1998). With regard to the relative efficacy of lithium against hypomania and depression in bipolar-II patients, one small study (Dunner et al.,

1976) found that the effect of lithium versus placebo was significant for depression but not for hypomania, a result reminiscent of some, but not all, of the mirror-image studies described previously.

Lithium's Prophylactic Efficacy in Recurrent Unipolar Depression

Many contemporary observers, particularly in the United States, will be surprised to learn that there are substantially more data on lithium's prophylactic efficacy in recurrent unipolar depression (primarily cases with recurrence frequencies in the bipolar range) than in bipolar-II disorder. Indeed, there are more data on lithium as maintenance treatment for recurrent unipolar depression than there are for all of the anticonvulsants and atypical antipsychotics combined as maintenance treatments for bipolar-I disorder (Davis et al., 1999).

In their extensive and careful meta-analysis, Davis and colleagues (1999) summarized nine randomized, blinded, placebo-controlled trials involving a total of 229 patients with recurrent unipolar depression. They found that relapse rates (primarily rehospitalization) averaged 75 percent for placebo versus 36 percent for lithium—virtually the same difference noted for similar studies of bipolar dis-

TABLE 20–9. Results of Studies of Maintenance Treatment with Lithium for Bipolar-II Disorder

Study	Sample Size	Duration	Drugs Studied	Results
Dunner et al., 1976	26	33 mo	Lithium vs. placebo	Effect of lithium greater than that of placebo for depression; not significant for hypomania (limited statistical power).
Fieve et al., 1976	18	48 mo	Lithium vs. placebo	Effect of lithium greater than that of placebo for prevention of depression.
Kane et al., 1982	22	24 mo	Lithium, imipramine, lithium + imipramine	Effect of lithium nonsignificant for bipolar-II (limited statistical power).
Tondo et al., 1998	129	75 mo (6.3 yr)	Lithium vs. placebo	Effect of lithium greater for bipolar-II than for bipolar-I.
Greil and Kleindienst, 1999	57	30 mo	Lithium vs. carbamazepine	No difference (limited statistical power).

Note: Studies with an observation period of 6 mo or less are not considered “maintenance” and are not included here.

order. Moreover, the lithium effect in these most rigorous designs was the same as that observed in the many placebo-controlled trials that involved lithium withdrawal, as well as in the numerous matched case–control and mirror-image trials, a point made by Baldessarini and colleagues (1996) with reference to trials in bipolar disorder.

Valproate

Although valproate is clearly an effective antimanic agent, its role in maintenance therapy is less clear than that of lithium. As early as the 1970s, Lambert and colleagues (1971) reported preliminary evidence of a long-term benefit of the drug in treating bipolar disorder. In the United States, much of the initial interest in what was then, for psychiatry, a new agent was focused on its potential usefulness in patients who were not doing well on lithium, principally rapid cyclers. Calabrese and colleagues (1993) reviewed six open trials that assessed the efficacy of valproate in the maintenance treatment of 124 rapid-cycling bipolar patients; the two largest of these studies, comprising 101 patients, found that both valproate and lithium had marked antimanic but poor antidepressant effect.⁶⁰ Denicoff and colleagues (1997a), studying 18 rapid-cycling patients, found that only 6 of 18 responded to valproate, and all but one of the responders were also taking lithium (the question of the efficacy of valproate in combination with lithium is discussed later in the section on combined treatments). Indeed, in their review, Calabrese and colleagues (2001) concluded that rapid cyclers have a relatively poor response to all treatments for bipolar disorder, especially monotherapies. In the most careful and

comprehensive comparison of divalproex versus lithium for rapid-cycling bipolar disorder ever conducted, Calabrese and colleagues (2005) followed 60 rapid cyclers who had been stabilized for up to 6 months on a combination of lithium plus divalproex and were then randomized to have lithium or divalproex gradually tapered off with placebo substitution. During the monotherapy phase, which lasted 20 months, no significant differences were seen in relapse rates between divalproex- and lithium-treated subjects (50 versus 56 percent),⁶¹ although there was a nonsignificant trend for the divalproex group to have a longer time to intervention. Studies of valproate and rapid-cycling disorder are included in Table 20–7.

With regard to maintenance valproate in non-rapid-cycling bipolar patients, a naturalistic study with a mean duration of follow-up of nearly 2 years (90 weeks) found that in a setting of minimal antidepressant use, divalproex was equivalent to lithium overall; lithium nonresponders did well on divalproex (50 percent by the Clinical Global Impressions-Bipolar [CGI-BP] scale) and vice versa (44 percent) (Ghaemi and Goodwin, 2001). Prevention of depressive relapses was noted with both agents, but divalproex was superior to lithium in reducing scores on the Hamilton Rating Scale for Depression (HAM-D) ($p < .003$).⁶²

By far the most extensive and well-controlled evaluation of the maintenance efficacy of valproate is the parallel-design, randomized comparison of divalproex, lithium, and placebo for the maintenance treatment of bipolar disorder undertaken by Bowden and colleagues (2000a); indeed, it represents one of the largest studies of the prophylaxis of

bipolar disorder to date.⁶³ The primary or planned analysis was a comparison of survival curves (i.e., time to first relapse) in the divalproex-, lithium-, and placebo-treated patients. This analysis found no significant difference among the three treatment groups. In secondary analysis, however, divalproex emerged as superior to placebo in having a lower rate of discontinuation for a recurrent mood episode, a finding consistent with that of a subsequent reanalysis of the data by a Cochrane Review group. The Cochrane reviewers concluded, however, that the results were difficult to generalize because “the inclusion of a placebo-treated group led to the inclusion of a less severely ill group of patients than is generally found in clinical practice” (Macritchie et al., 2002, p. 140). Here the reviewers were referring to the previously mentioned ethical constraints on a placebo-controlled study in which the end point is relapse.

In another secondary analysis, Bowden and colleagues (2000a) suggested less worsening of depressive symptoms during divalproex compared with lithium therapy, yet the high dropout rate in the lithium group (perhaps related to the high blood levels maintained) renders these comparisons problematic. It should also be recalled (as we review in Chapter 17) that secondary analyses are hypothesis generating, not hypothesis testing. Bowden and colleagues (2000a) suggested further that, compared with lithium, subjects treated with divalproex had symptom-free intervals of longer duration. A subsequent secondary analysis of this same database (Gyulai et al., 2003) found that among the patients given a “rescue” SSRI for breakthrough depressive symptoms, a lower percentage of those taking divalproex compared with placebo discontinued early because of depression. These authors also noted that those who had been given divalproex in the open period relapsed into depression later on divalproex than on lithium. But an advantage for divalproex in the maintenance phase might be expected among patients who were selected by their clinicians as being likely to respond to divalproex in the acute open phase. In a subsequent analysis of this maintenance treatment database, Bowden and colleagues (2005) examined the relationship between the symptom pattern during the acute manic phase and the subsequent response to maintenance treatment with either divalproex or lithium. They found that those patients whose manic episode had been dysphoric were more sensitive to the side effects of both lithium and divalproex during the maintenance trial. Regarding maintenance efficacy in the dysphoric group, the two drugs were equivalent. Among those patients who had been euphoric during their mania, more depressive symptoms (primarily motoric slowing) and more premature discontinuations were associated with lithium than with divalproex, although, as noted earlier, this finding might be explained by the high doses of lithium employed in this study.

With regard to valproate as maintenance treatment for bipolar-II disorder, we know of no controlled studies of pure bipolar-II patients that has directly addressed this question. However, in a double-blind, placebo-controlled study of 30 patients with bipolar-II disorder who also met DSM-IV criteria for borderline personality disorder, the divalproex group showed a significant reduction in dysphoric effects, such as irritability and anger (Frankenburg and Zanarini, 2002), but the drug did not separate from placebo in the prevention of depressive relapses.

Carbamazepine/Oxcarbazepine

Carbamazepine, initially used to treat a wide range of seizure disorders and various paroxysmal pain syndromes, was tried in manic-depressive (primarily bipolar) patients because it had stabilized the moods of some patients with convulsive disorders and because it counteracted kindling in laboratory animals. Much of the early work on carbamazepine in treating bipolar disorder was done in Japan during a time when lithium was unavailable for treatment of the disorder in that country because of regulatory issues, making identification of alternative treatments an urgent need. Okuma and colleagues (1973) found a prophylactic effect in 14 of their 27 bipolar patients in an open study, which they followed up with a 1-year placebo-controlled prophylactic trial in 22 bipolar patients (Okuma et al., 1981). Six of the 10 carbamazepine-treated patients, compared with 2 of the 9 taking placebo, had no affective recurrences during the trial, a result that tends to indicate a prophylactic effect. In what was actually the first double-blind trial, Ballenger and Post (1980) noted a prophylactic effect in 13 bipolar patients (many of whom had rapid-cycling illness or had failed to respond to lithium) maintained on carbamazepine for up to 4 months.⁶⁴ Kishimoto and colleagues (1983) suggested that responders to carbamazepine prophylaxis are likely to be those with onset of illness before age 20 and with frequent illness episodes, a conclusion similar to the analysis of the divalproex data by Swann and colleagues (1999). Additional studies that appeared through the 1980s suggested that carbamazepine is useful for the prophylactic management of bipolar patients who respond poorly to lithium (Placidi et al., 1986; Watkins et al., 1987). In the ensuing decades, five published controlled studies compared carbamazepine with lithium for the treatment of acute mania or depression.⁶⁵ Although these cannot be viewed as straightforward studies of prophylaxis of recurrences, they support some prophylactic benefit for carbamazepine.

There have been several prospective, parallel, randomized, double-blind trials comparing carbamazepine with lithium as a prophylactic agent in treating bipolar disorder. Coxhead and colleagues (1992) carried out such a

study of 31 stable bipolar patients, 16 of whom were switched from lithium to carbamazepine, and found no difference in relapses, which had occurred in 50 percent of both groups by the end of the 12-month study. All relapses in the carbamazepine group had occurred within 2 months of switching, while only 3 of the 8 relapsing lithium-treated patients had relapsed at 2 months. The remaining 5 had relapsed between 2 and 6 months after the start of the trial. This study was too small for formal statistical analysis. Denicoff and colleagues (1997b) entered 52 bipolar patients into a randomized crossover 3-year trial comparing the efficacy of lithium, carbamazepine, and the combination (for 1 year each) in preventing recurrences.⁶⁶ The combination was significantly superior to either drug alone in preventing recurrent manic episodes and was also more effective in previously rapid-cycling patients.^{67,68}

Greil and colleagues (1997) conducted a larger comparative trial of carbamazepine versus lithium over 2.5 years in 144 bipolar patients (Fig. 20–4).⁶⁹ Survival curves for rates of full relapse and rehospitalization showed trends favoring lithium, but the differences were not statistically significant. When relapse was defined by the need for other psychotropic medications and/or symptoms of depression or mania, however, the advantage for lithium achieved statistical significance ($p = .03$). When the curve was calculated using treatments and/or need for additional medication and/or dropouts due to side effects, lithium's advantage was even greater (35 percent [26/74] versus 51 percent [36/70]; $p = .007$). A placebo control group was not used for ethical reasons, given earlier studies showing lithium's advantage over placebo in bipolar disorder.

Figure 20–4. Survival curve for maintenance patients taking carbamazepine ($n = 70$) or lithium ($n = 74$), based on intention-to-treat analysis. Lithium showed a clear superiority ($p = .007$) when dropouts for hospitalization, symptom recurrence, need for additional medication, or intolerable side effects were considered. (Source: Greil et al., 1997. Reprinted with permission.)

Subsequent analyses by these authors found that lithium's prophylactic benefit was particularly strong for "classical bipolar cases" (bipolar-I patients with no mood-incongruent delusions) (lithium > carbamazepine, $p < .01$), while carbamazepine was slightly (but not significantly) more efficacious than lithium for "nonclassical" bipolar disorder, a category including patients with mixed states. The authors also concluded that for the group as a whole, lithium's prophylactic effect was superior to that of carbamazepine when assessed by global measures of outcome (likelihood of remaining in treatment, rehospitalization, and residual symptomatology not requiring hospitalization) (Kleindienst and Greil, 2002).

With regard to carbamazepine in bipolar-II disorder, a 2-year randomized open trial of 57 patients with bipolar-II or bipolar-not otherwise specified (NOS) disorder was conducted, in which no significant differences were found between carbamazepine and lithium in preventing recurrence of symptoms (Greil and Kleindienst, 1999). However, the study was underpowered for establishing the absence of a difference.

To date there have been no controlled prophylaxis trials of oxcarbazepine. In one small study (Ghaemi et al., 2002)—a retrospective analysis of 13 subjects treated with the drug (either adjunctively or as monotherapy) for bipolar disorder—2 patients (16 percent) showed moderate improvement and 6 (46 percent) mild improvement during a period of 1–24 weeks. Unfortunately, 7 (54 percent) of the 13 patients stopped the medication because of side effects. Munoz (2002) reported on 28 patients with acute symptoms who were able to reduce the mean number of other medications taken over 12 weeks. Nasr and Caspar (2002) found that 28 patients with bipolar disorder who took oxcarbazepine for 9 months had significant improvement in severity of illness; bipolar-II patients appeared to benefit the most. Clearly, further study of oxcarbazepine for maintenance treatment of bipolar disorder is needed.

Lamotrigine

Lamotrigine has now been studied in a number of open and controlled trials as a maintenance treatment for bipolar disorder. Open add-on trials lasting several weeks to several months showed similar encouraging results in bipolar-I and -II subjects (Sporn and Sachs, 1997; Calabrese et al., 1999a; Suppes et al., 1999a).⁷⁰

Two large randomized, placebo-controlled, double-blind studies of lamotrigine for maintenance treatment of bipolar-I disorder have been completed, both comparing it with lithium and placebo. The first involved 175 patients who had recently been manic/hypomanic (Bowden et al., 2003a), while the second involved 349 patients who had recently

TABLE 20–10. Drugs Demonstrating Maintenance Prophylactic Efficacy versus Placebo in Randomized, Double-Blind Trials

Drug	No. of Studies	Sample Size	Findings
Lithium	17	1,551	About half of the studies involved abrupt lithium withdrawal before randomization, but lithium–placebo differences were similar in studies with and without abrupt withdrawal.
Carbamazepine	2	32	The carbamazepine–placebo difference was modest.
Lamotrigine	2	645	Superiority to placebo was due primarily to prevention of depressive episodes, while for the comparator, lithium, it was due primarily to the drug’s effect against mania/hypomania.
Lamotrigine (in rapid cycling)	1	182	In secondary analysis, lamotrigine was found to be superior to placebo among the bipolar-II subgroup.
Divalproex	1	372	The primary outcome variable did not separate divalproex from placebo, but divalproex did separate in some secondary analyses.
Fluoxetine	1	10	Possible benefit was found in the bipolar-II subgroup in retrospective post hoc analysis of a unipolar cohort.
Olanzapine	1	361	Compared with placebo, olanzapine delayed relapse in bipolar-I patients who responded to open-label acute treatment with olanzapine for a manic or mixed episode. This was a 1-year trial, but 75% of placebo relapses occurred in the first 2 mo.
Aripiprazole	1	567	Time to relapse of manic symptoms was significantly longer, and there were fewer total manic relapses with aripiprazole treatment than with placebo. This was a 6-mo trial.
Total	26	3,720

been depressed (Bowden et al., 2003b) (Fig. 20–5). Patients entered these studies in an open phase of up to 16 weeks during which lamotrigine was slowly titrated up while other psychotropics were gradually withdrawn. Patients who met criteria for stabilization on lamotrigine plus

the medication that was gradually withdrawn (they were taking lamotrigine alone for at least 1 week) were then randomized to receive either lamotrigine, lithium (to achieve serum levels of .8–1.1 mEq/l), or placebo. The partially enriched sample that was randomized represented about half

TABLE 20–11. Drugs Demonstrating Prophylactic Efficacy in Randomized, Non–Placebo-Controlled Comparison Trials or Placebo-Controlled Add-On Trials

Drug	No. of Studies	Sample Size	Findings
Lithium	5	261	More effective than imipramine (against both manic and depressive episodes).
Valproate	1	251	Equivalent to olanzapine.
Carbamazepine	2	64	Slightly less effective than lithium in study of mostly “typical” patients; slightly more effective than lithium in study of “atypical” patients.
Oxcarbazepine	1	15	Equivalent to lithium, but study underpowered.
Flupenthixol	2	53	Equivalent to placebo when added to lithium, but study underpowered.
Olanzapine	3	778	Equivalent to lithium or valproate; more effective than placebo when added to lithium or valproate among nonresponders or partial responders.
Clozapine	1	38	Clozapine plus treatment as usual (TAU) more effective in prevention of mania than TAU among nonresponders to two mood stabilizers.
Imipramine	2	192	Equivalent to placebo when added to lithium; significantly more manic episodes over 3 yr in one study with careful monitoring of lithium levels.
Omega-3 Fatty Acids	1	30	Somewhat more effective than placebo when added to standard mood stabilizers in a rapid-cycling sample.
Total	18	1,682

of the approximately 1,300 patients who initially met the study’s screening criteria. Time until the need for intervention for breakthrough symptoms was the primary end point in both studies. In the study of recently manic/hypomanic patients, both lamotrigine and lithium were found to be superior to placebo in delaying the need for interven-

tion for any mood episode (about 50 percent of patients in both treatment groups needed some additional treatment, compared with more than 80 percent of the placebo group). When the measure of any early discontinuation from the study was used as an end point, both active drugs were still statistically superior to placebo, but the difference

Figure 20–5. Comparison of lithium or lamotrigine with placebo for the prevention of mood episodes. Shown are Kaplan-Meier survival curves for time to intervention for any mood episode (e.g., need for additional medication) in 171 patients with bipolar disorder. (Source: Bowden et al., 2003b, p. 392. Reprinted with permission.)

was less impressive. With respect to time to intervention for any episode and survival in the study, essentially the same results were obtained with the recently depressed patients. In both studies considered independently, lamotrigine (but not lithium) was superior to placebo in delaying or decreasing the likelihood of interventions for depressive symptoms, while lithium (but not lamotrigine) was superior in delaying or decreasing the likelihood of interventions for manic/hypomanic symptoms.

However, a combined analysis of both datasets (employing appropriate statistical adjustments) showed that lamotrigine was significantly superior to placebo not only for depressive episodes, but also for manic episodes, although lithium was significantly better than lamotrigine for prevention of mania. As noted earlier in our discussion of lithium, there was only a trend for lithium to be superior to placebo in delaying time to relapse for depression, but it should be recalled that this sample was partially enriched with lamotrigine responders, who may represent a somewhat different clinical profile from that of lithium responders (see the later discussion). The fact that lithium works best “from above” while lamotrigine works best “from below” implies that in the maintenance treatment of bipolar-I disorder, the two drugs should be combined. However, given that lamotrigine apparently has a modest prophylactic effect against mania, it should be possible when using the drug for prevention of depression in a bipolar-I patient to use lower doses of an adjunctive stabilizer, such as lithium or valproate, “from above,” thereby reducing the overall side-effect load and preserving one of lamotrigine’s major advantages—its impressive

tolerability (especially lack of weight gain and neurocognitive side effects).

The data from these two studies have been interpreted as supporting the conclusion that the polarity of the acute episode predicts the polarity of relapse in the maintenance phase. However, a subsequent analysis by Calabrese and colleagues (2006) found that when the early relapses (those occurring in the first 3 to 6 months) are not considered, both lamotrigine and lithium continue to separate robustly from placebo, suggesting that they are preventing new episodes (recurrences) rather than just relapses. In addition, a separate analysis of the 6 to 18 month data among those randomized to placebo (Goodwin and Calabrese, in preparation) showed that these late relapses (recurrences) were much more likely to be into the *opposite* phase; that is, following an index mania, 85 percent of the late relapses were into depression and vice versa for index depressive episodes.⁷¹ This new analysis brings these clinical trial data into line with results of studies of the natural course of the illness described in Chapter 4 (manic episodes tend to follow depressive ones and vice versa). What is perhaps most important about this new analysis is that it effectively undermines the all too common recommendation (which unfortunately has found its way into some treatment guidelines) that whatever works for the acute episode should simply be continued as the foundation for long-term maintenance treatment.

Lamotrigine’s ability to stabilize mood over time has been reported in rapid-cycling patients as well.⁷² In the first double-blind, placebo-controlled trial of any agent for rapid-cycling bipolar-I and -II disorder, a prospective 26-week

study of lamotrigine, the drug showed a small but not significant advantage over placebo in time to additional intervention for symptoms in the entire sample, but in a post hoc analysis of the bipolar-II group, it was found to be superior to placebo (Calabrese et al., 2000)⁷³ (see the discussion of bipolar-II that follows). This stands as the first placebo-controlled maintenance study with rapid-cycling bipolar patients. In a 1-year open trial of lamotrigine versus lithium in 14 rapid-cycling bipolar patients, those taking lamotrigine were much more likely to have fewer than four affective episodes during the year of the study (Walden et al., 2000). The authors acknowledged that, as in the earlier lithium–divalproex comparisons, their protocol favored inclusion of prior lithium-nonresponsive patients, which obviously could bias any comparisons with lithium.

Passmore and colleagues (2003) compared several clinical and family history characteristics of 21 patients with bipolar disorder—14 classified as responders to lamotrigine and 7 as responders to lithium. They found that the lamotrigine responders tended to have more chronic symptoms, rapid cycling, and comorbid panic disorder and substance abuse and to have larger numbers of family members with schizoaffective disorder, major depression, and panic disorder. They suggested that lamotrigine may be especially helpful for patients with these clinical characteristics. An overall impression of lamotrigine's effectiveness in a clinical setting can be gleaned from recently reported STEP-BD data from Stanford University in the United States (Champion et al., 2006). Among 201 trials with a mean duration of 432 days, lamotrigine was continued throughout in 64 percent of the trials (32 percent as monotherapy, 42 percent with an additional drug).⁷⁴ Six percent of patients discontinued lamotrigine because of lack of efficacy. There were no serious rashes, but 3 percent discontinued the drug because of a benign rash.

Other Anticonvulsants

Emerging but not definitive maintenance data exist for several other anticonvulsants. Some of these agents were studied in the past with ambiguous results as to their efficacy; several others are being actively studied as of this writing.

Gabapentin

Although some evidence supports an anxiolytic and sedative effect of gabapentin, no evidence from controlled trials supports its benefit as monotherapy in maintenance treatment of bipolar disorder. Trials of gabapentin versus lamotrigine and placebo at NIMH provided no evidence that gabapentin's benefit exceeded that of placebo (Frye et al., 2000). This result, coupled with the drug's failure as an antimanic agent (Pande et al., 2000), has discouraged

pursuit of its use in prophylaxis for bipolar disorder. A few open reports and one recent controlled study do suggest acute antimanic and antidepressive effects of *adjunctive* gabapentin. For example, in a study of 23 patients with bipolar disorder (Altshuler et al., 1999), 19 patients were taking two or more medications in addition to gabapentin. Thus although most did recover during the study period, it is impossible to assess critically the role, if any, played by gabapentin. Knoll and colleagues (1998) reported similar results for 12 treatment-resistant patients taking multiple medications and followed for up to 60 weeks. In the only controlled maintenance trial of gabapentin in bipolar disorder, Vieta and colleagues (2006) randomly assigned 25 euthymic bipolar-I and -II patients already taking lithium, carbamazepine, or valproate (or any combination of these, but excluding antidepressants and antipsychotics) to receive either adjunctive gabapentin or placebo under double-blind conditions. This trial is notable for its use of a true prophylactic design rather than one based simply on relapse prevention following acute response (see Chapter 17). Compared with those taking placebo, the gabapentin group showed significantly more change on the CGI-BP, Modified long-term outcome scale ($p < .005$); that is, the blinded clinician raters perceived more overall improvement among those taking adjunctive gabapentin.

Tiagabine

To date there have been no controlled studies of tiagabine in bipolar disorder (Young et al., 2006). As noted in Chapter 18, the drug did not have obvious antimanic benefit in an early study of eight acutely manic inpatients for whom other treatments had failed (Grunze et al., 1999). However, Schaffer and Schaffer (1999) reported on two patients with recurrent manic, mixed, and to some extent depressive relapses who appeared to improve over 3 and 5 months, respectively, when tiagabine was added to their medication regimen. A later study conducted by the same authors (Schaffer et al., 2002) assessed tiagabine as an adjunctive treatment for patients with refractory bipolar disorder and found that 8 of 22 patients (36 percent) were “much” or “very much” improved on the CGI scale after 6 months of taking tiagabine.⁷⁵

Topiramate

Topiramate has been used to treat acute phases of bipolar disorder, and the results reported have been equivocal at best (see Chapters 18 and 19). Results of several open reports on slightly longer-term use of the drug are also inconclusive. Nevertheless, topiramate is a fairly common component of the pharmacotherapy of bipolar disorder, given its ability to reduce appetite and weight. Yet for many patients it can be a challenge to find a dose that produces positive effects without causing unacceptable

neurocognitive side effects.⁷⁶ Marcotte (1998) reviewed the charts of 44 patients treated for bipolar-I manic or mixed states or bipolar-II disorder with an average of 200 mg/day of topiramate in addition to existing therapy for an average of 16 weeks. Of these patients, 23 (52 percent) were rated as showing moderate to marked improvement, and 5 (11 percent) were rated as worse; 1 patient became delirious.

McIntyre and colleagues (2002) reported on 109 outpatients with bipolar-I and -II disorder with chronic mood instability in whom topiramate was added to lithium, valproate, or both for 16 weeks. Although more than one-third (39) of the patients dropped out of the study because of adverse events or insufficient response, about two-thirds of those remaining showed reductions of 50 percent or more in their Young Mania Rating Scale (YMRS) or Montgomery-Asberg depression scores at the end of the 16 weeks. Vieta and colleagues (2002) conducted a 6-month open-label add-on trial of topiramate in 34 subjects with treatment-resistant bipolar spectrum disorders (schizoaffective disorder-bipolar type, bipolar-I, bipolar-II, and bipolar-NOS). More than half of the patients (who had refractory manic, depressive, or mixed symptoms) could be classified as responders based on reductions in YMRS, HAM-D, and CGI scores (Vieta et al., 2002). The same group reported comparable results in a similarly designed 12-week study involving 16 subjects with bipolar-II disorder (Vieta et al., 2003).

In sum, topiramate's efficacy for the maintenance treatment of bipolar disorder is far from clear. Indeed, as reviewed in Chapter 18, it has not yet been possible to demonstrate the drug's antimanic effects acutely. Clearly, then, more data will be required before this agent can be recommended with any confidence, even for adjunctive use.

Phenytoin

Mishory and colleagues (2003) studied 23 subjects with bipolar-I or schizoaffective disorder taking a variety of other medications in a double-blind, placebo-controlled, crossover study of add-on phenytoin, with a 6-month observation period for each phase. During a total of 30 observation periods in these subjects, 3 relapsed while taking phenytoin and 9 while taking placebo. These results suggest that phenytoin may be helpful in prophylaxis, but more controlled studies clearly are needed.

Antipsychotics

Until fairly recently, there had been few studies of antipsychotic medications for the long-term treatment of bipolar disorder except in combination with other agents. In the mid-1990s, however, the development of the atypical antipsychotics led to a resurgence of interest in antipsychotics for maintenance treatment of bipolar disorder. Actually, the

first evaluation of an antipsychotic as maintenance treatment for manic-depressive illness predated the atypical drugs by nearly 20 years. In an early open study whose coauthors included Schou and Bastrup, the typical antipsychotic flupenthixol was given to 93 patients with manic-depressive illness (bipolar disorder or recurrent unipolar depression) who had experienced a poor response to or were unable to tolerate lithium (Ahlfors et al., 1981). The patients experienced a significant decrease in manic episodes but an excessive number of depressive episodes compared with when they were taking lithium alone. Overall, the antipsychotic was considered a suitable substitute for lithium therapy only for those patients who failed to respond to lithium or who would not or could not take it. A second study, with a randomized, double-blind, crossover design, failed to show any benefit of flupenthixol (Esparon et al., 1986).

During the mid-1990s, the first atypical antipsychotic, clozapine, was the subject of case reports and open series reporting that it was helpful as an adjunctive treatment in patients with bipolar disorder (Banov et al., 1994; Zarate et al., 1995). Ciapparelli and colleagues (2000) retrospectively reviewed the naturalistic use of clozapine in 91 patients with treatment-refractory symptoms of schizophrenia, bipolar disorder with psychotic features, or schizoaffective disorder and found that those with mood disorders showed significantly greater improvement than those with schizophrenia. In a randomized study of adjunctive clozapine versus treatment as usual in 38 patients over a period of 1 year, the clozapine-treated group showed significant improvement on scales for global functioning, psychotic symptoms, and mania, but not on those for depression (Suppes et al., 1999b).⁷⁷

There have been preliminary but promising reports as well on the efficacy of risperidone for maintenance treatment of bipolar disorder. Ghaemi and Sachs (1997) prospectively assessed the outcome of openly adding risperidone to the medication regimen of 12 outpatients with bipolar-I disorder who suffered breakthrough episodes despite adequate maintenance medication (lithium, divalproex, or carbamazepine, or a combination of these).⁷⁸ Four patients discontinued medication—two because of lack of efficacy and two because of side effects. Among the remaining eight patients, four experienced an improvement of 10 to 25 points in Global Assessment of Functioning scores and were rated much better on the CGI-Improvement scale. Although one patient suffered a major depressive recurrence (at week 22), none experienced worsening of mania. A more recent continuation study of adjunctive risperidone, while somewhat larger, was limited by the brevity of the follow-up period—just 10 weeks. Among 48 bipolar patients who completed the 10 weeks of treatment after an acute manic episode, those who received a mood stabilizer plus risperidone showed significantly more improvement in mania and

depression ratings than those who were taking a mood stabilizer plus placebo (Bowden et al., 2004). The recent availability of a long-acting (about 2 weeks) form of injectable risperidone (Respiridol Consta in the United States) expands the options for dealing with adherence problems.

The atypical antipsychotic that has been studied most extensively as a maintenance treatment for bipolar disorder is olanzapine. Several open studies of the adjunctive use of this atypical agent have showed encouraging efficacy in reducing breakthrough symptoms and preventing relapses in patients whose illness was difficult to control (Narendran et al., 2001; Vieta et al., 2001b). These findings led to interest in the use of this agent as monotherapy for the maintenance treatment of bipolar disorder, first investigated in the continuation phase of a placebo-controlled study of the drug for treatment of acute mania (Sanger et al., 2001). In this study, 113 patients who had responded acutely in the open-label extension and remained well on olanzapine during the 3-week placebo-controlled phase continued into a 49-week open-label phase. The investigators had the option of adding lithium or fluoxetine for residual or breakthrough symptoms and did so for nearly two-thirds of the patients. Like many longer-term studies of patients with bipolar disorder, this study had a high dropout rate (over 60 percent). Nevertheless, the 41 percent of patients who received olanzapine monotherapy recovered and remained well over a period of 1 year. Somnolence and weight gain and complaints of “depression” were the most frequently reported side effects.

Tohen and colleagues reported on three separate double-blind studies of olanzapine for relapse prevention after successful treatment of a manic or mixed episode with olanzapine—one comparing olanzapine with lithium in 431 patients (Tohen et al., 2002), one comparing it with divalproex in 248 patients (Tohen et al., 2003), and one comparing it with placebo in 361 patients (Tohen et al., 2006). In the olanzapine versus lithium study, patients were entered into the maintenance phase if they both tolerated and had a complete antimanic response to the open-label combination of olanzapine plus lithium (representing 33 percent of the initial population); they were then randomized to have one of the drugs discontinued abruptly and followed for up to 52 weeks. The group that remained on olanzapine had a significantly lower rate of relapse back into mania (28.0 versus 14.3 percent) than the group that remained on lithium, while relapses into depression were nearly identical in the two groups. This international collaborative study, which included many sites with considerable experience in the use of lithium, represents the first large-scale demonstration of any drug’s surpassing lithium in the prevention of relapse back into mania. In a subsequent post hoc analysis, Ketter and colleagues (2006) examined treatment response in relation to the number of

previous manic episodes. For those with two prior episodes (early-stage illness), olanzapine was significantly better than lithium in preventing relapse into mania, while for those with either three to five (intermediate-stage illness) or more than five (later-stage illness) prior episodes, there was no significant difference between the two treatments, although the intermediate-stage group showed a trend favoring olanzapine. The authors concluded that olanzapine maintenance after acute recovery from a manic episode may be particularly effective early in the course of the illness.

The 47-week randomized study of olanzapine versus divalproex started with the acute double-blind treatment of manic or mixed patients, the results of which are reviewed in Chapter 18.⁷⁹ Responders then entered a 44-week double-blind extension, in which they remained on the drug to which they had responded acutely (flexibly dosed olanzapine or divalproex⁸⁰). The mean improvement in YMRS scores was significantly greater for the olanzapine group, and the median time to symptomatic remission of mania was shorter for olanzapine. On the other hand, the overall rate of bipolar relapse, including relapse into depression, did not differ, and adverse effects (including somnolence, dry mouth, weight gain, and akathisia) were significantly more frequent among the olanzapine-treated patients. The high dropout rates for both olanzapine- and divalproex-treated patients (84 percent overall) limit the interpretation of these results, especially for a study with no placebo group.⁸¹ A subsequent post hoc analysis of these 47-week data (Suppes et al., 2005) examined differential treatment response as a function of the presence or absence of rapid cycling; the advantage of olanzapine in mean improvement in mania ratings was seen only in the non-rapid-cycling patients.

The study of olanzapine versus placebo (Tohen et al., 2006) started with bipolar patients whose manic/mixed episode had responded to and tolerated olanzapine (representing 49 percent of the initial group); after being well for a period of 1 to 4 weeks, the patients were randomized to either continue olanzapine or be assigned to placebo (that is, they were abruptly withdrawn from olanzapine). Compared with the placebo group, the olanzapine continuation group was significantly less likely to relapse back into mania (hazard ratio 3.9) or (to a lesser extent) into depression (hazard ratio 2.1).⁸² The ability of olanzapine to prevent relapse was independent of psychotic features during mania or a history of rapid cycling. Perhaps the most important issue in evaluating this study as evidence of a “maintenance” effect is the fact that the bulk of the drug–placebo difference was evident in the first 2 months, suggesting that a withdrawal effect contributed substantially to the results (Fig. 20–6). The authors addressed this possibility by

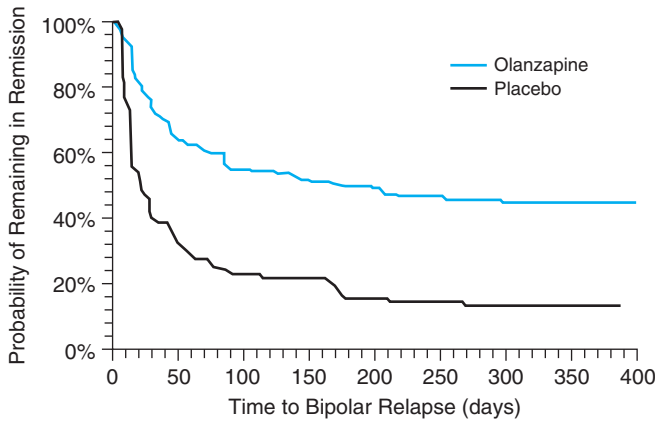

Figure 20–6. Time to relapse into mania or depression with olanzapine versus placebo. (Source: Tohen et al., 2003. Reprinted with permission.)

pointing to two post hoc analyses.⁸³ However, those analyses did not address the fundamental issue—that most of the drug–placebo difference occurred within the first 2 months, a period of time we believe is too short to allow evaluation of whether olanzapine prevents the occurrence of new episodes. Although the FDA has approved olanzapine for “maintenance” treatment,⁸⁴ studies of the drug’s long term *prophylactic* efficacy are still needed. The reader is referred to Chapter 17 for a discussion of maintenance designs and their meaning.

The most recent evaluation of an atypical antipsychotic for use beyond the acute episode involved aripiprazole. Following stabilization of an acute manic/mixed episode with open-label aripiprazole for a minimum of 6 weeks, 567

bipolar-I patients (37 percent of those who entered the open phase)⁸⁵ were randomized to continue the drug for up to 6 months or to have it withdrawn abruptly and replaced by placebo (Keck et al., 2006). The majority of relapses were into mania—hardly surprising for patients who had recently recovered from a manic episode. Time to relapse into manic symptoms was significantly longer and fewer total manic relapses occurred with aripiprazole treatment than with placebo. Relapses into depression were low in both groups and were virtually identical. The only adverse effects that were more common (by t test) in the aripiprazole group were anxiety and nervousness, while sedation and somnolence were actually less frequent with aripiprazole than with placebo (McQuade et al., 2004). As with the olanzapine studies, however, this study was underpowered to detect differences in side effects, and under these circumstances, a simple t test can be quite misleading.⁸⁶ As with the olanzapine studies, moreover, both the efficacy and side-effect results can be generalized only to those who tolerate and respond acutely to aripiprazole. Relative to the olanzapine–placebo comparison, this study’s results are less confounded by withdrawal effects because it employed a longer open-label stabilization period (minimum of 6 weeks) before randomization and because the aripiprazole–placebo difference continued to widen throughout the 6 months. Nevertheless, a randomized phase lasting a maximum of only 6 months is too short to permit evaluation of true prophylactic effects; longer studies of aripiprazole are awaited. Table 20–12 summarizes the strength of the evidence from the controlled monotherapy maintenance studies reviewed above.

TABLE 20–12. Strength of the Evidence for Efficacy of Mood Stabilizers from Placebo-Controlled Monotherapy Studies

Drug	Depression	Mania	True Prophylaxis ^a (prevent recurrence)	Continuation/“Maintenance” (FDA) (prevent relapses)
Lithium	++	+++	++++	++++
Valproate	+	+++	+?	+?
Carbamazepine	+/-	+++	+	?
Lamotrigine	++	—	+++	+++
Olanzapine	+	+++	+?	+
Aripiprazole	No data	+++	No data	+
Quetiapine	++	+++	No data	No data

^aProphylaxis is defined based on data from placebo-controlled studies demonstrating efficacy during the maintenance phase (>6 mo after the acute phase).

Note: The + signs indicate the strength of the data, not the size of the effect.

Combination Maintenance Treatments for Bipolar Disorder

Retrospective and open-label studies of the use of combinations of psychotropic agents for maintenance treatment of bipolar disorder are too numerous to review individually. Some of these studies involved as few as 5 to 15 patients, and many lasted less than 1 year. As with the treatment of acute depression and mania with combinations of drugs, the literature offers scant empirical information to guide the clinician in the choice of agents for complex regimens. (The reasons for the paucity of controlled studies of combination treatments are discussed in Chapter 17.) Most studies of combination treatments start with a group of patients who are not responding or are inadequately responding to a monotherapy; this limits the generalizability of the results. Another problem with this literature is that almost exclusively, full doses of each drug are used, whereas in clinical practice, additive effects are generally taken into account so that lower doses of each drug are used. Further, when there is some suggestion from studies of mechanism of action that two drugs may act synergistically, combining lower doses of two drugs with different side-effect profiles can result in a higher ratio of therapeutic to side effects (Goodwin, 2003). Finally, because of the higher side-effect burden of combination treatments, dropout rates from such studies are high, making statistical comparisons somewhat problematic.

Lithium and Anticonvulsants

Freeman and Stoll (1998) provided a comprehensive review summarizing the large and inconclusive compilation of uncontrolled studies of combinations of lithium and anticonvulsants, noting that the “interactions of such combinations are sometimes complex, often very useful, and potentially dangerous.” They suggested that the combinations are safe, with that of lithium and valproate probably having the best overall profile of safety and efficacy given the limitations of the published data on combination treatments. They suggested further that this combination may be especially useful for patients with rapid cycles and mixed states.⁸⁷ It has also been suggested that the combination of lithium and carbamazepine is particularly effective (Kishimoto, 1992). Bocchetta and colleagues (1997) reported on 22 patients with bipolar or schizoaffective disorder, followed for up to 13 years, whose cumulative affective morbidity was markedly reduced when carbamazepine was added to lithium.

With regard to controlled studies of the lithium plus anticonvulsant combination, in our earlier review of carbamazepine we mentioned the randomized, placebo-controlled study of Denicoff and colleagues (1997b), which included a crossover design and which found that combination to be superior to either drug alone, particularly

among patients with a history of rapid cycles. In a further study of 24 patients who had failed to respond to lithium plus carbamazepine, this same group found that 59 percent did respond to lithium plus valproate; 3 of the 7 who failed to respond to lithium plus valproate did respond to the triple combination of lithium plus valproate plus carbamazepine. Another small randomized study (Solomon et al., 1997) found fewer relapses among bipolar patients taking the combination of lithium plus valproate compared with lithium plus placebo, but the former combination was associated with more side effects.

Recently, considerable experience has been gained with the combination of lithium and lamotrigine (see, e.g., Ghaemi et al., 2006), which, as noted previously, is an especially advantageous combination for maintenance treatment of bipolar-I patients, combining prevention “from below” with that “from above.” Because lithium has no drug–drug interactions with lamotrigine, in these circumstances it has an advantage over valproate (which inhibits the metabolism of lamotrigine). Also, as noted earlier, lamotrigine has some modest mania-preventing capacity of its own, so its use should enable lower doses of the antimanic agent (lithium, another anticonvulsant, or an atypical antipsychotic) when treating bipolar-I patients, thus reducing the overall side-effect burden (Goodwin and Goldstein, 2003).⁸⁸

Combinations with Antidepressants

Despite the frequency with which antidepressants are prescribed for patients already taking medications for bipolar disorder, a 2001 review by Ghaemi and colleagues (2001a) concluded that the use of antidepressants on a long-term basis in patients with bipolar disorder has been “extraordinarily understudied.” Indeed, surveys indicate that twice as many prescriptions are written for antidepressants as for mood stabilizers for bipolar patients (Garza-Trevino et al., 1992; Ghaemi et al., 2001b; Baldessarini et al., 2006). Thus in a naturalistic study of outpatients with affective disorders, Ghaemi and colleagues (2000) found that only 33 percent of the bipolar subset had ever received mood stabilizers alone, while 78 percent had been prescribed antidepressants at some time. Additionally, mania or hypomania was observed after the initiation of antidepressants in 55 percent of the bipolar patients, and 23 percent experienced rapid cycling or cycle acceleration. In the largest study to date, Baldessarini and colleagues (2006) analyzed initial prescriptions for 7,760 bipolar patients in the United States and found that half of them were for an antidepressant, while only 24.6 percent were for a mood stabilizer.

Seven long-term studies have involved combinations of lithium and antidepressants.⁸⁹ These studies (summarized in Table 20–13) were of varying design and allow few conclusions about the efficacy or safety of these combinations.

TABLE 20–13. Blind, Controlled Trials of Long-Term Antidepressant Treatment in Bipolar Disorder^a

Study	Diagnoses (Sample Size)	Design	Duration (mo)	Outcome Assessed	Results
Prien et al., 1973b	BP-I (44)	Lithium vs. imipramine vs. placebo	Up to 24	Hospitalized or new treatment	Efficacy: lithium > imipramine = placebo
Wehr and Goodwin, 1979	BP-I (5)	Lithium carbonate vs. lithium carbonate + desipramine	27 (mean)	Nurse ratings	Efficacy: lithium + desipramine > lithium (?); switch and cycling rate: lithium + desipramine ≫ lithium
Quitkin et al., 1981	BP-I (75)	Lithium vs. lithium + imipramine	19 (mean)	RDC episodes	Efficacy: lithium = imipramine; mania: imipramine > lithium (women)
Kane et al., 1982	BP-II (27), UP (22)	Lithium vs. imipramine vs. lithium + imipramine vs. placebo	11 (mean)	RDC episodes	Efficacy: lithium > placebo; imipramine = placebo
Prien et al., 1984	BP-I (117), UP (150)	Lithium vs. lithium + imipramine vs. imipramine	Up to 24	RDC episodes	Efficacy: lithium = lithium + imipramine; imipramine more manic switches
Sachs et al., 1994	BP-I (15) (19 treatment trials)	Bupropion vs. desipramine	Up to 12	DSM-III-R episodes	Efficacy: lithium + bupropion = lithium + desipramine; mania: desipramine > bupropion
Amsterdam et al., 1998	BP-II (80), matched UP (79), unmatched UP controls (661)	Fluoxetine vs. placebo	Up to 14	DSM-III-R episodes	Efficacy: fluoxetine similar in BP-II and UP; switch rate: BP > UP
Parker et al., 2006	BP-II (10) (4-day duration for hypomania not required; no previous treatment with antidepressant or mood stabilizer)	Escitalopram vs. placebo, followed by crossover	9 (3-mo baseline, 3-mo SSRI or placebo, 3-mo placebo or SSRI)	Various self-ratings daily, monthly HAM-D and YMRS	Compared with placebo, a significant reduction in depression severity and days spent depressed or high; no worsening of course

^a See the companion Web site for an updated version of this table.

Note: Efficacy results related to BP depressive symptoms unless otherwise stated.

BP = bipolar disorder; DSM-III-R = *Diagnostic and Statistical Manual*, 3rd edition, revised; HAM-D = Hamilton Rating Scale for Depression; RDC = Research Diagnostic Criteria; SSRI = selective serotonin reuptake inhibitors; UP = unipolar depression; YRMS = Young Mania Rating Scale.

Source: Adapted from Ghaemi et al., 2001a.

None of these studies showed an advantage of imipramine over lithium for preventing depression, but their results do point to the risk of hypomanic and manic switches in bipolar patients taking imipramine. The table also includes three studies involving second-generation antidepressants. (See Chapter 19 for a more extensive discussion of both the acute and long-term efficacy of antidepressants in bipolar disorder and the relationship between antidepressants and switching and/or illness destabilization.)

Combinations with Antipsychotic Medications

Many patients discharged from the hospital after having been treated for mania are taking antipsychotic medications and continue to do so for weeks or months thereafter. Clinical variables associated with being treated with antipsychotics for at least 6 months after discharge from the hospital include being male, having multiple manic episodes with severe symptoms, and failing to adhere to the treatment regimen (Keck et al., 1996; Frangou et al., 2002). Results of studies involving the older (typical) antipsychotic medications have been rendered less relevant with the emergence of the newer, atypical agents and their putative lower risk of EPS and tardive dyskinesia.⁹⁰ The potentially serious risk of significant weight gain was noted earlier.

Results of several relatively long-term studies of atypical antipsychotics added to lithium or anticonvulsants are now available. In the preceding section on the atypical antipsychotics, we discussed the randomized study of Suppes and colleagues (1999b), which showed that adjunctive clozapine was associated with significant clinical improvement, but the improvement did not include depressive symptoms. An Italian study of 60 patients with schizoaffective disorder or bipolar disorder with psychotic features found significant improvement on the CGI-Severity of Illness scale that extended over a 24-month period after clozapine was added to their regimen (Ciapparelli et al., 2000). Chang and colleagues (2006) found that, among 51 treatment-refractory bipolar patients given adjunctive clozapine and followed for at least 6 months, 90 percent experienced a reduction in the number and duration of hospitalizations ($p < .01$); significant reductions were noted in hospitalizations for both manic and depressive but not mixed episodes. Two similar studies by Vieta and colleagues used adjunctive risperidone for 6 months in more than 400 patients with schizoaffective or psychotic bipolar disorder (Vieta et al., 2001a) and olanzapine for 43 weeks in 23 patients with bipolar-I or -II disorder (Vieta et al., 2001b); comparable results were obtained in the two studies.

Tohen and colleagues (2004) compared the efficacy of olanzapine added to lithium or valproate with that of the mood stabilizer alone for the prevention of mood episodes

in an 18-month randomized, double-blind study of bipolar-I subjects. Participants in a previous study of the treatment of acute manic or mixed episodes who had a prior documented failure to respond to either lithium or valproate were given an open-label combination of olanzapine plus one of the two mood stabilizers for 6 weeks. Those who achieved remission were randomized under double-blind conditions to either continued use of the combination or abrupt withdrawal of olanzapine with continuation of the mood stabilizer plus placebo. The time to relapse into a manic, mixed, or depressive episode according to DSM-IV criteria did not differ between the two groups. However, a secondary analysis revealed that the time to development of a "symptomatic relapse" (defined as a YMRS or HAM-D-21 score of 15 or greater) was significantly shorter for the mood stabilizer monotherapy group.⁹¹ At the same time, the apparent symptomatic advantage of adjunctive olanzapine must be balanced against the 10-fold higher incidence of weight gain associated with its use as compared with lithium or valproate alone (20 versus 2 percent). There was no significant difference in the polarity of the relapses with and without the adjunctive olanzapine. As we noted earlier when presenting the results of the monotherapy study of olanzapine versus placebo, most of the difference in symptomatic relapse occurred during the first 2 months (which is part of the continuation phase of treatment), suggesting that withdrawal effects played a role.

Other Agents and Approaches

Additional approaches to the maintenance treatment of bipolar disorder have been examined in the literature. These include the use of maintenance ECT, thyroid hormones, calcium channel blockers, psychostimulants such as methylphenidate, nutritional supplements, and extended bed rest and darkness.

Maintenance Electroconvulsive Therapy

A number of case reports and open series have addressed maintenance ECT for the prevention of mood episodes in patients with various disorders, including affective disorders, schizophrenia, and Parkinson's disease. These reports have uniformly described patients with intractable symptoms poorly controlled with medications who have benefited from ECT given on a schedule ranging from weekly to monthly, or even less often (for reviews see Abrams, 1990; Andrade and Kurinji, 2002; Vaidya et al., 2003). Petrides and colleagues (1994) reported on the institutional experience of continuation and maintenance ECT for patients with affective disorders between 1985 and 1991, including 1-year follow-up data for 21 patients; they cited a reduction in relapse rate compared with rates before the start of the ECT

program. Vanelle and colleagues (1994) reviewed the records of 22 patients who received approximately monthly ECT treatments for intractable, recurrent unipolar and bipolar mood disorders, some for up to 2 years, including many with rapid cycles. They reported a substantial reduction in the time these patients spent hospitalized (7 percent) compared with the previous year (44 percent). Recently, a very favorable response to maintenance ECT was reported for two bipolar patients whose treatment-resistant recurrences were predominantly manic (Nascimento et al., 2006; Sien-aert and Peuskens, 2006).

As the results of these studies indicate, maintenance ECT is considered an appropriate choice for patients who consistently relapse when attempts are made to stop ECT and maintain remission with medications, and it has been incorporated into some of the international guidelines for maintenance treatment, such as those of the World Federation of Societies of Biological Psychiatry (Grunze et al., 2002). As new pharmacological approaches become available, it may be possible to reduce the number of patients for whom maintenance ECT is necessary. Rhodes (2000) described the case of a woman who had to stop taking lithium because she developed renal insufficiency while taking it, and who was able to stay reasonably well without it (although with considerable residual depressive symptoms) only by receiving an ECT treatment every 4 to 6 weeks. After starting on lamotrigine, she experienced complete remission and was able to stop ECT. Her recovery had lasted 34 months at the time of the report.

Newer techniques involving electrical stimulation of the CNS (transcranial magnetic stimulation and vagus nerve stimulation) have been examined only in short-term studies focused on the relief of acute symptoms (see Chapter 19). How beneficial these techniques may be for prophylaxis remains to be demonstrated.

Thyroid Hormones

Thyroid indices in the “normal” range do not necessarily indicate sufficiently robust thyroid functioning for some patients with bipolar disorder to remain well. Cole and colleagues (2002) examined the relationship between pre-treatment thyroid hormone levels and time to treatment response in 65 depressed bipolar-I patients and found a significant association between delayed response to treatment and lower-normal free thyroxine index (FTI) and higher-normal TSH levels. They concluded that nearly two-thirds of bipolar patients may have a thyroid profile that, although technically in the normal range, is nevertheless inadequate for an optimal treatment response. Related findings were published by Frye and colleagues (1999), who found that among bipolar patients with free T_4 in the

“normal” range, those below the median were more depressed, had poorer antidepressant responses to lithium or carbamazepine, and had more mood instability regardless of their mood stabilizer status.

Substantial numbers of patients with bipolar disorder have a blunted TSH response to thyrotropin-releasing hormone (Hendrick et al., 1998), and under these circumstances, the absence of a TSH elevation may be misleading. Psychiatrists should be familiar with thyroid physiology, especially the concept of subclinical hypothyroidism, and become comfortable with the assessment and therapeutics of thyroid replacement for their patients taking lithium. T_4 supplementation is an effective strategy for managing hypothyroidism associated with lithium therapy (Kusalic, 1992; Kirov et al., 2005).

Supraphysiological doses of T_4 have been reported to increase the efficacy of pharmacological treatments for affective disorders. A prospective open-label study of 21 patients included 13 patients with bipolar disorder who had failed two previous prophylactic trials. These 13 patients took a mean dose of 378 μg of T_4 along with their other medications and were followed for a mean of about a year. They showed improvement on the CGI-BP, as well as having fewer relapses and spending less time in the hospital compared with the period before starting treatment (Bauer et al., 2002).⁹² Baumgartner (2000) reviewed eight open trials of the use of supraphysiological doses of T_4 involving a total of 78 patients, and concluded that the T_4 benefited approximately 50 percent of patients who were entirely resistant to all other antidepressant and prophylactic treatments. Further detail on the use of thyroid hormones in treating bipolar disorder is provided in Chapter 19.

Calcium Channel Blockers

Interest in the use of calcium channel blockers for the treatment of mania has extended to maintenance treatment. Pazzaglia and colleagues (1993) reported on the results of the first double-blind, placebo-controlled study of the calcium channel blocker nimodipine in 12 patients with treatment-resistant “ultra-ultra-rapid-cycling” bipolar disorder in a placebo–nimodipine–placebo design. Of the 9 patients completing the study, 5 were classified as responders, with 1 bipolar-II subject showing a complete response. The results with these 9 subjects were included in a subsequent analysis of 30 treatment-resistant patients with affective disorder (23 bipolar-I or -II) who were receiving nimodipine monotherapy and were studied over periods of approximately 6 months; 10 patients showed a moderate or marked response. Fourteen of the 20 patients who did not respond to nimodipine had carbamazepine added to their regimen in a blinded fashion (Pazzaglia et al., 1998), and 4 of them responded to the carbamazepine augmentation.

Because verapamil, another calcium channel blocker, is relatively safe during pregnancy, it has been cited as a substitute for lithium or anticonvulsants in women with bipolar disorder who become pregnant (see Goodnick, 1993; Wisner et al., 2002).⁹³ In addition to the need for safer alternatives during pregnancy, there is a need for better treatments for unstable, rapid-cycling illness. These factors underline the need for more work on the calcium channel blockers as prophylactic treatment for bipolar disorder.

Psychostimulants

Our major discussion of the role of psychostimulants in the maintenance treatment of manic-depressive illness is in Chapter 23, dealing with the treatment of children and adolescents. As noted in Chapter 19, the literature on the use of these agents in the treatment of depressive symptoms in adults is scant, no doubt in part because of their status as controlled substances. We could find only one published report on the long-term use of a psychostimulant (methylphenidate) in bipolar patients: a chart review of 16 patients taking adjunctive methylphenidate for an average of 14 months (Lydon and El-Mallakh, 2006). Most patients reported various kinds of improvement following the addition of the stimulant to their ongoing treatment, including better concentration and less depressed mood; the most common side effects were mild irritability and/or agitation. There were no manic/hypomanic switches and no apparent abuse of the stimulant or other substances. Obviously, controlled studies of this treatment are needed.

Nutritional Supplements

Because nutritional supplements cannot be patented, there is no large industrial base of support for research on these compounds. Nevertheless, it is important for clinicians to be as educated as possible in this area, in which patients regularly have many questions.

There now have been a number of reports on the use of nutritional supplements in the treatment of mood disorders. As discussed in Chapter 19, clinical research thus far, while not definitive, has yielded some encouraging results (along with some negative findings) about the addition of omega-3 fatty acids to the armamentarium of treatments for affective disorders. The exploration of the therapeutic potential of these compounds grew out of epidemiological observations that linked high levels of fish oil with relatively low rates of depression and bipolar disorder (see Chapter 5). Many clinicians are now routinely recommending fish oil for their patients to supplement the established mood stabilizers. A number of case reports and an open case series in adults with bipolar disorder (Kaplan et al., 2001) and in a group of children with a variety of mood and behavioral problems, three with bipolar disorder (Kaplan et al., 2004), demonstrated

significant improvement in mood stability in these subjects over a period of months. Controlled studies of the use of micronutrients (the collective term for minerals and vitamins) are ongoing (see Popper, 2001). Assistance in sorting out the various levels of “information” in this area can be obtained from the Alternative Medicine Foundation (<http://www.amfoundation.org> [accessed September 14, 2006]), the *PDR for Herbal Medicines* (3rd edition) (Gruenwald et al., 2004), and <http://www.quackwatch.com> (accessed September 14, 2006).

Extended Bed Rest and Darkness

In Chapter 19, we discuss the potential effectiveness of sleep deprivation, sleep phase manipulation, and light therapy in treating depression. Given that each of these techniques has also been shown to carry some risk of triggering mania, Wehr and colleagues (1998) explored what might be called the opposite of sleep deprivation and light in the management of a patient with treatment-resistant rapid-cycling bipolar disorder.⁹⁴ Over a period of several years, the patient's clinical state was assessed with twice-daily self-ratings, once-weekly observer ratings, and continuous activity recordings with a wrist monitor; sleep was assessed periodically with polygraph recordings. The results were striking: compared with the unstable sleep and mood the patient experienced on his “normal” schedule, extended bed rest and darkness (14 hours a day) were associated with stabilization and normalization of both sleep and mood.

CONCLUSIONS

Because manic-depressive illness, particularly the bipolar form, is a chronic, episodic illness involving substantial functional impairment, long-term prevention of new episodes and enhancement of interepisode functioning should be the core first principles of clinical management. Unfortunately, the priority that should be accorded maintenance treatment is not reflected in the amount and quality of available controlled data. Virtually every drug on the market for bipolar disorder has been introduced as an antimanic agent. While it is common clinical practice simply to continue an effective antimanic agent as maintenance treatment, this approach, with the exception of lithium and lamotrigine, is not based on solid evidence of true *prophylactic* efficacy—meaning the ability to prevent new episodes. Obtaining such data will require that the field, the regulatory agencies, and the pharmaceutical industry move beyond contemporary relapse prevention designs.

Clearly, today's major unmet need is for more effective and more tolerable agents for the prevention of depressive episodes in bipolar patients and in those with highly recurrent unipolar depression. Given that (1) there is no

convincing evidence that long-term antidepressants are effective in the prevention of bipolar-I depression, while (2) the results of three placebo-controlled studies indicate that at least some antidepressants can be associated with destabilization of the disorder, this class of drugs cannot be recommended for routine long-term use, at least for the bipolar-I patient. Fortunately, emerging evidence suggests that certain mood stabilizers, such as lithium and lamotrigine, and potential mood stabilizers, such as quetiapine, have some efficacy in preventing depressive relapses without destabilizing bipolar illness (see Table 20–12).

Given the limited efficacy of single agents for many patients, combined treatment is more or less standard for the majority of patients. But here we face a paradox: virtually all of the large randomized, placebo-controlled trials have been of monotherapy, even though such treatment is the exception in the real world of clinical practice, while the amount of controlled data to inform the use of medication combinations is comparatively limited. Moreover, much of the existing data on combination treatments is of limited relevance to clinical practice because the data are based on full monotherapy doses of each drug; as might be expected, the result is more side effects, which can offset any enhanced effectiveness by causing decreased adherence. Recent attempts to close the gap between clinical practice and research, under the auspices of the Stanley Foundation Bipolar Network and the NIMH STEP-BD program, clearly represent important efforts in the right direction.

NOTES

1. This classic distinction between continuation and maintenance derived from consideration of the natural history of the disease. For noncyclic unipolar depression, there was a clear consensus that the continuation phase comprised the first year after the episode, and anything beyond that was considered maintenance or prophylactic treatment (Frank et al., 1991). For the average bipolar patient, an untreated depressive episode would be expected to last about 6 months, with a manic episode lasting 3 to 6 months; hence the shorter continuation phase for bipolar treatment.
2. Coryell and colleagues (1997) speculated that lithium may protect against relapse in the period immediately following an episode of illness, but not against recurrence of illness months later. They also questioned the necessity of longer-term lithium prophylaxis for patients who have had 8 months or more of euthymia and suggested that lithium discontinuation studies be performed to elucidate the issue. This argument, however, has been rebutted by several other groups (see the section on “Renewed Controversies” in our later review of the literature).
3. Moreover, the tendency of the illness to accelerate in some patients as they age, with episodes occurring more frequently and lasting longer, has been noted since Kraepelin’s descriptions of the disorder more than a century ago.
4. If the natural sequence of recurrent unipolar illness goes from depression to recovery and then eventually to the next episode, treatments that accelerate recovery of the index depression could also accelerate the onset of the next episode.
5. This practice is based on findings from some large contemporary “maintenance” trials that the polarity of the acute episode predicts the polarity of relapses; apparently, however, this prediction holds only for relapses within the first few months after the acute episode (i.e., in the continuation phase) (Joseph Calabrese, personal communication, March 2004).
6. An excellent patient-generated mood chart with instructions for its use can be downloaded from the Harvard Bipolar Research Program at <http://www.manicdepressive.org/moodchart.html> (accessed September 14, 2006).
7. For a review of the literature on lithium levels, see Hopkins and Gelenberg (2000). Lithium levels should generally be obtained 12 hours after the last dose. With slow- or sustained-release preparations, the 12-hour level will be about 15 to 20 percent higher than that seen with the immediate-release preparations.
8. The fact that the charge for this simple and rapid procedure will be reimbursed by insurance companies should increase its acceptance by practitioners.
9. Slow- or controlled-release formulations are not generally associated with gastric symptoms, but some patients taking these formulations may initially experience more diarrhea.
10. The clinical features and treatment of lithium toxicity (lithium poisoning) were outlined in the first edition of this text and have recently been described by Eyer and colleagues (2006), based on an analysis of 22 cases of lithium overdose. Most patients received hemodialysis (the treatment of choice); loop diuretics did not enhance lithium clearance, contrary to what would have been expected from animal studies.
11. It is thought that the effect of lithium on carbohydrate metabolism, including a mild anti-insulin effect, plays a role in weight gain, and therefore carbohydrate restriction is recommended.
12. Goodwin and Goldstein (2003) suggested the following measures to help control lithium-induced weight gain. Lifestyle measures include regular exercise, restriction of sugary fluids, and avoidance of simple carbohydrates, especially early in the day since they can induce mild hypoglycemia and thus increased caloric intake as patients “chase” their blood sugar throughout the day. Medical and pharmacological measures include supplementing T_4 if necessary, avoiding concurrent medication with an additive weight gain effect (olanzapine, clozapine, quetiapine, conventional antipsychotics, valproate, gabapentin, some selective serotonin reuptake inhibitors [SSRIs]), and consulting with a primary care physician about other options if weight gain exceeds 5 lb despite preventative measures.
13. However, some patients will experience lithium-related activation and insomnia when the full dose is taken at bedtime.
14. A recent randomized, double-blind, placebo-controlled crossover study by Allan and colleagues (2004) found that inositol supplements reduce psoriasis associated with lithium treatment, but not that in patients not taking lithium.
15. For an excellent review of lithium’s renal effects, see Gitlin (1999).
16. For a detailed discussion of the renal pathology associated with progressive renal insufficiency due to lithium, see Markowitz et al., 2000.

17. In the retrospective study by Lepkifker and colleagues (2004), covering durations of lithium therapy ranging from 4 to 30 years, nephrogenic diabetes insipidus was associated with longer durations of lithium treatment, past episodes of lithium intoxication, and medical illnesses or treatments that could affect renal function. Others have found the renal effects of lithium to be associated with the cumulative amount of the drug ingested over the years (Presne et al., 2003).
18. If renal concentrating ability is substantially impaired or the patient excretes more than 4 liters of urine per 24 hours, careful monitoring (by patient and physician) of fluid balance is required to avoid dehydration and lithium intoxication (Vestergaard and Schou, 1987). Although the renal concentrating ability usually improves if lithium is discontinued, the improvement can be quite delayed and incomplete if the impairment has been long-standing. Lithium discontinuation studies indicate that increases in 24-hour urine output remain the same or decrease only slightly after lithium is discontinued.
19. A 24-hour urine volume greater than 3 liters is generally considered clinically significant polyuria. Estimates of the condition's frequency range from 15 to 40 percent; it has been reported that concomitant use of other unspecified psychotropic drugs is associated with reduced urinary concentrating ability and increased urinary volume (Bendz et al., 1983). More recently, Movig and colleagues (2003) found that, compared with lithium monotherapy, coadministration of SSRIs is associated with four times more polyuria, perhaps related to hyponatremia (Movig et al., 2002). Nonpsychotropic drugs that can decrease urinary concentrating ability (and increase urine volume) include thiazide diuretics, nonsteroidal anti-inflammatory drugs (NSAIDs), and angiotensin-converting enzyme (ACE) inhibitors. Although there is not yet a full consensus on the relationship between renal function and frequency of lithium dosing, most of the evidence supports the assertion we made in the first edition of this text, that once-a-day dosing is associated with a lower frequency of renal problems (see Plenge et al., 1982; Bowen et al., 1991; Gitlin, 1999).
20. A retrospective chart review study of 718 British patients also concluded that the risk of developing hypothyroidism is greatest during the first 2 years of lithium therapy (Johnston and Eagles, 1999).
21. Because some patients with an affective disorder have hypothalamic dysfunction reflected in a failure to mount a normal TSH response to infused thyroid-releasing hormone (TRH), a normal TSH level may not always be a reliable indicator of the integrity of thyroid function.
22. Isojarvi et al., 1993; Bauer et al., 2000; Ernst and Goldberg, 2002; Joffe et al., 2003.
23. In the GlaxoSmithKline study, the lamotrigine and valproate were used either as monotherapy or adjunctively; the period of observation was up to 1 year.
24. Funded jointly by NIMH and Abbott Laboratories.
25. More sedation and ataxia occur with rapidly rising levels of carbamazepine than with most other modern anticonvulsants; as a consequence, titration often needs to be slowed, especially when multiple drugs are being used together.
26. The occurrence of these complications is rare, at a rate of about 1 in 20,000 patients. Most of these cases have been in the elderly and within the first 4 months of treatment.
27. In a retrospective case review at five epilepsy centers in England, Wong and colleagues (1999) found that higher starting doses, a rapid titration (increase) of the dose of lamotrigine, and the combined use of lamotrigine with valproate (which increases the half-life of lamotrigine, resulting in higher serum levels) were associated with the greatest risk of serious rashes requiring hospitalization. Gradual dose titration is therefore recommended by the manufacturer for patients starting lamotrigine, with an extremely slow titration recommended for those who are taking valproate (starting at 25 mg every other day for 2 weeks).
28. Ketter and colleagues (2005) have developed "antigen precautions" for consideration prior to the initiation of lamotrigine; using this approach, they have been able to reduce rates of benign rash substantially.
29. Serious side effects are associated with typical antipsychotics. Common CNS side effects involve altered thermoregulation, extrapyramidal syndrome (EPS), neuroleptic malignant syndrome, and tardive dyskinesia. Orthostatic hypotension is also observed. Erectile dysfunction, blurred vision, constipation, and urinary retention are common anticholinergic effects. Cardiovascular effects include ECG changes, tachycardia, and torsade de pointes. Changes in the endocrine system, including amenorrhea and galactorrhea, occur as well. Occasionally, the hematological system is involved, with agranulocytosis and leucopenia occurring. Liver enzyme elevations are sometimes seen early in treatment; they usually resolve even with continued treatment, but can cause release of bilirubin with cholestatic jaundice. Other pertinent side effects include allergic reactions and skin photosensitivity and all immune-mediated agranulocytopenias. Sedation and weight gain are observed as well. So-called low-potency antipsychotics cause more sedation and vascular side effects (orthostasis), whereas the more-potent drugs are more commonly associated with EPS. The greatest concern arises for EPS, the potentially fatal neuroleptic malignant syndrome, and for potentially irreversible tardive dyskinesia.
30. Risperidone is now available in a long-acting depot form.
31. Risk of EPS was assessed using the Abnormal Involuntary Movement Scale, Barnes Akathisia Rating Scale, and Simpson-Angus Scale. Mean duration of treatment was 25.5 weeks, and 61 percent of the patients were female. The EPS rate found in this study—63 percent—is somewhat higher than that reported in similar studies of patients with schizophrenia, consistent with earlier findings that bipolar patients are more sensitive to antipsychotic-induced EPS (Goodwin and Jamison, 1990).
32. Leucht and colleagues (2003) referred to meta-analyses by Baldessarini (1988) and Bollini and colleagues (1994), which concluded that no additional efficacy is achieved in the treatment of schizophrenia when doses of chlorpromazine or its equivalent exceed 500 to 600 mg/day.
33. Also relevant are the findings of the recent NIMH Clinical Antipsychotic Trials in Intervention Effectiveness (CATIE) (Dettling and Angheliescu, 2006), comparing a typical antipsychotic with several different atypicals in "real-world" settings. No differences in rates of EPS were noted between the typical agent, perphenazine, and the atypicals.
34. Ziprasidone is the one atypical antipsychotic in which the "start low, go slow" approach is not recommended because at low doses its activating effects, predominate.

35. In a recent cross-sectional study of 171 bipolar-I and schizoaffective patients in a clinic, almost half met the National Cholesterol Education Program criteria for abdominal obesity, and 30 percent met criteria for metabolic syndrome. Most patients were taking more than one medication, 29 percent were taking one of the atypicals associated with weight gain, and 44 percent were taking lithium (Fagiolini et al., 2005). Among 367 patients taking atypicals, the presence of the metabolic syndrome (in 37 percent of the patients) was associated with a two-fold increase in the risk of coronary events (angina, myocardial infarction, and sudden cardiac death) (Correll et al., 2006).
36. Guo and colleagues (2006) used a large managed-care database to conduct a retrospective, population-based case-control study of the relative risk of diabetes among bipolar patients treated with various atypicals. After controlling for age, gender, other drugs, and psychiatric and medical comorbidities, they found significant risk ratios for clozapine (7.0), risperidone (3.4), olanzapine (3.2), and quetiapine (1.8).
37. Adjunctive topiramate has also been reported to control olanzapine-induced weight gain in schizophrenic patients (Levy et al., 2002).
38. For a review of management options for the weight gain associated with antipsychotics, see Birt (2003) and Keck and McElroy (2003).
39. When low doses of some atypical antipsychotics are added to mood stabilizers, enhanced cognitive organization is sometimes observed.
40. Applaby et al., 1998; Ernst and Goldberg, 2002; Newport et al., 2002; Bonari et al., 2004; Spinelli, 2004; Yonkers et al., 2004; Eberhard-Gran et al., 2005.
41. Austin, 1992; Viguera et al., 2000; Wisner et al., 2004; Jones and Craddock, 2005.
42. For a more comprehensive discussion of these issues, see Viguera et al. (2002).
43. Anticonvulsants such as valproate can be used for a few weeks before parturition and in the postpartum period. However, the effectiveness of valproate for the prevention of postpartum episodes has been called into question by a study failing to find any benefit (Wisner et al., 2004).
44. See Stewart (2000) for a discussion.
45. On the other hand, Moretti and colleagues (2003) followed 11 babies who were breastfed while their mothers were taking lithium and found that for half of the mothers, the calculated dose the infant received via breast milk averaged only about 10 percent of the mother's weight-adjusted dose; more important, no overt adverse effects were observed among the 11 infants. Accordingly, some experts suggest that the benefits of breastfeeding probably outweigh the risk posed by lithium (see, e.g., Chaudron and Jefferson, 2000).
46. The recurrent unipolar group in this study may have included some patients who today would be diagnosed as having bipolar spectrum disorder.
47. The study of Prien and colleagues (1974) also included some patients already taking lithium, so the question of a bias toward lithium is relevant.
48. Although mirror-image studies are frequently criticized, in their meta-analysis of the literature, Davis and colleagues (1999) showed convincingly that the efficacy suggested by the results of such studies is of the same magnitude as that reported in randomized, placebo-controlled trials.
49. Compared with the lithium-treated patients, however, those on valproate were less likely to discontinue treatment for adverse effects or lack of efficacy (12 versus 23 percent). Adherence to either treatment was associated with better functional outcome and more than three-fold lower total medical care costs.
50. Studies were excluded if randomization to placebo involved abrupt withdrawal of lithium after the patient had been stable on the drug for a long time.
51. Dickson and Kendell, 1986; Markar and Mander, 1989; Harrow et al., 1990; Licht et al., 2001.
52. These authors noted that "diagnostic drift" is also a factor contributing to a smaller lithium effect size in contemporary studies, although it has a much smaller impact than the enrichment differences. Specifically, the older literature used diagnostic criteria, such as the Research Diagnostic Criteria (RDC), that excluded psychotic features, whereas contemporary studies use the much broader DSM-IV diagnostic criteria, which include psychosis and other "atypical" features.
53. Baastrup et al., 1970; Coppen et al., 1973; Prien et al., 1973a,b.
54. Subsequently this research group (Faedda et al., 1993; Baldessarini et al., 1997) and others (G. Goodwin et al., 1997; Cavanagh et al., 2004), using more refined analyses, further developed the research base, confirming that rapid discontinuation carries substantially more risk and that most relapse events occur within a few months of withdrawal.
55. This result can explain why the previously mentioned analysis of the efficacy literature by Baldessarini and colleagues (1999b) found that *long-term* lithium effectiveness was no different in trials with and without the placebo group's having been withdrawn from lithium.
56. There was a trend for both lithium and valproate to be superior to carbamazepine among rapid-cycling patients.
57. Kleindienst and colleagues (2005) applied the following criteria for inclusion in their review of predictors of response: (1) the observation period lasted at least 6 months; (2) lithium was the primary prophylactic agent, or the lithium group was analyzed separately; (3) at least one clinical response "predictor" was evaluated in a quantitative manner; and (4) the study was focused on a bipolar sample or analyzed a bipolar subgroup separately.
58. The related phenomenon of "continuous cycling" did predict a relatively poor response to lithium.
59. Other variables that appeared to predict poor lithium response, but in a small number of studies that failed to pass the "fail safe" test, were comorbid personality disorder and mood-incongruent psychotic features. Longer treatment latency had also been reported to be associated with decreased lithium response, but as noted earlier, Baldessarini and colleagues (2003) and Baethge and colleagues (2003) have pointed out that this relationship can best be explained by the fact that the sickest patients receive treatment earlier; given that such patients have the most pathology, the treatment effect appears larger. Kleindienst and colleagues (2005) suggested that the potential predictors identified in their review should each undergo this same kind of detailed analysis.
60. In a small retrospective chart review, Ghaemi and Goodwin (2005) found that the maintenance effectiveness of lithium and valproate was equivalent (54 versus 53 percent responders, respectively).
61. This lack of difference between lithium and valproate in rapid-cycling patients was also found in the meta-analysis of Tondo and colleagues (2003).

62. HAM-D ratings are weighted toward items that might be expected to respond favorably to divalproex, such as anxiety and insomnia.
63. A 2-year randomized trial comparing lithium monotherapy, valproate monotherapy, and a combination of the two in patients with a history of mania studied in "real-world" settings is currently under way in the United Kingdom (Geddes et al., 2002). An attempt is being made to recruit more than 1,000 subjects for this study.
64. In most of the patients, carbamazepine was added to lithium, and so this evaluation is, in reality, an assessment of adjunctive carbamazepine.
65. Okuma et al., 1976; Ballenger and Post, 1978; Placidi et al., 1986; Watkins et al., 1987; Luznat et al., 1988.
66. In this study, 29 (69 percent) of 42 patients completed the year on lithium, 12 (34 percent) of 35 patients completed the year on carbamazepine, and 22 (76 percent) of 29 patients completed the year on the combination. The proportion of patients with moderate to marked improvement was 33 percent for lithium alone, 31 for carbamazepine alone, and 55 for the combination.
67. The authors pointed out that a large fraction of the patients had previously received lithium alone, carbamazepine alone, and/or a combination of the two. Thus, the results of the study must be seen in the context that these patients were not naïve to the study drugs and had, for the most part, responded poorly to them in the past.
68. A small double-blind trial of carbamazepine versus lithium for treatment of bipolar disorder was carried out by Hartong and colleagues (2003). In this study, 12 (27 percent) of 44 patients assigned to lithium had recurrences during treatment, compared with 21 (14 percent) of 150 patients assigned to carbamazepine.
69. The mean serum carbamazepine level was 6.4 µg/ml, and the average serum lithium level was .63 mEq/l.
70. In the Calabrese et al. (1999b) open study, conducted over 48 weeks, lamotrigine was added to the currently used maintenance treatment in 60 bipolar-I and -II patients and was used as monotherapy for another 15 patients. Fifty percent (48) of the patients had depressive symptoms at the onset of the trial, while 40 percent (31) were experiencing hypomanic, manic, or mixed symptoms. The majority of patients showed significant improvement in ratings on depression and mania scales, although several developed manic symptoms, perhaps not unexpected in this preliminary study involving patients with complex illnesses and taking a variety of other medications (more than one in most cases), including antidepressants, lithium, valproate, carbamazepine, and antipsychotics.
71. Thus among those patients on placebo, later recurrences after an index depression were 6 times more likely to be a mania/hypomania than another depression; conversely, for those whose index episode had been mania/hypomania, later recurrences were 6 times more likely to be a depression than another mania/hypomania. In other words, overall, 85 percent of the recurrences were of the opposite polarity.
72. Walden and colleagues (1996) reported on a patient with lithium-resistant rapid-cycling bipolar disorder who improved within days when lamotrigine was added to valproate monotherapy; the improvement was sustained for more than a year.
73. However, for the entire group there was a small but significant advantage of lamotrigine over placebo when treatment dropout was considered, an event the authors suggested may often be a sign of relapse.
74. Of the adjunctive agents used, 21 percent were for anxiety/insomnia, 19 percent for depression, and 12 percent for mood elevation.
75. Doses ranged from 1 to 8 mg/day. Thirteen patients did not improve but also did not tolerate the side effects of tiagabine at higher doses; the remaining patient did not adhere to the regimen. A German group reported that tiagabine at doses of 20 mg/day and higher was not useful because of severe complications encountered at this dose range (Carta et al., 2002). Further evaluation of tiagabine at lower doses is needed for full assessment of its utility.
76. There have been scattered reports suggesting that agents used in the treatment of dementia may be helpful in managing neurocognitive side effects of psychoactive medications. Thus Jacobsen and Comas-Diaz (1999) found the cholinesterase inhibitor donepezil to be helpful for memory loss associated with a variety of psychotropic agents, while Burt and colleagues (1999) reported that it improved mood scores in treatment-resistant bipolar disorder. More recently, Schrauwen and Ghaemi (2006) reported that the new cholinesterase inhibitor/nicotinic receptor agonist galantamine was effective in reducing cognitive impairment in two of four medicated bipolar patients.
77. In a subsequent comparison of adjunctive clozapine over 1 year in rapid-cycling versus non-rapid-cycling bipolar-I patients, Suppes and colleagues (2004) found that the latter group evidenced greater improvement.
78. Patients were rated prospectively on the CGI and Global Assessment of Functioning scales for a mean of 6 months and took a mean dose of 2.75 mg/day of risperidone (range 1–4.5 mg/day).
79. Although there was some controversy about the dosing of the acute mania study (conducted by the manufacturer of olanzapine)—that the Depakote dose, while following the *PDR* (3rd edition), was not as high as subsequent studies had indicated it should be for optimal response in acute mania (Allen et al., 2006)—the 47-week double-blind continuation study used flexible doses based on clinical response and side effects.
80. The only adjunctive drug allowed was lorazepam, up to a maximum of 2 mg/day.
81. The 84 percent dropout rate could be interpreted as meaning that neither drug was particularly effective, but without a placebo group, one cannot know.
82. This study employed HAM-D ratings to evaluate the impact of olanzapine on depression. Since the HAM-D scale was developed to assess unipolar depressed patients, it is not considered as good as other rating systems (e.g., the Montgomery-Asberg scale) for the assessment of bipolar depression. In particular, because the HAM-D places much emphasis on such items as insomnia and anxiety, it would be expected that an atypical antipsychotic could reduce ratings on this scale without having a significant effect on core depressive symptoms.
83. These analyses indicate (1) that time in remission before randomization (1, 2, 3, or 4 weeks) was not associated with risk of relapse, and (2) that the drug-placebo differences were similar (and both were significant) among those who remained in remission in the double-blind phase for a minimum of 2 weeks compared with the smaller group who

- remained in remission for a minimum of 8 weeks (half of those originally randomized to olanzapine and one-fourth of those randomized to placebo).
84. FDA indications do not use the terms “prophylaxis” or “mood stabilizer”; “maintenance” is a much broader term encompassing both the classic concept of continuation treatment and prophylaxis. Since giving maintenance indications to olanzapine and aripiprazole, the FDA has revised its guidelines and recommendations. Future maintenance indications should be based on studies in which there has been at least a 6-month period of stabilization before randomization into the maintenance phase.
 85. Apparently only 37 percent of those who entered into the open-label phase both tolerated and responded to aripiprazole. And because the dropout rate during the randomized phase was 58 percent, it would appear that only 21.5 percent of the original sample were still stable after 6 months of treatment.
 86. For example, compared with patients taking placebo, those taking aripiprazole were 13 times more likely to have clinically significant weight gain and 6 times more likely to have EPS.
 87. Baethge and colleagues (2005) offered an up-to-date review of the lithium plus carbamazepine combination in a post hoc analysis of their own long-term data on 46 bipolar-I patients—data that generally reflect the literature by showing both substantial benefit and increased adverse effects.
 88. For other excellent reviews of combination mood stabilizers, see Pies (2000) and Zarate and Quiroz (2003).
 89. Prien et al., 1973a; Wehr and Goodwin, 1979; Quitkin et al., 1981; Sachs et al., 1994; Post et al., 2001.
 90. The conclusion that atypical antipsychotics pose a negligible risk of tardive dyskinesia is based in part on extrapolating the low rates of EPS reported from randomized controlled trials.
- However, it should be remembered that these trials involved patients with a single diagnosis who received a single drug. In real-world settings, rates of EPS are not negligible, with one recent report estimating that more than half of the bipolar patients taking atypical antipsychotics were positive for EPS by rating-scale criteria (Ghaemi et al., 2006).
91. See note 82 on the limitation of the HAM-D scale for evaluating bipolar depression.
 92. Earlier, Bauer and Whybrow (1990) treated 11 refractory rapid-cycling bipolar patients with high-dose adjunctive levothyroxine; 10 showed a “clear-cut” response of depressive symptoms, and 5 of the 7 patients with manic symptoms experienced a decrease in these symptoms while taking T_4 . In all but one of the responsive patients, “supranormal” levels of circulating T_4 were required for the clinical response.
 93. Goodnick (1993) described the cases of three women who took verapamil during pregnancy; two had become manic at the beginning of pregnancy, one taking no medication and one having discontinued carbamazepine. The other patient was in remission from mood symptoms on lithium when she discovered she was pregnant; she stopped the lithium and started verapamil. All three women had a good response. The two patients with mania had a good acute response to verapamil, and all three remained well during pregnancy while taking the drug. Wisner and colleagues (2002) reported on nine women with bipolar-I and -II disorder who took verapamil for 2 to 14 months (two patients took the drug as monotherapy). Six of these nine women remained well while taking verapamil.
 94. While a single case report would not ordinarily merit this much coverage in a text such as this, the innovative nature of this study deserves our attention.

21

Medication Adherence

The endless questioning finally ended. My psychiatrist looked at me; there was no uncertainty in his voice. “Manic-depressive illness.” I admired his bluntness. I wished him locusts on his lands and a pox upon his house. Silent, unbelievable rage. I smiled pleasantly. He smiled back. The war had just begun.

—*Patient with manic-depressive illness*¹

Many patients with mood disorders appear to have little or no difficulty with taking potent daily medications for an indeterminate period. They do not appear to be unduly concerned about potential or actual side effects, nor do they struggle with the existential issues that might reasonably be raised when a person is required to take powerful mind- and mood-altering drugs. For whatever reason—perhaps temperament or past experience—they do not protest or disobey their physicians’ orders; instead, they are grateful for the medications and appreciative of the doctors who prescribe them. Often such patients state that lithium, other mood stabilizers, or antidepressants have rescued them from chaos, despair, hospitalization, or suicide. These patients are an interesting, although inadequately studied, group. Certainly they are a source of gratification to their physicians.

For every patient who follows the treatment course, however, there is at least one who does not—one who resists, protests, objects, takes too little, takes too much, or takes none at all. The perspective of one such patient, more common than most clinicians perhaps appreciate, is presented in Box 21–1.

This chapter deals with medication adherence among patients with the bipolar form of manic-depressive illness, a topic that merits a separate chapter for several reasons:

- The consequences of medication nonadherence are profound and can be life-threatening, clinically equivalent to those of untreated or inadequately treated manic-depressive illness. Nonadherence commonly precipitates the recurrence and intensification of affective episodes that may in turn result in personal anguish, conjugal failure, chaos in other family and interpersonal relationships, alcohol and drug abuse, financial crises, psychiatric hospitalization, suicide, and violence. A recent study

of bipolar juvenile offenders, for example, found that the number of felonies and misdemeanors committed among those off medication was 4.8 times higher than among those on medication (Dailey et al., 2005). This point may be obvious, but it is frequently ignored. Unlike nonresponsiveness to treatment, however, nonadherence is potentially reversible and can be changed through experience, education, learning, and psychotherapy. Such interventions are discussed later in this chapter and in Chapter 22.

- Lithium, anticonvulsants, and antipsychotic medications are prescribed on an exceptionally long-term or lifelong basis. For this reason, unique challenges arise for the patient, the physician, and other clinicians involved in the treatment program.
- Medication nonadherence is a frustrating, common, and perplexing clinical problem, and yet far less discussion and training are devoted to this matter than to the intricacies of prescribing medication effectively.
- Poor adherence is almost certainly the single most important factor in poor treatment response.
- Failure to consider nonadherence may bias research findings in clinical studies related to the outcomes of medication treatment. Frank and colleagues (1985, p. 42) stressed that investigators “have an obligation to account for nonadherent patients in their analyses” by specifying how many and which patients fail to comply (patient, history of illness, and therapist variables) and accounting for dropouts and discontinuation in their statistical evaluations of outcome. Such accounting is rarely undertaken and seldom adequate.

In this chapter, we first discuss approaches to clinical management of medication adherence. We then review

BOX 21-1. Rules for the Gracious Acceptance of Lithium Into Your Life

1. Clear out the medicine cabinet before guests arrive for dinner or new lovers stay the night.
2. Remember to put the lithium back into the cabinet the next day.
3. Don't be too embarrassed by your lack of coordination or your inability to do well the sports you once did with ease.
4. Learn to laugh about spilling coffee, having the palsied signature of an 80-year-old, and being unable to put on cufflinks in less than 10 minutes.
5. Smile when people joke about how they think they "need to be on lithium."
6. Nod intelligently, and with conviction, when your physician explains to you the many advantages of lithium in leveling out the chaos in your life.
7. Be patient when waiting for this leveling off. Very patient. Reread the Book of Job. Continue being patient. Contemplate the similarity between the phrases "being patient" and "being a patient."
8. Try not to let the fact that you can't read without effort annoy you. Be philosophical. Even if you could read, you probably wouldn't remember most of it anyway.
9. Accommodate to a certain lack of enthusiasm and bounce you once had. Try not to think about all the wild nights you once had. Probably best not to have had those nights anyway.
10. Always keep in perspective how much better you are. Everyone else certainly points it out often enough, and, annoyingly enough, it's probably true.
11. Be appreciative. Don't even consider stopping your lithium.
12. When you do stop, get manic, get depressed, expect to hear two basic themes from your family, friends, and healers:
 - But you were doing so much better. I just don't understand it.
 - I told you this would happen.
13. Restock your medicine cabinet.

the key findings of the literature on nonadherence, particularly among bipolar patients. Before proceeding, however, we must note two issues of terminology. First, the term *compliance* has been roundly criticized as having a paternalistic connotation, suggesting a doctor–patient relationship not typical of current practice. Many believe that the term *adherence* reflects more accurately the complex processes of collaboration and mutual decision making involved. Therefore, we use the latter term in this chapter. Second, most of the research and clinical discussion concerning the problem of medication adherence has

focused on lithium, as opposed to other mood stabilizers. Consequently, much of this chapter addresses lithium in particular; however, the discussion is relatively generalizable to other medications, with exceptions being noted as they arise.

CLINICAL MANAGEMENT

As discussed in earlier chapters, both clinician and patient face a number of challenges in maintaining an effective treatment regimen. From the patient's point of view, many daunting issues arise concerning the meaning of the illness, attitudes and expectations about the role of medication, the supportive resources available, and the consequences of adherence or nonadherence. These issues are complex, involving both rational and irrational, conscious and non-conscious processes. Moreover, adherence is a dynamic phenomenon, changing over time.

The clinician's task is critical, as well as difficult, with respect to the goal of treatment adherence, and it encompasses multiple potential roles: a teacher providing clear, complete, and accurate information; a skilled therapist allowing for an open, safe, accepting discussion of the patient's concerns, beliefs, and expectations; a skilled psychopharmacologist knowledgeable about options, dosages, side effects, and drug interactions; an advocate/facilitator informing significant others and enlisting their positive participation in treatment; and a scientist maintaining knowledge and skills concerning effective treatment practices in the context of rapidly expanding research on the etiology and course of illness. Among the inherent obstacles to the effective management of adherence are several noted briefly in the following sections; suggestions for addressing these issues and facilitating adherence are also provided. Chapters 18, 19, 20, and 22 elaborate in greater detail some of these considerations in psychopharmacology and psychotherapy.

Clinician Attitudes

Patients who fail to follow their therapists' suggestions have in the past been perceived as motivated by pathological processes and nefarious personal traits, labeled "resistant," and thereby in some measure blamed for the failure of their treatment. Yet nonadherence rarely involves only the patient's pathological or irrational side; the truth is far more complex. The clinician plays a vital role in creating a collaborative, honest, and supportive environment in which to raise issues concerning treatment adherence with the patient.

Clinicians, of course, experience frustration, impatience, and even anger when patients discontinue medication or fail to follow the prescribed regimen—particularly when the stakes are high and involve personally devastating

consequences to the patient. But even more subtle processes may undermine the effectiveness of the treatment collaboration. Clinicians may not take enough time to elicit information about adherence, attitudes, or side effects. They may focus excessively on medical side effects to the relative neglect of other effects that patients may find more distressing, such as cognitive changes and blunted enthusiasm and diminished energy.

Physicians are relatively poor judges of adherence and may assume that patients are fully adherent when they are not (Blackwell, 1980; World Health Organization, 2003; Osterberg and Blaschke, 2005). It is important to question patients about adherence directly and frequently. When discussing the issue of adherence, it is also important to do so in a nonjudgmental way, making an admission of nonadherence socially acceptable, for example, by asking: “Many people have trouble taking all their pills. Do you have trouble taking all of yours?”

Also critical are the attitudes of treating clinicians toward mood-stabilizing and other medications. In general, clinicians who are ambivalent about the paramount role of biological factors in the causation and treatment of affective disorders tend to convey that ambivalence to their patients and may thereby contribute to nonadherence. Results of a study by Cochran and Gitlin (1988) underscore the importance of the role of the patient’s psychiatrist in ensuring adherence. Their findings suggest that the more strongly the psychiatrist believes in the treatment regimen, the more likely the patient is to take the medication as prescribed.

While it is increasingly uncommon for bipolar patients to encounter clinicians who are reluctant to acknowledge the biological basis of the disorder, the opposite problem may be encountered and can also be detrimental to patients’ attitudes. Clinicians with an extreme biological bias may oversell the efficacy of medication, for instance, and thereby pave the way for the patient’s disillusionment when relapses occur. Or they may underestimate the role of psychological factors in the illness and its treatment, underutilize psychotherapy, and overlook “subjective” symptoms, such as emotional dulling or memory disturbance, that many patients find troublesome. Excessively narrow clinical perspectives that unduly emphasize the biology of the disorder may undermine patients’ own views of the complex nature of their problem; medication adherence may be discouraged if patients experience a sense of futility and are led to believe that only medication can help them.

Suggestions for Facilitating Adherence to Medication

A brief list of practical suggestions for all clinicians who treat bipolar patients is presented in Box 21–2. Schou (1997),

BOX 21–2. Practical Suggestions for Maximizing Medication Adherence

Assessment and Education

- Educate the patient and family members about the course of the illness and the benefits of treatment.
- Teach monitoring and recognition of early symptoms of mania and depression.
- Assess adherence history and potential risk factors for nonadherence.
- Include family members, and inform them about the illness, its treatment, and the risks of no treatment.
- Encourage patients and family members to read about bipolar illness and its treatment; encourage them to question what you are doing and why you are doing it.

Medication and Treatment Alliance Issues

- Create a collaborative relationship, facilitating the patient’s role in dosage/treatment decisions as appropriate.
- Minimize the number of daily doses, and discuss techniques for facilitating regular use of the medication (including pill-boxes), as well as management of multiple medications.
- Involve family members as appropriate.
- Provide oral and written information about side effects.
- Elicit and respond to concerns about and treat side effects.

Monitoring of Adherence

- Initiate an open discussion of adherence issues; provide enough time for assessing and discussing patients’ concerns.
- Inquire about and discuss adherence frequently.
- Obtain regular blood levels of medications as appropriate.
- Encourage support and monitoring by significant others as appropriate.

Adjunctive Treatments

- Recommend, as appropriate, psychotherapeutic treatment for adherence issues specifically, or for bipolar disorder generally.
- Encourage participation in self-help groups.

along with many other researchers and clinicians, emphasized the importance of patient education. He recommended that patients and their families be given instruction booklets concerning the benefits and costs of using and not using medications, as well as the costs of interrupting or discontinuing treatment. He noted that constructing life charts of the course of illness may help patients understand the recurrent nature of the disorder and how the risk of recurrence is magnified by nonadherence. Advocacy of such patient and family education is reflected in many psychoeducation programs, increasingly sophisticated psychotherapeutic techniques, and the development of a wide

network of self-help organizations and support groups (see Chapter 22).

Enlisting the support of family members is important. Not only do relatives need to be educated about the facts of bipolar disorder and its course and treatment, but they can also play a unique role in facilitating adherence by conveying their attitudes about the need for regular medication, providing encouragement and reinforcement for adherence, and facilitating regular routines that include medication consumption.

Several investigators have suggested that, given the magnitude of the problem of nonadherence and the need for close patient monitoring, specialty clinics may be advisable to address adherence issues (e.g., Gitlin and Jamison, 1984; Goldberg et al., 1996; Schou, 1997). Such clinics may be best equipped to follow practice guidelines carefully, monitor adherence closely, and deal with unique patient clinical profiles and side effects through the use of multiple therapeutic agents and psychotherapy. The development of easier monitoring methods (for example, a new 2-minute, office-based test for serum lithium levels) may also have an impact on adherence (Glazer et al., 2004).

Adjunctive Psychotherapy and Self-Help Alliances

As we emphasize in Chapter 22, psychotherapy often helps bipolar patients deal with a variety of issues. A number of specialized psychotherapeutic treatments have been developed for bipolar patients to supplement medication regimens, and a major component of these treatments relates to the management of adherence issues. Cognitive-behavioral approaches, family-based treatments, and interpersonal psychotherapy, for example, have been tested and are continuing to be evaluated in more extensive trials. Research presented in Chapter 22 indicates that such interventions improve clinical and functional outcomes. Some of the studies have specifically included a treatment adherence component, and their findings indicate that psychotherapeutic interventions may facilitate adherence to medication.

Self-help groups, such as those organized by the Depression and Bipolar Support Alliance and the National Alliance on Mental Illness, are beneficial as well to many patients and their families. The increasing use of the Internet to facilitate self-help and chatroom discussions may prove to be beneficial in encouraging the sustained use of medications and in providing educational materials that can make patients informed consumers, aware of their illness and their treatment options. Caution must be exercised, however, in that the accuracy of information provided on the Internet is highly variable. A list of Web sites and other sources of information about bipolar illness, including self-help groups, is given in the Resources section at the end of this volume.

REVIEW OF THE LITERATURE

This section begins with a discussion of definitional and measurement issues related to adherence. Next we present findings on rates of nonadherence among bipolar patients. We then discuss two key questions commonly addressed in research on this subject: What are the reasons for nonadherence that can be articulated by patients, and what are the empirical correlates of nonadherence? Finally, we present an overview of the effectiveness of psychotherapy in facilitating adherence, a topic developed more fully in Chapter 22.

Before proceeding, it is important to note that nonadherence to medication regimens is not at all unique to bipolar disorder, although the latter has certain distinctive characteristics that will be discussed. Overall, as Young and colleagues (1999) pointed out, rates of adherence in general medical practice are about 50 percent, and various studies have found a range of 15 to 85 percent for common medical illnesses.² These rates are consistent with estimates of the World Health Organization (2003) that adherence among patients with chronic diseases in developed countries averages only 50 percent. Nonadherence is especially common in outpatients and in those with chronic relapsing disorders, such as diabetes and hypertension. Blackwell (1973) found, for example, that adherence is lowest when the condition is prolonged and requires prophylactic treatment and when the consequences of discontinuation are not immediate. Even in situations in which the fear of fatal consequences is high and the period of treatment is short, adherence is not ensured. Rates of adherence to antibiotic prophylaxis during the highly publicized 2001 anthrax threat, for example, ranged from only 31 to 64 percent (Brookmeyer et al., 2003).

Table 21–1 shows the factors associated with adherence and nonadherence in general medical patients. Factors that appear to predict adherence include chronicity of illness, number of symptoms experienced, extent of disability, health beliefs of the patient (perceived seriousness of illness and perceived efficacy of treatment), and social supports. Aspects of the treatment regimen—such as complexity, number and cost of medications, and route and ease of administration—are also predictive, as are aspects of the health care delivery system (convenience of the clinical setting, continuity of care, and extent of supervision by others). Demographic variables, such as age (except in its extremes), gender, intelligence, and education level, are not generally predictive of adherence. The relationship of personality variables and medication side effects to general medical adherence is uncertain, although these factors appear to be more relevant to adherence to mood-stabilizing drugs (Aagaard and Vestergaard, 1990; Colom et al., 2000).

Source: Based on data in Haynes et al., 1979, 2003; Blackwell, 1980; McDonald et al., 2002; World Health Organization, 2003; DiMatteo, 2004; Osterberg and Blaschke, 2004.

A great deal of research on nonadherence among psychiatric patients has focused on schizophrenia and has yielded findings of considerable relevance to bipolar disorder. Young and colleagues (1999) reviewed 29 studies of nonadherence to antipsychotic oral medications, conducted between 1986

and 1997. They found a median nonadherence rate of 46 percent, with a range of 5 to 85 percent. Fenton and colleagues (1997) reviewed empirical correlates and predictors of nonadherence among schizophrenic patients; their findings are summarized in Box 21–3. Consistent with these

BOX 21-3. Empirical Correlates of Nonadherence in Patients with Schizophrenia

Patient-related factors

Greater severity of illness, grandiosity, or both
Lack of insight into the illness
Substance abuse comorbidity

Medication-related factors

Medication side effects, especially dysphoric ones
Subtherapeutic or excessively high dosages

Environmental factors

Inadequate support or supervision
Practical barriers, such as lack of money or transportation

Clinician-related factors

Poor therapeutic alliance

findings, Young and colleagues (1999) noted important shifts of emphasis in the treatment of schizophrenia, supporting the significance to adherence of a strong therapeutic alliance and patient insight. A recent study of 228 patients hospitalized with schizophrenia, for example, found that patients' relationships with staff and the prescribing physician were predictive of attitudes toward treatment (Day et al., 2005). Perkins and colleagues (2006) conducted a 2-year prospective study of 254 patients recovering from a first episode of schizophrenia or schizophreniform or schizoaffective disorder. They found that patient beliefs about the benefits of medication and the need for treatment, as well as the perceived negative aspects of the antipsychotic medications (haloperidol or olanzapine), were predictive of medication nonadherence. Nearly one-half of the patients were nonadherent by the end of the first year of treatment; those who received olanzapine were significantly more likely to be adherent than those receiving haloperidol.

A meta-analysis of adherence rates for antidepressant treatments (Pampallona et al., 2002) showed high rates of nonadherence (approximately one-third). The authors suggested that adjunctive treatments, such as psychotherapy, that address issues relevant to taking medication may enhance adherence—although they identified no one such intervention as being uniformly effective. We revisit these themes in a later section.

Definitional and Measurement Issues

What is meant by treatment adherence? Various definitions exist, and different studies operationalize the concept in different ways, often as a percentage of time during which

physician directions are followed as prescribed. According to Boyd and colleagues (1974a, p. 326), medication nonadherence is “the failure to comply (intentional or accidental) with the physician’s directions (expressed or implied) in the self-administration of any medication.” Blackwell (1976, 1980, 1982) specified how nonadherence can occur through four types of errors: (1) omission, where the patient either fails to fill the prescription at all or, once having filled it, fails to take the drug; (2) dosage, taking too much or too little; (3) timing, including failure to follow directions about when to take the drug or for how long, or when to change levels; and (4) purpose or commission (taking the drug for the wrong reason). One study of nonpsychiatric patients (Boyd et al., 1974a,b) found the most common medication errors to be mistimed dosages (56 percent of prescriptions), premature termination of the drug (45 percent), and deliberate skipping of dosages (35 percent).

Patterns of nonadherence to mood stabilizers may also vary over time and from patient to patient. Some patients refuse to take the medication at all; some adhere to a given medication but titrate their own dose instead of following the physician-prescribed schedule; and some alternate between total and partial adherence. *Full adherence* refers to the practice of patients who take medication in the manner prescribed and for the period of time specified by their physicians. This pattern is relatively uncommon; most patients who are considered adherent only approximate full adherence. A pattern of *late adherence* is often observed—initial resistance to medication, followed by recurrences of affective illness and subsequent hospitalizations. There may then be a sudden shift toward adherence as patients begin to recognize the relationship between stopping the medication and recurrence of their illness. In *intermittent adherence*, probably the most common pattern, patients adhere for a period of time (usually days to months) and then stop taking the medication (or start taking it in a manner not prescribed) against medical advice. After a recurrence of their illness, they begin taking the medication again. Before more consistent adherence is achieved, these patients stop and start the medication, take it in subtherapeutic dosages, and experience recurrences of illness. This pattern, however, varies greatly from patient to patient. The most extreme pattern is, of course, *total nonadherence*, which every physician encounters at some time and which is the focus of most of the research in this area. It may also be noted that “behavioral nonadherence” may involve issues apart from pharmacological nonadherence: failure to keep appointments; failure to divulge important information on symptoms; and a lack of willingness to follow suggestions, such as getting regular sleep (Colom and Vieta, 2002).

The most commonly employed methods for measuring adherence include review of chart notes, patient self-reports, records of unkept appointments and unfilled prescriptions, blood and urine levels of the drug in question, spousal estimates of the patient's drug-taking behavior, physician assessments of such behavior, pill counts, and measures of illness outcome (the latter assuming a direct relationship between medication adherence and exacerbation or recurrence of illness). All of these measures of medication adherence pose substantial problems of reliability and validity. Physician ratings of adherence generally agree poorly with other sources, and it has been noted that patient self-reports of adherence are far less potentially valid than those of nonadherence (e.g., Young et al., 1999). A recent study found that self-reported adherence levels and actual plasma levels of mood stabilizers were inconsistent predictors of outcome (rehospitalization); the investigators suggested that self-reported adherence may be a proxy measure for additional health-enhancing behaviors and may therefore be predictive of better outcomes (Scott and Pope, 2002b).

Rates of Nonadherence among Bipolar Patients

The first reported instance of lithium nonadherence in a bipolar patient was the first patient treated with the drug. Years after recounting the initial dramatic success of lithium, Cade (1978, p. 13) described the subsequent course of events:

It was with a sense of the most abject disappointment that I readmitted him to hospital 6 months later as manic as ever but took some consolation from his brother who informed me that Bill had become overconfident about having been well for so many months, had become lackadaisical about taking his medication and finally ceased taking it about 6 weeks before.

Of the thousands of articles written about lithium and other mood stabilizers, remarkably few deal in a substantive way with nonadherence—the primary clinical problem associated with these treatments. This lack of research is extraordinary given the extent of the clinical problem posed by patients who refuse to take medications as prescribed. There is little information about how many patients stop taking mood stabilizers against medical advice; for what reasons they do so, for how long, and at what point in their therapeutic regimen or mood cycles; and whether there are gender and age differences in reasons for nonadherence or incomplete adherence. Little systematic research has been done on patients' perceptions of the positive and negative consequences of taking medications regularly and the effect of these perceptions on actual patterns of use. There is even less information on the use of frequently prescribed combination treatments.

Despite its paucity, the research on rates of medication nonadherence in bipolar patients, summarized in Table 21–2, clearly establishes the magnitude of the problem. In a recent review of 25 studies of medication adherence published between 1976 and 2003, Perlick and colleagues (2004b) calculated the median rate of nonadherence in bipolar patients to be 42 percent. Studies based on multiple medications have reported similar figures. Keck and colleagues (1997), in a study of 140 bipolar manic patients, found an overall adherence rate of 49 percent during a 1-year follow-up, with 31 percent of patients being totally nonadherent. The authors reported 59 percent adherence among those receiving lithium and 48 percent among those receiving divalproex; adherence was only 11 percent for those receiving carbamazepine monotherapy. Of particular note, there was 100 percent adherence to the combination of lithium and divalproex; the sample size of this subgroup was not reported, however, and the authors observed that patients were not randomly assigned, so that self-selection may have affected adherence. (Nonetheless, it is of interest that a recent 18-month comparison of lithium or divalproex plus placebo or olanzapine found that the dropout rate was higher for patients on monotherapy [90 percent] than for those on combination therapy [69 percent] [Tohen et al., 2004]. Likewise, a recent study of 184 bipolar patients found that adherence was higher in patients who were taking a greater number of different medications [Sajatovic et al., 2006a]).

Weiss and colleagues (1998) obtained bipolar patients' retrospective recall of rates of adherence to their medications since first prescribed. About 60 percent of patients reported having adhered to the various medications "more than two-thirds of the time." However, full adherence was reported by 50 percent for divalproex and by only 21 percent for lithium. According to the authors, these figures may reflect in part longer histories with lithium, and hence more opportunity for nonadherence, than was the case for the more recently prescribed divalproex. All of the patients were also substance abusers, and it may be that divalproex is better accepted among that subgroup. By far the largest study of adherence was undertaken utilizing the Veterans Affairs National Psychosis Registry (Sajatovic et al., 2006b). Approximately 45 percent of the 73,964 bipolar patients ($n=32,993$) were prescribed antipsychotic medications; as a group they were younger and more often had comorbid substance abuse or post-traumatic stress disorder than those bipolar patients who had not been prescribed antipsychotics. Approximately half (52 percent) of those prescribed antipsychotics were fully adherent; 21 percent were partially adherent, and 27 percent were nonadherent.

Another way to view the issue of nonadherence is to track the number of days of continuous use. Johnson and

^dDiscontinued at least once in 6 yr follow-up. Half of 76 lithium patients were bipolar. No differences between diagnostic groups.

^eAny prescribed mood stabilizer.

^fPartially adherent, 21 percent; nonadherent, 27 percent.

McFarland (1996) studied records of a large number of lithium users in a health maintenance organization. They determined that the median period of continuous lithium use was 65 days in a 6-year observation period.

Whether one looks at rates of nonadherence or days of use, the above figures indicate that, across diverse

medications, populations, and facilities, a lack of adherence to medication regimens is a substantial problem for patients with bipolar disorder. The consequences of this nonadherence appear obvious but bear emphasis: patients who discontinue medication or use it incompletely or inappropriately greatly increase their risk for relapse and

recurrence of episodes, as well as suicide (e.g., Suppes et al., 1991). Results of several studies underscore earlier findings in this regard. For instance, Marken and colleagues (1992) cited nonadherence—along with substance abuse and stressful life events—as a key factor precipitating rehospitalization among their inpatient sample (see also Johnson and McFarland, 1996).

From the reverse perspective, Keck and colleagues (1998) found that full adherence was associated with significantly better syndromic recovery during a 1-year follow-up. Likewise, Tsai and colleagues (2001) found that full medication adherence was the strongest predictor of good clinical outcome over a 15-year period among a sample of Taiwanese bipolar patients. Another study, unique for its use of serum lithium levels to monitor adherence, revealed that poor lithium adherence was the strongest predictor of more episodes per year over the follow-up period among a large sample of Indian bipolar patients (Kulhara et al., 1999). And Silverstone and colleagues (1998), having compiled follow-up data on several samples in the United Kingdom and New Zealand, found that 94 percent of patients who totally discontinued lithium became manic, usually within a few weeks; these patients accounted for a sizable portion (44 percent) of those who experienced recurrences over a 2-year course. Although the authors pointed out, as have many others, that the recurrence rate is high even when medication adherence is good, it is clear that nonadherence is a potent determinant of significantly poorer clinical course. Chapters 8 and 25 further underscore the various clinical costs and suspected biological consequences of both sudden discontinuation and intermittent use of mood stabilizers.

Reasons for Nonadherence

Why do patients in general, and individuals with bipolar disorder specifically, not follow their prescribed medication regimen? The common but seemingly irrational failure to take steps prescribed to prevent unwanted medical and psychiatric consequences has been studied from several perspectives, the most important of these being the clinical and the empirical/descriptive. From the clinical perspective, anecdotal and impressionistic information about medications from both patients and practitioners has led to a number of widely held assumptions, which serve as the basis for questionnaires and interviews. The empirical/descriptive approach, adopted largely in medical and psychiatric studies of adherence, typically involves examining variables in four domains: medication-related, patient-related, environmental, and clinician-related. Finally, although less common, theories based in social psychology and behavioral medicine have been proposed. An example is

the Health Belief Model, which emphasizes complex interactions among variables, including a mental calculus of attitudes about the costs and benefits of adherence in relation to personal goals and resources.

While all of these research perspectives contribute important information, they also remind us that each investigator's approach may encompass some but not all of the important factors. Moreover, the various factors likely interact in highly complex ways for different individuals. And some of the most important variables may be exceptionally difficult to measure. These include beliefs, expectations, personal predictions, and subjective weighing of costs and benefits—all cognitive operations that may be distorted by mood and judgment.

Clinical Reports of Reasons for Nonadherence

Several anecdotal reports on lithium nonadherence have been published, along with proposed explanations for the phenomenon. In an early study, Polatin and Fieve (1971) emphasized that patients often attribute decreases in creativity and productivity to lithium. They also stressed the role of denial in chronic, serious illness. Fitzgerald (1972) speculated that refusal to take lithium stems from intolerance of reality-based depressions, preference for a hypomanic way of life, or provocation from a spouse or other family member who also misses the patient's hypomanic episodes. Van Putten (1975), in addition to stressing the preference for hypomania, noted the importance of side effects and lithium-induced dysphoria, characterized by a driveless, anhedonic condition. Like Schou and colleagues (1970), he suggested that depressive relapses, as well as a tendency to feel well and to see no further need for medication, are significant variables in lithium refusal. Grof and colleagues (1970) reported that the majority of their patients who stopped lithium of their own accord had been free of relapse and felt no motivation to continue. Van Putten and Jamison (1980) likened the clinical situation to that of penicillin prophylaxis in rheumatic fever, where adherence is positively related to the individual's estimate of the likelihood of having another attack; many bipolar patients in the early stages of their illness are not convinced that a relapse is probable. Schou and Baastrup (1973) cited several reasons for lithium nonadherence: decreased energy, enthusiasm, or sexuality; increased marital difficulties; and a common perception that life is flatter and less colorful than before lithium treatment began. Some of these complaints no doubt result from direct effects of lithium on the illness, such as dampening or eliminating periods of hypomania, and some are due to side effects. Kerry (1978) suggested that the social stigma associated with manic-depressive psychosis may lead to

rejection of lithium, the most concrete symbol of the illness. After several decades of work with patients taking lithium, Schou (1997, p. 361) summarized the factors that he and other researchers believe are involved in lithium nonadherence as follows:

Non-adherence is a complex phenomenon and may have a number of causes. Patients may be inadequately instructed or negligent, they may stop taking lithium because it is not as effective as they had expected it to be, or they may stop taking the drug because it is so effective that there are no further recurrences and they think that they no longer need medication. Patients may stop taking lithium because of side-effects, because they dislike having their mood regulated by a drug, or as a result of anti-drug pressure by the media or the patients' immediate environment.

Patients may also stop lithium because they miss the exhilaration and excess energy experienced during previous hypomanias. If, despite lithium maintenance treatment, patients develop a slight manic recurrence, they may feel unusually well, "on top of the world," and in no need of further lithium. They may then discontinue the treatment, with the result that the impending mania develops into a full-blown one. . . .

It is also clear that attitudes toward medication and adherence may change over time. Cochran (1982), while conducting a brief intervention focused on adherence among bipolar patients, noted that during treatment of nonadherence, patients often followed a pattern in their ability and willingness to articulate their attitudes toward lithium. Initially, they discussed their appreciation of the drug and expressed little ambivalence. By the third session, however, they frequently spoke of extreme ambivalence about lithium and expressed considerable concern about future adherence. Cochran observed that patient concerns centered on the following issues:

- Personal control—frustrations with the "medical model," which patients perceived as focused more on symptoms than on personal gains, and insufficient emphasis on the establishment of alternative means of control, such as changes in diet or reduction in stress.
- Changes in life brought about by successful lithium treatment—missing of highs and the impact of stabilization on relationships.
- Lack of predictability in the course of the illness, possible breakthrough episodes, and length of time on lithium and discomfort about having to be passive in light of possible impending episodes.
- Issues concerning lithium, such as its safety, mechanism of action, side effects, and efficacy.

These issues, observed by most clinicians who have treated bipolar patients, are discussed in greater detail later in this chapter.

Empirical Studies of Reasons for Nonadherence

It is important to note that a "reason" for adherence or nonadherence may not be the same as a "cause." Patients may vary in their ability to articulate or identify their beliefs or theories about why they take (or fail to take) medication as prescribed. Moreover, while information based on consciously held perceptions is vitally important, it may be limited by awareness, influenced by cognitive and emotional factors, and shaped by beliefs that are subject to inaccuracies of various kinds.

In one of the first systematic explorations of the earlier clinical reports of beliefs described previously, Jamison and colleagues (1979) pursued two obvious sources of information and experience about taking medication for bipolar illness: the attitudes of patients (47 lithium patients from the Affective Disorders Clinic at the University of California, Los Angeles [UCLA]) and, independently, the attitudes of clinicians well experienced in the use of lithium (50 physicians, each of whom had treated at least 50 patients with lithium). Nearly one-half of the patients reported having stopped taking lithium at some time against medical advice, and 34 percent of those patients said they had stopped more than once. Of those who reported not having stopped, more than 90 percent stated that they had never considered doing so. These findings raise the possibility that patients tend to divide into two distinct subgroups with regard to adherence—a distribution perhaps more bimodal than continuous in nature.

The results of this study and others investigating reasons for and predictors of nonadherence are summarized in Table 21–3 (see also the later discussion on empirical correlates of nonadherence). The UCLA study revealed no significant demographic (gender, age, education, or income) differences between those who discontinued lithium and those who continued. It is interesting that the adherent and nonadherent groups had equally positive beliefs about the effectiveness of the drug in preventing recurrences of mania and, to a somewhat lesser extent, depression. Both groups also indicated that fear of depression was a stronger motivation for adherence to lithium than fear of mania.

Table 21–4 lists, in order of importance, the reasons for nonadherence cited by the entire patient sample in the UCLA study, by the group that reported nonadherence, and by the clinicians. (When patients reported that they had always complied, they were asked to give reasons that might cause them not to comply.) From the nonadherent

TABLE 21–3. Correlates of Medication Adherence: Data-Based Studies

Study	Sample Size	CORRELATES OF	
		Adherence	Nonadherence
Bech et al., 1976	74 (49 BP) ^a		Side effects; lack of efficacy
Jamison et al., 1979	47 (38 BP)		Disliked the idea of moods being controlled by medication; missed highs; felt depressed
Connelly et al., 1982	48 (40 BP)	Male; perception of continuity of care	Elevated mood; not married
Kucera-Bozarth et al., 1982	37 BP		Lower SES; not married; higher external locus of control score
Frank et al., 1985	216 BP	History of good adherence; higher education	Not married; younger
Danion et al., 1987	73 (36 BP)		Lower cognitive functioning; personality disorder
Cochran and Gitlin, 1988	48 BP		Lack of knowledge about medication; concerns about stigma; side effects
Maarbjerg et al., 1988	133 (61 BP)		Early age at illness onset; greater number of prior hospitalizations; personality disorder; substance abuse
Lenzi et al., 1989	67 ^a (53 BP)	Social support; unpleasant psychotic experience	Grandiosity; living alone; manic phase; somatic concerns
Aagaard and Vestergaard, 1990	133 (61 BP)		Substance abuse; personality disorder; greater number of hospitalizations
Miklowitz, 1992	23 BP	Mood-congruent psychosis; better social functioning	
Mukherjee et al., 1993	114 BP	Male; Caucasian	Older age; shorter duration of illness
Keck et al., 1997	140 BP		Substance abuse; denial; side effects
Weiss et al., 1998	44 BP		Substance abuse; side effects; denial
Bonin, 1999	149 BP		Younger; male; less perception of treatment efficacy
Schumann et al., 1999	76 (38 BP)		Resistance to long-term treatment; side effects
Colom et al., 2000	200 BP		Personality disorder; schizotypal symptoms; fewer episodes but more hospitalizations
Greenhouse et al., 2000	32 BP	Acceptance of illness; good coping and low-denial strategies	
Scott and Pope, 2002a	98 (78 BP)		Denial; history of nonadherence

(continued)

TABLE 21–3. Correlates of Medication Adherence: Data-Based Studies (continued)

Study	Sample Size	CORRELATES OF	
		Adherence	Nonadherence
Stratigos et al., 2002	111 BP		Disliked the idea of moods being controlled by medication; felt well, saw no need for medication; felt illness more related to life events than biologically based
Pope and Scott, 2003	72 (61 BP)		Disliked the idea of moods being controlled by medication; disliked the idea of having a chronic illness; felt depressed
Kleindienst and Greil, 2004	171 BP	Higher age; greater trust in medication and physician ^b	
Perlick et al., 2004b	101 BP ^c		Greater perceived family burden; emotional overinvolvement of caregiver
Sajatovic et al., 2006a	184 BP	Greater number of medications	Current substance abuse
Sajatovic et al., 2006b	32,993 BP ^d		Younger age; minority ethnicity; substance abuse; homelessness

Note: Most earlier studies focused primarily on lithium treatment; more recent studies have included anticonvulsants and antipsychotic medications.

BP = bipolar; SES = socioeconomic status.

^a35 patients on lithium, 32 on carbamazepine, all female.

^bFor lithium but not carbamazepine patients.

^c101 patients matched with identified caregivers.

^dPrescribed antipsychotic medications.

TABLE 21–4. Rank Ordering of General Reasons for Nonadherence: UCLA Study

Rank Order	Total Patient Sample (n = 47)	Patients Who Reported Discontinuing Lithium Treatment (n = 22)	Independent Clinician Sample (n = 50)
1	Bothered by idea that moods are controlled by medication	Bothered by idea that moods are controlled by medication	Felt well; saw no need for lithium
2	Felt depressed	Missed highs	Missed highs
3	Bothered by idea of chronic illness	Felt depressed	Bothered by idea of chronic illness
4	Felt less attractive to spouse	Bothered by idea of chronic illness	Felt less creative
5	Felt well; saw no need for lithium	Felt well; saw no need for lithium	Felt less productive
6	Hassle to take medication	Hassle to take medication	Bothered by idea that moods are controlled by medication
7	Missed highs	Felt less attractive to friends	Hassle to take medication
8	Felt less creative	Felt less creative	Felt less attractive to friends
9	Felt less productive	Felt less productive	Felt depressed
10	Felt less attractive to friends	Felt less attractive to spouse	Felt less attractive to spouse

Source: Adapted from Jamison et al., 1979.

patients’ perspective, the four most important reasons for nonadherence were as follows:

- They disliked the idea of medication controlling their moods.
- They missed their highs.
- They felt depressed.
- They disliked the idea of having a chronic illness, symbolized by the necessity for lithium therapy.
